The transition was in line with the company's financial direction towards reduction of fixed assets and achieving an 'asset-light' state. The initiative was supposed to take up to three years, in which 80% of operations capacity had to be transferred to the company's external partners. The ambitious scale and the timeline of the initiative posed a number of challenges for the company. For example, high volatility in demand, due to seasonal fluctuations and changing trends, prevented the company from building sufficient buffer stock for the transition period. It posed a serious challenge of maintaining on-going production while transferring production to external partner sites and coordinating their activities. Next, difficulties were encountered with constantly transferring know-how to external partners. Approximately 60-70% of the company's annual turnover was generated through the continuous launch of new products. This required very close collaboration between product development and the supply chain, with an uninterrupted flow of information and know-how between the two. In the new outsourcing reality, this flow had been substantially hampered because the customer of the development process had changed from internal to geographically and cognitively distant external production units. However, these challenges did not stop the analytical group, involving a number of middle-level managers in charge of the initiative, from engaging the company in the quickly escalating offshoring initiative.

The focus on managing the process was increased though the introduction of a dedicated monthly process responsible for monitoring and coordinating the production network based on the capacities, roles and responsibilities assigned to various facilities. The company had been heavily relying on this process in coordinating its partners' activities with its own lead plant activities remaining in Denmark. Although the process proved to be successful in managing the network during the transition period, in the beginning of 2008 it also revealed its limitations, when the company announced its plan to 'backsource' or bring back in-house one plant run by its partners.

Case F: Shift in Paradigm - from Manufacturing to System Integration

Company F is an SME offering high quality woven textiles to industrial customers. Originally, it mastered a broad variety of production processes in-house. In the late 1990-s, the accelerating velocity of competition and transformations in the external environment of the company revealed the need for changes in its strategic activities. During this period, the company started outsourcing some of its activities and later also began to buy finished fabrics from external suppliers.

Outsourcing was a major strategic decision affecting the entire organisation and was vividly compared with an octopus reaching into every nook and cranny of the business. Having been a manufacturing company in the past, today it primarily manages a network of suppliers and serves as a systems integrator with close contact to customers. This involves not only managing daily operations and logistics, but also monitoring and negotiating with all actors in the value chain. For example, the logistics manager maintains personal contact with the vendors of wool in New Zealand. The company buys the wool and calls on full scale spinning and weaving factories abroad to process the wool to specifications.

At factories in one of the Baltic countries, weaving takes place on machinery owned by the company. The machines were previously located in Denmark and are currently leased by the foreign supplier. The demand for high quality has led the Danish company to maintain and further develop its production engineering competencies when the spinning and weaving operations were outsourced. The partner's plant outside Denmark was essentially an offshore full-scale operation focused on cost and efficiency, while product and process development, laboratory and prototype production resided in the Danish headquarters. After the offshoring journey of the company started in 2000, some quality sensitive operations, such as dying, softening and washing, were carried out by the company's own main factory in Denmark. However, in 2006, the decision was made to transfer them abroad, as well. The radically shifted the role of the Danish facilities from manufacturing to innovation, systems integration and supply chain management. Supplier relationship management became one of the focus areas of the company. Because the strategic partners of the company are not contractually bound, the relational approach plays the key role in how the company manages its operations network.

The subsequent downstream processes, such as sewing and upholstery, had traditionally been carried out by customers and were of their concern. But now, in line with developing the new role as a systems integrator, the company also offers the service of finding suppliers for these processes. The company is not likely to undertake production itself, but is more likely to further build up sourcing and negotiation skills, e.g. to offer prototyping and ramp-up at suppliers' sites.

DISCUSSION

Patterns Observed in the Cases

The main aim of this discussion is to generate a framework, leading to a number of propositions relating offshoring to dimensions of national culture. However, first we summarise the patterns of offshoring observed in the six case studies. The cases presented above can be analysed in relation to the offshoring process variables identified in the theory section of this chapter. Table 3 summarises the characteristics of the cases in terms of their production offshoring mode, drivers, impediments, implications, pace and geographic spread. The strategic trajectories found in the six cases correspond to the general trends identified in the literature.

The data point to a number of similarities and differences between the Japanese and Danish companies. Significant similarities can be found in: 1) their motivation for initiating offshoring projects and 2) the geographic spread of offshoring. Differences, on the other hand, are visible across all other dimensions of offshoring, including mode, pace and factors hampering further expansion of offshoring in these companies. The impacts of offshoring on domestic bases also differ in the Japanese and Danish cases. In the Danish cases, the process of transferring production activities overseas led to the downsizing or complete closure of the domestic production facilities. In contrast, the domestic plants in the Japanese cases remained almost intact and even enhanced their strategic role, with respect to foreign plants.

Many factors may explain these offshoring trajectories and singling out one factor may be difficult. Therefore, we apply the unexplained variance approach (Poole et al., 2000). We ask ourselves, what aspects of the offshoring processes in the cases cannot be explained by the system-level and firm-level factors? In these instances, culture may become an important explanatory factor.

Both at the system and firm levels, the case companies have similar goals for engaging in the offshoring of activities. At a macro level, there is a country size differential, but in terms of policies and the economic development level both countries are similar and represent high-wage and knowledge-intensive economies. At the firm level, all six companies represent industries with a relatively high labour intensity and a propensity towards offshoring. Although we cannot fully isolate the cultural factor, these similarities at the macro and firm levels justify the exploration of the role of national culture as a potentially important variable affecting their offshoring developments.

Table 3. The offshoring process characteristics in the cases

	Japan			Denmark		
	Case A	**Case B**	**Case C**	**Case D**	**Case E**	**Case F**
Offshoring impacts	Domestic production and R&D bases intact	Domestic R&D enhanced; Production base intact	Domestic production and R&D bases intact	Domestic production phased out; R&D downsized	Domestic production downsized	Domestic production phased out
Mode	Captive	Captive	Captive	Captive	Offshore Outsourcing	Offshore Outsourcing
Geographic spread	Mix of nearshoring and distant locations	Mix of nearshoring and distant locations	Mix of nearshoring and distant locations	Mix of nearshoring and distant locations	Mix of neashoring and distant locations	Neashoring
Drivers	Cost Market Currency exchange rates	Cost Market Currency exchange rates	Cost Market Currency exchange rates	Cost Market	Cost Market	Cost Market
Impediments	Loss of control; loss of core business skills	Loss of control; loss of core business skills	Loss of control; loss of core business skills	Loss of core business skills; loss of control	Loss of core business skills; coordination cost	Loss of control; coordination cost
Pace	Slow and incremental	Slow and incremental	Slow and incremental	Fast and radical	Fast and radical	Fast and radical

The cultural lens may help us to reveal that the offshoring process is more than just an anonymous response to the emerging challenges and opportunities of the global market, but rather that it is strongly accorded with a unique set of cultural characteristics of the parent company.

Cultural Context Impacts on Offshoring

Hofstede's (1983, 2001) five dimensions of national culture provide a useful framework for accounting for the effects of culture in the offshoring process. As Table 4 indicates, Denmark's and Japan's national cultural contexts differ substantially across all five dimensions. Denmark is characterised as a feminine, highly individualistic society with low power distance, weak uncertainty avoidance and a short term orientation. In contrast, Japan is a more collectivist society, with high power distance, a strong tendency towards uncertainty avoidance, and traditional masculine values permeating the society having one of the highest long term orientation indices.

In the following discussion, these features are related to offshoring patterns identified in the two contexts. The first dimension of national culture is concerned with how one individual is related to other individuals in a society. As can be seen from Tables 4 and 5, Japan is much more collectivistic than Denmark. According to Hofstede (1983), in a collectivistic society, the degree of interdependence between organisations and their members is much higher than in an individualist society. Individuals in a collectivistic society can expect other individuals and organisations to look after them, in exchange for loyalty and belongingness, while in an individualistic society, the relationship between employees and employers is, to a large extent, perceived as a business transaction in a labour market. We can relate this dimension to the implications of offshoring for domestic bases in the Danish and Japanese cases. In Denmark, offshoring led to the closure or downsizing of domestic facilities, while, in Japan, it had a very limited impact on the domestic base in the companies. We can assume that the management offshoring decisions in the Japanese cases were made taking into account possible negative implications of offshoring for employees of the domestic plants. In the Japanese companies, an aggressive approach, dictated by market logic only, would imminently clash with the society's collectivistic orientation and harmony seeking. Such approach might have also been interpreted as an unacceptable loss of face, but it was justified in the Danish cases.

The second dimension of national culture is power distance. We can again point to a difference between the two countries. Japan has a higher power distance than Denmark. This dimension can be seen as complementary to the first dimension, with a negative correlation between the two, i.e. a high individualism index is related a low power distance in the society and vice-versa. This explains why hierarchical order and hierarchical organisational structures are more common in Japan than in Denmark. Relating the power distance

Table 4. Interpretation of the values of the five dimensions of culture for Denmark and Japan (based on Hofstede (2001))

Country	Individualism/ Collectivism	Power Distance	Uncertainty Avoidance	Masculinity/ Femininity	Long/Short Term Or.
Denmark	Individualistic Society	Short Power Distance	Weak Uncertainty Avoidance	Feminine Society	Short-Term Orientation
Japan	Collectivistic Society	Large Power Distance	Strong Uncertainty Avoidance	Masculine Society	Long-Term Orientation

dimension of national culture to the offshoring trajectories in the cases, we can build on Mulder's (1977) hypothesis that powerful individuals strive to maintain power distance and the existing power structure. The management of the Japanese cases strived for preserving a high power distance and existing hierarchical structure. In contrast, in the Danish cases, this factor did not play a significant role in preventing the closure and downsizing of domestic facilities. Furthermore, in the Danish cases, middle management enjoyed extended autonomy. For example, in Case F, a number of direction-determining in-process decisions were made at the middle management level. On the other hand, the Japanese cases were much more top management driven.

The third national cultural dimension is uncertainty avoidance, which addresses how a society deals with uncertainty and ambiguity. Here, again, Denmark and Japan score very differently. Denmark has weak uncertainty avoidance, while Japan has strong uncertainty avoidance. Although uncertainty avoidance should not be confused with risk avoidance, a low rating in uncertainty avoidance is an indication that a nation is generally more willing to take risks and tolerate new ideas that deviate from well established norms. The uncertainty avoidance dimension is especially important in explaining the differences in approaches to offshoring in the context of the two countries. The case companies' decisions were clearly affected by the level of tolerable uncertainty. For the Danish case companies, offshoring all or larger part of their domestic manufacturing (and in Case D, spreading the R&D function globally) to a cognitively and geographically distant low-cost countries, took a much higher risk than the Japanese companies. The latter exercised a much more cautious approach to offshoring, by keeping the production and R&D capacity and competencies domestically in-house or offshoring only to cognitively and geographically close low-cost countries of South-East Asia. Certain Japanese companies (Case A and C) could not avoid opening R&D centres overseas, in order to remain responsive to foreign markets they were operating in. Nevertheless, they approached this task very differently from the Danish companies. The Japanese cases took years to establish even peripheral support centres, while in the Danish cases, the process was much more compressed in time and the scope of activities was more far reaching.

The fourth dimension of national culture is related to how masculine or feminine a society is. In masculine societies, values related to aggressiveness and striving for success are common for the whole society or, as Hofstede (1983) puts it, the values include the importance of 'big is beautiful', while a more feminine society adheres to the 'small is beautiful' concept. Referring to Tables 4 and 5, we see that Japan and Denmark represent extremes on the scale, Denmark being a feminine society, while the masculine values prevail in Japan. These cultural norms also affected the management actions underlying the trajectory of the offshoring process in the case companies. Factors such as corporate pride played a particularly important role in guiding the offshoring decisions in the Japanese cases. On the other hand, in the Danish cases the particular mental framing of manufacturing activities played a different role and, to a large extent, served as a driver of offshoring.

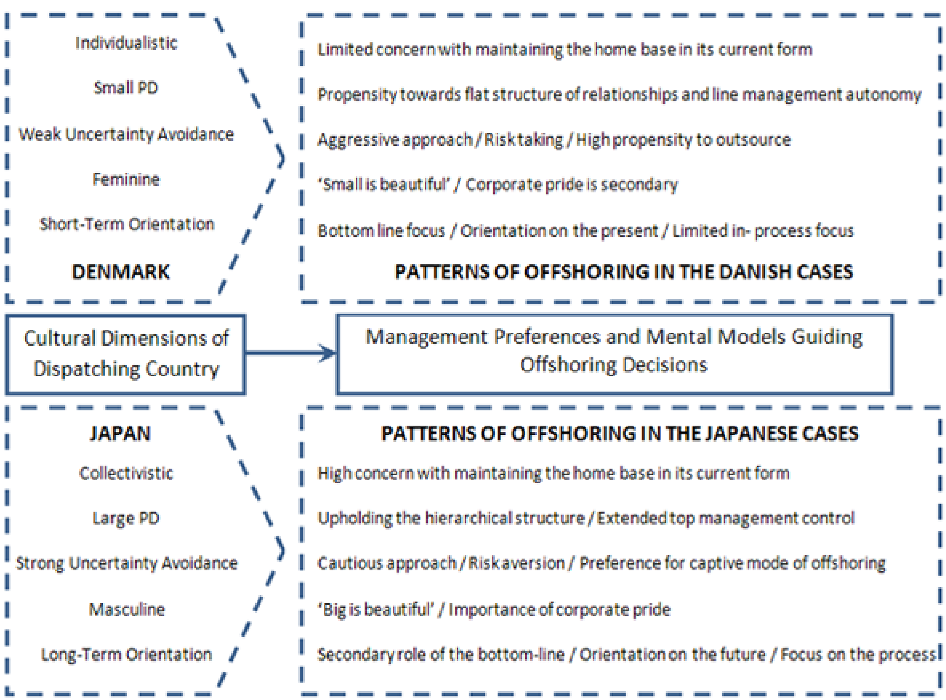
The fifth dimension of culture is long- versus short-term orientation. As its name suggests, this dimension is related to the choice of focus for people's efforts – the future or the present. As discussed by Hofstede (2001), the scores on this dimension index show that Asian countries score the highest, and Western countries are on the low-medium end. Denmark and Japan are not exceptions to this. Denmark represents the cluster with a short-term orientation, while Japan belongs in the cluster with a long-term orientation. Businesses in a long-term oriented culture are expected not to have a focus on immediate results, while in a short-term oriented culture the focus on the bottom line is a major concern of management (Hofstede, 2001; Mamman & Saffu, 1998). However, this view of time is not fully conclusive. For example, the findings of Voss and Blackmon (1998) suggest that the Western view of time is primarily linear and short-term, while the Japanese perspective is polychronic, i.e. focusing on both the long-term and short-term simultaneously. The role of this dimension is also evident in the cases used in our study. In the Danish cases, representing short-term orientation society, the offshoring initiatives are compressed in time, and management decisions seem to follow the logic of seeking quick economic results with minimum possible costs. The decision making process in the Danish cases is based on more technical rational analysis deriving from the most immediate economic reality. This is illustrated by the swift and frequent change of the strategic roles of plants in all the three Danish cases. In the Japanese cases, on the contrary, the process is spread out in time; it links short-term activities and long-term goals. It does not disregard, but rather tolerates, the extra resources required for preserving manufacturing competences in the domestic base.

The main points of the discussion presented above are summarised in Figure 2. The framework links the five cultural dimensions with the preferences and mental 'programs' of the management teams in the case companies. These preferences guide offshoring decisions and, ultimately, the distinguishing trajectories of offshoring.

This framework represents an attempt to take a more in-depth look into the process of offshoring and how this process may depend on the dispatching company's cultural context. It can be distilled into five propositions:

Proposition 1: *Companies from a cultural context dominated by collectivistic values are likely to adopt a more cautious and community responsive approach to offshoring than companies from a cultural context dominated by individualistic values,*

Figure 2.



Proposition 2*: In companies from cultural contexts dominated by low power distance the middle managers play a more prominent role in offshoring initiatives than in companies from cultural contexts dominated by a high power distance,*

Proposition 3*: In companies from cultural contexts dominated by weak uncertainty avoidance, the propensity to adopt an aggressive approach to offshorin,g involving risk and uncertainty, is higher than in companies from cultural contexts dominated by strong uncertainty avoidance,*

Proposition 4*: In companies from cultural contexts dominated by masculine values, the importance of corporate pride is more prominent than in companies from cultural contexts dominated by feminine values,*

Proposition 5*: In companies from cultural contexts dominated by a short-term orientation, the focus on short-term financial results drives offshoring processes to a larger extent than in companies from cultural contexts dominated by a long-term orientation.*

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

Our main findings show how certain developments in offshoring processes and international operations management practices can be explained by differences in the dispatching companies' cultural contexts. We, by no means, claim that, based on these results, we can predict an accurate scenario for the offshoring process for every country. However, we believe that the findings and the ensuing propositions may be useful in informing our expectations about the propensity of companies from a particular context towards a particular offshoring process trajectory.

Although there is no 'one size fits all' approach to offshoring, it is clearly culturally dependent. The chapter demonstrates that, despite the offshoring phenomenon often being discussed in technical rational terms, it is not a universal process; it is, rather, subject to strong cultural influence. On the basis of the literature review and investigation of a multiple-case studies strategy, we find that, on the one hand, there are many similarities between Danish and Japanese companies. These similarities are especially visible in the realm of offshoring motivational factors (cost-minimisation and market-seeking). On the other hand, the findings of this chapter indicate that there are substantial differences between Danish and Japanese companies in: 1) how they approach offshoring in terms of mode and pace; 2) how they perceive strategic risks resulting from offshoring; and 3) how the process influences the domestic bases of the companies. We find that cultural variables affect the management viewpoints which guide their offshoring decisions. These findings support the findings of Pagell et al. (2005) about the validity of culture as an explanatory variable in operations management research. Furthermore, they also contribute to understanding of how the dimensions of culture affect specific underlying mechanisms of the offshoring process.

However, this study has a number of limitations. Rather than providing definititive answers, it develops a number of propositions and raises the need for further research on cultural variables and their influence on the offshoring process. Although the cultural approach may have sufficient explanatory power for an analytical comparison between Japanese and Danish companies, the cultural variables used in the study may not have a substantial explanatory power for intra-regional comparisons. Another limitation is that, although national culture is a valid approach to the offshoring phenomenon, there are a number of other influencing factors. Future research is needed to formulate specific propositions relating other factors to the offshoring process and cultural variables. These other factors may include the location of plants (where a firm offshores to matters to how it does it), resource-based advantages, the capital structure and size of firms.

Another limitation of the study is related to the case approach employed in the investigation. Potential biases of this strategy may occur due to selective memory of the respondents. In this study, this was offset by triangulating the interview data with related corporate documentation of the process. Next, while ensuring contextual rootedness, the case methodology offers limited generalisability (Eisenhardt, 1989). However, as examples from other studies suggest, the findings are nonetheless indicative of the respective Japanese and Danish approaches to offshoring. Moreover, the limited generalisability of the study does not undermine its findings. They still remain important for a number of reasons.

The aim of this investigation was to add to the knowledge about the offshoring phenomenon, i.e. what Woodside and Wilson (2003) call the principal objective of case study research. The findings of the chapter foster a better understanding of the process of offshoring and cultural variables as a factor significantly affecting it. The findings also can be used by managers who deal with global work transfers and challenges associated with these transfers.

KEY TERMS AND DEFINITIONS

Captive Offshoring: The type of offshoring which occurs on an 'intrafirm' (in-house) basis.

Culture: The collective mental programming with consequences for beliefs, attitudes, and skills.

Dispatching Organisation: A parent company located in the domestic base where an offshoring initiative originates from.

Offshore Outsourcing: The type of offshoring which occurs on an 'inter-firm' basis.

Offshoring Process Trajectory: A set of variables, such as location and organisational boundary decisions, which are assumed by an offshoring initiative over time under the influence of internal and external forces.

Offshoring: The relocation of a business process or entire manufacturing facility to a foreign country.

Receiving Organisation: A wholly owned subsidiary or a third party facility in a foreign country where a business process is being relocated to.

Chapter 71
Network Marketing and Supply Chain Management for Effective Operations Management

Raj Selladurai
Indiana University Northwest

ABSTRACT

The use of network marketing by an organization as a distribution strategy in its global supply chain management activities is increasing and becoming very popular. This chapter looks at the "new" network marketing-supply chain paradigm, and analyzes some implications of the strategies for effective operations management. The network marketing paradigm has been greatly enhanced by the growth and popularity of the internet, which provides a powerful impetus to the whole concept of effective global network marketing-supply chain management area. This mainly theoretical study also provides a practical perspective by discussing manufacturing and service companies that are implementing the network marketing-supply chain strategy model in some form. It analyzes the supply chain management activities used by these organizations to achieve unprecedented success in their respective industry. This chapter concludes by developing an effective network marketing-supply chain management model that uses network marketing and supply chain management as key strategies in operations management.

INTRODUCTION

Business organizations across the globe have used a variety of network marketing strategies and integrated them into their operations in many creative ways, to achieve great success. Many businesses have effectively used network marketing strategies that network marketing's reputation, and the popularity of such strategies has grown rapidly in the world over the last several decades. Recently, Warren Buffet's Berkshire Hathaway company got into network marketing when it bought The Pampered Chef, a leading network marketing company. Southern Living at Home, another

DOI: 10.4018/978-1-4666-1945-6.ch071

successful network marketing leader in the home decorating industry, generated more than $100 million a year for AOL Time Warner, its parent company at the time (Woodburn, 2003). Network marketing has extended beyond the U.S. shores, and other countries have begun to take a close look at this "new" phenomenon. This American-style network marketing model has been referred to as the "new" paradigm which is being experimented with and implemented by many businesses and other organizational structures in Japan (Imura, 2004). In China, the world's biggest market, several companies and many local people are getting into network marketing (Rayasam, 2007).

In a recent study, Coyne, Clifford, and Dye (2007) suggested 21 questions that effective companies need to ask, in developing new products. These include specific questions related to buyers and users (knowing the target market and audience well; examining in depth some of the binding constraints (overcoming limitations); exploring unexpected successes (looking at new creative and imaginative uses for the products); moving toward perfection by imagining it (continuous improvement); focusing on and adapting to the external environment ("thinking outside the box" strategies); and taking a closer look at and revisiting products' strengths and weaknesses, opportunities, and threats (mission and vision perspectives). This chapter focuses on a few of the specific questions that leading companies are addressing effectively via specific strategies which have contributed to their success – namely network marketing and supply chain management.

BACKGROUND

Uniqueness and Significance of Network Marketing

Network marketing, also more commonly referred to as direct sales, direct marketing, multilevel marketing and/or other similar concepts, is basically the direct distribution strategy of a product or service, from the company to the consumers, through building effective relationship marketing between distributors and customers. Typically, a network marketing strategy is implemented via a structure or system in which the manufacturing company chooses to distribute its products and services directly to its customers through a network of distributors. This is usually done through a selective group of dynamic and highly motivated people outside the company (distributors, dealers, affiliates, partners, etc.) who market the products and services directly to the consumers and get paid by the manufacturer for doing so. These distributors are also given the opportunity to develop and build their own independent business networks, usually called a downline or multi-level organizational structure, through recruiting, training, and inspiring others to duplicate their efforts. Products are sold mostly from outside of fixed retail locations and usually from the home, primarily through one-on-one personal contact and through product demonstrations. With the increasing popularity of the internet, several companies' dealers and representatives are using the internet to market their products, and are building their business networks by using proven lead generation systems, in collaboration with specialized lead generation companies.

Network marketing, or direct selling overall, may also be referred to as an industry -- a fast growing, successful industry. In 2007 alone, the direct selling industry reported 30.8 billion in total sales in the US, with a workforce of about 15 million involved in some way in this industry (http://www.dsa.org/pubs/numbers/#SALES).
What makes network marketing so popular and unique? The one-to-one personalized, relationship marketing interaction that takes place between distributor and customer is the key to network marketing. Most people would prefer and choose to buy from someone whom they know, like, and trust – network marketing personifies this concept extremely well. People would generally prefer to

buy their product/s from a local distributor – a friend, neighbor, associate, coworker, peer or colleague, fellow member of a church, social club, etc. - rather than from an impersonal corporate office or company sales office. Direct selling or network marketing promotes this personalized touch to selling and buying amongst distributors and customers. Recent studies showed that about 74 percent of Americans have purchased goods or services through the direct sales method. This is more than the number who have purchased through television shopping and on-line computer services, combined. People seem to highly value the products available through direct selling channels and about 45 percent of Americans want to buy from direct sellers (http://www.dsa.org/aboutselling/benefits/). Direct selling is increasingly used as a viable alternative or supplement to traditional marketing. As growth and expansion in the traditional retail, catalog, and online selling channels slows down and often stagnates, many companies are using direct selling to stimulate growth (Duffy, 2005).

Another strong reason for network marketing's growth and popularity is the cost advantage that it provides. Cateora (1990) characterizes channel maintenance costs as the margins, mark-ups, and commissions of channel members in the network. Reducing or eliminating the middlemen in the supply chain so as to allow for greater margins, would be the ultimate goal of manufacturers and traders, and has been from the beginning of trade. The potential to increase profits by eliminating intermediate channels of distribution is a strong motivating factor for the growth of direct marketing. Although network marketers often boast about their channel's efficiency in avoiding wholesalers and conventional retailers, this channel is not a completely low cost channel (Croft & Woodruffe, 1996). However, it still is a profitable source to the manufacturer, as this channel has the ability to command a higher price for its products, compared to similar products which are distributed through traditional retail stores (Eisenberg, 1987).

The advantages that network marketing offers, in terms of capital requirements and cash flow implications, would contribute further to its attractiveness. This channel symbolizes the ideal, where the entire distribution network in the supply chain pays cash with orders and holds inventory at its own expense. For example, Mary Kay Cosmetics encourages its distributors to have a minimum of $600 worth of inventory and this may be increased by a distribution up to around $3000, in order to support her customers. Amway has generated significant cash flows from its operations by requiring its distributors to hold inventory (at least 3 to 8 weeks' stock) and pay upfront for their inventory items (Croft & Woodruffe, 1996).

Network marketing also provides more control and promotes quicker action in the supply chain. Companies can easily communicate with the entire distribution network today through email, online platforms and messages, telephone, and video conferences and can effectively manage the physical distribution of their products through company controlled warehousing. Hence, communication is fast and effective, which enables the quick and efficient introduction of new products, through the distributors in the supply chain, to their customers all over the country and even the world – in a relatively short time and at very lost costs. Network marketing stimulates fast action, compared to traditional retail outlets, in terms of product introduction, sales, after-sales service, handling returns, and prompt delivery of goods and services (Kaikati, 1993).

Network marketing also provides excellent coverage related to maximizing sales volume, market share, and market penetration (Cateora, 1990). Weitzen (1993) stated that network marketing companies stimulate hypergrowth because they can effectively inform, educate, and persuade customers and distribute products quickly and at relatively low cost, especially by using the internet. Further the close relationship building that network marketers focus on and develop with their customers enhances concentrated efforts and activities within particularly social groups, regional, religious, or ethnic community groups. For example, Amway's Malaysian network marketing operations grew faster in the minority Chinese community, compared to other groups (Amway, 1993). EcoQuest International, another leading network marketing company in the health wellness/healthy living industry, had a strong majority Christian group amongst its 80,000+ distributor network.

The unique characteristic of cross-cultural appeal of the network marketing channel is another strong contributing factor for its widespread success (Yarnell, 1994; Weitzen, 1993). It has universal appeal and works in a variety of cultures. Amway's strategies have exhibited remarkable success in Japan where extended family relationships and lifelong close relationships are especially well suited to the direct marketing methods employed by the company (Amway, 1994). Further, a "retail revolution" took place in Japan that enhanced network marketing strategies (Sanghavi, 1990). More Japanese women were employed in the workforce, leading to less shopping hours available, and more of the younger people bought products based on trust, very typical of the network marketing channel. Also, more people were willing to experiment with newer shopping ways such as direct marketing, and a greater number of the aging population was looking for convenience in shopping, perhaps from home.

The entrepreneurial spirit that network marketing encourages is appealing to many who are interested in independent entrepreneurial activities outside traditional business settings (Gabriel, 1993). Many middle-aged Japanese managers, as well as managers from other nationalities in many parts of the world, are looking for independence from the typical employer-employee relationship at work and are venturing out on their own exploring nontraditional self-managed businesses. Network marketing provides a very viable opportunity in this area. When a firm uses a variety of network marketing strategies as tools for distribution and combines these with sustainable supply chain management activities, it is more likely to move toward achieving effective operations management and sustainability.

Significance of Supply Chain Management

Effective supply chain management, or sustainability in supply chain networks, focuses on a sequence of organizations, including facilities, activities, and functions, all integrated toward efficient production and delivery of products and services continually over a long period of time. Sustainability should be measured by not only profits, but also by the impact of the supply chain on ecological and social systems (Jennings & Zandbergen, 2005). An organization that performs well should be focused on doing well on traditional profit and loss measures, as well as on the expanded conceptualization of performance which includes social and environmental dimensions. This is often referred to in the supply chain literature as the triple bottom line (Kleindorfer et. al, 2005).

According to the literature on sustainability and supply chain management, the triple bottom line is affected by three major factors – existing best practices, supply chain strategy, and integration. Several studies have shown a connection between existing best practices in supply chain management, and environmental outcomes and practices. Positive relationships have been found between TQM (Clark, 1999) and JIT (King & Lenox, 2001) and environmental outcomes. Best practices related to sustainable supply chain management include collaboration between supply chain members, cooperation with suppliers, and certifications. Collaborative behaviors between suppliers and customers can enhance environmentally sustainable supply chains (Carter & Carter, 1998; Zhu & Sarkis, 2004). Practices that promote collaborative behaviors include incentives for suppliers to reduce their risk for trying novel collaborative practices required for the sustainability in the supply chain (Goodman, 2000). Firms should share knowledge and educate their suppliers, and these suppliers should educate other suppliers within their supply chain (Rao and Holt, 2005). Supplier certification, which denotes higher levels of quality, is another practice that promotes sustainable supply chain management (Teuscher, Gruninger & Ferdinand, 2005).

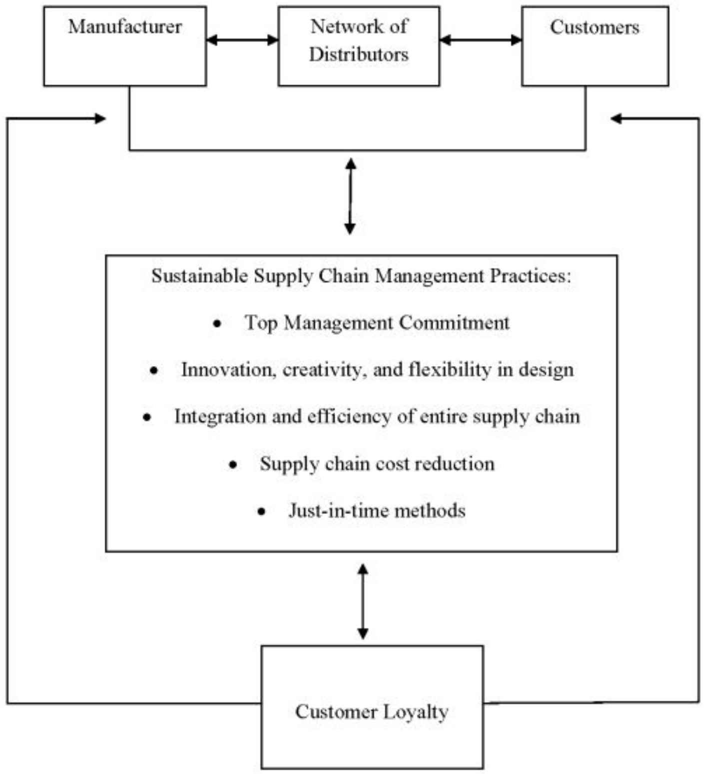
Supply chain strategy has a major impact on supply chain sustainability. Literature studies have described the use and significance of an ecocentric perspective for achieving sustainability -- referring to the organization's ability to adapt well to its social and natural environments (Seuring, 2004). The more flexible and adaptable the organization to its environment, the better its potential for achieving supply chain sustainability. This would allow the organization to include nongovernmental agencies, community groups and agencies, and perhaps even competitors which have traditionally been ignored. Collaboration amongst various members, including nontraditional members in the supply chain, enhances supply chain sustainability (Johnson & Linton, 2000). The use of innovation by a firm as a strategic option enhances sustainability. Sometimes, a firm can be innovative and adopt a service oriented strategy, providing more than the minimum level of service that would be traditionally provided. For example, some chemical suppliers offer chemical management services to other companies in their supply chains (Sharma & Henriques, 2005). They work with the buying firms and provide additional services such as helping design the production facility, facilitating with delivery and handling of materials, and perhaps even helping with waste treatment. Supply chain members are more like partners in a new, mutually beneficial relationship, where all members work together to enhance sustainability for the entire supply chain.

Another factor than enhances sustainability in the supply chain is the integration of sustainability goals, practices, and attitudes into day-to-day activities of supply chain management. Sustainability is everyone's responsibility within the supply chain, starting from top management of every firm. Firms that take a proactive stand toward the environment become more sustainable (Klassen & Whybark, 1999). Further, top management must show a strong commitment, along with taking a proactive stand toward sustainability, which often gets implemented as a written environmental policy (Ramus & Steger, 2000). Other factors that promote sustainability include improved measurement and design processes. Effective supply chain managers design improved measurement processes that show a connection between certain behaviors and desired outcomes, leading to rewards that employees value. This motivates employees toward improved performance, as well as achieving sustainability goals. Redesigning products and processes to eliminate or reduce pollution has shown to be associated with improvements in plant performance (Klassen & Whybark, 1999). It all begins with top management's willingness to provide a strong commitment to achieving sustainability in the supply chain. This may be enhanced by redesigning products and processes geared toward sustainability. Sustainability is made possible only with the cooperation of all employees, who will become involved if motivated properly with appropriate, relevant, and attractive incentives. Therefore, supply chain sustainability can be blended with network marketing by an organization to achieve positive outcomes, specifically customer loyalty, as illustrated in Figure 1.

Effective Network Marketing-Sustainable Supply Chain Integration (ENM-SSCI) Model

Figure 1 illustrates an integrated model, developed and discussed in the following section. This model blends together the strengths of network marketing strategy and supply chain management strategy. The model, referred to as the Effective

Figure 1. Effective Network Marketing-Sustainable Supply Chain Integration Model (ENM-SSCI)



Network Marketing-Sustainable Supply Chain Integration (ENM-SSCI) Model, focuses on the manufacturer using a network marketing strategy, via a network marketing structure or distribution channel, to interact with its customers. The network marketing distribution channel implements certain sustainable supply chain management strategies, which when blended together contribute toward establishing customer loyalty. Positive and strong customer loyalty, in turn, impacts the manufacturer-network marketing channel-customer chain thereby providing a continuous improvement aspect to the model.

The manufacturer makes a conscious decision to specifically choose a network marketing strategy and/or distribution channel because of multiple advantages, including the one-on-one personalized touch between distributor and customer, the cost benefits to the manufacturer in employing this distribution structure, capital requirement and cash flow advantages, improved and quicker action in terms of communication, promotions, new product introduction, improved coverage related to maximizing sales volume, market share, and market penetration, cross-cultural appeal that enables targeting expanded markets; and the entrepreneurial spirit that is encouraged amongst the distributors. All these advantages lead toward motivating stronger performance by the distributors and also enhance manufacturer-distributor relationships. The sustainable supply chain management strategies that are recommended in this model include top management commitment, design innovation, creativity and flexibility, supply chain integration and efficiency, overall supply chain cost reduction, and just-in-time methods for high performance in the supply chain.

To achieve sustainable supply chain management, top management has to be proactive and provide support and commitment to supply chain activities (Klassen & Whybark, 1999). Commitment and a proactive orientation are established through the integration of the economic and non-economic aspects of sustainability. Environmental and social goals should complement and tie in with economic goals and activities, such as revenue generation, profit, marketing, communication and distribution. A proactive orientation is exhibited through organizational attitudes toward sustainability. In a proactive organization, sustainability is part and parcel of the firm's tasks and activities and the mindset throughout the organization and at all times -- 24/7. All decisions made at a proactive and sustainable organization must impact the triple bottom line in some way. In addition, a proactive and committed firm focuses on guiding values or a philosophy related to sustainability that drives the entire organization and its decision making. Responsibility for sustainability must be shared amongst all members of the supply chain – it has to be a shared responsibility for the whole organization and not the responsibility of any one particular person. In this way, organizational sustainability is every organizational member's passion – when people have input in the decision making process for achieving and maintaining sustainability, they are more likely to implement it.

Innovation, creativity, and flexibility in supply chain design also enhance sustainability. These new practices include traceability and transparency (Roth, et. al, 2008). Traceability is an internal information sharing practice to facilitate supply chain performance and minimize risks in the whole chain. For example, information on ingredients or materials used in products in the entire chain, including all items that the supplier bought, should be provided and traced to the source, in order to ensure meeting the specifications and standards for quality and other aspects. Transparency refers to the access/information provided about the flow of money and all related activities, such as profitability, throughout the supply chain. Sustainability is enhanced through information sharing via transparency and traceability in the entire supply chain (Lee & Whang, 2000).

Sustainability is also improved through integration and efficiency of the supply chain by use of strategies such as maintaining supplier continuity and loyalty. As Japanese supply chain management practices have shown, supplier continuity and loyalty are key elements of sustainability (Liker & Choi, 2004). Companies that have continuity in long-term relationships with their suppliers have improved efficiency and integration, as well as the efficiency and integration of the entire supply chain. Sustainable companies treat their suppliers as family members and ensure keeping them successful and in business, as well as helping them to invest, innovate, and grow. Long-term, continuous supplier partnerships imply the use of fewer reliable suppliers, long-term relationships, continuity, loyalty, sharing of information, and cooperation in planning, all of which contribute toward the sustainability of both firms and their suppliers. Further, supplier continuity reduces supplier risk and offsets higher costs, as supply chain members help each other and ensure reliability in the supply chain. Local firms close to the manufacturer are supported and encouraged via long-term contracts and relationships through these supplier continuity strategies, thus providing mutual benefits to the manufacturing firms and their suppliers. Sustainability is enhanced through supplier certification. Supplier certification such as ISO 9000, the most widely used international certification, may provide the status of world class suppliers to firms that obtain it. A major advantage of using certified suppliers is that the buying firms can eliminate all or most of the inspection and testing costs of delivered goods, thus benefitting from lower costs of inspection and testing as well as saving time. Rather than checking and testing the supplies after they arrive, the manufacturing firm can use the items straightaway in their production processes, when they have arrived from a certified supplier. Honda Motors and Toyota use certified suppliers for many components, and both benefit tremendously, especially in terms of lower costs.

Another supply chain practice that promotes sustainability is the implementation of cost reduction strategies and tradeoffs when structuring a supply chain (Lee & Billington, 1992). The lot size-inventory tradeoff, when managed well, can lower the overall cost for both suppliers and the firms. Producing in large batches or ordering large lots provide benefits in terms of quantity discounts and lower setup cost; however, the carrying costs are higher for suppliers which carry these large inventories. An optimal tradeoff here can benefit both suppliers and firms. Similarly, the inventory-transportation cost tradeoff should be balanced. Suppliers prefer to ship large full truckloads to optimize their costs, but this leads to higher inventory carrying costs for customers. Optimal solutions include combining several orders, decreasing truckload capacity, cross-docking, where storage at the warehouse is eliminated, thereby incurring zero storage costs. Several companies including Wal-Mart have used a cross-docking strategy to offset transportation and storage costs. Lead time-transportation cost tradeoffs are enhanced through providing improved forecasting information to suppliers, which helps them in turn improve the timing of their production and orders to their suppliers. The product variety-inventory tradeoff may be optimized through delayed differentiation, which offsets the higher costs associated with product variety. Delayed differentiation minimizes production costs through standardization, rather than product variety and customization, in the production process. Similarly, the cost-customer service tradeoff may be influenced by shipping directly from warehouse to customer, by-passing the retail store. This saves on lead time and reduces storage costs, although it may increase transportation costs. Just-in-time methods enhance sustainability in supply chains. Dell Computers, for example, uses lean manufacturing to maintain sustainability in its supply chain. Dell uses a tiered approach, in terms of its suppliers, which means that, rather than buying from hundreds of suppliers, it buys from a small number of suppliers. It works with few first-tier suppliers which work directly with Dell or which supply major subassemblies. The first-tier suppliers take responsibility for managing their second-tier suppliers which supply components for subassemblies, thereby allowing the final buyer, Dell, to avoid dealing with many suppliers. This type of just-in-time structure enhances speed of delivery, quick and smooth flow of materials, efficiency, zero or little inventory, lower costs, improved quality, and overall increase in productivity, which benefits the entire supply chain.

The effective network marketing-sustainable supply chain management integration model has implications for several factors, including efficiency, profitability, growth and customer loyalty. This chapter focuses especially on customer loyalty -- an essential element for continuous and repeated business, which contributes to overall performance, profits, and growth (Reichheld, 2006). Customer loyalty is greatly enhanced, due to the strong relationships developed between manufacturers, suppliers, distributors, and customers through effective network marketing. This integrated relationship marketing is well illustrated in practice by the Coca Cola Company. The world famous soda company has successfully maintained its major strength for a long time, a strong distribution excellence, which it achieves through providing excellent customer/client satisfaction directly and indirectly to its customers. Strong customer satisfaction is generated by providing one-on-one personalized service to its direct customers and intermediaries – its highly trained network marketing professionals and relationship building experts such as wholesalers and retailers -- who are in constant close touch at the local levels with their final customers and end users. These strategies emphasize Coke's focus on customer service, customer satisfaction, personal stake, and sincere interest in the customer, which customers are looking for in today's business environment. Such a customer-oriented focus and ongoing strong customer service gives Coca Cola the distinctive competency and edge to stay ahead of the competition.

The loyalty factor is also illustrated by Chick-fil-A, the leading fast-food chicken franchise in the U.S. The turnover rate for operators at this chain is five percent a year in an industry which has about a 40 percent turnover rate. Chick-fil-a managers are proud of the way they treat their employees and consider themselves to be very successful, compared to their competition like McDonalds and Burger King, despite working six days a week (Chick-fil-A is closed on Sundays due to religious reasons). Loyalty leaders like Chick-fil-A, The Vanguard Group, and Enterprise Rent-A-Car have all grown at more than double the rate of their competition and enjoy a 15 to 20 percent cost advantage, which further enhances their growth and profit potential (Reichheld, 2006). Thus, the economics of loyalty are tremendously powerful in any industry. It is simple economics though – customer loyalty leads to repeat customers, and repeat customers mean more sales and revenue, which then leads to more profits and growth. What affects customer loyalty? Good customer service drives customers to become loyal repeat customers, and these repeat customers influence their friends and others to become customers too. Network marketing, together with sustainable supply chain management practices, lead to customer loyalty. Reichheld (2006) recommended some ways for building customer loyalty which many successful companies follow. One way includes win-win strategies and solutions – a company has to find processes, strategies, and solutions aimed at mutually beneficial outcomes for itself and its customers. Dell exemplifies this win-win strategy. Dell provides some unique customer services such as bundling software and making it available by shipping directly to the customer's desk. Dell's Premier Pages provide corporate accounts and their personnel a direct access to company-specific online information for delivery related information.

Another approach is to be selective with customers. Loyalty leaders cannot possibly give the world's best value to everyone, as this is almost impossible to do so. Enterprise Rent-A-Car illustrates this strategy. The average rental cost for a car at the airport from Enterprise was about half the price charged by its leading competitors like Avis and Hertz (Reichheld, 2006). Yet, Enterprise is a leader in its market. This is possibly due to its strategy of focusing on special agreements Enterprise has made with selected customers like State Farm Insurance and its clients, who due to prior good experience with Enterprise, will give the company a first try. This facilitates growth for Enterprise through its selective efforts and loyal customers. Another loyalty strategy is making the business simple and flexible in its customer service and transactions. The size of the team structure is a big factor in company flexibility. For Enterprise, Vanguard, and eBay, the ideal team structure is around seven to ten people – many of their competitors are structured larger and are inflexible. Across these successful companies, the relatively small team size make a positive contribution toward customer loyalty.

Loyalty-building companies use sensible and motivating incentives and rewards to enhance loyalty in customers and employees. Unlike some companies that may often try to attract new customers by offering them all kinds of incentives while ignoring their loyal customers (as they are hooked already or trapped), some innovative loyalty leaders like The Vanguard Group do just the opposite. Vanguard rewards its 10 years+ loyal customers by offering them special incentives including cutting their prices by one-third and other better deals that it does not offer to its short term customers.

Another innovative loyalty building strategy focuses on open, direct, communication between customers who help one another share information about the products and/or company and who interact with one another to solve the related problems affecting them. Cisco Systems, eBay, Microsoft and others all offer open communication message boards or similar platforms for their customers to interact, discuss, listen and talk with one another – this approach enhances customer loyalty amongst their customers, especially since this communication is free, current, updated, and available online. Further, companies must not only practice what they preach, but also preach what they practice. They must communicate to their loyal customers what they are loyal to – core values, principles, mission, vision, etc. and run their business according to what they have stated as their guiding principles. The most successful companies, including Chick-Fil-A, Hobby Lobby, Southwest Airlines and Enterprise, all follow this strategy.

Reichheld (2006) pointed out that companies need to focus on the "promoter" type of customers. These are the loyal customers who come back as repeat customers. For McDonalds, 80 percent of its sales revenue is obtained from 20 percent of its loyal repeat customers who eat at their restaurants at least three times per week. The "undecided," the "passive" and the "detractor" types of customers (all of whom do not help the company much) should have as minimal a focus as possible. The bottom line is that company growth is enhanced when a company has more "promoters" than its competition – more long-term repeat customers lead to higher loyalty, thus leading to higher sales, revenue, profits, and growth.

Some examples of progressive companies using variations of network marketing and sustainable supply chain management practices include Continental Power Corporation (CPC) based in Pennsylvania, and EcoQuest International based in Dallas, Texas. CPC, a partial network marketing company with one level of authorized distributors, is an environmentally conscious "green" company. It manufactures and markets commercial, residential, and industrial electrical products that improve the efficiency of electrical system, protect against spikes and surges, and reduce electrical noise, thereby prolonging the life of devices (Personal interview with Allen Johnston, Vice President, Continental Power Corporation, July 15, 2009). CPC has installed one half million systems nationwide and provided reduced consumption of electricity, saving 42,250 tons of coal, 231,500 barrels of oil, 940M cu ft of natural gas, reduced the emission of221,500 pounds of sulphur dioxide, 42,000 pounds of nitrous oxide, and 98,350 tons of carbon dioxide (Allen Johnston, 2009). CPC uses sustainable supply chain practices, such as being environmentally proactive in pursuing environmental, social, and economic goals and a variation of the just-in-time distribution system where large custom product systems are built on demand, usually within two weeks of receiving the order from a commercial client.

EcoQuest International, another environmentally conscious "green" company, produces and markets, through the network marketing model, a variety of environmental and healthy living products, including air, water and laundry purifiers. EcoQuest uses a variation of the network marketing-supply chain management system to distribute its innovative products directly to consumers. Other unique practices include providing rapid and almost instant delivery, excellent customer service, quality products and services, building customer loyalty and strong interpersonal relationships with customers and consumers. EcoQuest seeks environmental, social, and economic goals and focuses on activities that enable it to be a socially responsible company. In 2001, EcoQuest International exhibited corporate social responsibility by donating air purifier units that were used to help in the cleanup operations after 9/11 by the Department of Defense and other US government agencies (www.ecoquestintl.com).

Issues, Controversies, and Problems

The network marketing strategy is sometimes been considered controversial, due to the negative connotations it evokes in some people's minds. The controversial aspects of network marketing may occur due to some random abuse or misuse by some unscrupulous individuals who may unnecessarily hype or exaggerate the benefits of a network marketing strategy. However, this strategy, in itself, is not necessarily bad – like any other marketing strategy, when used properly it can reap adequate or even extraordinary benefits and rewards for networking marketers which implement their strategies effectively. Another problem with a network marketing strategy is that it is not meant to be "one strategy fits all" strategy. It is more suitable for specific consumer products, such as food related products, cosmetics, nutritional items, household appliances and goods, all of which benefit from a personalized touch, to stimulate buying behaviors. Further, such items lend themselves to being easily marketed over the internet, which enhances their distribution strategy in terms of speed of delivery, easier availability of information, products, and related services, and faster promotion of new products and services. Some suppliers have also been criticized for their practices, in terms of excessive profiteering and lack of a cooperative spirit. They often are guilty of minimizing transparency and traceability issues, both of which are essential to sustainability in the supply chain.

When implementing this model, organizations should be careful to ensure that the overall integration of the model is a critical outcome. The model works together, with each component complementing the others in a strong integrative manner. Also, it is a continuous improvement model, in that the entire model's components are constantly interacting and affecting one another toward greater effectiveness and sustainability. To make this implementation more feasible, organizational leadership (often provided by the manufacturing company) is mandatory. Whether it is Amway, EcoQuest International, Tupperware, Pampered Chef or any other network marketing company, the manufacturer/network marketing company should take responsibility for providing supply chain leadership.

Many network marketing companies operate in an international environment. Their network marketing strategies are usually standardized across the countries (with each company establishing and promoting its own unique network marketing strategies) as this is more cost-effective, but supply chain management practices are generally customized to each country's local culture, in order to ensure smooth supply chain integration and management within that county. For example, Amway in Malaysia or Japan follows the standardized network marketing principle of expecting its distributors to hold a certain required amount of inventory, however, that amount varies and is customized to adapt to the local culture. The specific attributes, experience, qualifications, and other selection criteria of the supply chain members vary from country to country and should be customized to fit each country's needs, laws, practices, etc.

A major difficulty is that this model is one-dimensional, in that it can either fully follow a traditional distribution strategy or the network marketing strategy – a blend of the two in the same country would be highly complex and virtually impossible. If a manufacturer wishes to adopt a blend of the two distribution strategies, then two separate divisions should be created to follow separate strategies. Companies that have chosen to go the network marketing route all the way and in every country they operate in believe that this strategy is more beneficial to all parties involved and very rewarding to themselves, their distributors, as well as to their customers.

SOLUTIONS AND RECOMMENDATIONS

To address these issues, a stronger integrative approach is necessary between the network marketing strategy and the supply chain. More cooperative efforts, coordination, and working together are necessary for the benefit of the entire network marketing organization and all of its supply chain members. Constant monitoring and evaluation, to ensure accountability and responsibility of all members of the entire supply chain, are essential to ensure smooth functioning of the whole system and to maintain sustainability within it. Effective leadership must be provided, usually by the manufacturer, to promote sustainability of the supply chain. The larger the organization becomes, the more complex it is to manage it effectively, especially in a cross-cultural and global context. It is highly recommended that such a large manufacturer/network marketing organization adopt some type of enterprise resource program (ERP) software, such as SAP, in order to effectively manage the whole realm of operations across the world. Enterprise resource programs help coordinate and integrate all functions and divisional units of the large organization and help promote improved decision making, communication, information-sharing, productivity, and growth.

FUTURE RESEARCH DIRECTIONS

As this chapter focused on a theoretical model of network marketing-supply chain management, it is suggested that future research studies should focus on empirically testing this model fully or at least major aspects of it. Also, testing this model in different global settings will provide a more comprehensive understanding of the model and its applications in cross-cultural contexts. It would also provide a more logical rationale for generalizing the conclusions and implications of the model discussed in this study.

CONCLUSION

This chapter has looked at the effective network marketing-sustainable supply chain management model and its implications for organizations especially in terms of customer loyalty. Using unique and innovative strategies for network marketing, blended together with sustainable supply chain management practices, an organization can pursue environmental, social, and economic goals which lead to significant outcomes, such as customer loyalty. Positive and strong customer loyalty, in turn, will impact the manufacturer-network marketing channel-customer chain, thereby providing a continuous improvement aspect to the model.

KEY TERMS AND DEFINITIONS

Network Marketing: Also more commonly referred to as direct sales, direct marketing or multilevel marketing and/or other similar concepts, is the direct distribution strategy of a product or service from the company to the consumers through effective relationship marketing between distributors and customers.

Sustainable Supply Chain Management: Effective supply chain management or sustainability in supply chain networks focuses on a sequence of organizations, including facilities, activities, and functions, all integrated toward efficient production and delivery of products and services continually over a long period of time. Sustainability should be measured by not only profits but also by the impact of the supply chain on ecological and social systems.

Chapter 72
Knowledge Management in SMEs:
A Mixture of Innovation, Marketing and ICT: Analysis of Two Case Studies

Saïda Habhab-Rave
ISTEC, Paris, France

ABSTRACT

Global economy is transforming the sources of the competitive advantages of firms, especially for firms embedded in local manufacturing systems. Based on the theoretical contributions to knowledge management and industrial districts, this paper describes alternatives firm's strategies and upgrading options by exploring the relationships among innovation, marketing and network technologies. Starting from the analysis of the global competitiveness report and the European Innovation Scoreboard, this paper focuses on the case of firms specializing in "furniture and textile" industries (fashion, mode, home products) to outline a framework explaining the new competitive opportunities for SMEs. Through a qualitative analysis, this paper presents two case studies of French firms that promote successful strategies based on a coherent mix of R&D based innovation, experienced marketing and design, by leveraging on ICT.

INTRODUCTION

Global economy is transforming the sources of firms' competitive advantages and especially for firms embedded in local manufacturing systems. As in the case of France, small and medium enterprises (SMEs) localized in industrial districts and specializing in low or medium-tech industries have built their success on productive flexibility, quality certification and incremental innovation. Literature on industrial districts has provided evidence of the sources of competitiveness of local systems (Porter, 1990). As opposed to large multinational corporations, district SMEs emphasize an alternative model of economic organization (Porter, 1998), in which external economies

DOI: 10.4018/978-1-4666-1945-6.ch072

support distributed production processes within the local networks of firms. From this perspective, on the one hand, scholars focused on the advantages offered by proximity in terms of technology spillovers and economic externalities (i.e., Krugman, 1991) (collective goods). On the other hand, studies on the knowledge economy (Arora et al., 1998) consider industrial districts as knowledge management systems, where the local context is able to sustain and facilitate creation, exploration and exploitation of knowledge, rooted into social practices (Nonaka and Takeuchi, 1995).

In the actual environment, SMEs are now facing competitive forces that impact on the sustainability of their strategies in the next years. First, manufacturing internationalization pushes firms operating in local supply chains to extend their networks beyond local boundaries to catch the opportunities of global value chains (Gereffi et al., 2005). While, on the one hand, a growing part of local productive activities may be transferred internationally with cost advantages, on the other hand, those paths may reduce a small firm's control over economic processes with negative influence on learning-by-doing innovation.

A second major challenge refers to the development and management of sales networks on a global basis, in a framework of stronger connections with the market. As many scholars have outlined, the interaction between customers and the firm through sales networks, as well as the web, is crucial in order to understand the market and anticipate demand trends. More important, building relationships with active customers (lead users and communities of customers) is part of a firm's innovation strategy, to obtain profitable knowledge for product and brand management (i.e. Sawhney, Prandelli, 2000). From this perspective, SMEs have to improve their competencies in interaction with customers at the international level, overcoming local, social and cultural boundaries as well as their traditional manufacturing approach. Such strategic options require more sophisticated marketing competencies, which are not usually available within SMEs operating in local productive systems.

Thirdly, the evolution of information and communication technologies (ICT) contributes to the debate about the transformation of the district firm model and the advantages of local embeddedness. Global supply chains and international commercial outlets ask the firm to increase control on processes at the organizational level and within the firm's extended value system. From this perspective, network technologies can strengthen information sharing, process transparency and interaction among players in the value system (final customers included). Large multinational companies were able to fill the gap with the flexible SME model in the 1990s, thanks to network technologies. These tools supported distance cooperative work, also increasing process monitoring, knowledge management and communication within a renovated firm model (Scott Morton, 1991). In the present scenario, SMEs are asked to update their strategies benefiting from network technologies. SMEs have to overcome the local environment as the prime source of innovation –local tacit knowledge mainly manufacturing-oriented and informally managed- by developing new capabilities to manage extended networks including research centers, designers, and customers.

Based on the theoretical contributions to knowledge management and industrial districts, this paper describes alternative firm's strategies and upgrading options by exploring the relationships among innovation, marketing and networks technologies. The paper focuses on the case of firms specializing in "furniture" and "clothes and shoes" industries (fashion, mode clothes, and equipments, home products) to outline a framework explaining new competitive opportunities for SMEs. Our hypothesis is that the learning-by doing innovation model that has characterized district firms in the past is no longer sufficient to sustain their competitive advantage. The RD based innovation, efficiently adopted in large corporations, can offer new strategic options to face international competition. However, it cannot be implemented easily in all district SMEs. Moreover, innovation cannot be limited to scientific knowledge management, but can benefit also from customer input and experience related to technical features as well as associations and symbols the product incorporates (Krippendorf, Butter, 1984). From this perspective, the capabilities of SMEs to manage networks of relationships and to translate customers' needs into products may open new competitive opportunities, under the condition of a well-defined ICT strategy.

In the first section, this paper analyzes the district SMEs' model and its impact on French competitiveness, based on the contributions and approaches to innovation of the Global Competitiveness Report and the European Innovation Scoreboard. The second section focuses on the drivers of competitive advantage and strategies of firms in terms of science-driven and market-driven innovation, also considering the role of ICT. Through a qualitative analysis, in the third section, this paper discusses two case studies of French firms that promote successful strategies based on a coherent mix of R&D based innovation, experienced marketing and design, by leveraging on ICT.

1. SMEs' COMPETITIVENESS IN THE INTERNATIONAL SCENARIO

Despite scholars' interests in the emerging countries economic model based on competitive local systems of SMEs, international analysis stresses the marginal role of France in the global arena as regards SME's capabilities to manage codified innovation. The Global Competitiveness Report of the World Economic Forum put France out of top 10, 16th in the international ranking. This study emphasizes the dynamics of growth and competitive factors of countries (with a focus on technology innovation, economic systems and institutional framework) through a comparative approach and identifies the competitive potentials of firms localized in each country. As opposed to success during the '80s and '90s, French economic system, and specifically SMEs specializing in "furniture" and "clothes and shoes" industries (home products, fashion, equipment…), seem to lack competitiveness, due to low investments in R&D and patents. Even in the European Union Framework, the tool used to evaluate competitiveness and performances of nations and regions – the European Innovation Scoreboard- describes a quite negative picture of French firms, based on a few indicators on firm's expenditure on R&D, the numbers of patents registered, and investments in advanced services.

As stressed by analysts, the prevalence of small and medium firms in the economic system is the principal reason for French weakness in managing innovation successfully. According to the data of European researchers, the French SMEs are characterized by learning-by-doing innovation. Thus, SMEs are not able to translate new knowledge into patents and codified outputs. Moreover, SMEs do not approach (formal) innovation with strategic intent and, hence, do not invest a relevant amount of resources in R&D, training and new technologies. Despite this negative picture, those studies mention a few French SMEs' strengths related to organizational innovation and strategic control on technical activities such as product design.

From our perspective, the explanation of such contradictory results can be explained by considering a broader approach to innovation, which does not cover only R&D based activities. Instead, innovation can also be linked with the development of intangible features of the product and customer experience as the main drivers of value creation. From this standpoint, there are many different ways through which innovation can be deployed: the value created through innovation and its impact on competitiveness is rooted in the variety of forms and processes of the innovation each firm is able to design in its own original way. Following this approach, recently, the European

Union has upgraded its framework of analysis by creating the Innovation Diversity Index, which is a measure oriented to capture the alternative forms of innovation characterizing countries and regions. Such an index is influenced not only by innovative firms that invest in R&D and patents, but also firms that have positive performances based on organizational innovation and innovation in marketing and design.

From this point of view, the competitive advantage of France becomes clearer. Despite their specialization in low or medium-tech industries, French SMEs and their leadership in the area of technological innovation (16th in the innovation pillar) are important attributes that have helped to boost the country's growth potential with regards to innovation management processes that develop and transform informal knowledge into value for the market. France's labour market flexibility continues to be ranked very low (131st) because of the rigidity of wage determination, high nonwage labour costs and the strict rules on firing and hiring. Another area of concern is macroeconomic stability (65th): the government budget deficit and the related public-sector debt ratio remain large, and the national savings rate, while growing, still remains low by international standards.

In this scenario, of near formalized procedures that lead to innovation –typically used in large corporations- one should also evaluate, on the one hand, the openness of the innovation cycle (innovation inputs beyond scientific knowledge and R&D) and, on the other hand, the results of innovation (outputs) and its use. Based on the Innovation Diversity Index of the EU, French SMEs show strong ability in the management of networks and collaboration. Traditional innovation drivers (R&D, skilled labor force and lifelong training) are weak in SMEs (ranked 21 out of 25). Instead, small firms are stronger in new knowledge generation and implementation.

According to the categories developed by the EU, French firms are classified as "modifier" in their innovation strategy because they capture and transform external knowledge into products through informal processes. Such approach is perceived either negatively, as it is not codified (and represents incremental innovation) or positively, as SMEs are flexible in knowledge management. Firms can reinvent products and processes in many original ways thanks to their reactivity to market inputs and demand and by developing differentiation strategies. This capability is supported by specific professional practices focused on product specialization available at the territorial level. We explain those results by referring to the economic district model, where small businesses belonging to local networks of production organize knowledge management through distributed innovation systems, instead of a large organization.

During the fordism paradigm, the large firm model has been considered the best way and scientific knowledge (and R&D) was the main driver of innovation. In the open innovation paradigm, distributed networks sustain innovation (Chesbrough, 2003) and customers can contribute with their knowledge (Von Hippel, 2005). Moreover, customers are available to pay for products that offer not only new features (technological innovation), but also which offer them an experience and the tangible value linked to associations with sensemaking supported by brand strategy, design and social participation (Prahalad, Ramaswamy, 2003). From this perspective, innovation cannot be limited to technological innovation, but should also include aesthetic and intangible elements created through marketing strategy (communication) (Bettiol, Micelli, 2005). According to this perspective, French firms may improve their position in the international competitive arena because of their specific capacity to face innovation.

2. STRATEGIES, KNOWLEDGE MANAGEMENT AND ICT

In low or medium-tech industries such as textile or furniture, the competition is increasing and requires firms to choose either cost leadership in the mass market or niche differentiation, while positioning in the middle-market is becoming more and more unsustainable (Silverstein, Fiske, 2003). As opposed to high-tech industries, in which the role of patents and collaboration with research institutions is crucial for product innovation, in the mentioned industries innovation cannot usually be perceived as patent-driven. Instead, innovation is linked to creativity, a firm's ability to manage variety (innovation as organizational capability), and mix inputs coming from the market, designers and marketing (Schmitt, Simonson, 1997). From this perspective, an evaluation of a firm's innovation performance and its strategy should not be limited only to R&D activities and its outputs. Rather, from our perspective, in the open-innovation paradigm (Chesborugh, 2003) it should also consider the extension and characteristics of the networks that sustain a firm's innovation (as inputs of knowledge) as well as innovation outcomes. Marketing scholars emphasize the role of the intangible as part of the innovation process and a result of the value offered to customers. Products are not sold only because of their new features and functionalities, but also, and often, due to the meaning they transmit through their shapes (design) and the experience they give to customers (Pine and Gilmore, 1999).

Studies on innovation process have stressed the role of codified knowledge in knowledge management cycles, while the analysis of social dynamics (Brown and Duguid, 2000) has outlined the situated learning system and the relevance of experience as a driver to develop and share complex knowledge. According to this point of view, SMEs operating in local manufacturing systems benefit from physical proximity to customers, suppliers and relevant communities of practices embedded into local contexts. However, the global competitive scenario forces SMEs to upgrade and develop new strategies where innovation processes are sustainable on an international level. In a complex and global market, where leading customers are far from the firm and there are numbers of potential knowledge sources for a firm's innovation (Tapscott & Williams, 2007), the local economic and social system is inadequate to offer SMEs all the relevant and useful knowledge to compete. On the one hand, modularity and codification can guarantee a more open and extended circulation and use of knowledge, across contexts. On the other hand, the more complex knowledge to manage, the higher the difficulties in codification and the need for promoting more sophisticated sharing strategies based on "pragmatic collaboration" (Helper, MacDuffie, Sabel, 2000) (people-to-people by face-to-face interaction or web-based).

Based on this distinction and the literature contributions on the topic, we can represent the sources of firms' competitive advantage (Grant, 1996; Kogut & Zander, 1996) by comparing the different role of knowledge developed by firms and the alternative strategies of knowledge management adopted. We identified alternative models (Table 1). On the one side, we can identify firms that compete by leveraging on R&D and scientific knowledge. Codification allows firms to enter into global networks of innovation and exchange knowledge on a broad scale with universities and research centers (regional innovation systems, Asheim Coenen, 2006). Local dynamics are supported by international connections, through which the firm is able to explore opportunities and exploit knowledge. On the other side, competitive advantage is based on customer relationship management built on experience. The firm is interested in selecting lead users and involving customer communities into the innovation processes, aiming at their sharing relevant knowledge (Von Hippel, 2005). It is a form of entrepreneurial innovation, with a strong role of marketing, as the firm's organization and processes are oriented to the market and to interact with external players (customers and lead users) to co-develop the product and the meaning related to it (Muniz & O'Guinn, 2001). Our hypothesis

Table 1. Competitive advantage and firm strategy

Technology	Organization	Marketing
R&D (patents)	Mix of different types of knowledge	Brand strategy design
Human Capital	Management of extended manufacturing and Commercial networks	communication and interaction with customers (lead Users, community)
Technological Innovation	Distributed innovation	
Science-based Innovation	Non technical – Marketing based innovation Entrepreneurial innovation	
←---→		
Focus on research	*Focus on organizational Processes*	*Focus on communication*

is that in the complex competitive scenario, firms may develop sustainable competitive advantage by mixing the strengths of the opposite models, where patents and R&D based innovation may be enhanced through marketing based innovation and vice versa.

- **Technology & R&D:** R&D within the traditional corporate value chain has been regarded as a function closely related to product development or manufacturing. However, there are indications that this is changing through the introduction of knowledge management and the fact that R&D is more often performed within networks across traditional corporate boundaries. Griffin and Hauser (1992a, 1992b) focus their research on the interaction of marketing and the R&D interface. Additionally, customers are rising as potential innovators, which should be included into the R&D process as early as possible. Based on the above discussion we suggest in this paper that a more market- and customer-oriented approach to R&D could be obtained by applying a radically different view of R&D activities. We propose a relationship marketing approach based on knowledge management.
- **Organization:** Attempts to define KM mirror and reflect the intangible, fragmented and multifaceted nature of knowledge itself. KM has thus been defined in a whole host of ways that vary in scope and focus. In terms of scope, the term has been used broadly to refer to "the capacity (or processes) within an organization to maintain or improve organizational performance based on experience and knowledge". In terms of focus, definitions emphasize, variously: organizational processes and routines; performance improvement outcomes; processes for networking and collaboration; practices for harnessing, storing and distributing expertise; specific tools and methodologies such as data-mining and storage systems. These definitions suggest a variety of practices and organizational processes "a skillful blend of people, business processes and IT". However, research and practice in KM has been dominated by a focus on using Information Technologies (Its) to store, search and transfer knowledge within and across organizations. The logic behind this technocratic approach to managing knowledge is that by implementing various kinds of IT (databases, intranets) coupled with relevant search engines, knowledge can be captured and transferred from place to place. The assumption here is that if knowledge is transferred via technology, it can be used for innovation in other parts of the organization and so means that the chances of needless-

ly what has already been done elsewhere will be minimized. The notion that knowledge can be extracted from where it lies, codified and moved, using Its, en masse from one place to another has been challenged for failing to adequately address the problems of managing tacit knowledge. Tacit knowledge by definition is, at best, difficult or, at worst, impossible to articulate, values and experiences that give tacit knowledge its meaning. Moreover, it is precisely because tacit knowledge is tacit that makes it difficult to for other organizations to imitate or import and therefore makes it an important organizational resource for securing competitive advantage. But the cognitive model of KM adopts a partial view of knowledge, assuming that knowledge lies with individuals and largely ignoring the socially constructed and socially mediated nature of knowledge. So, organizational knowledge is thus both widely distributed and embedded in collective systems of meaning and action. The aim is to discover the best practice in KM. with the development of the field of KM there has been a massive outpouring of articles and books dealing with these issues from a prescriptive standpoint. The problem is that many of these best practice prescription assume a direct, functional relationship between knowledge, marketing and innovation, despite evidence to suggest that this is over-simplistic.

- **Marketing:** The importance of marketing for business success is not new. Highly respected scholars like Peter Drucker and Theodore Levitt published their classic writings on these subjects as early as 1974 and 1975 respectively. Drucker (1974) argued that the only purpose for a business is to create a customer and that is achieved through marketing and innovation. Levitt (1975) argued that marketing is largely ignored because top management is wholly transfixed by the profit promises of technological R&D. Levitt also argued that product-orientedness in high technology works well where firms are pushed into new frontiers where they did not necessarily have to find markets but to fill them. Based on the above discussion we suggest in this paper that a more market-and customer-oriented approach to innovation could be obtained by applying different view of innovation activities.

In such competitive scenario, the analysis of a firms' strategy about innovation management cannot be developed without the study of their approach to information and communication technologies (ICT). On the one hand, these technologies support information management at a distance, by stressing the advantages of efficiency. On the other hand, thanks to multimedia tools, ICT allow the development of a virtual, interactive environment, where participants live the experience and are involved in social interaction on line. This environment offers opportunities related to knowledge creation and sharing, even in the case of complex knowledge (i.e. product innovation).

It is not our aim to describe the debate on the impacts of ICT on knowledge management in detail. We would outline the SMEs' approach to ICT investment and its influence on innovation. The international reorganization of manufacturing activities, as well as sales networks, push firms to adopt technological solutions that sustain coordination of activities in extended networks and organizations (Scott Morton, 1991). Moreover, the transformation in the consumption models described above asks firms to interact with customers in order to exploit the linkages with lead users and communities for innovation purposes. In both the strategic options of a science-based, competitive advantage (i.e. patents) and value-driven by "customer intimacy" and sensemaking (Treacy & Wiersema, 1997), network technologies become key factors in supporting competitiveness. In the open-innovation paradigm, ICT is in fact the valuable infrastructure for knowledge management aims, where knowledge is spread across contexts, organizations, and people (employees, customers).

Computers-mediated communication offers tremendous advantages of tracking and tracing dialogues and interactive relationships, as well as content development and sharing (digitalization, multimedia solutions, social software)(Von Hippel, 2005), even in complex situations. Hence, technologies can help firms overcome barriers and leverage the networks of connections characterizing the on-line environment (in primis among customers). Traditionally, ICT found primary application in large corporations, to solve coordination problems and support knowledge gathering and retrieval efficiently and effectively (Sproull, Kiesler, 1991). The role of technological infrastructure as a necessary condition for knowledge management did not match with the SME's competitive model. Especially within local systems, small firms have developed knowledge management mechanisms rooted in the social sphere of their contexts of embeddedness (Becattini & Rullani, 1996). Knowledge processes are usually not codified in formal procedures, but lie in the intensive communication and personal linkages within the organization, as well as outside the working domain, in the social fabric of places.

As shown in studies on ICT adoption in district firms (Chiarvesio et al., 2004), as opposed to large corporations, small and medium firms localized in local manufacturing systems have focused their attention on commodity-based technologies, such as email and web sites. Those technologies can be considered ready-to-use tools, which can be implemented in the organizational structure with low financial investments, as well as limited organizational changes. In industrial districts, SMEs'strategies in ICT investments have been characterized by:

- Selectivity in the technological solutions chosen;
- Incremental innovation processes based on learning-by-doing paths;
- A bottom-up process (no "master mind" at the local level).

During the new economy many scholars and analysts stress the potentialities of e-commerce for SMEs in terms of market enlargement and efficiency. Instead, research on ICT adoption by French district SMEs show rates of e-commerce, while the web is exploited as an interactive marketing tool. Firms do not consider the e-commerce solutions available adequate to manage "French" products for transactional purposes. Rather, firms stress the importance of web-based communication: the web becomes a medium to gather customers' feedback on products and support brand strategies.

More advanced technologies such as ERP (Enterprise Resource Planning) or groupware, tailored to large firms, are less diffused in small organizations. However, those solutions are considered crucial tools to increase process transparency and the control on distributed networks at the international level. In this perspective, the more extended the firm's value chain, the higher the need for upgrading the SMEs' strategy, where ICT sustains the firm's management beyond the local system. From our perspective, all the technological solutions available can be included in the framework of the knowledge management system, not limited to the organizational boundaries, but involving the players operating upstream (suppliers, designers, etc.) and downstream (sales agents, customers) in the product innovation as well as marketing activities.

3. COMPETITIVENESS IN FRENCH FIRMS

In this theoretical framework, we considered the strategies of firms specializing in low and medium-tech industries to explore the connection between R&D based and marketing-driven innovation processes, and the role of ICT in supporting those activities at the local and global level.

In order to explore the strategies of French firms in the scenario described above, we carried out a qualitative study on district SMEs to analyze knowledge management processes and firms' innovation approach (Yin, 1984). Based on a first selection of firms specializing in "agriculture and textile" sectors and located in north east of France, we interviewed entrepreneurs and the managers of R&D, design and information system departments. Interviews focused on a firm's history and strategy, organizational structure and innovation management models and ICT adopted. The two cases discussed in the paper are summarized in Table 2.

Case 1: "World Champions" in Mixing Design and Patents

One of the most famous companies of the sport system, firm X started in 1973 producing clothes and shoes, followed by shoes and other products for child and younger people. During the '80s the company internationalized its business, thanks to soccer shoes and international partnerships with France and foreign stars. Moreover, firm X is among the first district firms that invested in internationalization of productive activities beyond the local manufacturing system. As a leading firm in Parisian district, firm X invests in innovation to support its competitiveness by coupling R&D-based activities (scientific research on new materials, design, etc.) and the involvement of lead users. One of its latest products is, in fact, a mode of jeans, designed in collaboration with stars. Meanwhile, in a framework of global production and commercialization of products, network technologies have been considered key elements in the management of extended supply and sales networks with the district as the core.

In the new millennium, the attention for the investment in product quality has been increased through an explicit strategy that emphasizes the role of design and innovation as drivers of competitiveness. In the global competitive scenario, firm X is oriented to reinforce its international presence. In this perspective, cost reduction as a key goal to face competition has to be coupled with continuous product innovation. The development of original ideas –jeans – is the starting point in X's strategy. The management of internal knowledge is relevant both in terms of R&D and design – more than 20 patents have been registered or are in the process of registration. The development of research relationships with French and international universities stresses X's interests in exploring knowledge paths beyond the local district networks to sustain the company internationally.

As an open network firm, firm X has invested in network technologies systematically, by gathering different technology solutions – from their web site, to e-commerce, ERP, groupware and supply-chain management applications. The technological infrastructure sustains information flows and communication between the company and its international networks of partners and

Table 2. Case studies

Company	Innovation strategy	Main ICT investments
Case 1: Firm X 230 employees; Sport system: shoes and apparel	Mix of R&D (patent, relation with universities) and design	Explicit management processes
Case 2: Firm Y 40 employees; furniture	Collaboration with external international designers Patents	Internet to support online distributed product design processes

markets, in a strategic and codified knowledge management approach. In fact, firm X is interested in acquiring and sharing informal knowledge available within the organization through ICT (digital archives, database for intellectual property rights management).

Case 2: From the District to International Design Network

Firm Y is a small firm specialized in the production of high quality furniture and wooden complementary house products. It was founded in 1989 and is located in Paris in France, in the furniture district. Firm Y has developed its strategy by focusing on product differentiation through design. Since 1998, firm Y has been obtaining economic success and growth thanks to the international recognition of a few of the firm's products – the Parisian, a famous French design award promoted by the French design association- designed by one of Y's founders. From these awards, this small firm started relevant collaboration with international designers. Due to investments in developing personal relationships and connections with designers all over the world (Japan, Europe, USA), the firm was able to increase the product range and international sales (60% of the turnover is export-based).

Y's strategy is oriented to exploiting internal strong competencies in wood transformation and production of "natural wood" furniture. The manufacturing process is organized in small-scale stocks, with particular emphasis on product customization as regards to the material used and finishing activities. Specifically, a mix of hand-made and technological innovation processes characterizes Y's made-to-order production. As opposed to the typical district approach in which local suppliers are key players in the firm's innovation processes, Y has developed innovation mainly internally, through R&D activities and patenting, and is able to increase the technological features of the products as well as their design characteristics. In the global competitive scenario, Y's approach to innovation is double: on the one hand, the focus is on design and aesthetical components of products as drivers of economic success; on the other hand, this small firm invests also in codified knowledge to protect their ideas against competitors (1 to 3 years in the average time of the product innovation cycle). Y does not invest in market research. Instead, the firm exploits international designers and entrepreneur's knowledge about customers and future trends, as an emerging process.

The entrepreneur is confident about the strategic role of ICT to sustain the firm's competitive advantage. Network technologies are key tools to support creativity processes, while the web infrastructure allows Y to interact with its commercial networks. Specifically, the firm's exploitation of multimedia applications and broadband opens new opportunities in product design and development at the international scale. In fact, the product "Riddled" – obtained through collaboration with the famous Steven Hollen's design studio based in new York and produced in 39 plus 30 items – has been made possible thanks to on line communication and document sharing at a distance between France and the USA. At the same time, Y has also created an open and distributed digital archive concerning all the documents and digital contents about products and innovation processes to use them for marketing and knowledge management purposes.

4. CONCLUSION

The two case studies are characterized by successful strategies based on a mix of R&D-driven innovation and marketing, where firms developed strong relationships with customers. Innovation processes blend codified knowledge and tacit knowledge based on specific practices related to consumption or professional profiles (exploitation as well as exploration in knowledge management, J.March, 1991). The firms interviewed are able to couple scientific innovation with product innovation based on design, the creation of experience and focus on communication. The local context in which these firms are embedded is important, but it is not the only source of knowledge in order to build their competitive advantage. On the one hand, these firms are interested in creating new connections with foreign research centers to promote projects for product, technology or material innovation. On the other hand, they develop relevant linkages with the loci of consumption and with key players for creativity, to nurture the innovation process interactively.

The local context offers competencies in the manufacturing domain and sustains the culture of the product. However, competitive SMEs are able to create and manage extended networks by operating in global value chains and approaching innovation through the entrepreneurial innovation model identified by the European Union. To be sustainable those strategies require information and communication technologies, where ERP systems support advanced process management and increase interoperability, while web-based solutions for communication and product (document) management are also implemented in supply chain and commercial sales networks.

Even if our study is still preliminary in its term, the case studies offer a few managerial implications in the way the innovation process is outlined as an open process. First, firms should understand the types of relationships characterizing the players involved in the innovation dynamics, in order to develop consistent mechanisms of management (codification vs. interaction). Second, there are interesting opportunities in combining different kinds and sources of knowledge, which have to be identified and coordinated. Today, firms are asked to develop capabilities in accessing external knowledge (exploration) through people-moving and electronic connections. In addition to this flexibility and openness they also have to pursue strategies and use tools (ICT) coherent with the relationships developed.

Chapter 73
Developments in Modern Operations Management and Cellular Manufacturing

Vladimír Modrák
Technical University of Kosice, Slovakia (Slovak Republic)

Pavol Semančo
Technical University of Kosice, Slovakia (Slovak Republic)

ABSTRACT

Operations management as a knowledge domain appears to be gaining position as a respected and dynamic academic discipline that is undergoing constant development. Therefore, from time to time it is sensible to monitor and analyze its developments by summarizing new features into comprehensive ideas. To support this necessity, the major publications/citations in this field and their evolving research utility over the decades are identified in this chapter. Because the goal of this book is to present the advancements in the area of operations management research, especially of advanced topics related to the layout design for cellular manufacturing, the second part of this chapter is focused on developments in cellular manufacturing approaches and methods by mapping literature sources during the last decade. Finally, the relationships between concept or/and tools in both areas that are empirically considered as consequences or coincidences are identified.

INTRODUCTION

Although the overviews of detailed historical developments in each cognition domain are useful, this survey will discuss modern eras of operations management and cellular manufacturing in a successive order.

DOI: 10.4018/978-1-4666-1945-6.ch073

Operations management (often called production management) may be defined in different ways depending upon one's attitude or point of view. Since this discipline is a field of management, it focuses on carefully managing processes to produce and distribute products faster, better and more cheaply than competitors. Operations management (OM) practically concerns all the operations within the organization and the objectives of its activities focus on the efficiency and effectiveness of processes. The modern history of production and operations management was initiated in the 1950s by the extensive development of operations research tools such as waiting line theories, decision theories, mathematical programming, scheduling techniques and other theories. However, the material covered in higher education was quite fragmented without the umbrella of what is called production and operations management (POM). Subsequently, the first publications 'Analysis of Production Management' by Bowman and Fetter (1957) and 'Modern Production Management' by Elwood Buffa (1961) represented an important transition from industrial engineering to operations management. Operations management finally appears to be gaining a position as a respected academic discipline. Thus, this may be a good time to update the evolution of the field. To achieve this goal, the major publications/citations in this field and their evolving research utility over the decades will also be identified in this chapter. Subsequently, opportunities and challenges of a modern operations management that managers were facing during the last decade will be examined.

Because the goal of this book is to present the advancements in the area of operations management, especially advance topics related to the layout design for manufacturing environments, the second part of this chapter focuses on developments in cellular manufacturing approaches and methods. A large body of literature has attracted a number of researchers to present different reports on the state of the art at different points in time. Several researchers have reviewed the literature and categorized the different methods. Our intention in this chapter is to analyze production-oriented cell formation methods based on the review mapping literature sources from 2000 to 2010.

Finally, in this chapter, we will note the relationships between concept or/and tools in both areas that are empirically considered as consequences or coincidences.

OPERATIONS MANAGEMENT IN THE CONTEMPORARY ERA

The process of building operations management theory and the definition of its scope or area has been treated by a number of authors. As mentioned above, the modern era of POM is closely connected with the history of industrial engineering (IE). The development of the IE discipline has been greatly influenced by the impact of operations research (Turner et al. 1993). Operations research (OR) was originally aimed at solving difficult war-related problems through the use of mathematics and other scientific branches. The diffusion of new mathematical models, statistics and algorithms to aid decision-making had a dramatic impact on industrial engineering development. Major industrial companies established operations research groups to help solve their problems. In the 1960s, expectations from OR were extremely high, and as was commented by Luss and Rosenwein (1997), "over the years it often appeared that the mathematics of OR became the goal rather the means to support solving real problems." This caused OR groups in companies to be transferred to traditional organization units within companies. As a reaction to this disappointment Corbert and Van Wassenhove (1993) classified OR specialists into three classes: theoreticians, management consultants, who focus on using the available methods to solve practical problems, and the "in-between" specialists called operations engineers, who adapt and enhance methods and approaches in order to solve practical problems. The term "operations engineers" was formulated due to the lack of a better term and accordingly the group could also be referred to as operations managers and the field conducting applied research to help solve practical problems could be named production and operations management. In further developmental stages of OR, the term POM was consolidated and presented as concepts, methods and approaches related directly to productive systems and enhancing their management. Based on such a derivation of the mentioned disciplines it is obvious that IE, OR and OM have commonalities and similarities in their definitions. However, it is also important to specify the main differences among them. OM is a field of management, OR is a branch of applied mathematics (AM) and IE is an engineering discipline (Chase and Aquilano, 1989). In addition, according to Anderson (2002), OM and OR differ substantially, since "OM is managerially and activity oriented while OR is mainly technique and mathematically oriented involving modeling a situation or a problem and finding an optimal solution for it." Figure 1 illustrates a conceptual map of the compared disciplines with two axes: Symbolic/Real and Analytic/Synthetic.

As can be seen from the figure above, OM and OR follow two complementary routes that create a win-win scenario. Fuller and Martinec (2005), based on their analysis of the parallels between OM and OR, mentioned that both disciplines can be considered as "innovations" of the twentieth century.

Development Features of Operations Management

To discuss the important features of operations management, the reasonable action is to define and explain how the term can be understood from the viewpoint of the book's theme. For this purpose the following definition can be adopted: Operations management is concerned with the ways of achieving the most effective and efficient use of an organization's resources to produce goods and services needed by customers. It goes without saying that there are many other definitions that are more or less similar to the above definition. Although Chase and Aquilano (1989) precisely documented the historical development of OM starting with its real roots given by Taylor (1911), operations management is as old as industry itself (Bicheno and Elliot, 1997) and was articulated in the context of industrial production only after the 1960s (Baber, 1996; Landes, 1998). Because Chase and Aquilano in their above-mentioned book mapped

Figure 1. Conceptual map of relations between OM, IE, AM and OR

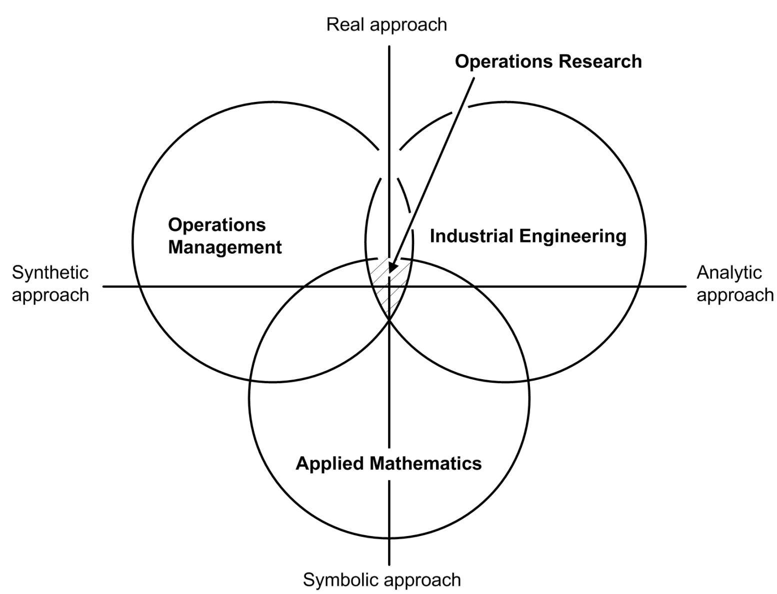

Table 1. Historical summary of the history of modern OM (adopted from Chase and Aquilano, 1989)

Decade	Concept or Tool	Originator or Developer
1950s	Extensive development of OR tools of simulation, Queuing theory, Decision theory, Project scheduling techniques of PERT and CPM	David Georg Kendall (UK) Erich Leo Lehmann (USA)
1960s	Mathematical programming in industrial applications, Extensions of linear programming	Tjalling Koopmans (Netherlands) George Bernard Dantzig (USA)
1970s	Software packages for: Shop scheduling problems, Layout design, Forecast methods, Material requirement planning (MRP)	Joseph Orlicky (USA) Oliver Wight (USA) George W. Plossl (USA)
1980s	JIT, TQC and TQM, Factory automation, CIM, FMS, CAD/CAM Manufacture resource planning (MRP II)	Taiichi Ohno (Japan) W. Edwards Deming (USA) Armand V. Faigenbau (USA) Joseph M. Juran (USA) Mikell. P. Groover (USA)
1990s	The principles process innovations and business process reengineering, Logistics and Supply Chain Management, Optimized Production Technology (OPT), Theory of Constraints,	Thomas H. Davenport, (USA) Michael Martin Hammer (USA) James A. Champy (USA) Richard J. Schonberger (USA) Martin Christopher (UK) Eliyahu M. Goldratt (Israel) Eliyahu M. Goldratt (Israel)
2000s	Management of technology change, Disruptive Innovations and Organizational Change Operations strategy,	Clayton M. Christensen (USA) Wick Skinner (USA) Slack Nigel (UK)

the history of the field of OM between circa 1910 and 1990, the following Table 1 gives an updated view of the historical development of operations management from the beginning of its modern era. The aim of this overview is to trace the key concepts and tools by decades from 1950 to 2010.

We are aware that the above specification of the latest developments in OM may not fully encompass all the decisive development directions, since operations management is a fair-sized and diversified field.

Opportunities and Challenges of Modern Operations Management

During the latest decennium operation managers had to react to unforeseen situations more frequently than they had needed to before. In this context they were facing new challenges of market globalization, information and communication technology advances as well as opportunities for organizational improvements and efficiencies.

One of the important challenges for the development of modern OM was the emergence of so-called global growth companies (GGCs). According to Jones (2005), during the mid-nineteenth century, thousands of European companies were formed exclusively to operate internationally with no prior domestic business. Those companies became momentous actors of economic globalization in international business. The emergence and influence of a new breed of high-growth global companies paying special attention to China and India was discussed by Kiggundu and Ji (2008). Concentrating on China and India as representatives of emerging economies explains the fact that these two countries were the best represented at the Dalian meeting in 2007 organized by the

Centre for Global Growth Companies. By then, "firms in emerging economies and developing countries tend to have weaker systems of corporate governance than those in developed economies." In this connection, findings from differences between emerging economies and developed economies provide excellent opportunities for the study of corporate governance among global growth companies.

The aim of specifying general decisive and substantial challenges that managers have faced during the last 10 years comprises a substantial task, as it depends on different aspects. In an attempt to complete this task, in the Table 2 we depict some topical challenges that are related to the latest concepts and tools shown in Table 1.

In the continuing text, some of the main features of accented concepts and tools assigned to the last decade (shown in the table 1) will be illustrated with the aim of proving their topicality.

Management of Technology Change

According to Thomas and B. Grabot (2006), two main factors have dramatically changed the industrial context in the manufacturing area: specialization and technological changes that have recently occurred in the information technology area. Attention to that fact along with a large diffusion of innovations in industries during the twentieth century most likely evoked the emergence of the new managerial discipline of management of technology (MoT). The term itself was first introduced at the European Management Forum held in Davos in 1981. There are several definitions of MoT, which differ in their understanding of the very object of technology management in the sense of what needs to be managed. Drejer (2002), in this context, commented that "the discipline of MoT is characterized by a vast number of contributions emerging in a divergent manner rather than a convergent one." A succint definition of MoT has been formulated, for example, by Bueno et al. (1997), according to whom it is "the

Table 2. Selected challenges of modern operations management

Challenge	Description
Global Competition	Global market is increasingly complex and constantly changing. Products are traded internationally and components are sourced internationally. It requires a greater degree of international and cross-cultural communications, collaborations, and cooperation than at any time before. All companies have to think in global terms as regional companies are rapidly becoming a thing of past. (Steers and Nardon 2006).
Developments in strategic management approaches	Hambrick and Fredericson (2001) in their paper have talk about their uncertainty of whether that most organizations do actually have a strategy. According to them a meaningful strategy might consist of five elements, providing answers to following questions: Where will we be active? How will we get there? How will we win in the market-place? What will be our speed and sequence of moves? How will we obtain our returns? In reality, most strategic plans emphasize one or two of the elements without giving any consideration to the others.
Supply Chain Standardization and Integration	During the last decade has been proved the slogan that, much competition occurs between supply chains, not just between individual firms. This is due to the fact that company can't act as isolated entity, but as a part of supply chain integrated system.
Complex external environments	It is of crucial importance to understand how external environment impacts on organization. Therefore, companies are quite interested in knowing about macro environment situation representing the information on trends for demography, market geography, technologies energy demand growth, labor productivity growth, etc.. The environment in a global economy and its interactions with organizations is not only a complex phenomenon, but it is constantly changing in nature. Accordingly, any aspects of the environment can't be study as deterministic entities. By Kazmi (2008), "the organization and the environment are, in reality, more unpredictable, uncertain and non-linear". Therefore, for their study the complexity theory including chaos theory and their applications are applicable.

combination of competences allowing technological capabilities aiding the achievement of business objectives to be promoted and controlled." Although definitions of MoT are specific to a concrete target platform, the main object of interest in this chapter is its relevant context to business activities. One of the important roles of MoT is to promote innovation. It is especially topical for organizations that face a serious problem when technological changes are necessary in response to market signals. The internal conditions for implementing advanced technology for routine production are not always adequate for achieving this aim. Draft (2010), in this context, saw a problem with the organization of work. He argued that this problem can be solved only through innovative-oriented organization, which is typically associated with change and is considered the best for adapting to a changing environment. Therefore, programmes for the development of employees' creativity have become an important element of a cohesive corporate strategy.

Disruptive Innovations and Organizational Change

Presently, distinctions between disruptive technologies versus sustaining technologies are frequently discussed. According to the findings of Bowers and Christensen (1995), disruptive changes in technology had a significant impact on industries and many leading companies failed when they were confronted with them. Paradoxically, these failed firms were well-managed companies that invested aggressively in new technologies, carefully studied market requirements and opportunities and sharpened their competitive edges. Christensen (2002) proposed five principles of disruptive technologies in order to find a way to understand and harness this phenomenon. In his fourth principle he focuses on an organization's capabilities and disabilities, stating that "to succeed consistently, good managers have to be skilled not only just in choosing, training, and motivating the right people for the right job, but in choosing, building and preparing the right organization for the job as well." So, it is axiomatic that the phenomena of disruptive innovations and management of technology change are mutually reinforcing.

Operations Strategy

Admittedly, the operations or manufacturing strategy is considered as an inherent part of the long-term corporate strategy. Chase et al. (2004) offered with his sketch of a short history of operations strategy a broader insight into current operations strategy research and determined its role in contributing operations management functions to a firm's ability to achieve its competitive advantage in the marketplace. Since a firm's strategies are often changing and developing, it implies making sensible decisions that affect the business performances directly. In that context Swink and Way (1995) saw the position of manufacturing strategy as "the decisions and plans affecting resources and policies directly related to the sourcing, production and delivery of tangible products." Slack and Lewis's (2002) view of operations strategy is that it is not only a single decision, but the total pattern of the decisions that include the extent and ability of its capacity; delivery of products and services; approach to developing process technology, etc. The importance of operations strategy follows on from the fact that the long-term success of manufacturing firms depends on their ability to vary their operations quickly enough to fill the changing requirements of customers. The key factor that makes the operations function faster is called the manufacturing vision. For this reason, all principal world-class manufacturers have explicitly formulated a strategic manufacturing vision. Practically, it means that all the decisions related to system design, planning, control and supervision made by shop-floor managers are consistent with a corporate vision. On the other hand, world-class manufacturing ambition is not the only issue that matters. Therefore, it is not always optimal to adopt the most offensive manufacturing concepts that are inherent in world-class manufacturers. Accordingly, investing in improving marketing activities, product design or manufacturing operations can be as effective.

DEVELOPMENTS IN CELLULAR MANUFACTURING APPROACHES AND METHODS

Cellular manufacturing (CM), considered as an application of GT philosophy and its principle that focuses on the identification of similar parts to the benefit of a particular production, offers promising alternative solutions for manufacturing systems. CM can essentially be comprehended as a strategy that divides machines and parts into small groups or cells, where each cell can produce a family of parts completely. The manufacturing cells are basically composed of the heterogeneous machines to produce particular families' parts, which are allocated to these cells. For this purpose, various approaches and methods have been developed. Moreover, the CM approach benefits both the job and mass production. The main enhancement of cellular manufacturing implementation incorporates reductions in set-up time, throughput time and material handling and improved quality management.

One of the basic problems that has to be solved before implementing CM is the cell formation problem (CFP). The objective of the CF is to establish the family of parts and the group of machines for subsequent processes. The process of cell formation differs with respect to whether manufacturing cells have been created by rearranging existing facilities on the shop floor or whether new facilities are acquired for the cells. During the decades, a significant amount of research papers have been devoted to this problem. In this regard, several attempts at the classification of CF methods have been introduced. The classification of CF approaches was introduced for instance by Offodile et al. (1994) and Irani et al. (1999) In order to generalize previous classification frameworks, Table 3 shows a basic categorization of CF approaches that is in accord with the already-introduced contributions. The cell formation methods in Table 3 are accordingly divided into three basic groups. Each group has its own direction for part or machine identification.

In the last four decades, CMS research has mainly focused on production-oriented approaches. Therefore, the comprehensive reviews and taxonomy of studies that are devoted to CFP have been presented in previous research works. The following authors participated with their research studies in arranging all these CF methods into groups based on criteria like the minimization of inter-cell moves, machine utilization and others. Wemmerlöv and Hyer (1986) categorized more than 70 papers into 4 representation groups. Subsequently, Selim et al. (1998) reviewed the lit-

Table 3. General classification of cell formation methods

Category	Brief description
Visual inspection methods	Visual inspection methods or eyeballing rely on the visual identification of the particular part families and machine groups.
Part classification and coding methods	PCA-based methods are oriented to design or shape feature. They attempt to group identical or similar design and manufacturing attributes into families. Therefore, they are ideal for reduction of product variety.
Production-oriented methods	The aim of these methods is to apply principles of line production to other types of production than mass production, even when the output is small and there is a large diversity of product. The PFA-based methods seek the optimal solution of cell formation in regard to objective and constraints.

erature (from 1963 to 1998) aimed at the cell formation problem, which is considered a fundamental issue in the CM environment. A comprehensive mathematical formulation of the CF problem has also been presented. The classification of reviewed papers based on multi-criteria cell design was employed by Mansouri et al. (2000), who applied the number of criteria as a measure for classification. They presented a review regarding the multi-criteria objective decision models that take into consideration the manufacturing cell formation problem.

Another view of the proposed taxonomy framework was introduced by Papaioannou and Wilson (2009). They also provided a review and comparison of 52 CF methods.

Production-Oriented Methods for CFP

Following the literature, the main scope within manufacturing cell formation methods focuses on production-orientated methods. In this section we present a modified classification framework for production-orientated CF methods and approaches based on the previous ones as shown in Figure 2.

In association with the proposed classification a brief review of the production-oriented CF methods in the following particular subsections is presented.

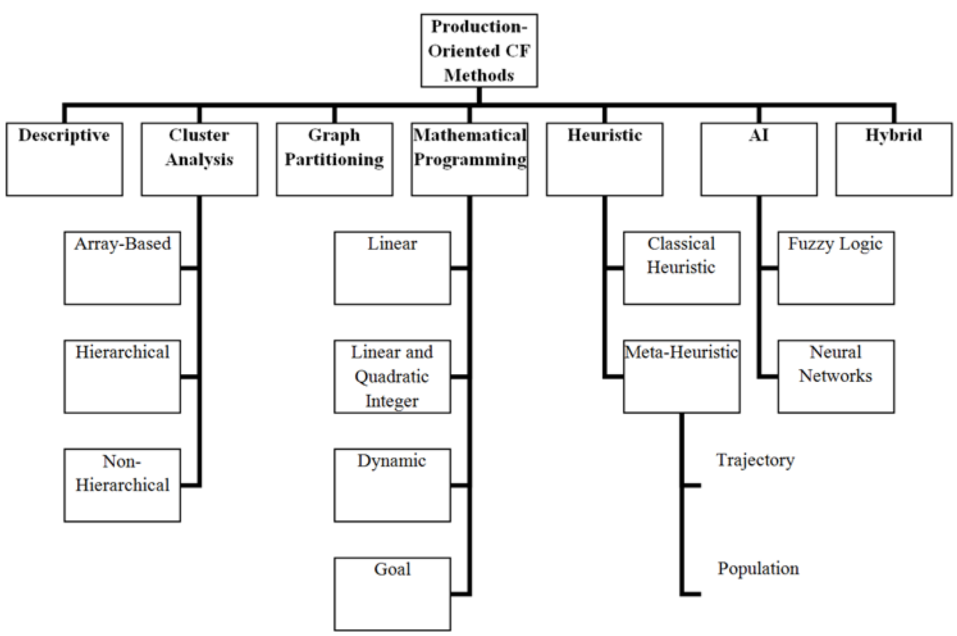
Descriptive Methods

One of the earliest descriptive approaches was developed by Burbidge, who began with the wave of CM systems. The proposed method by Burbidge (1971) is referred to as production flow analysis (PFA). The aim of PFA is to analyze the information from route cards to form cells. A manual method of Burbidge's PFA (1977) for CFP solutions is named nuclear synthesis.

Cluster Analysis Methods

Another group of approaches is presented as cluster analysis (CA). The objective of these methods is to group objects or entities or their attributes into clusters. Diverse techniques are applied in order

Figure 2. Classification of production-oriented methods for CF problem



to create clusters. Those techniques can be further classified as array-based clustering methods, hierarchical clustering methods and non-hierarchical clustering methods within their own subsection. The first one rearranges the order of rows and columns to find a block-diagonal structure of a machine-part incidence matrix (MPIM). They are also known as array-based methods. McCormcik et al. (1972) are counted among the first researchers to have developed the cluster analysis method for the CM environment. They introduced the bond energy analysis (BEA) method. The other well-known CA-based methods are rank order clustering (ROC) by King (1980), direct clustering analysis (DCA) by Chan and Milner (1982) and modified rank order clustering (MODROC) by Chandrasekharan and Rajagopalan (1986). The block-diagonal structure (BDS) uses the minimization of the number of exceptional elements (EE) as its objective. EE represent inter-cell moves, which means in practice that they imply undesirable movement of parts to machines between the individual cells. An exceptional element basically means a bottleneck machine allocated to a cell while it is required in the other cells simultaneously, or a part in a family that requires the capabilities of machines allocated to other cells. The traditional MPIM is also represented as the binary (zero-one) matrix. The rows of the MPIM are machines and columns stand for parts. The entries in the matrix are '0's and '1's, which indicate whether a part needs to be a machine for production or not. The mathematical formulation to create a binary machine-part incidence matrix is defined as follows.

$$a_{ij} = \begin{cases} 1 & \textit{if part } j \textit{ visits machine } i, \\ 0 & \textit{otherwise.} \end{cases} \tag{1}$$

where 'i' is the machine index (i = 1, 2, 3,…, M), 'j' the part index (j = 1, 2, 3,…, P), M stands for the number of machines, and P the number of parts.

Figure 3 a presents the initial machine-part incidence matrix with a size of 9 machines and 17 parts that is formed by Equation (1). Figure 3 b shows the block-diagonal structure that includes one exceptional element.

The hierarchical methods are aimed at the separation of the MPIM data in several stages. In the first stage the MPIM data are grouped into a few broad cells. Subsequently the broad cells are partitioned into smaller groups until terminal groups are generated. The most frequent hierarchical methods applied to cell formation have been

Figure 3. Illustration of (a) binary MPIM with size of 9x17 and (b) block-diagonal structure with one EE

8	0	0	0	0	0	0	0	0	0	0	0	0	0	1	1	1	1	1

b)

the three linkage methods. Single linkage (SL) was used by McAuley (1972), average linkage (AL) was used by Seifoddini and Wolfe (1986) and complete linkage (CL) was used by Mosier (1989). A representation of the hierarchical methods can be made by inverted tree structures also known as dendograms. The last of the cluster analysis methods, non-hierarchical methods, are iterative methods that need an initial partition of the data set. One of the well-known methods is ZODIAC, developed by Chandrasekharan and Rajagopalan (1987).

Graph Partitioning Methods

Graph partitioning methods consider machines or parts as nodes that are connected by arcs that represent the production flow between the machines. Graph methods enhance other methods like cluster analysis methods. Rajagopalan and Batra (1975) proposed the method that combines the use of a similarity coefficient and graph theory to solve the cell formation problem.

Mathematical Programming

Since the 1980s, a large number of research papers have been published in the field of mathematical programming with the aim of solving cell formation problems. Kusiak (1987), with his integer mathematical programming approach, was among the first of the authors to apply these methods to CFP. The formulation of mathematical programming (MP) can be employed to model CMS problems in a number of circumstances concerning a wide range of manufacturing data. The objective of MP is regularly maximization of the total number of part similarities in each cell, or minimization of inter-cell material handling costs. Most of the MP-oriented research papers are introduced and discussed by Selim et al. (1998). MP can be classified into four further groups with regard to their type of formulation: linear programming, linear and quadratic integer programming, dynamic programming and goal programming. Boctor (1991) dealt with the mathematical programming method. He proposed a linear formulation of the machine-part cell formation problem. Mathematical programming approaches belong to very time-consuming methods, which is why researchers have turned their attention to heuristic methods with their implementation in CMS.

Heuristic Methods

The heuristic methods are very fast in contrast to mathematical programming methods or others. It is generally known that the heuristic methods do not guarantee to find the optimal solution. However, if they are properly implemented and tuned up, the solution found will represent the optimum in most cases. They reach an optimal or pseudo-optimal solution in a reasonable amount of time. Heuristic methods start from a feasible solution then generate other random solutions, evaluate them and improve the effectiveness or goodness of the solution as time progresses. The presented classification framework in Figure 1 considers the further division of heuristics into classical heuristic methods and meta-heuristic methods, which incorporate evolutionary-based methods and population-based methods. There are numerous different heuristic approaches that are summarized in published review studies. Some of them are mentioned further.

Artificial Intelligence

Another significant group of methods aimed at CMS is introduced as artificial intelligence (AI) that is inspired by nature itself. Fuzzy logic and neural networks are the main approaches of this group. Kaparthi and Suresh (1992) proposed an application of neural networks to solve the cell formation problems. AI can be used to find patterns in manufacturing data in the CM environment. In most cases artificial intelligence approaches represent a robust and adaptive system. During the learning process they can perform a structure modification based on the information that flows through the network. Yang and Yang (2008) proposed a modified ART1 AI-based method to group data into machine-part cells. Guerrero et al. (2002) introduced the self-organizing neural network (SONN) approach, which solves the CF problem using a two-phase strategy. The first phase is dedicated to part-families formation and the second one assigns the machines to each part-family. Other contributors who have dealt with the artificial intelligence methods are shown in Table 2.

Hybrid Methods

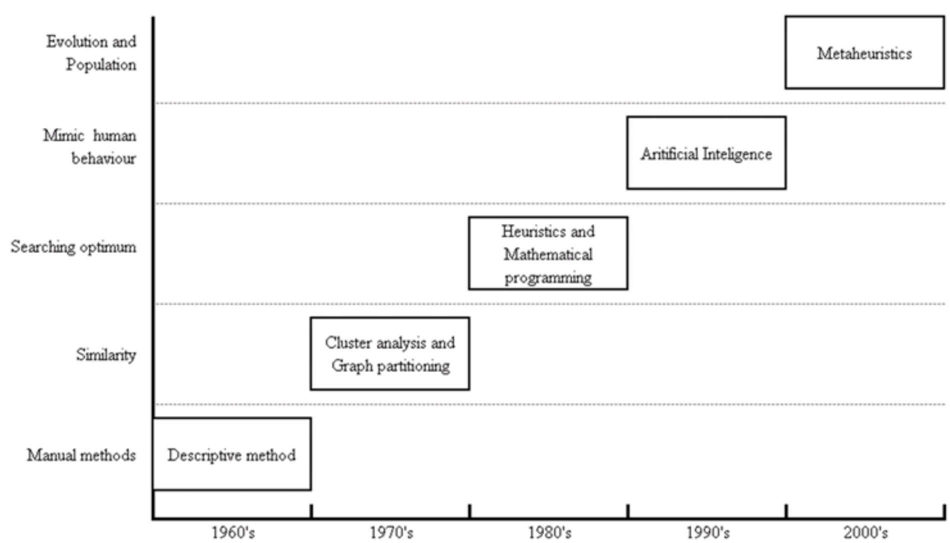
The last group, frequently referred to as hybrid methods, solves the CF problem by combinations of two different methods. In this case they are based on combinations of cluster analysis methods, mathematical programming methods, heuristics and AI approaches. The hybrids take advantage of both methods by applying them to the cell formation problems they can solve efficiently. Based on the literature, in the last decades the hybrid methods have become very popular for the cell formation process in CMS. Caux (2000) proposed an approach that combines both the simulated annealing (SA) and branch-and-bound (BB) algorithms. The proposed approach (SABB) can simultaneously solve CF problems consisting of grouping machines into manufacturing cells and selecting one process plan for each part. Other hybrid methods are incorporated in Table 3.

Review of Modern Methodologies for the Cell Formation Problem

Based on the literature we can introduce an overall view of the evolution of production-oriented methods in CMS. This overall view corresponds with the previously presented classification of CF methods. It is divided into decades, starting with the 1960s, as shown in Figure 4.

Based on the Figure 4 we can propose another classification of CF methods according to progressivity as follows: classical optimization CF methods and modern CF methods. The first category includes descriptive methods, cluster analysis methods, graph partitioning methods, mathematical programming methods and some of the heuristic methods. The second category is

Figure 4. Overall view of CF methods evolution



formed by meta-heuristics, hybrid methods and AI approaches.

Because there are a number of existing studies mapping the time period from 1960 to 2000, our review presented in Table 4 focuses on the last decade. For the purpose of this review a classification based on descriptive approaches, cluster analysis approaches, graph partitioning approaches, mathematical programming approaches, heuristics, artificial intelligence and hybrid methodologies has been applied to categorize recent works. In addition, the methods are reviewed by key elements, such as the maximum size of the problems solved and the performance measures used.

From the survey depicted in the graph (see Figure 5) it is possible to identify the frequency of production-oriented cell formation methods.

The graph shows that the most frequent category of production-oriented cell formation methods is heuristics, including meta-heuristics (category # 5). Heuristics have been employed in CFP due to their promptness and acceptable solutions. Besides the heuristics approach there is another category that has attracted attention over the last few years. This category includes hybrid-based CF methods, which have increased significantly among the researchers in combinatorial optimization. Hybrids exploit the best from both methods combined in one technique. This provides more efficient behavior and higher flexibility. Based on the findings depicted in Figure 5, hybrids along with AI-based CF methods (categories # 7 and # 6) create the second level of importance. The next level of importance includes cluster analysis and mathematical programming methods (categories # 2 and # 4).

Even though the mathematical programming and the heuristic method for the CF problem were firstly introduced in about the same decade, the use and further development of mathematical programming methods in CFP were affected by computational limitations for large-scale problems and they were also time consuming.

The heuristic category has been chosen to compare the usage of particular CF methods due to the fact that it is the most frequent category of all. Based on Figure 6, the most utilized CF methods of the meta-heuristic methods in decreasing order are GA, ACO and TS. The cumulative percentage of the methods used is about 67%. The rest of the methods do not exceed the 10% bound, including the classical heuristic-based CF methods along with the simulated annealing method, scatter search method, particle swarm optimization (PSO) method and water flow-like algorithm (WFA). The order of particular methods in Figure 5 is obviously influenced by the chronology of their development, which has been provided in Table 4. From the mentioned review of the modern cell formation approaches in the last decades it is evident that the scatter search (SS) and water flow-like algorithms (WFA) have just recently received attention for CME.

CONCLUSION

The presented parallel survey on modern operations management and cell formation approaches independently maps the major development features in both POM and CM areas. As shown by Figure 1, CM research also represents a subset of POM. Then, the relationships between concept and/or tools in both areas can be empirically considered as consequences or coincidences. The causal relationship depends on the chronological order and assumes that X precedes Y otherwise Y would not occur. Accordingly, the surveys are based on taxonomies (classes or categories of items) and the chronological timing of the development changes.

Based on the comparison of the two areas it is possible to imply that mathematical programming is a mutual technique for POM and CM, even though this technique was dominantly applied in the given areas in different time periods. It shows

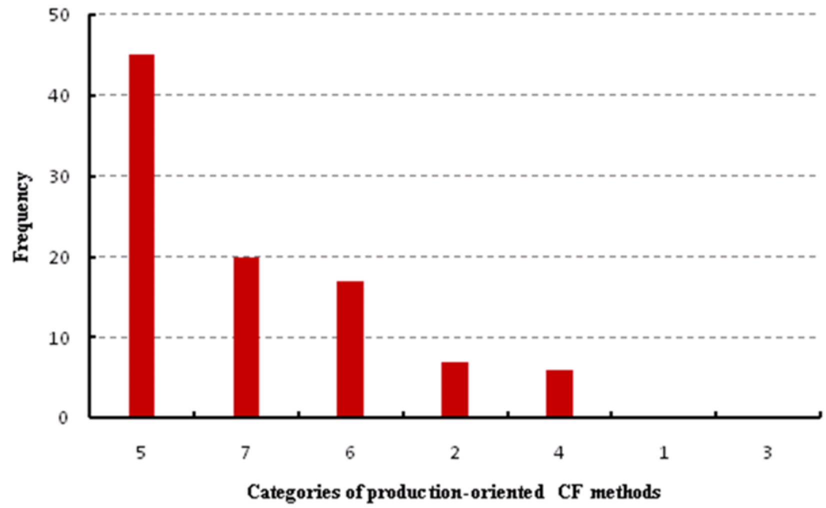
Notes:
(I) Source list of contributors
(II) Acronym of CF approach
ACO = ant colony optimization CA = cluster analysis F = fuzzy logic GA = genetic algorithm H = classical heuristic.
Hy = hybrid NN = neural network Pm = p-median PSO = particle swarm optimisation SA = simulated annealing.
SS = search scatter TS = tabu search WFA = water flow-like algorithm.
(III) Major categories of production-oriented cell formation methods
1 = Descriptive methods 2 = Cluster analysis 3 = Graph partitioning 4 = Mathematical programming.
5 = Heuristic methods 6 = Artificial intelligence 7 = Hybrid methods.
(IV) Performance and computational results of the CF methods used
A = max size of data set used (machines x parts) B = provides performance measure for max size of data set used.
C = comparison to other existing methods ('✓' = yes and '✗' = no) D = number of other existing methods used for comparison NA = not available.

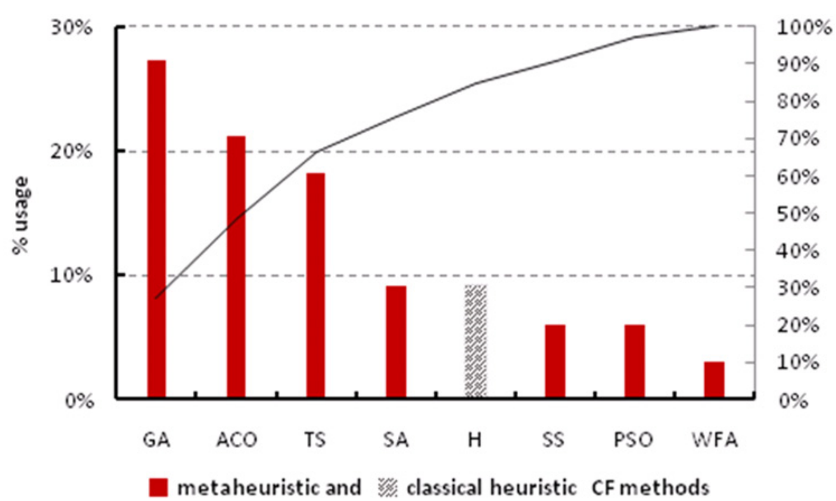
Figure 5. Frequency of individual categories for production-oriented CF methods



that CM research partially applies generic methods or techniques of POM.

From another point of view it is viable to identify causal relationships between concepts and tools in the two areas. This relationship can be seen, for example, between the JIT concept in the 1980s and an expansion of the heuristic methods in the 1980s. The extensive acceptance of the just-in-time (JIT) philosophy by various industries supported the development of cell manufacturing in firms as it is an important element in the successful implementation of just in time. With the rapidly increasing demand for such solutions, the need for more effective cell formation methods was naturally growing. This demand is likely to have accelerated the development of cell formation methods based on heuristics and mathematical programming.

Figure 6. The percentage usage of meta-heuristic and heuristic classical methods for CFP



Moreover, the surveys of POM and CM show some topical development directions, such as the importance of operation strategy in POM and the dominance of meta-heuristic techniques in cell formation problems.

Chapter 74
Fashion Supply Chain Management through Cost and Time Minimization from a Network Perspective

Anna Nagurney
University of Massachusetts Amherst, USA

Min Yu
University of Massachusetts Amherst, USA

ABSTRACT

In this chapter, we consider fashion supply chain management through cost and time minimization, from a network perspective, and in the case of multiple fashion products. We develop a multicriteria decision-making optimization model subject to multimarket demand satisfaction, and provide its equivalent variational inequality formulation. The model allows for the determination of the optimal multiproduct fashion flows associated with the supply chain network activities, in the form of: manufacturing, storage, and distribution, and identifies the minimal total operational cost and total time consumption. The model allows the decision-maker to weigh the total time minimization objective of the supply chain network for the time-sensitive fashion products, as appropriate. Furthermore, we discuss potential applications to fashion supply chain management through a series of numerical examples.

INTRODUCTION

In recent decades, fashion retailers, such as Benetton, H&M, Topshop, and Zara have revolutionized the fashion industry by following what has become known as the "fast fashion" strategy, in which retailers respond to shifts in the market within just a few weeks, versus an industry average of six months (Sull and Turconi (2008)). Specifically, fast fashion is a concept developed in Europe to serve markets for teenage and young adult women who desire trendy, short-cycle, and relatively inexpensive clothing, and who are willing to buy from small retail shops and boutiques

DOI: 10.4018/978-1-4666-1945-6.ch074

(Doeringer and Crean (2006)). Fast fashion chains have grown quicker than the industry as a whole and have seized market share from traditional rivals (Sull and Turconi (2008)), since they aim to obtain fabrics, to manufacture samples, and to start shipping products with far shorter lead times than those of the traditional production calendar (Doeringer and Crean (2006)).

Nordas, Pinali, and Geloso Grosso (2006) further argued that time is a critical component in the case of labor-intensive products such as clothing as well as consumer electronics, both examples of classes of products that are increasingly time-sensitive. They presented two case studies of the textile and clothing sector in Bulgaria and the Dominican Republic, respectively, and noted that, despite higher production costs than in China, their closeness to major markets gave these two countries the advantage of a shorter lead time that allowed them to specialize in fast fashion products. Interestingly and importantly, the authors also identified that lengthy, time-consuming administrative procedures for exports and imports reduce the probability that firms will even enter export markets for time-sensitive products.

Clearly, superior time performance must be weighed against the associated costs. Indeed, as noted by So (2000), it can be costly to deliver superior time performance, since delivery time performance generally depends on the available capacity and on the operating efficiency of the system. It is increasingly evident that, in the case of time-sensitive products, with fashion being an example par excellence, an appropriate supply chain management framework for such products must capture both the operational (and other) cost dimension as well as the time dimension.

For example, in the literature, the total order cycle time, which refers to the time elapsed in between the receipt of customer order until the delivery of finished goods to the customer, is considered an important measure as well as a major source of competitive advantage (see Bower and Hout (1988) and Christopher (1992)), directly influencing the customer satisfaction level (cf. Gunasekaran, Patel, and Tirtiroglu (2001) and Towill (1997)). Moreover, according to the survey of Gunasekaran, Patel, and McGaughey (2004), performance metrics for time issues associated with planning, purchasing, manufacturing, and delivery are consistently rated as important factors in supply chain management.

Conventionally, there have been several methodological approaches utilized for time-dependent supply chain management, including multiperiod dynamic programming and queuing theory (see, e.g., Guide Jr., Muyldermans, and Van Wassenhove (2005), Lederer and Li (1997), Palaka, Erlebacher, and Kropp (1998), So and Song (1998), So (2000), Ray and Jewkes (2004), and Liu, Parlar, and Zhu (2007)). However, according to the review by Goetschalckx, Vidal, and Dogan (2002), the paper by Arntzen et al. (1995) is the only one that has captured the time issue in the modeling and design of a global logistics system, with the expression of time consumption explicitly in the objective function.

In particular, Arntzen et al. (1995) applied the Global Supply Chain Model (GSCM) to the Digital Equipment Corporation so as to evaluate global supply chain alternatives and to determine the worldwide manufacturing and distribution strategies. In their mixed-integer linear programming model to minimize the weighted combination of total cost and activity days, the authors adopted a weighted activity time to measure activity days throughout the supply chain, which is the sum of processing times for each individual segment multiplied by the number of units processed or shipped through the link. However, we believe that the authors oversimplified the weighted activity time in assuming that the unit processing activity days are fixed, regardless of the facility capacities and the product flows. Also, in some other mathematical models dealing with time-sensitive demand, the lead time is used as the only indicator to differentiate the demand groups (see Cheong, Bhatnagar, and Graves (2004)). We note that Ferdows, Lewis, and Machuca (2004) recognized the nonlinear relationship between capacity and time in the context of the fashion industry and fast response with a focus on Zara and, hence, an appropriate model for fashion supply chain management must be able to handle such nonlinearities.

In this paper, we utilize a network economics approach to develop a mathematical model for fashion supply chain management that allows a firm to determine its cost-minimizing and time-minimizing multiproduct flows, subject to demand satisfaction at the demand markets, with the inclusion of an appropriate weight associated with time minimization. Hence, we utilize a multicriteria decision-making perspective. In addition, we allow the cost on each network link, be it one corresponding to manufacturing (or procurement), to transportation/shipment, and/or to storage, or to any other type of product processing, which may also include administrative processing associated with importing/exporting, to be an increasing function of the flow in order to capture the aspect of capacity and, in effect, congestion, as would result in queuing phenomena. Hence, we take some ideas from the transportation and logistics literature (cf. Nagurney (1999) and the references therein). Similar assumptions we impose on the link time functions since, clearly, the time to process a volume of fashion product should be dependent on the flow. Given the realities of the fashion industry in the US (see, e.g., Sen (2008)), it is imperative to have a methodological framework that can provide decision-makers with both cost and time information associated with the complex network of fashion supply chain activities. As early as Fisher (1997) it has been recognized that different products may require distinct supply chains.

Multicriteria decision-making for supply chain management applications has been applied in both centralized and decentralized decision-making contexts and in the case of general, multitiered networks (see, e.g., Nagurney (2006) and Nagurney and Qiang (2009) and the references therein) with the most popular criteria utilized being cost, quality, and on-time delivery (Ho, Xu and Dey (2010)). Nagurney et al. (2005), in turn, developed a multitiered competitive supply chain network equilibrium model with supply side and demand side risk (see also Dong et al. (2005) and Nagurney and Matsypura (2005)). Nagurney and Woolley (2010) studied the decision-making problem associated with supply chain network integration, in the context of mergers and acquisitions, so as to minimize the cost and the emissions generated. Nagurney and Nagurney (2010) added environmental concerns into a supply chain network design model. In this paper, we capture the explicit time consumption associated with fashion supply chain activities, along with the associated costs, within a network framework. The model in this paper provides decision-makers with insights associated with trade-offs between the operational costs and the time involved in a multiproduct fashion supply chain subject to multimarket demand satisfaction.

This paper is organized as follows. In ”The Fashion Supply Chain Management Model,” we develop the fashion supply chain management model and reveal the generality of the associated network framework. We provide both the multicriteria decision-making optimization model as well as its equivalent variational inequality formulation. The latter is given, for the sake of generality, since it provides us with the foundation to also develop models for multiproduct competition in the fashion industry, with results on supply chain network design under oligopolistic competition and profit maximization obtained in Nagurney (2010). In addition, the variational inequality form allows for the efficient and effective computation of the multiproduct supply chain network flows. We also provide some qualitative properties.

In “Numerical Examples” we illustrate the model and its potential applications to fashion supply chain management through a series of numerical examples. In the concluding section, we summarize the results in this paper and provide suggestions for future research.

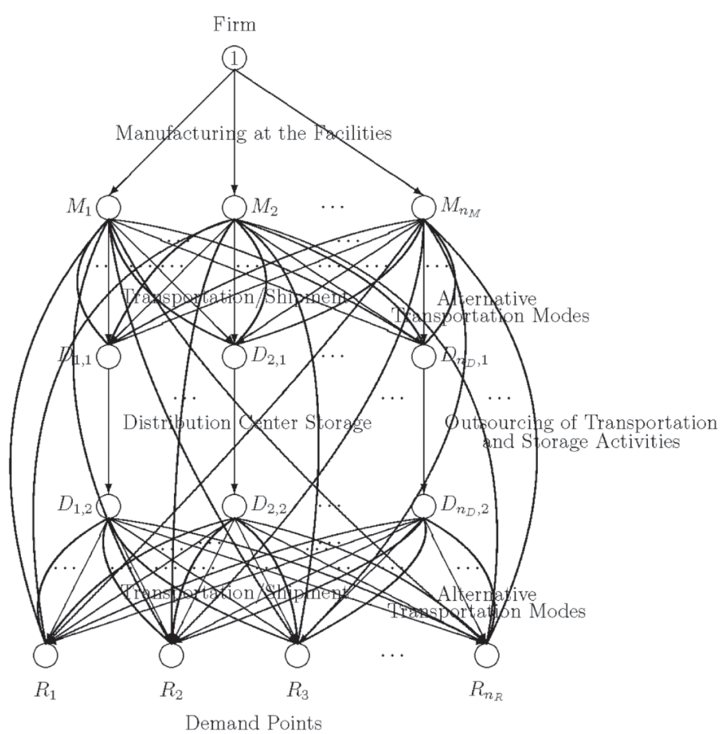
THE FASHION SUPPLY CHAIN MANAGEMENT MODEL

We assume that the fashion firm is involved in the production, storage, and distribution of multiple fashion products and is seeking to determine its optimal multiproduct flows to its demand points (markets) under total cost minimization and total time minimization, with the latter objective function weighted by the fashion firm.

We consider the fashion supply chain network topology depicted in Figure 1 but emphasize that the modeling framework developed here is not limited to such a network. This network is only representative, for definiteness. The origin node in the network in Figure 1 consists of node 1, which represents the beginning of the product processing, and the destination nodes, $R_1, \ldots, R_{n_R}$, are the demand points (markets) located at the bottom tier of the network. The paths joining the origin node to the destination nodes represent sequences of supply chain network activities corresponding to directed links that ensure that the fashion products are produced and, ultimately, delivered to the demand points. Hence, different supply chain network topologies to that depicted in Figure 1 correspond to distinct fashion supply chain network problems. For example, if the fashion product(s) can be delivered directly to the demand points from a manufacturing plant, then there would be, as depicted, links joining the corresponding nodes.

We assume that the fashion producing firm is involved in the production, storage, and transportation / distribution of *J* products, with a typical product denoted by *j*. In particular, as depicted in Figure 1, we assume that the firm has, at its dis-

Figure 1. The fashion supply chain network topology



posal, n_M manufacturing facilities/plants; n_D distribution centers, and must serve the n_R demand points. The links from the top-tiered node are connected to the manufacturing facility nodes of the firm, which are denoted, respectively, by: $M_1, \dots, M_{n_M}$. The links from the manufacturing facility nodes, in turn, are connected to the distribution/storage center nodes of the firm, which are denoted by $D_{1,1}, \dots, D_{n_D,1}$. Here we allow for the possibility of multiple links joining each such pair of nodes to reflect possible alternative modes of transportation/shipment between the manufacturing facilities and the distribution centers, an issue highly relevant to the fashion industry.

The links joining nodes $D_{1,1}, \dots, D_{n_D,1}$ with nodes $D_{1,2}, \dots, D_{n_D,2}$ correspond to the possible storage links for the products. Finally, there are multiple transportation/shipment links joining the nodes $D_{1,2}, \dots, D_{n_D,2}$ with the demand nodes: $R_1, \dots, R_{n_R}$. Distinct such links also correspond to different modes of transportation/shipment.

The outermost links in Figure 1 can also depict the option of possible outsourcing of the transportation and storage activities, with appropriate assigned costs and time values, as will be discussed below. Indeed, our supply chain network framework is sufficiently general and flexible to also capture alternatives (such as outsourcing of some of the supply chain network activities) that may be available to the fashion firm.

We assume that in the supply chain network topology there exists one path (or more) joining node 1 with each destination node. This assumption for the fashion supply chain network model guarantees that the demand at each demand point will be satisfied. We denote the supply chain network consisting of the graph $G=[N, L]$, where N denotes the set of nodes and L the set of directed links.

The demands for the fashion products are assumed as given and are associated with each product and each demand point. Let d_k^j denote the demand for the product j; $j=1,\dots,J$, at demand point R_k. A path consists of a sequence of links originating at the top node and denotes supply chain activities comprising manufacturing, storage, and transportation/shipment of the products to the demand nodes. Note that, if need be, one can also add other tiers of nodes and associated links to correspond to import/export administrative activities. Let x_p^j denote the nonnegative flow of product j on path p. Let P_k denote the set of all paths joining the origin node 1 with destination (demand) node R_k. The paths are assumed to be acyclic.

The following conservation of flow equations must hold for each product j and each demand point R_k:

$$\sum_{p \in P_k} x_p^j = d_k^j, \quad j = 1, \dots, J; \quad k = 1, \dots, n_R, \tag{1}$$

that is, the demand for each product must be satisfied at each demand point.

Links are denoted by a, b, etc. Let f_a^j denote the flow of product j on link a. We must have the following conservation of flow equations satisfied:

$$f_a^j = \sum_{p \in P} x_p^j \delta_{ap}, \quad j = 1, \dots, J; \quad \forall a \in L, \tag{2}$$

where $\delta_{ap}=1$ if link a is contained in path p and $\delta_{ap}=0$, otherwise. In other words, the flow of a product on a link is equal to the sum of flows of the product on paths that contain that link. Here P denotes the set of all the paths in Figure 1. The path flows must be nonnegative, that is,

$$x_p^j \geq 0, \quad j = 1, \dots, J; \quad \forall p \in P. \tag{3}$$

We group the path flows into the vector x and the link flows into the vector f, respectively.

Below we present the optimization problems in path flows and in link flows.

There is a unit operational cost associated with each product and each link (cf. Figure 1) of the network. We denote the unit cost on a link a associated with product j by c_a^j. . The unit cost of a link associated with each product, be it a manufacturing link, a transportation/shipment link, or a storage link, etc., is assumed, for the sake of generality, to be a function of the flow of all the products on the link. Hence, we have that

$$c_a^j = c_a^j(f_a^1,\ldots,f_a^J), \quad j=1,\ldots,J; \quad \forall a \in L. \tag{4}$$

Note that in the case of an outsourcing link for a fashion product the unit cost may be fixed, as per the negotiated contract.

Let C_p^j denote the unit operational cost associated with product j; j=1,…,J, on a path p, where

$$C_p^j = \sum_{a\in L} c_a^j \delta_{ap}, \quad j=1,\ldots,J; \quad \forall p \in P. \tag{5}$$

Then, the total operational cost for product j; j=1,…,J, on path p; p∈P, in view of (2), (4), and (5), can be expressed as:

$$\hat{C}_p^j(x) = C_p^j(x) \times x_p^j, \quad j=1,\ldots,J; \quad \forall p \in P. \tag{6}$$

The total cost minimization problem, hence, is formulated as:

$$\text{Minimize} \quad \sum_{j=1}^{J}\sum_{p\in P} \hat{C}_p^j(x), \tag{7}$$

subject to constraints (1) and (3).

In addition, the firm also seeks to minimize the time consumption associated with the demand satisfaction for each product at each demand point. Let t_a^j denote the average unit time consumption for product j; j=1,…,J, on link a, a∈L. We assume that

$$t_a^j = t_a^j(f_a^1,\ldots,f_a^J), \quad j=1,\ldots,J, \quad \forall a \in L, \tag{8}$$

that is, the link average unit time consumption is, also, for the sake of generality, a function of the flow of all the products on that link.

Therefore, the average unit time consumption for product j on path p is:

$$T_p^j = \sum_{a\in L} t_a^j \delta_{ap}, \quad j=1,\ldots,J, \quad \forall p \in P, \tag{9}$$

with the total time consumption for product j on path p, in view of (2), (8), and (9), given by:

$$\hat{T}_p^j(x) = T_p^j(x) \times x_p^j, \quad j=1,\ldots,J; \quad \forall p \in P. \tag{10}$$

The objective of time minimization problem is to minimize the total time associated with the supply chain network processing of all the products, which yields the following optimization problem:

$$\text{Minimize} \quad \sum_{j=1}^{J}\sum_{p\in P} \hat{T}_p^j(x), \tag{11}$$

subject to constraints (1) and (3).

The optimization problems (7) and (11) can be integrated into a single multicriteria objective function (cf. Dong et al. (2005)) using a weighting factor, ω, representing the preference of the decision-making authority. Please note that ω here can be interpreted as the monetary value of a unit of time. Consequently, the multicriteria decision–making problem, in path flows, can be expressed as:

$$\text{Minimize} \quad \sum_{j=1}^{J}\sum_{p\in P}\hat{C}_p^j(x)+\omega\sum_{j=1}^{J}\sum_{p\in P}\hat{T}_p^j(x), \tag{12}$$

subject to constraints (1) and (3).

The optimization problem (12) with the use of (2), (4), (5), (8), and (9), can be equivalently reformulated in link flows, rather than in path flows, as done above, as:

$$\text{Minimize} \quad \sum_{j=1}^{J}\sum_{a\in L}\hat{c}_a^j+\omega\sum_{j=1}^{J}\sum_{a\in L}\hat{t}_a^j, \tag{13}$$

subject to constraints (1)-(3) where $\hat{c}_a^j \equiv c_a^j(f_a^1,\ldots,f_a^J)\times f_a^j$ and the $\hat{t}_a^j \equiv t_a^j(f_a^1,\ldots,f_a^J)\times f_a^j$. We assume that the total link cost functions $\hat{c}_a^j$ and total time functions $\hat{t}_a^j$ are convex and continuously differentiable, for all products j and all links $a\in L$.

Let K denote the feasible set such that

$$K \equiv \{x \mid (1)\,\text{and}\,(3)\;\text{are satisfied}\}. \tag{14}$$

We now state the following result in which we derive the variational inequality formulations of the problem in both path flows and link flows, respectively. Having alternative formulations allows for the application of distinct algorithms (see, e.g., Nagurney (2006)).

THEOREM 1

A path flow vector $x^*\in K$ is an optimal solution to the optimization problem (12), subject to constraints (1) and (3), if and only if it is a solution to the variational inequality problem in path flows: determine the vector of optimal path flows, $x^*\in K$, such that:

$$\sum_{j=1}^{J}\sum_{p\in P}\left[\frac{\partial\hat{C}_p^j(x^*)}{\partial x_p^j}+w\,\frac{\partial\hat{T}_p^j(x^*)}{\partial x_p^j}\right]\times(x_p^j-x_p^{j^*})\geq 0,\quad \forall x\in K, \tag{15}$$

where

$$\frac{\partial\hat{C}_p^j(x)}{\partial x_p^j}\equiv\sum_{l=1}^{J}\sum_{a\in L}\frac{\partial\hat{c}_a^l(f_a^1,\ldots,f_a^J)}{\partial f_a^j}\delta_{ap},$$

and

$$\frac{\partial\hat{T}_p^j(x)}{\partial x_p^j}\equiv\sum_{l=1}^{J}\sum_{a\in L}\frac{\partial\hat{t}_a^l(f_a^1,\ldots,f_a^J)}{\partial f_a^j}\delta_{ap}.$$

A link flow vector $f^*\in K^1$ is an optimal solution to the optimization problem (13), subject to constraints (1) – (3), in turn, if and only if it is a solution to the variational inequality problem in link flows: determine the vector of optimal link flows, $f^*\in K^1$, such that:

$$\sum_{j=1}^{J}\sum_{l=1}^{J}\sum_{a\in L}\left[\frac{\partial\hat{c}_a^l(f_a^{1^*},\ldots,f_a^{J^*})}{\partial f_a^j}+\omega\,\frac{\partial\hat{t}_a^l(f_a^{1^*},\ldots,f_a^{J^*})}{\partial f_a^j}\right]\times(f_a^j-f_a^{j^*})\geq 0,\quad \forall f\in K^1, \tag{16}$$

where

$$K^1\equiv\{f \mid (1)-(3)\,\textit{are satisfied}\}.$$

Proof: The result follows from the standard theory of variational inequalities (see the book by Nagurney (1999) and the references therein) since the functions comprising the objective functions are convex and continuously differentiable under the imposed assumptions and the respective feasible sets consisting of the constraints are nonempty, closed, and convex. Q.E.D.

In addition, the following theoretical results in terms of the existence of solutions as well as the uniqueness of a link flow solution are immediate from the theory of variational inequalities. Indeed, the existence of solutions to (15) and (16) is guaranteed since the underlying feasible sets, K and K^1, are compact and the corresponding functions of marginal total costs and marginal total time are continuous, under the above assumptions. If the total link cost functions and the total time functions are strictly convex, then the solution to (16) is guaranteed to be unique.

It is worth noting that the above model contains, as a special case, the multiclass system-optimization transportation network model of Dafermos (1972) if we set ω=0. The fashion supply chain management network model developed here is novel since it captures both the reality of multiple products in this application domain as well as the significant relevant criteria of cost minimization as well as time minimization in the production and delivery of the fashion products to the demand markets.

Variational inequality (15) can be put into standard form (see Nagurney (1999)): determine $X^* \in$ K such that:

$$\langle F(X^*)^T, X - X^* \rangle \geq 0, \ \forall X \in \mathrm{K}, \tag{17}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product in n-dimensional Euclidean space. Indeed, if we define the column vectors: X=x and

$$F(X) \equiv \begin{bmatrix} \dfrac{\partial \hat{C}_p^j(x)}{\partial x_p^j} + \omega \dfrac{\partial \hat{T}_p^j(x)}{\partial x_p^j}; \\ j = 1, \ldots, J; p \in P \end{bmatrix}, \tag{18}$$

and K=K then (15) can be re-expressed as (17).

Similarly, if we define the column vectors: X=f and

$$F(X) \equiv \begin{bmatrix} \dfrac{\partial \hat{c}_a^l(f_a^1, \ldots, f_a^J)}{\partial f_a^j} + \omega \dfrac{\partial \hat{t}_a^l(f_a^1, \ldots, f_a^J)}{\partial f_a^j}; \\ j = 1, \ldots, J; l = 1, \ldots, J; a \in L \end{bmatrix}, \tag{19}$$

and K=K^1 then (16) can be re-expressed as (17).

Note that the above model may be transformed into a single product network model by making as many copies of the network in Figure 1 as there are products and by constructing appropriate link total cost and time functions, which would be nonseparable, and by redefining the associated link flows, path flows, and demands accordingly. For details, see Nagurney and Qiang (2009) and the references therein.

NUMERICAL EXAMPLES

We now, for illustration purposes, present fashion supply chain numerical examples, both single product and multiproduct ones.

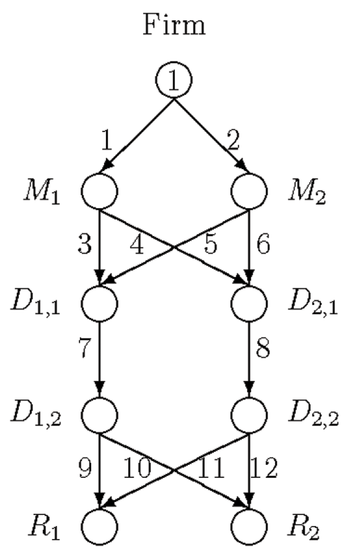
Single Product Fashion Supply Chain Examples

We assume that the fashion firm is involved in the production of a single fashion product and has, at its disposal, two manufacturing plants and two distribution centers. It must supply two different demand points. Hence, the topology is as depicted in Figure 2.

The manufacturing plant M_1 is located in the U.S., while the manufacturing plant M_2 is located off-shore and has lower operating cost. The average manufacturing time consumption of one unit of product is identical at these two plants, while the related costs vary mainly because of the different labor costs. The total cost functions and the total time functions for all the links are given in Table 1.

The demands for this fashion product at the demand points are:

Figure 2. The supply chain network topology for the numerical examples



d_1=100, d_2=200,

that is, the market at demand point R_1 is half that at demand market R_2.

We used the the general equilibration algorithm of Dafermos and Sparrow (1969) (see also, e.g., Nagurney (1999)) for the solution of the numerical examples.

We conducted sensitivity analysis by varying the value of time, ω, for ω=0,1,2,3,4,5. The computed optimal link flows are reported in Table 2.

We now display the optimal link flows as ω varies for the manufacturing links in Figure 3; for the first set of transportation links in Figure 4; for the set of storage links in Figure 5, and for the bottom tier of transportation links in Figure 6.

It is interesting to note from Figure 3 that, with the increase of the value of time, part of the fashion production is shifted from offshore manufacturing plant M_2 to onshore facility M_1, due to the onshore facility's advantage of shorter transportation time to distribution centers (or demand markets). Consequently, there is an increase in transportation flow from the onshore facility M_1 to the distribution centers, as depicted in Figure

Table 1. Total link operational cost and total time functions

Link *a*	$\hat{c}_a(f_a)$	$\hat{t}_a(f_a)$
1	$10f_1^2 + 10f_1$	$f_1^2 + 10f_1$
2	$f_2^2 + 5f_2$	$f_2^2 + 10f_2$
3	$f_3^2 + 3f_3$	$.5f_3^2 + 5f_3$
4	$f_4^2 + 4f_4$	$.5f_4^2 + 7f_4$
5	$2f_5^2 + 30f_5$	$.5f_5^2 + 25f_5$
6	$2f_6^2 + 20f_6$	$.5f_6^2 + 15f_6$
7	$.5f_7^2 + 3f_7$	$f_7^2 + 5f_7$
8	$f_8^2 + 3f_8$	$f_8^2 + 2f_8$
9	$f_9^2 + 2f_9$	$f_9^2 + 5f_9$
10	$2f_{10}^2 + f_{10}$	$f_{10}^2 + 3f_{10}$
11	$f_{11}^2 + 5f_{11}$	$f_{11}^2 + 2f_{11}$
12	$f_{12}^2 + 4f_{12}$	$f_{12}^2 + 4f_{12}$

4. Figure 5, in turn, illustrates that distribution center D_2 is getting to be an appealing choice as the time performance concern increases, although the storage cost there is slightly higher than at D_1. Also, as the value of time increases, a volume of the fashion product flow switches from transportation link 9 (or link 12) to transportation link 11 (or link 10), to reduce the total time consumption of the distribution activities (as shown in Figure 6).

In Table 3, we provide the values of the total costs and the total time at the optimal solutions for the examples as ω increases.

Table 2. Computed optimal link flows f_a^* as ω increases

Link *a*	*ω*=0	*ω*=1	*ω*=2	*ω*=3	*ω*=4	*ω*=5

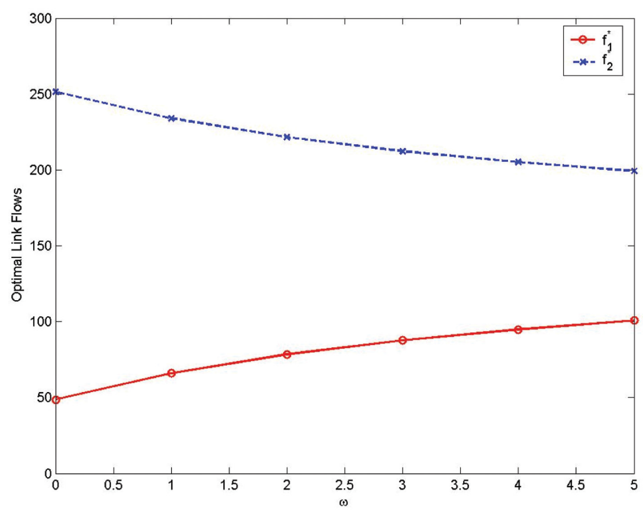
Figure 3. Optimal link flows on manufacturing links 1 and 2 as ω increases

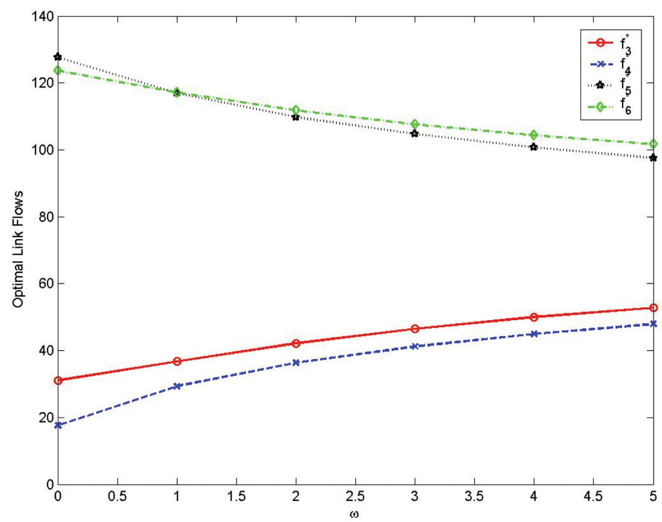


The values of the minimal total costs and the minimal total time for varying *ω* are displayed graphically in Figure 7. As can be seen from Figure 7, as the weight *ω* increases the minimal total time decreases, as expected, since a higher value of *ω* represents an increase in the decision-maker's valuation of time as a criterion.

Multiproduct Fashion Supply Chain Examples

We then considered multiproduct fashion supply chain problems. We assumed that the fashion firm provides two different fashion products with the same supply chain network topology as depicted in Figure 2. The total cost functions and the total time functions for all the links associated with

Figure 4. Optimal link flows on transportation links 3, 4, 5, and 6 as ω increases



product 1 and product 2 are given in Table 4 and 5, respectively.

The demands for the two fashion products at the demand points are:

$$d_1^1 = 100, \quad d_2^1 = 200,$$
$$d_1^2 = 300, \quad d_2^2 = 400.$$

To solves these problems, we used the modified projection method of Korpelevich (1977), embedded with the general equilibration algorithm of Dafermos and Sparrow (1969) (see also, e.g., Nagurney (1999)).

We also conducted sensitivity analysis, as in the section "Single Product Fashion Supply Chain Examples," by varying the value of time, ω, for

Figure 5. Optimal link flows on storage links 7 and 8 as ω increases

6	$2(f_6^1)^2 + .3f_6^1 f_6^2 + 20f_6^1$	$.5(f_6^1)^2 + .1f_6^1 f_6^2 + 15f_6^1$
7	$.5(f_7^1)^2 + .1f_7^1 f_7^2 + 3f_7^1$	$1(f_7^1)^2 + .5f_7^1 f_7^2 + 5f_7^1$
8	$1(f_8^1)^2 + .1f_8^1 f_8^2 + 3f_8^1$	$1(f_8^1)^2 + .5f_8^1 f_8^2 + 2f_8^1$
9	$1(f_9^1)^2 + .5f_9^1 f_9^2 + 2f_9^1$	$1(f_9^1)^2 + .2f_9^1 f_9^2 + 5f_9^1$
10	$2(f_{10}^1)^2 + .3f_{10}^1 f_{10}^2 + 1f_{10}^1$	$1(f_{10}^1)^2 + .4f_{10}^1 f_{10}^2 + 3f_{10}^1$
11	$1(f_{11}^1)^2 + .6f_{11}^1 f_{11}^2 + 5f_{11}^1$	$1(f_{11}^1)^2 + .25f_{11}^1 f_{11}^2 + 2f_{11}^1$
12	$1(f_{12}^1)^2 + .7f_{12}^1 f_{12}^2 + 4f_{12}^1$	$1(f_{12}^1)^2 + .25f_{12}^1 f_{12}^2 + 4f_{12}^1$

ω=0,1,2,3,4,5. The computed optimal link flows associated with products 1 and 2 are, respectively, reported in Tables 6 and 7.

We display the optimal link flows of products 1 and 2 as ω varies for the manufacturing links in Figure 8; for the first set of transportation links in Figure 9; for the set of storage links in Figure 10, and for the bottom tier of transportation links in Figure 11.

With the increase of the value of time, parts of the production of fashion products 1 and 2 are shifted from offshore manufacturing plant M_2 to onshore facility M_1 (as depicted in Figure 8), resulting in an increase in transportation flow from M_1 to the distribution centers for both fashion products (as shown in Figure 9). However, Figure 10 illustrates that the distribution center D_2 is getting to be appealing for product 1 as the value of time increases, while the distribution center D_1 becomes attractive for product 2, since the distribution center D_1 is more time-efficient for product 2. In Figure 11, as the time performance concern increases, a volume of fashion product 1 switches from transportation link 9 to link 11; in contrast, the volume of flow of fashion product 2 on link 9 increases. Also, a volume of fashion product 2 switches from link 12 to link 10, while the flows of fashion product 1 on link 10 and 12 change slightly.

10	$1(f_{10}^2)^2 + .5f_{10}^1 f_{10}^2 + 1f_{10}^2$	$1(f_{10}^2)^2 + .3f_{10}^1 f_{10}^2 + 6f_{10}^2$
11	$2(f_{11}^2)^2 + .5f_{11}^1 f_{11}^2 + 8f_{11}^2$	$1(f_{11}^2)^2 + .3f_{11}^1 f_{11}^2 + 3f_{11}^2$
12	$1(f_{12}^2)^2 + .4f_{12}^1 f_{12}^2 + 7f_{12}^2$	$1(f_{12}^2)^2 + .5f_{12}^1 f_{12}^2 + 4f_{12}^2$

The values of the total costs and the total time at the optimal solutions for the examples as ω increases are provided in Table 8, and displayed graphically in Figure 12. As expected, the minimal total time decreases as ω increases.

SUMMARY AND CONCLUSION AND SUGGESTIONS FOR FUTURE RESEARCH

In this paper, we developed a fashion supply chain management model, using a network economics perspective, that allows for multiple fashion products. The model consists of two objective functions: total cost minimization, associated with supply chain network activities, in the form of: manufacturing, storage, and distribution, and total time consumption minimization. A weighted objective function was then constructed with the weighting factor, representing the monetary value of a unit of time, decided by the firm.

We also provided the optimization model's equivalent variational inequality formulation, with nice features for computational purposes. The solution of the model yields the optimal multiproduct fashion flows of supply chain network activities, with the demands being satisfied at the minimal total cost and the minimal total time consumption. The model is illustrated with a spectrum of

numerical examples with potential application to fashion supply chain management.

The fashion supply chain network model allows the cognizant decision-maker to evaluate the effects of changes in the demand for its products on the total operations costs and time. It allows for the evaluation of changes in the cost functions and the time functions on total supply chain network costs and time. In addition, the flexibility of the network framework allows for the evaluation of the addition

Figure 8. Optimal link flows on manufacturing links 1 and 2 as ω increases

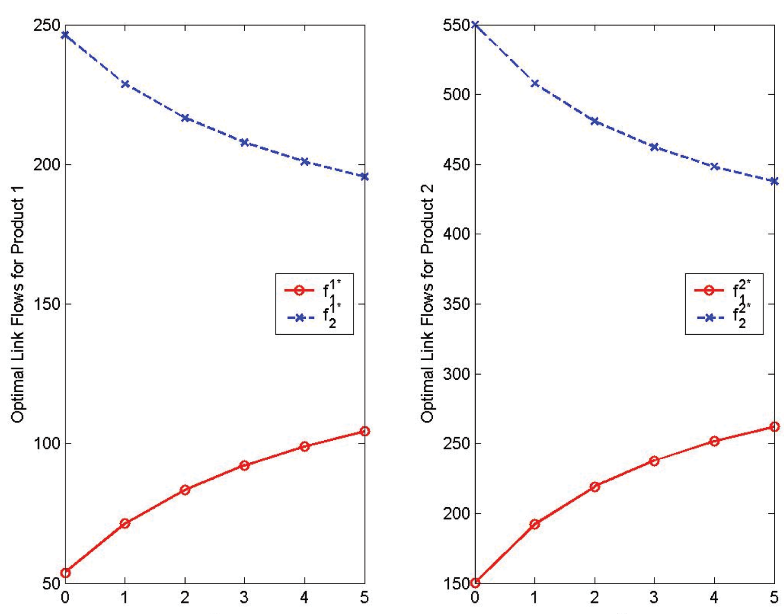

Figure 9. Optimal link flows on transportation links 3, 4, 5, and 6 as ω increases

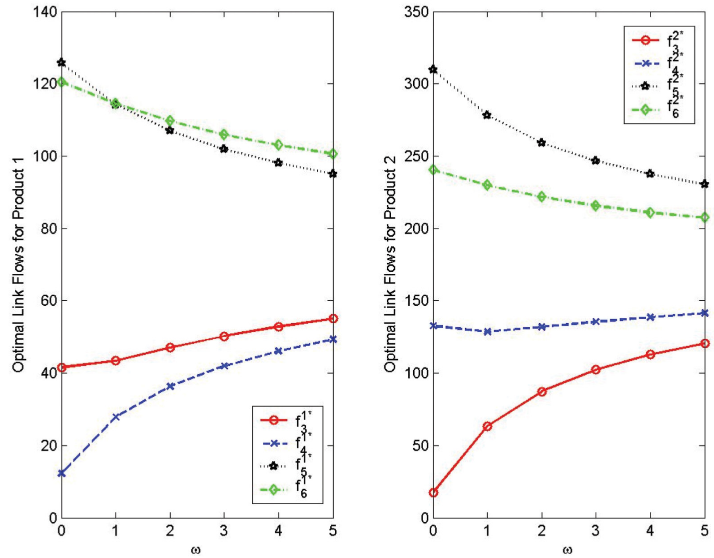

of various links (or their removal) on the values of the objective function(s). Finally, the model, since it is network-based, is visually graphic.

The research in this paper can be extended in several directions. One can construct a fashion supply chain management model with price-sensitive and time-sensitive demands under oligopolistic competition. One can also incorporate environmental concerns and associated trade-offs. In addition, one can explore computationally as

Chapter 75
An Exploratory Study on Product Lifecycle Management in the Fashion Chain:
Evidences from the Italian Leather Luxury Industry

Romeo Bandinelli
Università degli Studi di Firenze, Italy

Sergio Terzi
Università degli Studi di Bergamo, Italy

ABSTRACT

New Product Development (NPD) in most manufacturing sectors is stressed by an increasing global competition and pressure to improve product quality and innovation, reduce product cost and time-to-market (TTM), and rapidly respond to changing customer needs and shortened product lifecycles. These requirements are increasingly fulfilled by applying the PLM (Product Lifecycle Management) approach, a widely accepted concept that generally defines the adoption of a large number of ICT (Information and Communication Technology) solutions for managing product data along the product lifecycle. This contribution shows the results of research concerning the application of PLM within the luxury fashion supply chain, conducted in 2009 in Italy, with the analysis of 20 companies of the leather market. The research shows some of the differences that exist between the luxury industry and other more PLM-oriented sectors (e.g. automotive) in terms of adopted ICT tools, criticalities, problems, and benefits expected and realized.

DOI: 10.4018/978-1-4666-1945-6.ch075

INTRODUCTION

New Product Development (NPD) in most manufacturing sectors is stressed by an increasing global competition and pressure to improve product quality and innovation, reduce product cost and time-to-market (TTM), and rapidly respond to changing customer needs and shortened product lifecycles. These requirements are fulfilled by applying the PLM (Product Lifecycle Management) approach, a widely accepted concept that generally defines the adoption of a large number of ICT (Information and Communication Technology) solutions in order to support collaborative and coordinated environments, managing product data along the product lifecycle (from the cradle to the grave), and mainly focuses on the NPD process.

PLM has been extensively studied and analyzed in recent years, with different authors highlighting the holistic meaning of such acronym (e,g, Stark, Saaskvuoiri and Immonem, Grieves). For example, according to Stark (Stark, 2005), it brings together products, services, structures, activities, processes, people, skills, application systems, data, information, knowledge, techniques, practices and standards. Saaskvuori and Immonem (Saaskvuori and Immonem, 2005) define it as a comprehensive approach, entailing: (i) a strategic management perspective, wherein the product is the enterprise value creator; (ii) the application of a collaborative approach to better use the enterprise competences distributed amongst diverse business actors; and (iii) the adoption of plenty of ICT solutions in order to practically establish a coordinated, integrated and access-safe product information management environment in the extended context. Grieves (Grieves, 2006) identifies in PLM everything which deals with the management of the product data that are created, stored, and managed along the lifecycle of a product, from the design to end of life. Ma and Fuh (2008) state that PLM is a technical term to describe a comprehensive, systematic and scientific approach in managing enterprise performance based on a coherently and consistently integrated computer system that can effectively and efficiently fulfill the product and process information requirements within a dynamic, collaborative and networked environment.

PLM is one of the most recent evolutions of the enterprise ICT applications, characterized by an increasing integration and interoperability into and between tools and supported processes, both in design and management activities. In the last 30 years, CAx (Computer Aided, where x stands for Design, Styling, Manufacturing, Engineering, Process Planning, etc.) tools have successfully evolved from 2D to 3D modeling techniques, enabling a list of knowledge-based engineering approaches, generally addressed as Virtual Prototyping, Digital Mock-Up and Virtual Reality. Since the 1990's, collaboration in product design, development, and delivery has been enabled in integrated software platforms (alternatively addressed with new acronyms, like TDM Technical Data Management, EDM Engineering Data Management, PDM Product Data Management, PIM Product Information Management, etc.) where product data can be safely stored, retrieved, and reused. Since 2000, PLM has been used to define a comprehensive ICT market, nowadays composed of two main segments: (i) one constituted by a galaxy of design tools (i.e. CAx and engineering tools) and (ii) a second one composed by a plethora of Collaborative Product Definition/Development and Management platforms (CPDM). The first segment is dominated by ICT players historically dedicated to product design, like Autodesk, Dassault Systèmes, PTC, SIEMENS, while in the second these vendors compete with many other players coming from other backgrounds such as Oracle, SAP, etc.

PLM market is one of the most booming ICT markets irrespective of the global crisis, as many analysts (e.g. AMR Research, CIMdata, Daratech, Gartner) are continuously declaring, and PLM projects are considered as strategic investments, to be financed for surviving and preparing companies "for the next economy up-cycle" (Cimdata, 2008).

It has been widely applied in capital intensive industries such as aerospace and automotive. In such industries, the same PLM concept has been defined and it is still evolving, (Sapuan et al, 2006), (Tang and Qian, 2008), (Alemanni et al, 2008) becoming a comprehensive system supporting the information needs regarding products "from cradle to grave". This system involves many engineering stages such as industrial design, conceptual design, detailed design, process planning, manufacturing, assembly, sales, maintenance, and recycle or destroy (Ma and Fuh, 2008).

Today, aerospace, automotive, and similar mechanical-based sectors are considered traditional and conventional PLM markets in which PLM solutions (both CAx and CPDM) are well known and applied. In recent years, analysts and consulting companies have dedicated their attention to unconventional PLM sectors such as food, pharmaceutical, telecommunications, textiles, footwear, and apparel. Among these, the so-called "fashion luxury sector" has been addressed repeatedly as one of "the next" PLM sectors (Barret et al, 2007), (Sulesky et al, 2007), (Hojlo and Suleski, 2008).

Italy is commonly considered to be one of the most important "fashion and luxury" countries of the world (Brun et al, 2008), particularly with regard to the Italian leather industry. Within this context, the present contribution aims to investigate the declination of the PLM approach in the unconventional "fashion luxury sector", focusing on the application of PLM within the niche of the Italian leather sector, in order to understand the main commonalities and differences with more conventional PLM sectors.

Before presenting the results of the Italian-based research conducted by the authors in 2009, a brief description of this particular sector is reported. For supporting the reader, the Table 1 synthesizes the list of the acronyms adopted in the chapter.

BACKGROUND

The term "fashion" is used by practitioners and academics to generally refer to an industry which widely includes several sectors: textile, clothing, leather, knitwear, accessories, sunglasses, cosmetics, and jewelry. Each of these sectors show distinctive characteristics and may be further divided into different competitive segments characterized by a company's dimensions such as the served customers and markets, and applied technologies. Authors Saviolo and Testa (Saviolo and Testa, 2005) classify the fashion markets using the price and the number of sold units as variables that discriminate the type of the product, thus defining five main market segments: *couture*, *prêt-à-porter*, *diffusion*, *bridge*, and *mass*. From the last segment (*mass*) to the first one (*couture*) (i) the prize of the sold product increases, (ii) the number of sold units decreases, (iii) the perceived and the real quality increases, (iv) the product

Table 1. List of used acronyms

Definition	Acronym
Bill Of Material	BOM
Collaborative Product Definition / Development and Management	CPDM
Computer Aided Design	CAD
Computer Aided Manufacturing	CAM
Computer Aided x (where x stays for Technology, Design, Engineering, etc.)	CAx
Carry Over	CO
Engineering Data Management	EDM
Information and Communication Technology	ICT
New Product Development	NPD
Product Data Management	PDM
Product Information Management	PIM
Product Lifecycle Management	PLM
Small and Medium Enterprise	SME
Stock Keeping Units	SKU
Technical Data Management	TDM
Time To Market	TTM

differentiation and variety increases (from *mass* to *custom*) and (v) the demand predictability and stability generally decreases.

Each market segment has an impact in the structure of the fashion value chain in terms of TTM, lot dimensions, and number of sold units per product type. The value chain of the fashion industry has been studied by several researchers in the past years, and numerous publications can be found on such topic. Most of them are related to the fashion industry as general market (Brun et al, 2008) (Caniato et al, 2007), while some others are focused on textile and clothing (Burresi and Ravagni, 2006) (La Marca and Palamara, 2005) (Gereffi and Memedovic, 2003) (Richardson, 1996) (Bruce et al, 2004) (De Toni and Meneghetti, 2000). There are other papers as well focused on the description of specific value chain such as Zara (Ghemewat and Nueno, 2003) and (Vona, 2004), Burberry (Moore and Birtwistle, 2004) and Armani (Fernie et al, 1997). Saviolo and Testa (Saviolo and Testa, 2005) identify four types of fashion value chain according to the existing level of integration:

i. Integrated Griffe (e.g. Gucci, Prada, Ferragamo) companies which own and control nearly their entire value chains - from the design, to the production plants, until their branded shops.
ii. Industrial Integrated Groups (e.g. Tod's and Ermenegildo Zegna) which design, own their plants, and sometimes manage part of the distribution chain.
iii. Pure Brand Owners (e.g. Roberto Cavalli) which are generally small companies focused purely on design without involvement in the production, distribution, and selling processes.
iv. Industrial Players (e.g. Sergio Rossi) which provide their specific production and distribution competences and facilities (e.g. in the shoes making) to other brand owners.

Traditionally, a polarization can be observed in the fashion industry (Brun et al, 2008). Some companies choose to operate in the mass market, selling low-cost products that are available to a large number of consumers, whilst on the other hand other companies provide exclusive and expensive products to an elitist segment of consumers. The latter type composes the "luxury" segment. Companies which belong to both markets are not common. Like fashion, luxury itself is a transversal concept which dominates a plethora of manufacturing sectors including clothing, jewelry, furniture, wine making, automotive, and the yacht industries. Luxury is "a way of live" in which the customers search for elitist emotions. In the last decade, different authors (Fernie et al, 1997), (Silverstein et al, 2003) and (Sen, 2008) analyzed the intangible sense of elitism and desirability which pervade the luxury segment. For example, D'Arpizio (D'Arpizio, 2008) defines the 3A's of luxury (Absolute, Aspirational, and Accessible) which constitutes sub-segments of the whole luxury market. In the Absolute luxury, the products must be elitist, represent an icon, and include characteristics of tradition and uniqueness. In the Aspirational luxury, the main value for the customer is represented by aspiration, recognizability, and diversification. The Accessible luxury is characterized by a higher economic accessibility, where the sense of membership and status symbol plays a relevant role.

Within the luxury apparel fashion markets, style and design excellence are achieved by keeping the design activities in-house while collaborating with experienced external designers and stylists (Brun, 2008). The process of New Product Development (NPD) is characterized by a large number of product revisions, in which the continuous interactions between designers, stylists and marketing functions take a long time and iterations (Sen, 2008). Revisions and modifications are realized also when the final product is already in the market, in order to align the production to the customer demand (e.g. change colors for a model).

NPD is characterized by high seasonal demand, which depends on the seasonal nature of fashion products. The whole NPD process is managed at least four times per year - one time for each season - with a short TTM (15 months in the apparel industry, 12 months in the leather industry)

In the luxury fashion market, NPD is a comprehensive process which includes the following five stages:

i. Design
ii. Modeling/prototyping (for realizing the demonstration products to be shown at the fashion fairs)
iii. Detailed engineering: Many companies complete the engineering phase at the same time as the sourcing phase. For example, in most cases, the generation of the final Bill of Material (BOM) takes place when orders have already been launched. Once the company confirms the order decisions, the BOM and the raw material purchase orders must be completed quickly. Moreover, the production quantities and decisions may continue to change very rapidly during the fashion shows seasons (i.e. the appearance of a Hollywood star with a particular bag can completely change the prevision regarding the sold units of that product, and this can happen also the last day of the last fashion fair). In some companies, the engineering phase is completed for all the products before the beginning of the fashion fairs. Although this strategy permits quick management of the sourcing activities, it likely overloads the engineering staff with less valued activities, as the actual goods produced are usually a small percentage of the all items presented at the fashion shows.
iv. Material sourcing: The sourcing phase is very peculiar, as its duration can fluctuate from 2 weeks up to one and a half months depending on the duration of the commercial launch, which generally takes place in conjunction with the fashion shows and fairs (e.g. Pitti Florence fair, Milan and Paris fashion weeks, etc.). At the beginning of the sourcing phase, a provisional and generic order of raw material is submitted to the suppliers. The confirmation of the raw material quantity is given at the end of this phase, with a 20-30% maximum difference in quantity from the provisional order to the final order. During this very short period, the company board receives information on the number of sold units for the current season and must quickly decide which products will be produced for the upcoming season, thus defining the raw material order needs.
v. Production and distribution: The production phase usually lasts 3-4 months, beginning when material sourcing is completed.

PRODUCT LIFECYCLE MANAGEMENT IN THE FASHION CHAIN

The Italian Luxury Leather Industry

"Made in Italy" is synonymous with quality, fashion and luxury. In previous years, Italian companies (most of them Small and Medium Enterprises, SMEs) of the fashion market have concentrated their activities in the highest value added luxury segments, guaranteeing the success of the national industry. Still today, despite the global crisis, luxury is still supporting the economic development of Italy (Brun et al, 2008), (AIMPES, 2009).

In the luxury fashion segment, the leather industry is one of the most active compartments. Pushed by an increasing global demand, the first decade of the Twenty-First century was a time for many fashion brands to introduce leather products in their product lines. Leather treatment has a long history in Italy, particularly in the region of Tuscany where many craft laboratories have existed for more than one century. The Italian leather industry is composed of shoe-making, suitcase and baggage making, and tanning treatment. The luxury leather market may be used as a reference market for the entire luxury fashion market, as addressed below.

This research has been conducted through an empirical, explorative research. It was carried out through personal interviews which were supported by a reference questionnaire. The reference questionnaire, adopted as an interview guideline, is a mix of open and closed-ended questions, composed of the following three sections:

i. General data about the company and the market.
ii. Details about CAx and CPDM tools adopted in the NPD process.
iii. Information about the deployment of PLM (CAx and CPDM) projects.

In this way, the data has been explicated through the analysis of the level of application of PLM, in terms of CAx and CPDM installed solutions, with the tentative purpose to make a comparison between unconventional PLM-oriented industries and more traditional PLM-oriented contexts.

The research has been limited to the luxury leather sector, with companies producing only finished leather goods (i.e. bags, suitcases, shoes, wallets and belts). According to the national leather association, AIMPES, (Associazione Nazionale Pellettieri) this sector is composed of 54 firms in Italy, including transnational companies belonging to the luxury sector with at least one business unit and at least one production plant in the country. All these companies are very well know international luxury names such as Burberry, Roberto Cavalli, Dolce & Gabbana, Dior, Fendi, Ferragamo, Etro, Furla, Gucci, Missoni, Montblanc, Prada, Sergio Rossi, Tod's, Trussardi, Versace and Ermenegildo Zegna - just to name a few. All of the 54 companies have been contacted and 20 of them (37% response rate) agreed to be interviewed and anonymously surveyed. Interviews have been conducted with product managers of the leather business units and/or to the responsible party of the relative technical departments. In some cases, the questionnaire has been submitted also to the responsible party of the ICT departments, when existing (less than the 25% in the sample). The data of the survey have been analyzed through qualitative instruments, hereafter presented and discussed.

All the surveyed companies operate in the luxury leather market, at the top of the fashion pyramid (Couture). According to the classification (D'Arpizio, 2008), 60% of the sample operates in the Absolute luxury segment and the remaining 40% in the Aspirational segment, and they serve global markets, typically within single brand shops.

The sector is composed of international companies, most of which are fully integrated and multi-product, belonging to multi-brand groups, with considerable amounts of capital available. Using the definition of value chain of (Saviolo and Testa, 2005), 10 companies are well known Integrated Griffe, 6 are part of Industrial Integrated Groups and 4 are Pure Brand Owners. Most of them (70%) are Italian owned companies, while 30% are business units of international transnational companies (25% based in Europe, 5% based in the US). In all the cases, the leather segment is just one of the luxury segments served by the companies. 90% of the sample companies are located in central Italy's region of Tuscany, while the remaining 10% are located in Northern Italy.

In terms of products, 70% of the sample produces only leather bags and suitcases, while the remaining 30% make leather shoes too. The majority of the sampled companies (55%) identify their core business in the leather sector (35% leather accessories, 20% leather footwear), while the remaining 45% companies report that clothing is their core business, and leather is just a slice of it.

An interesting "volume" parameter is the number of different Stock Keeping Units (SKUs) processed during the fashion season by the companies. A SKU is a single product code realized and sold during a fashion season (a "collection") and encompasses all the possible factors, such as color. For example, if the same model of a bag is produced blue and brown, then two different SKUs might be defined, one for the blue bag and one for the brown bag. More than 50% of the companies realize collections of more than 500 SKUs per season. Among them, 20% of the sampled companies define more than 2,000 SKUs per season. Only 3 companies show fewer than 100 SKUs per season. In the new SKUs per season, some of them are directly related to SKUs of the previous season (e.g. just a new color – black – for an old model bag) and they are defined as Carry Over (CO) units - items produced continuously every year. More than 70% of the companies have a reduced CO (less than 30% on the total SKU per season), highlighting the constant innovation of the companies to continuously look for new fashion trends-waves for satisfying their customers.

It is widely recognized (Brun et al, 2008) that the fashion sector widely applies outsourcing strategies (Table 2). In more than 90% of the sample, production is partly outsourced to external production laboratories, generally located near the main plant and primarily based in Tuscany. On average, a company has more than 35 external small and medium laboratories working in its supply chain. Moreover, almost 50% of the companies design their products with the support of external designers.

Table 2. Percentage of outsourced activities

Outsourced activities	%
Production	95%
Prototyping	70%
Product development	50%
After sales	30%
Logistic	30%

ICT in the Leather Industry

In terms of ICT tools, all the companies have an ERP (Enterprise Resource Planning) suite installed in order to manage their actives and passive order cycle. In the NPD process, a significant difference has been observed between CAx and CPDM tools, for instance, 80% normally apply CAx tools (80% CAD, 45% also CAM), while only 40% of them have installed a CPDM solution.

45 percent of the companies adopt a CAD 2D, 30% adopt both CAD 2D and 3D, while 5% apply only a CAD 3D, and 20% of the cases do not have a CAx suite in their design departments. These companies just agree on the concept of the product and then totally outsource the detailed design and engineering to external professional designers. The leather sector calls for a CAD tool specifically designed for the leather/textile activities. Fewer than 20 percent of the sampled companies apply a multipurpose CAD (i.e. SolidWorks by Dassault Systèmes, ThinkDesign by Think3), while the majority of the sample uses a list of dedicated tools, most of them created in Italy (i.e. Mozart CAD, Romans CAD, Naxos, AIMPES CAD, Bitron CAD, etc.). Generally, when it exists, the installed CAM is provided by the same vendor of the CAD system. Furthermore, 40 percent of the companies have installed a CPDM solution.

Collaborative platforms enable cooperation among functions and business processes, generally proving a common data warehouse (vault) for sharing data, metadata and information. CPDM platforms can be implemented with different degrees of functionalities, supporting knowledge sharing in unstructured (e.g. simple file sharing email-based) or structured ways (e.g. automatic workflow). Further, CPDM platforms are used within small working groups (e.g. only the technical department) or larger teams (e.g. involving key actors of other phases, like marketing, production, etc.). In the analysed sample, 5 companies installed a CPDM solution (a traditional PDM platform) in the technical department, just for storing and sharing product data (i.e. drawing and 3D models) and managing NPD projects. In fewer than 5% of the companies, commercial web-based CPDM platforms have been installed for enabling collaboration along the NPD process, supporting product data (e.g. models and drawings) and metadata (e.g. BOM and configuration rules) sharing among the different phases (design, sourcing and production). In most of the cases, a deep customisation of CPDM commercial platforms was needed to adapt the available solution to the peculiarity of the industrial context.

Most of the benefits reported by the companies regarding CAD application are the reduction of TTM and process quality improvements. The former is given more appreciation, since it enables faster realization of models and easier re-use of produced parts. The concept of process quality has been explained by the interviewees as better management, better storage of models, more security, and increased control on stage. Regarding CAD 3D, it was evident that, in this sector, solid modelers are used mostly for marketing purpose (i.e. display of 3D models that could replace, in some cases, the real prototype), while CAD 2D is still enough for the objectives of the designers. The main registered benefits related to the implementation of CAM application are time reduction (cutting speed), quality improvement (more precision and less errors) and costs reduction (reduced waste materials and use of unskilled manpower). In summary, CAD and CAM tools contribute to increase the efficiency in the NPD process.

With regard to problems encountered by the companies during the introduction process of a PLM system, the resistance of people to change is reported as the most critical one - as stated by more than 50% of the cases. This evidence confirms that, in most cases, the deployment of the PLM approach in a company (in particular in the CPDM segment) is linked to a process or organizational innovation, as happens in other more PLM-oriented sectors. This behavior is often explained in terms of "political resistance", apprehension of managerial control, evading personal initiatives and so on. Other criticisms indicated by companies' managers are related to technical issues and software specifications, even if none of these problems were considered as reasons for any particular project failure.

Pertaining to difficulties met by the companies after the introduction of a PLM tool, certain problems existed. In half of the analyzed projects, the introduction of the system do not reduced the employee's resistance, which felt their benefits during the start-up of the projects. In more than half of the projects technical problems have been detected, during the introduction's phase, because PLM tools needed users dexterity and involves high personalization and integration (in particular CPDM platforms) in this industry. At the end of the project, most of the surveyed companies were satisfied by the introduction of the new software products. Only 10% of the companies reported the PLM introduction project as a failure.

Two cases of failures are analyzed in this research, both related to the introduction of basic CPDM platform. In the first case, the causes were related to technical issues (the proposed solution did not meet company's needs), while in the second case the resistance of the business units and less of a commitment of the company managements have to be considered as the main reasons for the projects failure. These two cases confirm a common thinking widely debated in literature and common to ICT projects: during the introduction of ICT tools, human elements are the critical factors in determining the success or the failure of the projects. Furthermore, a good management and a strong commitment are needed to guarantee the success of implemented projects.

Software specification is another crucial aspect to ponder. In the first part of a project, an important step is the definition of how a commercial tool has to be personalized in order to full fill a company's particular needs. In many cases, the effort needed to support this part of a project was underestimated by managers, causing problems and delays.

Other causes reported by the companies as possible criticalities in the introduction of CPDM systems often had to do with the dimension of a company. One common thought is that, if the collections are made of fewer SKUs, or a division has fewer personnel, it does not seem relevant to introduce this kind of collaborative systems. On the other hand, the commitment coming for a corporate strategy, even if not supported by real company's needs, is more effective for adopting CPDM software, rather than for CAx tools. In fact, CPDM systems enable collaboration among departments, functions and sites. In a small context normal communication could be enough to foster collaboration, while in big contexts (like corporations and transnational companies) collaboration might be pushed and physically supported by using dedicated ICT CPDM platforms. CAx tools are directly related to the activities which they are designed for, so their adoption is independent by a company structure and dimension.

Despite the criticalities mentioned above, CPDM systems can offer many benefits to companies. CPDM platforms generally permit a better cost control of a product, beginning from the design phase, and provide the opportunity to increase cross-functional collaboration and establish a better control on internal processes. CPDM systems guarantee to the user that he/she can assess a structured and shared archive where he/she can easily find the right product information (i.e. the right version of the SKU), thus enabling a more efficient use of time, a reduction of the risks and errors in the management of the BOM. A typical benefit achieved with a CPDM system in traditional PLM-oriented sectors is a general improvement in the component and part reuse and management. In this particular industry, because of the peculiarities of the fashion sector itself, in which market demands for new products, forms, and materials, such kind of benefit was not considered useful by the companies.

ANALYSIS AND DISCUSSION

Within the sample, those companies with the most advanced and integrated CAx solutions (i.e. CAD 2D and 3D integrated and also directly connected with CAM) are managing more SKUs per year, with more products are being designed continuously using sophisticated ICT solutions.

In order to evaluate and classify the attitude of a company in the adoption of PLM tools, a proxy variable has been created and named as ICT Maturity Degree. This variable has been defined considering the interaction between the degree of functional coverage and the existing integration among the software of the company, where functional coverage is a parameter linked to the internal processes supported by ICT tools, and integration means the system capability to share information and to communicate inwards and outwards the company. Regarding the integration, the levels have been defined as:

- None: companies without any CAx and CPDM systems.
- Low: in case of isolated CAx tools and/or CPDM systems.
- Medium: when CAx tools and/or CPDM systems are partially integrated among themselves or with other ICT suites.
- High: in case of fully integrated ICT solutions.

In a similar way, four levels of functional coverage, with increasing complexity, have been defined as:

- A zero level, in which companies without any CAx and CPDM systems have been included and classified with "Inexistent" functional coverage.
- A first level (Low), in which takes place a simple transaction of drawings and data sheets among business functions, implemented with an extemporaneous use of e-

mail or data warehouse. Companies without a CPDM system belong to this level.

- A second level (Medium), where there is a more complex management of data and metadata among company's functions; at this level is required the existence of a relational database and a data warehouse system, able to manage controlled and restricted access, without using automated workflow. Companies with traditional commercial PDM belong to this group.
- A third level (High), with an intensive use of automated workflow among functions, data warehouse systems able to manage of product data and other complex information. In the present study, this level represents the highest definition of PLM-oriented ICT system.

Crossing functional coverage and integration (Table 3), it is possible to define four levels of ICT Maturity Degree, which are:

- Group 1(None): in case where both functional coverage and integration are absent.
- Group 2 (Low): with a low level of functional coverage associated to low and/or medium integration level.
- Group 3 (Medium): when both parameters are medium.
- Group 4 (High): in the following cases: high functional coverage and a medium and/or high integration level; medium functional coverage and high integration level.

The 40 percent of the sample have a low maturity degree, generally due to a limited use of collaborative software. The remaining 60% of the sample is equally divided among the other three levels. The highest level corresponds to the application of a comprehensive PLM approach.

Some of the most interesting results of the survey come from the comparison of the ICT Maturity Degree variable with other companies' parameters, as the number of SKU and the percentage of CO. Table 4 and Figure 1 map the ICT Maturity Degree with the number of SKU, in Figure 1 the bullets represent the companies. Even if the nature of the research cannot demonstrate this sentence, a direct relation between the number of SKUs (then the dimension of the seasonal collection) and the ICT Maturity Degree seem to exist. That is, the bigger is the collection, a more sophisticated and integrated ICT infrastructure is needed. In Figure 1 there are two outliers (i.e. two companies with high SKU, but without a CPDM system). The empirical nature of the research does not explain this phenomenon, but the possible causes are the budget constraints and a general mistrust of ICT solutions which still exist in some companies of the fashion market.

Table 5 crosses ICT Maturity Degree with CO percentage. From these results, two possible relationships can be supposed:

Table 3. Analysis of the ICT Maturity Degree

Level of functional coverage	**Inexistent**	**I (Low)**	**II (Medium)**	**III (High)**
Level of Integration				
None	20%	-	-	-
Low	-	25%	-	-
Medium	-	15%	20%	5%
High	-	-	5%	10%

Table 4. SKU classes and ICT Maturity Degree

ICT Maturity Degree	Group 1	Group 2	Group 3	Group 4
SKU classes				
< 100	25,0%	25,0%	-	-
100 - 200	25,0%	12,5%	-	-
200 - 500	25,0%	25,0%	25,0%	-
500 - 1000	-	25,0%	50,0%	-
1000 - 2000	25,0%	12,5%	25,0%	-
> 2000	-	-	-	100%

- A small CO percentage could indicate high variability in the collection, which calls for more sophisticated ICT tools.
- A high CO percentage could indicate a relevant continuity among collections, which could call for sophisticated CAx for enabling a better design reuse.

As mentioned, NPD process (or part of it) is often outsourced in the leather industry. Table 6 maps ICT Maturity Degree with NPD outsourcing. Obviously, 100 percent of the companies of Group 1 operate in outsourcing, even if in many other cases (with a higher ICT Maturity Degree) part of the NPD process is realized externally. Evidently, PLM (CAx and CPDM) systems enable for a better management of the relationship with suppliers (e.g. for CAD models display, collaborative management of technical data, etc). However, it might be said that in most of the sample cases unstructured traditional web-based technologies (like e-mail and FTP) are used to exchange product data with outsourcers, while structured solutions (e.g. CPDM workflows) are not so well diffused.

Analyzing the relationship between the size of the leather business unit – measured as the number of people belonging to the business unit and ICT Maturity Degree, it appears that all the cases without any ICT tool, and 87.5% of those who have only CAx tools, have a staff under 100 employees (Table 7). Moreover, in all the cases with CPDM systems installed have more than 100 people. These cases can be further divided into two groups, one with basic CPDM systems (66.7% of the companies), and the other with advanced CPDM solutions (100% of the companies). The data seem to show a link between the size of the business unit and the presence of PLM solutions despite their level of complexity. The same results have been reached by evaluating through the number of people dedicated to the NPD process. The implementation of CPDM systems seems to be linked also with the dimensions of the design and technical department (Table 8). Having more

designers and engineers involved in the leather business unit, the higher the ICT Maturity Degree appears. Due to the explorative nature of the survey, however it is not possible to confirm this hypothesis, even if many indicators seem to confirm this thesis. Such a relation (i.e. company dimensions versus ICT Maturity Degree) represents one of the biggest limits of PLM in this sector. The available PLM technologies seem to be still dedicated to big companies, while SMEs are excluded from this market.

Others possible correlations have been sought e.g. the core business of the brand and the ICT Maturity Degree, but any relevant connection regarding adopted tools has come out. It appears that 100% of the companies without any tools have clothing as their core business: this evidence could partially explain small ICT investments in the leather sector, but it doesn't provide any information about a possible higher ICT Maturity Degree of the core division.

One of the objectives of the research was the identification of possible trends in adopting CAx systems and CPDM solutions in fashion sectors. In this way, during the research, past and future ICT projects regarding the NPD process have been also investigated. Regarding past projects (Table 9), results show that the last tool introduced by the companies belonging to Group 2, having only CAx tools, in 75% is the CAD system itself,

Table 7. Leather Business Unit Personnel versus ICT Maturity Degree

ICT Maturity Degree	Group 1	Group 2	Group 3	Group 4	Total Companies
Leather BU Personnel					
< 50 50-100 101- 250 251- 500 > 500	100,0% - - - -	62,5% 25,0% 12,5% - -	16,7% 16,7% 33,3% 16,7% 16,7%	- - - 50,0% 50,0%	50% 15% 15% 10% 10%

Table 8. Number of Business Unit Designers versus ICT Maturity Degree

ICT Maturity Degree	Group 1	Group 2	Group 3	Group 4	Total Companies
Number of BU Designers					
< 50 50-100 100-250 250-500 > 500	100% - - - -	62,50% 25,0% 12,5% - -	- 16,7% 33,3% 16,7% 16,7%	- - - 50,0% 50,0%	50% 15% 15% 10% 10%

percentage equally divided among 2D and 3D. Companies owning basic CPDM solutions, in 25% of the cases have recently introduced 2D CAD tools, as substitutions of obsolete software or as integrated system to CAM (system implemented in 25% of these companies). The remaining 25% have recently adopted their current CPDM solutions. The results of Group 4 is interesting too: in this case, for 75% of the companies, the last implemented system is the CPDM solution, while in the remaining part, the last tool is a CAD 3D, as a renewal or extension of an existing structure.

These results show that, in the luxury leather sector, the introduction of collaborative solutions is recent and currently in progress, while CAD systems have been adopted since several years in most of the cases. For that matter, CAD 2D tools are still sufficient for the industrial needs and substitution with CAD 3D seems to be still far away.

A specific set of questions were related with the investigation of ICT projects planned by the companies in the next 3 years, the results are interesting and can be summarized in the following statements:

- 75 percent of companies without any tools in their NPD are not planning to introduce them in the next years. This evidence can be justified in some cases with the presence of other ICT projects currently in progress, or due to budget and/or human resources limitation for a new project, or because they are considered not strategic for the firm by the management. The remaining 25% have planned the introduction of basic CPDM systems.
- All the companies with only CAx tools are preparing new projects. Where in 30% of the cases extension of CAD or CAM tools are considered in order to cover additional functionalities. While in the remaining 70%, they consist of projects for the introduction of CPDM solutions. In the end, it is important to underline that the cost of these projects, due to their extension, is always considered significant by the management of the companies.
- Companies belonging to the third group, which own a CPDM system, 75% of them have projects regarding these tools. These projects are mainly related to the extension of functionalities or to improve the integration level, and in most of cases changing their own basic solution into a most advanced one.
- Focusing on companies with advanced CPDM solutions (only 3), despite the common thinking, results that all of them have already planned projects of functional coverage extension or improvement of the integration level. In authors' opinion, this evidence confirms that the benefits obtained by the companies are the main incentive to promote a full implementation of the PLM business model. Obviously these kinds of projects, such as those of the previous paragraph, consisting of extensions of solutions already implemented, will be low-

Table 9. Last ICT tool installed by the company (within the four groups of ICT Maturity Degree)

ICT Maturity Degree	Last ICT tool installed						
	ERP	CAD 2D	CAD 3D	CAM	Basic CPDM	Advanced CPDM	Other
1	100%	-	-	-	-	-	-
2	-	37,5%	37,5%	-	-	-	25%
3	25%	25%	-	25%	25%	-	-
4	-	-	25%	-	-	75%	-

er than the size of those introduced from scratch.

Moreover, in most professional literature, dominated by vendors and consultants publications, there is a recurrent interest on the application of PLM (in particular in its CPDM segment) in fashion sectors. Some contributions ((e.g. (Barret, 2007), (Hojlo and Suleski, 2008), (Suleski et al, 2007)) state that fashion will be the next PLM market. This exploratory research partly confirms such an interest, though PLM is at the fledging stage in these sectors. However, it might be noticed how in the last five years many companies in the luxury leather industry have changed their CAx tools and have introduced their first CPDM systems, and many others plan to introduce a CPDM solution in the next years. This means that PLM is certainly gaining growing interest across these companies.

CONCLUSION

In this contribution the main results of an empirical research concerning the application of PLM solutions for supporting the NPD process in the luxury leather sector are reported. Even if the luxury leather sector is a niche market of the largest fashion sector, it can be considered well representative of the criticalities and features of all the other sectors. Despite this, obviously, the analysis of such a specific market is one of the most relevant limits of the research, which has an explorative purpose and can't be considered as exhaustive.

However, in its limitations the research underlined the main peculiarities of PLM projects in the fashion industry, identifying some commonalities and differences that characterized this sector in comparison with more PLM-oriented sectors, like the mechanical one.

From this preliminary analysis some interesting new research items have been identified. For example, it is interesting to notice how after sale service is not considered at all in the ICT strategies of the analysed companies. A common thought widespread among the interviewees is that the non-durable nature of products implies a short lifecycle. This evidence moves companies to have "lack of memory" on themselves. Thus after sales, in spite of other sectors where maintenance is a strategic phase of the lifecycle, in the luxury fashion sector is currently a marginal phase of the process, where no resources focus on it. In this sector, after sales is still considered as a service that the companies as to provide, and not as a source of further earnings or competitive benefits (e.g. aerospace). The adoption of a "complete PLM approach" is still too far to be implemented in fashion contexts as in more PLM-oriented sectors such as aerospace (Tang et al, 2008) and automotive (Alemanni et al, 2008).

Finally, it is evident that the fashion context has a particular NPD process, which urges for a specific adaptation of PLM solutions. Such a peculiarity needs a new reference model different from the traditional mechanical NPD process. It will thus be interesting to conduct more in-depth analysis on the topic. For instance, more samples can be collected and rigorous statistical analysis can be conducted to reveal more important academic and managerial insights. Moreover, as motivated by the findings of this exploratory research, mathematical models can be constructed for further studies.

Category: Processes of Knowledge Management

INTRODUCTION

While there are many aspects to managing corporate knowledge, one key issue is how to disseminate corporate documents with appropriate context. Upon finding an article on a certain subject, for example the material properties of titanium, a reader is likely to be interested in related articles such as applications of titanium or manufacturing methods for titanium parts. Each related article has the potential to increase the reader's knowledge of the subject. Therefore, organizing documents into categories of interest plays an essential role in discovering and interpreting information. Furthermore, categories can be expected to provide historical context, describing how titanium was used in early designs or initial practices used for the repair of titanium parts.

While most large companies make a practice of cataloging and controlling well-established documents, there is a vast set of *explicit information* that has not traditionally been effectively disseminated. This class of information is less formal and may be exchanged, updated, and otherwise managed at the local level. Such information is usually not controlled at the corporate level or governed by the same organizations established to handle more stable information. Processes to disseminate such information tend to be ad hoc or nonexistent. In this article, we discuss the elements necessary to effectively disseminate informal and explicit

DOI: 10.4018/978-1-4666-1945-6.ch076

information not controlled at the enterprise level. While the main emphasis of the article is to promote a general process for the dissemination of this type of material in large corporations, we will use a specific implementation of this process at the Boeing Company as an illustrative example.

BACKGROUND

Traditionally, the dissemination of corporate knowledge has taken a number of different forms. First, there are the methods of classic library science often as implemented by a formal corporate library staffed by trained librarians (Taylor, 2000). This is used for things that are well established: e.g. textbooks, established how-to knowledge on a subject, published papers on a subject, and so on. Second, it has long been necessary to disseminate official policy and procedure through "Command and Control" processes and associated media. In addition, certain industries also require configuration control processes for special classes of information such as product data, drawings, and manufacturing rejection and acceptance documentation. These are all subject to an authentication process, flowing top-down to intended users. A third, extremely important, approach to knowledge maintenance and dissemination has been through mentoring and establishment of departments aligned to technical specialties and communities of interest. This last type of approach is particularly well suited for *tacit knowledge*. A fourth category of knowledge sharing applies to the communication of explicit knowledge among peers but also includes dissemination to management and other reference groups. This method applies to information that is less formal and frequently ephemeral. See Table 1.

This fourth method is of an entirely more fluid nature and, in some cases, represents the majority of a corporation's explicit knowledge. While it is appropriate for the enterprise to disseminate formal information using traditional, formal means, there is a need to disseminate less formal information as well. This informal knowledge often includes the most current information within a company and without adequate dissemination corporate decision-making is likely to fall short. In summary, stable and formal information is well handled by existing library or document release systems. Ephemeral, less formal, and generally less controlled content, while important, is currently only shared across the enterprise by a variety of ad hoc means, if at all.

MAIN FOCUS OF THE ARTICLE

This article focuses on how to systematically share this fourth category of informal and uncontrolled knowledge. The ideal for knowledge dissemination is to make sure information of this type can be well integrated into existing formal content,

Table 1. Summarization of four traditional dissemination methods

Methods	Types of Information	Tacit/ Explicit	Scope of Control	Status of Information
1. Corporate Library	Formal: books, research periodicals, white papers	Explicit	Enterprise-wide	Stable
2. Command and Control	Formal: documentation of standards, regulations, policies, procedures	Explicit	Enterprise-wide	Relatively stable
3. Undocumented	Informal: skill, experience, expertise	Tacit	Local	Both Stable and Ephemeral
4. Uncontrolled	Informal: test notes, presentations, lessons learned, emails	Explicit	Local	Both Stable and Ephemeral

taking advantage of the context that has been created over time by librarians and other formal content management systems. To achieve this, it is necessary to organize this knowledge in a way that is consonant with the information categories of multiple existing systems. This is made possible by using an enterprise *ontology* (see below) or some form of controlled system of keywords which can be mapped to existing vocabularies. Portals, and other tools which allow content aggregation and term mapping, enable sharing of this knowledge at a physical level. It provides search and simple navigation across sources, as well as security services to restrict access as needed. A central shared ontology combined with an interactive text classification tool make dissemination of this knowledge possible.

In the matter of assigning documents to categories, we emphasize the importance of involving subject matter experts. Traditionally, this is done by librarians who are trained to catalog (categorize) content. However, in the case when authors are widely distributed throughout a complex corporate enterprise, we suggest that text classification software can be used by these subject matter experts to facilitate broad knowledge dissemination. The challenge is to provide text classification services which can be used to produce high quality results by users who are not trained in library science.

The essential elements of a distributed dissemination scheme for this type of explicit but informal knowledge are: a portal, an ontology, a text classification system, and a publication process. In combination, these four elements allow autonomous subgroups of a corporate entity to interact with common resources and tools to publish their local work in a way that places it within a context comprehensible to an enterprise audience.

Knowledge dissemination, as used here, applies specifically to explicit knowledge captured in documents from many sources. There are a number of frameworks that address the life-cycle of explicit knowledge (Bock, 1997, O'Dell, 1998), but here we will follow the steps outlined by Mack et al. (2001). In this framework, the basic tasks in knowledge work are Capture/Extract, Analyze/Organize, Find, Create/Synthesize, and Distribute/Share. In particular, text classification has direct benefit to the Analyze/Organize and Find stages and portal services will be the basis of the Distribute/Share stage. As discussed here, knowledge dissemination applies to the Analyze/Organize, Find, and Distribute/Share stages.

Portals

A portal is used to collect content from many different sources, resulting in a virtual collection available through a single point of access. This aggregation of content is perhaps the key characteristic of all portal products. In addition, a portal provides some capability for metadata management whereby tags and values can be directly replicated from source documents or harmonized within the virtual collection by mapping them to a centralized schema. In addition, a portal may permit the addition of metadata based on characteristics of the source system or based on the decisions made by the group about how ontology terms will be attached to documents. The documents themselves remain in their source system, maintained, refreshed, or deleted by the groups that own them.

Other kinds of information systems besides portals can be useful for knowledge dissemination. For example, several enterprises make use of Wikipedia-style systems (Burton, 2008, Gardner, 2008) Also, influenced by the success of applications such as MySpace and Facebook on the internet, some enterprises are building these types of social computing applications on their corporate intranet, for example IBM's Beehive (Associated Press, 2008). However, portals, in one form or another, are well suited for publishing a distributed collection based on the intellectual products of many subgroups. Further, because of their flexibility in combining a variety of tools and services, portals can be customized to create a rich knowledge-sharing environment. In addition, they can be extended to support personalization services, which would allow even more focused dissemination.

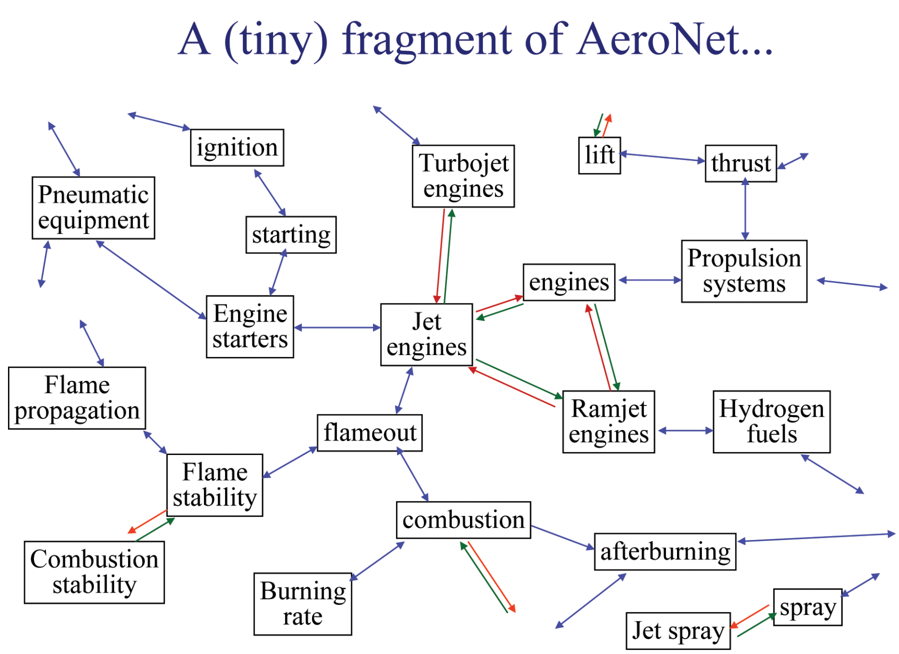
Thus, portals are a natural element to aid in knowledge dissemination. They can be used to achieve the key goal of achieving awareness (Alavi & Leidner, 1999, Prusak, 1997). Indeed, creating awareness is a goal of dissemination and is a prerequisite to collaboration or further synthesis.

Ontologies

To produce an organization of corporate documents that can be readily shared, it is essential to have some broadly shared source of terms that represent the concepts in our shared ontology. Ideally this would come in the form either of a corporate *taxonomy*, a corporate *thesaurus,* or both. What is minimally necessary is simply a list of controlled keywords expressing the topics that are important to the enterprise. We refer to the concepts expressed by these keywords as *knowledge categories*. Ideally, there is some kind of structure or organization to the knowledge categories, for example, a *generalization-specialization hierarchy*. Such a specification of the things that can be talked about and their relationships is referred to in artificial intelligence as an ontology. There is a strong advantage to organizing documents this way, because it enables much easier and better quality search, and greater use of the knowledge in those documents. In the Boeing case, there were about 60,000 knowledge categories, as well as generalization-specialization relationships, synonymy relationships, and more general "is-related-to" relationships, so that the ontology is somewhat richer than a hierarchy (see Figure 1), (Clark et al., 2000).

This approach benefits most when it can build on an existing cataloging scheme, such as one maintained by an enterprise library system or a professional organization (e.g., the Institute of

Figure 1. The AeroNet ontology contains more than 60,000 concepts used as categories for text classification and subsequent knowledge dissemination. This figures shows a small fragment of the total ontology.



Electrical and Electronics Engineers), or a taxonomy provided by an industrial consortium (e.g., the Air Transport Association). The ontology used in the Boeing realization of the approach derives from the corporate thesaurus, a list of controlled keywords sanctioned by the Boeing technical library system, together with the relationships among them. By using a set of controlled keywords created by corporate librarians, not only was an immense amount of time saved in constructing the taxonomy but the system was also able to leverage off of their collective and accumulated expertise.

However, with some additional effort, categories can be established and applied even when such a resource is not available or is not sufficiently complete. In this case, one approach is to use text clustering and automatic summarization (Kao et al., 2004). Text clustering serves to group documents together based on the words they contain. The words with the greatest frequency or strength either throughout or near the center of each cluster can summarize the documents in that cluster. Using this summary, domain experts, knowledge administrators or managers, or librarians can decide which clusters represent important categories to the enterprise, and supply standard names for those categories. If desired, they can further subdivide or group the resulting categories giving generalization-specialization relationships, and shared summary words may suggest other relationships. Of course, while this approach will provide more consistency within the enterprise, it will lose the historical context provided by leveraging off of existing ontologies.

A folksonomy, as created by social tagging applications, is another option as a source of terms when an enterprise has no pre-existing ontology, thesaurus, or taxonomy (Vander Wal, 2007, Hayman, 2007). Vander Wal described this as a "user-created bottom-up categorical structure development with an emergent thesaurus." An argument against using folksonomies as a source of terms for a formal ontology is that folksonomies typically contain tags that are mostly personal (e.g. "to-read"), or subjective (e.g., "hilarious" or "awesome"); however, Al-Khalifa and Davis (2007) and Sen et al. (2006) find that about 2/3 of user-generated tags are content related (e.g., "lean+", or "web2.0") and, therefore, provide a useful source of terms for a corporate ontology. As with the document-based text clusters mentioned above, folksonomies do not necessarily capture historically relevant or traditional categories.

Once an ontology is available, the concepts must be attached to documents and used to retrieve those documents. We do not assume that those who are involved in knowledge dissemination, whether as knowledge provider or consumer, have either the training or perspective of librarians. Nevertheless, by allowing participants to interact with a controlled vocabulary in the context of their subject matter of interest and giving them a means to do so easily, the process can improve dissemination of knowledge by grouping topically similar documents together regardless of their original local vocabulary usage. What is required is a tool to aid the author or searcher in finding the appropriate categories.

Text Classifier

An automatic text classifier takes a piece of text (e.g. a memo, an abstract, or a longer document), and based on its features (typically the words it contains) determines automatically which of a set of predetermined categories should be assigned to it. There are a number of different approaches, as summarized in Sebastiani (2002), including naïve Bayes (McCallum & Nigam, 1998), support vector machines (Joachims, 1998), and logistic regression classifiers (Komarek, 2003).

The first step in creating a classifier is to collect a *training sample* of texts that are already associated with the appropriate knowledge categories. At the Boeing Company, the abstracts for about 500,000 corporate documents in the technical library were used as the training sample.

If the categories are not a pre-existing set created by librarians or other standard professional body but have been developed as described above using a text clustering algorithm, there may still be an easy way to create a training set. If the clustering algorithm generates convex clusters, as does K-means (Hartigan, 1975, Hartigan & Wong, 1979), the central members of the chosen clusters could serve as a training sample for those categories.

A text classifier is then constructed or trained based on the knowledge categories and the training sample of already categorized documents. The text classifier is then made available to both producers and consumers of the documents.

Authors of new documents to be entered into the system can use the text classifier to automatically propose knowledge categories appropriate to their document. In the Boeing implementation of this process, using the Graphical User Interface (GUI) shown in Figures 2 and 3, they first either type in the name and location of their document or browse to enter it into the classifier. The classifier then proposes the most likely knowledge categories ranked in order of likelihood in the box under the "Thesaurus Terms" label (see Figure 2). The Authors can either select these terms or use AeroNet, a semantic network of thesaurus keywords developed at the Boeing Company (Clark et al., 2000), to navigate through the relationships among the categories to find more precise or more general knowledge categories to better describe their document. For example (see Figure 3), the knowledge category "data management" might have been returned by the classifier. By highlighting that and clicking on "EXPAND", AeroNet will bring up specializations like "factory data access system" and "data integration" and generalizations like "management" from which the user can select or use as a starting point for further navigation. A category can be removed from the list by highlighting it and then clicking on the "Remove" button. Finally, clicking on the "OK" button will associate the selected list of categories with the document. An extension of this would be to allow users to have a hybrid system where the users could use tags suggested either from the controlled vocabulary or from a user-generated folksonomy, or enter any word they think would be an appropriate tag if they cannot find anything in the controlled ontology.

During the Find phase, the same text classifier can be used to identify information the user is interested in, without requiring the user to know the controlled vocabulary. Users may search for documents in the Knowledge Management system by entering a natural language query in a similar GUI and then selecting from the knowledge categories suggested to construct a precise query based on the content metadata.

Publication Process

A workgroup needs to have a process that uses the classifier and portal for knowledge to be shared outside the group. Minimally, individuals would be required to add metadata to all documents they wish to publish. They can interact directly with the enterprise ontology where one exists, they may apply user-generated tags from a folksonomy, or they could use the text classifier on a representative sample of their documents to produce an initial down-selection of knowledge categories appropriate for most documents they are likely to produce.

Although social tagging applications are attractive, our main interest is to provide information in context so that the publishing process genuinely constitutes the dissemination of knowledge. By choosing tags that have been used to catalog the broad assets of a corporate library this goal is arguably achieved.

In a discussion of "Library 2.0", (Maness, 2006) suggests that formally controlled terms (e.g., from taxonomy, ontology, or thesaurus) can be profitably combined with terms from a folksonomy and that the approaches are not mutually exclusive. So while folksonomies provide

Figure 2. The Graphical User Interface (GUI) allows users to scan documents and find suggested categories from the AeroNet ontology based on the results of a text classifier.

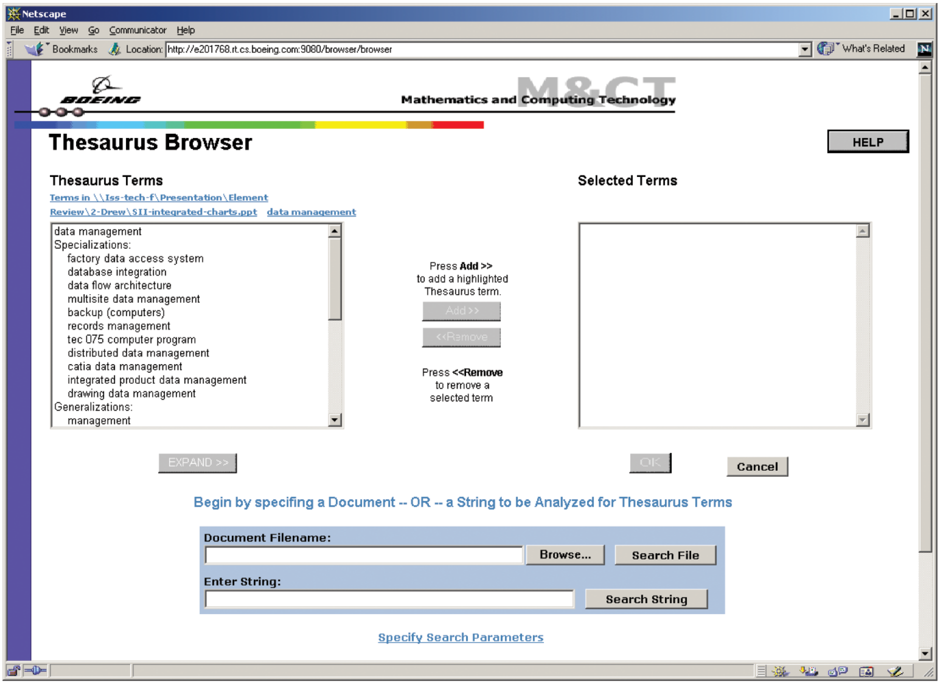


Figure 3. Users can use the GUI to expand terms and then select those that represent the best categories for a given document.

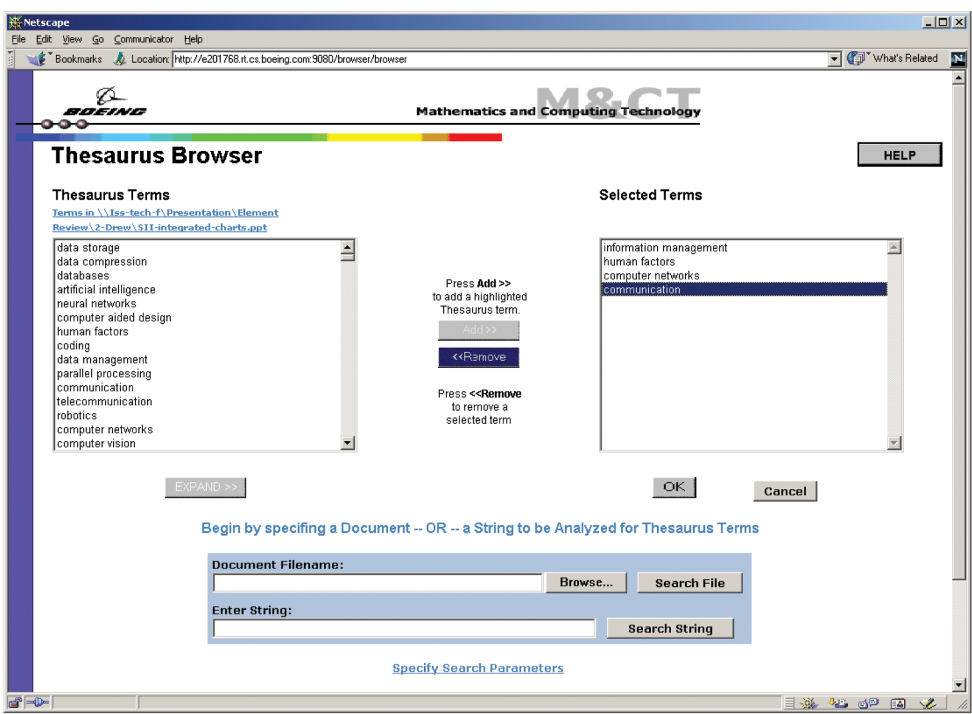

an alternative for enterprises without a library system or a controlled vocabulary, the best case may be where these two practices are combined. In this combined scenario, assets will be placed in the context of historical practice provided by the corporate library but also given meaningful current personal and subjective context through social tagging. Thus context is enhanced in a combined practice. Indeed folksonomies are likely to provide a better representation of current and emerging terminology and this should become an obvious source for updating the authoritative, controlled vocabulary.

FUTURE TRENDS

Effective classification and processes for knowledge dissemination have a positive impact on the evolution of the *semantic web* (Berners-Lee et al., 2001). The basic idea of the semantic web is to make content on the web machine-sensible with regards to its semantics (what the content is about) and with regards to machine reasoning (what the content is related to or implies). In achieving semantics it will be important to classify content in terms of one or more ontologies. Tools involving automatic text classification will probably be essential in making this feasible. Using classification based on existing library practices, as an underpinning, to provide these semantics will have the same advantage mentioned above; the meaning assigned to web content will be more likely consistent with existing catalogs of knowledge. In knowledge dissemination as discussed here, users are able to traverse the relationships in the ontology when choosing terms. However, in the future semantic web, reasoning over one or more ontologies is expected to occur automatically, at runtime, whenever a query is activated. One function of the semantic net will be to improve knowledge dissemination by using software agents to execute queries selectively, taking advantage of both the context of the content and the matching profiles of end users. The different ways that reasoning, and multiple domain ontologies, can be leveraged in the future semantic web should substantially extend what is used in current knowledge classification and dissemination. Nonetheless, the four essential elements discussed here will still be crucial. Without effective text classification, reasoning capabilities can not be expected to provide significant improvements.

CONCLUSION

There is a broad class of explicit but informal knowledge created within almost any enterprise which is not well disseminated by conventional means. Taking advantage of the web infrastructure and the current trend towards social computing, this knowledge can be effectively disseminated using four essential elements: a portal, an ontology, a text classification system, and a publication process. Perhaps most important is a broad, cost effective means to classify content according to either an ontology or folksonomy. Because folksonomies are more likely to contain current, up to date vocabulary and a formal ontology is more likely to reflect historical context, the broadest context can be achieved by combining both as a source of tags. Also, terms within a folksonomy that have garnered substantial consensus, are obvious candidates for subsequent inclusion within the enterprise ontology. We suggest that text classifiers can play a role in either case. Furthermore, while other vehicles such as wikis, blogs, and personal networking applications provide alternatives, portals are well suited to this role as they serve as an information aggregation platform that can combine content from many heterogeneous sources (including Web 2.0 sources), provide role based access, and personalization features. Given this, portals can be used to disseminate knowledge, subject to appropriate publication processes, according to consistent categories. This provides context that links each new item of content to the information previously collected in library catalogs and published from other content resources.

Further, both social tagging and text classification help overcome a substantial obstacle to knowledge dissemination within a large enterprise as users are otherwise reluctant to assign metadata to documents that they author or maintain. By providing aids to classification, basic users can accomplish cataloging tasks without much training, time or effort, and are therefore more likely to do it. In the approach outlined, when based on a formal controlled ontology, the list of proposed knowledge categories is essentially consistent with the practice of professional librarians. Overall, the quality of the user-selected categories is likely to be much better compared to categories selected without assistance from a large ontology. When a folksonomy is used, the knowledge categories will instead favor current usage, rather than a consistent professional practice. Consequently, using these four elements, enterprises have at their disposal a means to disseminate a class of information that is likely to aid corporate decision making and which should qualitatively increase a company's understanding of itself.

KEY TERMS AND DEFINITIONS

Explicit Knowledge/Information: Knowledge that is external in the form of documents, graphs, tables etc.

Folksonomy: A set of terms generated by the collective action of an online community where users tag information or objects using their own terms or the terms recommended by others.

Generalization-Specialization Hierarchy: A set of concepts organized by specialization and generalization relationships into an inverted tree-like structure, such that concepts higher in the tree are broader and encompass the concepts lower in the tree

Knowledge Categories: Categories used to characterize the topics or areas of knowledge dealt with by documents.

Ontology: The set of the things that can be dealt with in a particular domain, together with their relationships.

Semantic Web: A vision of how the world-wide web could be more intelligent, based on metatagging the content together with the ability to inference automatically about different web objects are related to one another.

Tacit Knowledge/Information: Knowledge that is in people's heads and not externalized in documents or any other form.

Taxonomy: Any system of categories used to organize something, including documents, often less comprehensive than a thesaurus.

Thesaurus: Generally, a set of keywords used for indexing and information retrieval; in the Boeing case, various relationships, including synonymy, generalization, specialization, and related-to, were also included.

Training Sample: A set of documents or other pieces of text together with categories that are assigned to them to be used for training an automatic text classifier; there may be exactly one category assigned to each or there may be any number of categories, including zero, assigned to each piece of text.

Chapter 77

A Comparative Analysis of Activity-Based Costing and Traditional Costing Systems: The Case of Egyptian Metal Industries Company

Khaled Samaha
American University in Cairo, Egypt

Sara Abdallah
British University in Egypt, Egypt

EXECUTIVE SUMMARY

Today, organizational environments are increasingly characterized by an expanding use of advanced technologies. A company's management accounting system should capture the underlying technology, be consistent with corporate commitment to total quality and increased automation, and promote its efforts to compete on the basis of cost, quality, and lead time. However, the recent literature reveals that traditional cost accounting systems systematically introduce serious product cost distortions, which lead to inappropriate strategic decisions. Activity-Based Costing (ABC) represents an alternative paradigm that is giving more accurate and traceable cost information. The objective of this case is to illustrate the application of ABC method in a single manufacturing organization operating in the metal industry and to compare the results of ABC with volume based costing (traditional costing) method. The results of the application highlight the weak points of volume based costing which assigns factory overhead costs using direct labor-hours or machine-hours as a cost driver. As a result, volume-based costing under-costs low-volume product (i.e. products requiring fewer direct labor hours in total), while it over-costs high-volume products (i.e. products requiring more direct labor-hours in total), and thus, a product is subsidized at the expense of others. In cost accounting this is called cross-subsidization. However, activity-based costing traces overhead consumption by each product and thus provides a more accurate per-unit overhead cost.

1- ORGANIZATION BACKGROUND

Egyptian Metal Industries Co. (Metalco), an ISO 9002 certified company, was established in 1987 as the first Egyptian manufacturing company in the field of 'Hot Water Boiler and Radiators'. With headquarters in Egypt, Metalco provides superior quality products, serving both the domestic and international sectors. After over 20 years of long experience, and being always on top of all forms of new scientific improvement and technical developments, its research and development teams were able to further improve the production of hot water boilers to a more practical and higher efficient 'Hot Water Boilers', while maintaining the superior quality and designs that Metalco associates its name with. These new hot water boilers were given a new brand name "*Kinz*" which translates to the word "Treasure".

Heat exchangers are common components in many of the everyday devices. Central heating boilers and radiators all contain heat exchangers. Their purpose is to transfer heat from a hot liquid or gas to a colder one. In industry, steam is often used for heating and cold water for cooling. A variety of heat exchangers have been designed to suit the range of heating or cooling applications. Boiler and radiator heating systems are already green in many respects, since they are one of the cleanest heating systems around when it comes to fostering good indoor air quality - a big plus in green remodeling circles. Nevertheless, boiler or radiator heating system can still benefit from going green, especially when it comes to reducing the heating costs and improving the energy efficiency.

In 2005, the total world domestic boiler market was estimated at $ 10.9 billion and 10.46 million units, while it is expected to grow at a moderate rate over the next few years. The United Kingdom is the biggest market in both value and volume terms, followed by South Korea and Italy. Growth rates vary significantly between countries, with smaller markets generally offering higher growth potential. These are found in North Africa, the Middle East and Central Asia, with double-digit growth forecast in Kazakhstan, Tunisia, Morocco, Jordan and Turkey up to 2010. The growth expected in these markets occurs from a low base.

Today, Meltaco Company is one of Egypt's most mature manufacturing sectors operations, exclusively distributing and servicing more than 70,000 clients both in Egypt and in the world. Meltaco's goal is to exceed the expectations of every client by offering outstanding customer service, increased flexibility, and greater value, thus optimizing system functionality and improving operation efficiency. Meltaco associates are distinguished by their functional and technical expertise combined with their hands-on experience, thereby ensuring that our clients receive the most effective and professional service. Meltaco Company's policy is to provide a culture of continual improvement that is committed to exceed Customer expectations and requirements, by providing products and services of excellent quality. Customer support is number one at Meltaco Company

Meltaco Company is caring to develop its employee's staff and provide them with good work environment to achieve its goals and to maintain highly regarded performance level. Currently, it has a staff of 10 managers and 50 professionally trained maintenance personnel available 24 hours a day, 7 days a week to service all clients' needs. The company offers many different service plans. Meltaco's professional sales staff would assist the clients in choosing the best system of boilers or water heaters to meet their specific needs. The company warranties all its equipment, installation and spare parts. Customers are welcome to stop by the Spare Parts Department. While there, the company's professionally trained personnel will consult with each client to find the spare parts and equipment they need for their operation.

Meltaco produces a wide range of hot water boilers, including residential boilers, commercial boilers, swimming pool boilers, water heaters and laundry equipments. The most significant highly demanded product lines are Commercial Boiler (COM) and Residential Boiler (RES). Between those two products' lines, capacities range from 30,000 Kcal/hr up to 2,240,000 Kcal/hr. Each boiler type is produced in three types (1) Gas Boiler and (2) Oil Boiler and (3) Electric Boiler.

Seeking adequate operational information flow, the firm invests approximately 5% of their $30 million annual turnover in information systems adaptation. However, due to the information technology rapid advances, the company's management realizes the emerging need to update its current working systems. Top management support is imperative within this organization as they are the ones making the decisions. The organization seems to be under developed with regard to accounting information system (AIS) strategy planning; however they don't believe that it is a major problem. It is apparent that the president of the firm believes that investing in AIS will give a significant financial return. This shows a commitment by top management to forecast the long term benefits of AIS.

2- SETTING THE STAGE

Nour Khaled, the Factory Accountant, was sitting in a meeting with Glenn Hoddle, the General Manager of Egyptian Metal Industries Co. They were reviewing the March 2010 quarter's management accounts and discussing cost information on the company's two main product lines.

The general manager of the company was in full flight, frustrated as ever with the output from the company's costing system. 'How can it be? I just don't understand it. We've been losing business on the Residential Boilers line over the past quarter. Yet, your data indicates that it's our most profitable product. It doesn't seem logical to me.'

Glenn continued..........

Hisham Ibrahim (the Production Manager) insists that the Residential Boilers is so much harder to make than the commercial boilers range. How can it cost less to manufacture? Magda Khaled (the Sales Manager) is absolutely confident that, if they could reduce the commercial boilers selling price, they would see an even higher increase in sales. Are you sure that these costs are correct? How have you computed the overhead content of each product cost?'

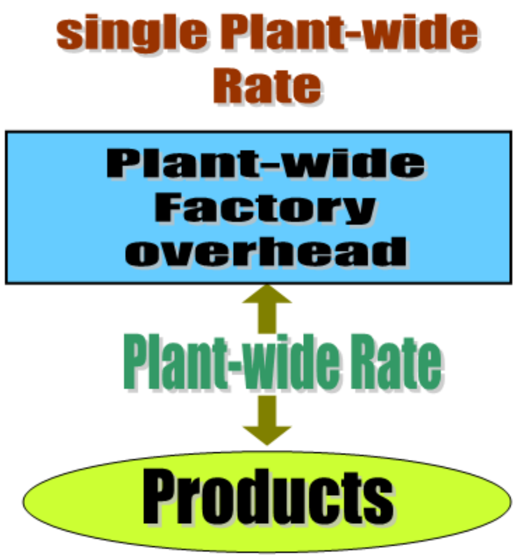
Khaled had covered this ground on many previous occasions with Hoddle and, yet again, set out to explain the operation of the company's costing system. In particular, she detailed the different steps in the allocation of overhead to the two product lines.

The overhead allocation process involves two separate steps. General Factory Overhead is spread across the two production departments (Assembly and Test) on the basis of the direct labor cost incurred in each department. The relevant portions of General Factory Overhead are then added to the separate overhead costs of the Assembly and Test departments before being divided by the total amount of direct labor hours required in each department. This exercise produces an overhead rate per direct labor hour for each production department. We then determine factory overhead rate for the entire production (i.e. plant-wide rate). Finally, we go on to apply that overhead per direct labor hour to the individual product's usage of direct labor hours (see Figure 1). We have used the same approach for years - long before we introduced the current products. No one has ever queried it. It's always worked before,..'

Before Khaled could continue, Hoddle interrupted her. It was clear that Hoddle was far more than impressed with this detailed and complicated explanation.

'Hmmm... Nour, plain common sense tells me that it's time to look again at the way we tackle costing. I was talking to Romani George at Liverpool Products limited last week and he said that his company had brought in something called XYZ, or was it ABC - some kind of new approach to costing. Would that be any simpler than that we do now? More important, do you think that it

Figure 1. Current overhead allocation in Metalco: A single plant wide rate



would produce any better quality cost data? Can you find out about it and let me know? We need fast answers on this - there are some good market opportunities out there, but we need to be in a position to respond to them. Come back to me as soon as you have had an opportunity to look into this.' In other words, the General Manager asked Khaled to provide a detailed analysis on *Overhead Allocation under the present costing system, and detailed computations on the effect of the implementation of an ABC approach on the allocation of total factory overhead.*

3- CHALLENGES FACING THE ORGANIZATION

A potential problem with this company's costing system is that overhead is calculated based upon direct labor cost, which is not the driving force behind the incurrence of the indirect costs in this company. Further, decision making regarding the company's product lines is not supported adequately to be of use to management.

Because volume-based costing uses an aggregate rate rather than a specific one, it loses a lot of information and control over product costs. A selected volume-based cost driver (e.g. direct labor-hours) might have little to do with how factory overhead costs accumulate. This can cause not only product price distortions, but it can also decrease the incentives for department managers to control product costs.

In traditional costing systems, direct materials and direct labor are the only cost components that can be traced directly to the product. Traditional costing systems were designed in the late nineteenth and early twentieth centuries, where the business environment was far less automated and the product line heterogeneity was less common. In this early era, the direct materials and direct labor truly reflect the primary components of the production costs, indirect overhead costs were relatively low, and the distortions arising from inappropriate overhead allocations were not significant. Information processing costs were high, and it was therefore difficult to justify more sophisticated overhead allocation (Xiong et al., 2008). However, today with far more automated production environment and companies produce a wide range of products, direct labor represents only a small fraction of total costs, and overhead indirect costs are far more of considerable importance. Such increase in indirect costs causes the overhead component to be the truly production prime costs. Simplistic overhead allocations using a declining direct labor base cannot be justified, particularly when information processing costs are no longer a barrier to introducing more sophisticated systems.

The increase in overhead cost portions distorts the product costing as traditional costing systems aggregate these overhead costs to product lines, and apply the aggregated overhead on a basis not necessarily consistent with the resources consumed by the product lines. Traditional overhead allocations are based on volume related bases (based on direct labor, direct materials, or machine hours), which may not be the driving force of the overhead activities. However, many organizational resources exist for activities that are unrelated to physical volume. Non-volume-related activities include probable support activities such as material handling, material procurement, set-ups, and production scheduling and first-item inspection activities. Also, the consumption of resources in production may differ extensively among product lines. Some costs or departmental cost pools may apply to a single or a few product lines, rather than to all products. Traditional product cost systems, which assume that products consume all resources in proportion to their production volumes, thus report distorted product costs (Hicks, 2006). Cooper and Kaplan (1988) claimed that the commonly used systematic overhead allocation methods distorts production costs, resulting in under-costing of low volume products and over-costing of high volume products, and thus, producing unreliable product costs to be utilized by management in attempt to control costs in the current highly competitive markets.

According to Cooper (1989), the traditional product costing misrepresentation could be regard to three prominent causes: (1) the failure to use direct costing where it is economically "feasible". In spite of the fact that advances in information technology have greatly reduced the costs associated with tracking and assigning costs to specific products and services, many companies under-utilize this technology. Rather than using meters to measure different products' energy consumptions, motion sensors to detect the amount of time employees spend at given tasks, and bar codes to help calculate the costs associated with moving specific materials and finished products, the majority of companies allow these costs to lapse into a general, catch-all category called 'overhead'; (2) the failure to segregate overhead costs into unique cost pools. All costs that cannot be classified as direct materials or direct labor the company categorizes into one cost pool, or at best a mere handful of cost pools. No attempt is made to separate overhead costs into common overhead cost categories. As a result, the company's ability to associate overhead costs with specific products, services, customers, or some other equally important attribute is blunted.(3) The failure to apply appropriate cost allocation bases. Just as there is often only one or a very limited number of overhead cost pools, so too there is often only one or a very limited number of cost drivers used to allocate the overhead costs. Frequently, direct labor hours or direct labor dollars are used to allocate the overhead costs. Critics have long charged that such a practice is antiquated and outmoded as labor costs as a percentage of product, and even service, are rapidly decreasing. For many of today's manufacturers direct labor costs represent less than 10 per cent of the product's total cost. Therefore, say these critics, the allocation of over-head based on direct labor is likely to result in distorted product costs.

In light of the above, Metalco Company may be operating with distorted product cost information, and thus likely to make incorrect pricing and product mix decisions. In particular, the company's general manager fears are stemming from the fact that the company may believe it is incapable of matching its competitors' prices on the high volume business, and thus likely to become increasingly committed to chasing the illusory profits that its cost accounting system suggests are available on the low volume business. Invariably the company ends up with low market share, high per unit overhead costs, and large losses. Ironically, therefore, it is often the company itself, or more precisely the accounting function, that strikes the mortal blow.

4- CASE DESCRIPTION

Nour left the General Manager's office, suppressing an inward groan. She had heard of ABC - activity based costing - but she was uncertain whether it would bring any benefits to the company's costing system.

Her main concern was that any change to the company's costing system would be painful to introduce and involve her in a considerable amount of extra work.

For the next month, Nour threw herself into acquiring as much knowledge as possible on ABC. She obtained copies of a couple of new text-books and scanned the ABC case study examples to see if they were relevant to the company. She contacted the accountant at Liverpool to learn from their experience in ABC implementation.

Nour noticed that an activity-based costing (ABC) system is a complex cost system that provides detailed and accurate information about each product's cost and thus each product's profitability. The ABC system is very expensive and time-consuming system to implement due to the high cost of collecting, measuring, and recording production information, especially for her company that is producing many different products that require hundreds of various activities. For a large company like Metalco, it might take millions of dollars and many years to develop and implement an ABC system. Despite its high cost, ABC systems have many benefits to offer.

The Advantages of an Activity-Based Costing System

An activity-based costing system has the following advantages:

Accurate product cost and product and customer profitability measurement: An ABC system provides accurate and detailed product information that can be utilized by management in decision making process. It can help to make better-informed management decisions concerning product pricing, product volumes, market segments, product lines, and target costing.

- Better-informed strategic decisions: The information about cost drivers for each activity enables management to make better-informed decisions concerning product design, customer support, etc.
- Production improvement: An ABC system provides information helpful in improving production processes.
- Better product cost information: An ABC system provides a lot of information necessary for strategic budgeting, planning, and product pricing decisions. It also takes into consideration cost of unused capacity and measures it at all levels (i.e. product, batch, and facility-levels).

Mechanics of ABC implementation

Nour recognized that there are five main steps involved in the implementation of ABC. These steps consist of:

1 identifying activities;
2 determining the costs of activities;
3 identifying cost drivers for each activity;
4 determining the annual capacity for the activity;
5 calculating the activity overhead rate.

The first step in implementing ABC is the identification of activities. Activities are best viewed as groupings of related actions. For example, the activity called 'machine set-up' is the outcome of a variety of individual actions. These actions might include cleaning or flushing the machine of any residue remaining from the previous batch that was run, adjusting the feed and speed of the machine for the new batch's requirements, and inspecting the first item produced to ensure that it conforms to the product's standards for fitness.

The second step in implementing ABC involves determining the costs of activities. Continuing with the machine set-up example used above, all the costs involved in executing machine set-ups need to be accumulated.

The third step in the implementation of ABC involves the selection of cost drivers. Actually, this third step consists of two sub stages.

The first-sub stage requires the identification of what are commonly called first-stage drivers. First-stage drivers trace the costs of inputs or resources into the cost pools that comprise each activity; remember an activity consists of a number of company-defined interrelated actions. It is possible, for instance, that a company may wish to include as a set-up cost the costs of moving material from inventory storage to the shop floor. Consequently, it is for this reason that an activity may consist of a number of cost pools. The appropriateness of these first-stage drivers has an important influence on the accuracy of the calculated product costs. Poorly chosen, first-stage drivers will likely jeopardize the usefulness and accuracy of the ABC system. The cost distortions that may arise will ripple through the ABC system and potentially be exaggerated by the more prone to error second-stage drivers. It is to this reason that companies may wish to trace the consumption of resources directly (as opposed to allocating them) to cost pools.

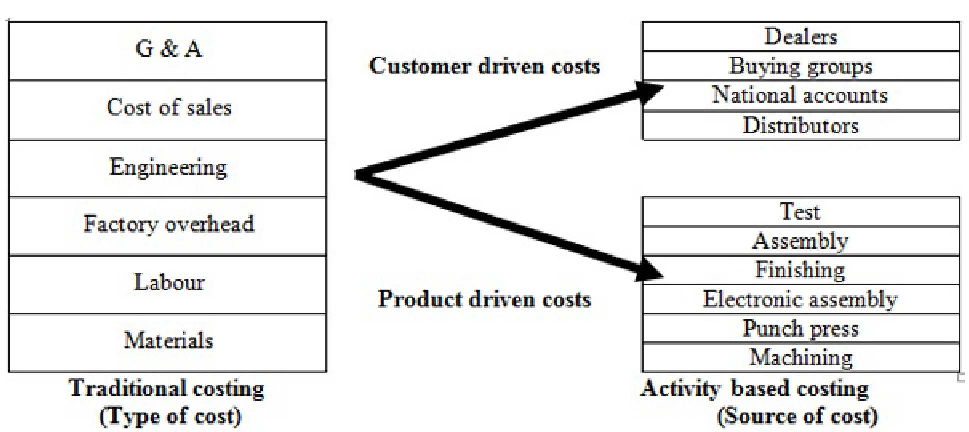
Second-sub stage drivers are used to allocate the cost pool overheads to products. The cost driver chosen should relate to the product's consumption of the particular activity's cost pool.

The fourth stage in the implementation of ABC requires the determination of the annual capacity for each activity. For example, if set-up hours are used as the cost driver for assigning the costs related to machine set-ups, then the company must determine the number of hours it has made available and therefore committed to this activity.

The fifth stage of ABC implementation involves the calculation of activity over-head rates. Let us say for the sake of illustration that 15,000 hours of machine set-up have been made available for the year at a cost of $ 600,000. Then the overhead rate for the set-up activity is $40 per set-up hour. This $40 rate will be used not only to cost products, but can also be used for the purpose of budgeting as well.

Activity-based costing focuses on the relative differences in assigning support costs. It uses the experience of operations people, and quantitative information, where available, to develop causal relationships between work drivers (what causes work to be done) and work to be done (activities). It allows the value of each activity to be assessed, identifies the factors that cause the activity to happen, and gives a true representation of the unit of measure of those activities (Figure 2).

Figure 2. ABC looks at what drives the cost



5- COMPARATIVE ANALYSIS AND PRACTICAL INSIGHTS: TRADITIONAL VERSUS ABC

To better understand the differences between the traditional and activity-based costing and how those differences affect product profitability analysis as well as management decisions, we will look at the Egyptian Metal industries company (Metalco) which has the data shown in Table 1 for the two products.

Using a Volume-Based Costing System

Under traditional costing, the factory overhead cost is assigned based on direct labor-hours (DLH). The factory overhead rate is determined as follows:

Factory Overhead Rate per DLH =

$$\frac{Total\ Factory\ Overhead}{Total\ DLH}$$

In this case, the factory overhead rate per DLH = $600,000 / 50,000 = $12 per DLH (i.e. plant-wide rate). Using this information, we can determine the total amount of factory overhead assigned to each product and the factory overhead cost per unit for both products (see Table 2).

Now we can calculate the unit margin profit for each product and determine how profitable the products are (see Table 3).

Table 1. Cost data for the two major products

	RES	COM
Production Volume	10,000	5,000
Selling Price	$78.00	$130.00
Unit prime cost	$21.00	$35.00
Direct labor-hours	30,000	20,000
Direct labor-hours per unit	3	4
Budgeted factory overhead	**$600,000**	
Budgeted direct labor-hours	**50,000**	

Table 2. Factory overhead cost per unit under traditional costing

	RES	COM
Factory overhead cost per DLH	**$12.00 per DLH**	
Direct labor hours	30,000	20,000
Factory overhead assigned	$360,000	$240,000
Production volume (in units)	10,000	5,000
Factory overhead cost per unit	$36.00	$48.00

Note: $360,000 = $12.00 x 30,000 and $240,000 = $12.00 x 20,000.

Table 3. Unit margin profit for each product under traditional costing

		RES	COM
Unit Selling Price	A	$78.00	$130.00
Less: Unit Prime Cost	B	($21.00)	($35.00)
Less: Unit Overhead Cost	C	($36.00)	($48.00)
Unit Margin	**D=A-B-C**	**$21.00**	**$47.00**
Unit Margin Percentage	**E=D/A × 100%**	**26.92%**	**36.15%**

Note C: $36.00 = $12.00 x 3 hrs and $48.00 = $12.00 x 4 hrs.

Therefore, using the volume-based costing we can see that the product COM is much more profitable than the product RES. However, let's use the activity-based costing and see if we can get the same or similar results.

Using an Activity-Based Costing (ABC)

Nour was able to gather some thoughts on other possible approaches to the apportionment of overheads. At last, she felt that he was ready for another meeting with the General Manager. Over the two weeks, Nour has assembled information which she believes will be relevant to the implementation of an ABC approach. In particular, she has reviewed the content of total factory overhead (including Assembly and Test departments' overheads) and considered how to set up appropriate cost pools and identify cost drivers.

Nour has identified the activities, costs, and activity consumption cost drivers shown in Table 4.

Nour also collected the activity data for each product (see Table 5).

Using the total cost for each activity and the total amount of activity cost driver we can determine the activity cost rate (see Table 6).

As we can see from Table 6, one set-up costs $294.12, one machine-hour costs $7.41, one inspection-hour costs $10, and one packing order costs $5.36. Now, let's calculate the per-unit cost of each product manufactured by Metalco Company (see Table 7).

Table 4. Activities, costs, and activity consumption cost drivers

Activity	Budgeted Cost	Cost Driver
Machine set-ups	$100,000	Number of set-ups
Machine running	$400,000	Machine-hours
Inspection	$70,000	Inspection-hours
Packing	$30,000	Number of packing-orders
Total	**$600,000**	

Table 5. Activity data for each product

Cost Driver	RES	COM	Total
Number of set-ups	80	260	340
Machine-hours	18,000	36,000	54,000
Inspection-hours	3,000	4,000	7,000
Number of packing-orders	2,100	3,500	5,600

Table 6. Activity cost rate

Cost Driver	Cost ($)	Activity Amount	Activity Rate ($)
	A	B	C=A/B
Number of Set-ups	100,000	340	294.12
Machine-hours	400,000	54,000	7.41
Inspection-hours	70,000	7,000	10.00
Number of packing-orders	30,000	5,600	5.36

The allocation of factory overhead using activity-based costing is summarized in Figure 3.

Using the obtained data we can perform the product profitability analysis; that is, we will determine the unit margin profit of each product (see Table 8).

According to the data presented in Table 8, the COM product is actually $22.57 ($37.18 – $14.61) less profitable than the RES product. The unit margin percentage for the COM product is lower than the one for the RES product when using the activity-based costing. Therefore, the management of Metalco Company might consider changing the production process of the COM product (e.g. increase batch-size to decrease the cost of machine set-ups per item produced) and increasing the selling price (i.e. as long as the increase in selling price would not substantially decrease product sales).

Using this example we can see that activity-based costing provides a lot of information about production activities and how they affect the cost of products, which the volume-based costing system does not explain.

Let's compare the product profitability analyses under volume-based and activity-based costing (see Table 9).

As we can see from Table 9, the product per-unit cost and per-unit margin profit differ under the volume-based and activity-based costing. The reason is that activity-based costing traces overhead consumption by each product and thus provides a more accurate per-unit overhead cost.

On the other hand, volume-based costing assigns factory overhead costs using direct labor-hours or machine-hours as a cost driver. As a result, volume-based costing under-costs the low-volume products (i.e. products requiring fewer direct labor hours in total), while it over-costs high-volume products (i.e. products requiring more direct labor-hours in total). In our example, the production of RES product and COM product required 30,000 and 20,000 direct labor-hours, respectively. Therefore, the overhead per unit cost

Table 7. Per-unit cost of each product manufactured under ABC

RES (10000 units)				
Activity Cost Driver	**Activity Rate**	**Activity Amount**	**Total Over-head**	**Overhead per Unit**
	A	B	C=A x B	D = C /10,000
Number of Set-ups	$ 294.12	80	23,529.60	$ 2.35
Machine-hours	7.41	18,000	133,380.00	13.34
Inspection-hours	10.00	3,000	30,000.00	3.00
Number of packing-orders	5.36	2,100	11,256.00	1.13
Total				*19.82*
COM (5000 units)				
Activity Cost Driver	**Activity Rate**	**Activity Amount**	**Total Over-head**	**Overhead per Unit**
	A	B	C=A x B	D = C /5,000
Number of Set-ups	$ 294.12	260	$ 76,471.20	$ 15.29
Machine-hours	7.41	36,000	266,760.00	53.35
Inspection-hours	10.00	4,000	40,000.00	8.00
Number of packing-orders	5.36	3,500	18,760.00	3.75
Total				**80.39**

Figure 3. Factory overhead using activity-based costing

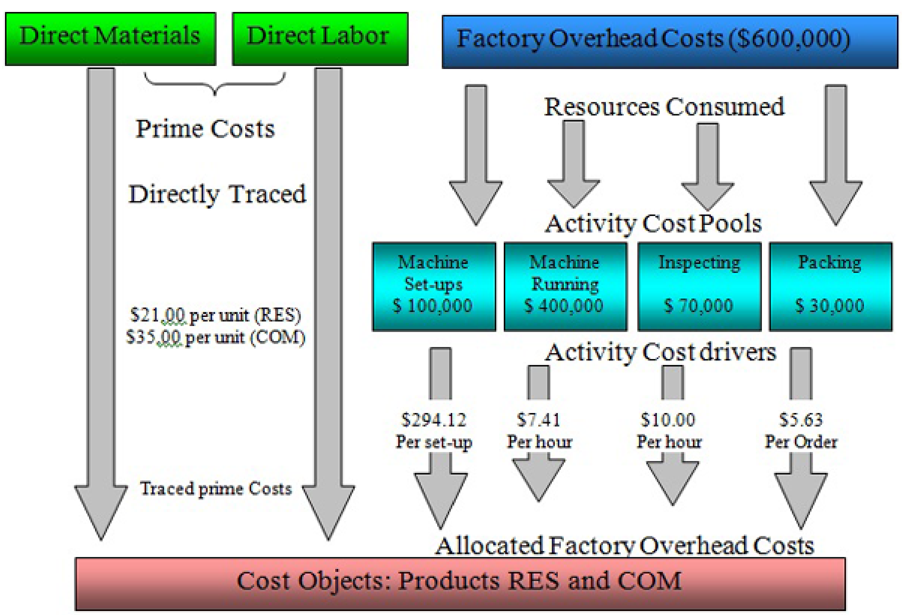


Table 8. Unit margin profit for each product under ABC

		RES	COM
Unit selling price	A	$78.00	$130.00
Less: Unit prime cost	B	($21.00)	($35.00)
Less: Unit overhead cost	C	($19.82)	($80.39)
Unit margin	**D = A-B-C**	**$37.18**	**$14.61**
Unit margin percentage	**E=D/A x 100%**	**47.67%**	**11.24%**

for products RES and COM were overstated and understated, accordingly.

Using the data obtained under the activity-based costing, for example, we can see that the overhead per-unit cost of product RES is overstated by $16.18 (i.e. $16.18 = $36.00 – $19.82) under the volume-based costing because the production of RES requires more direct labor-hours (in total). Thus, a product – COM in this case – is subsidized at the expense of others. In cost accounting this is called cross-subsidization.

Table 9. Product profitability analyses under volume-based and activity-based costing

	Volume-based costing		Activity-based costing	
	RES	**COM**	**RES**	**COM**
Unit selling price	$78.00	$130.00	$78.00	$130.00
Less: Unit prime cost	($21.00)	($35.00)	($21.00)	($35.00)
Less: Unit overhead cost	($36.00)	($48.00)	($19.83)	($80.39)
Unit margin	**$21.00**	**$47.00**	**$37.18**	**$14.61**
Unit margin percentage	**26.92%**	**36.15%**	**47.67%**	**11.24%**

KEY TERMS AND DEFINITIONS

Activity Cost Driver Rate: Is calculated by dividing activity expenses by the total quantity of the activity cost driver (e.g. machine set up expenses divided by total number of machine set up hours).

Activity-Based Costing (ABC): Is a product costing system when a company allocates factory overhead costs to activity centers (e.g. machine set ups, running machines) and then uses activity cost drivers to allocate factory overhead costs to individual products or services

Actual Costing: Is a product costing system when a company measures actual costs of direct materials, direct labor, and factory overhead. Actual costing system is rarely used because it does not provide accurate information on a timely basis: many costs can be measured only at the end of the production, and some actual costs fluctuate a lot leading to potential errors in price recording.

An activity Cost Driver: Is a quantity of activities needed to produce a product (e.g. 'machine set ups' activity center will have set-up hours as the activity cost driver).

Job Costing: Is a product costing system when costs are accumulated by specific job orders (e.g. Job Order XX2, Job Order 02357) and assigned to batches of products. In other words, manufacturing costs are assigned to specific jobs: specific customers, specific orders, specific projects, specific contracts, etc. Job costing is often used by small and medium-sized firms. Also, it is often used in the following industries: professional services (e.g. medical, legal), advertising agencies, construction, shipbuilding, custom equipment/furniture manufacturing, etc.

Normal Costing: Is a product costing system when a company measures the actual costs of direct materials and direct labor, but uses predetermined factory overhead rates to measure the factory overhead cost for a period. In other words, throughout the production time, the company measures and records the actual costs of direct materials and direct labor used, but it estimates a portion of factory overhead to be assigned to the product(s) (i.e. factory overhead applied). Normal costing system provides a timely cost estimate of a product or batch of products.

Process Costing: Is a product costing system when costs are accumulated by departments or processes (e.g. Printing Department, Assembling Department) and assigned to a large number of homogenous, identical products. In other words, manufacturing costs are assigned to each process in each manufacturing department: assembling costs (including direct materials, direct labor, and factory overhead) in the assembling department; cost of printing (direct labor, direct materials, and factory overhead) in the printing department, etc. Process costing is usually used by companies characterized by continuous mass production (i.e. firms that produce one or a few homogenous products). Process costing is often used in the following industries: textiles, food processing, automobile manufacturing, and electronics.

Standard Costing: Is a product costing system when a company measures all costs – direct materials, direct labor, and factory overhead – using standard quantities and costs.

Volume-Based Costing: Also called traditional costing, is a product costing system when a company allocates factory overhead costs to a single cost pool (e.g. factory overhead) and then uses volume based cost drivers to allocate factory overhead costs to individual products or services. The company uses volume-based cost drivers that depend on number of units manufactured. Cost bases (or drivers) often used are: labor hours, machine hours, labor costs, etc.

An easy way to remember the relationship between products: activity cost drivers, and resources, is to recall that products consume activities and activities consume resources.

Chapter 78
Complex Real-Life Supply Chain Planning Problems

Behnam Fahimnia

ABSTRACT

Supply chain planning concerns the selection of strategies and methodologies to facilitate the optimal flow of material from raw material suppliers to end-users through procurement, production and distribution activities. Supply chain (SC) implementation has significant impacts on the financial performance of manufacturing and distribution companies. Developing real-life SC models with centralised planning naturally leads to complex models which are difficult to solve optimally. This chapter firstly presents a comprehensive review on the current literature of SC planning and optimisation and classifies the published models based on their complexity. Next, a mixed-integer non-linear formulation is presented for modelling complex real-life SC planning problems which accommodates the identified gaps in the current literature. Evaluation of the available tools and techniques for the optimisation of the proposed SC model will conclude this chapter.

1. INTRODUCTION TO SUPPLY CHAIN PLANNING

A supply chain (SC) can be defined as an integrated system synchronising a series of interrelated business processes in order to: (1) acquire raw materials and parts, (2) transform these to finished products (adding value), and (3) distribute final products to retailers or final customers. A SC plan facilitates the flow of information among SC participants including suppliers, manufacturers, distributors, retailers and final customers (Min & Zhou, 2002). Today, under the threat of increasing competition, firms must use effective planning and optimisation models and algorithms, decision support systems (DSS), and computerised analysis tools to improve

DOI: 10.4018/978-1-4666-1945-6.ch078

their operational performance along SCs (Yilmaz & Çatay, 2006). For this, researchers and practitioners have developed and implemented many SC planning models and methods for optimising their entire operations to win business (M. Chen & Wang, 1997).

The two core partial optimisation problems in the SC network are production planning and distribution planning problems. In production planning, decisions regarding hiring and firing of labour, regular time and overtime production, subcontracting, as well as machine capacity levels are made for a definite planning horizon (i.e. usually a one year period). Distribution planning decisions, on the other hand, pertain to determining which facility(ies) would cater to the demands of which market(s) (Mohamed, 1999). In a conventional SC, independent manufacturers, wholesalers, and retailers are separate business entities seeking to maximise their own profits although this goal is known to eventually produce profit for the system as a whole (Barbarosoglu & Ozgur, 1999). However, it is now widely acknowledged that production and distribution decisions are mutually related problems and need to be dealt with simultaneously in an integrated manner (Park, Choi, & Kang, 2007).

Unfortunately, developing real-life integrated SC models with centralised planning naturally leads to complex, large-scale models which are difficult to solve optimally. For this reason many alternative solution techniques developed in the literature are only able to provide near optimal solutions for small and medium-size integrated models (Barbarosoglu & Ozgur, 1999). This chapter presents a comprehensive review on the current literature of SC planning and optimisation. To accommodate the identified gaps in the current literature a mathematical formulation is presented for modelling complex real-life SC planning problems.

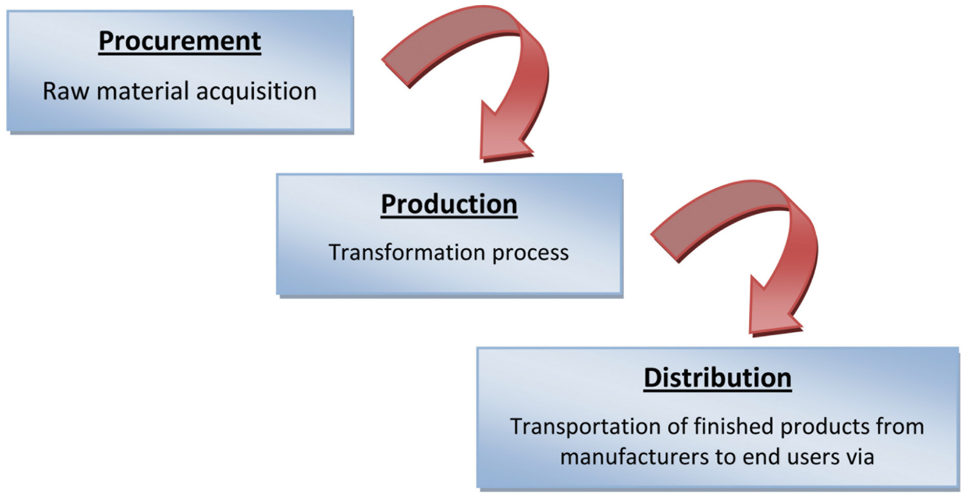
2. SUPPLY CHAIN PLANNING PROBLEM

A SC network includes procurement, manufacturing and distribution organisations working together to profitably provide the right product to the right customer at the right time (see Figure 1). Supply planning concerns with the selection of strategies and methodologies by the participating organisations (i.e. procurement, manufacturing and distribution) for satisfying the SC's short and long-term objectives (Gavirneni, 2006). From this definition, a SC manager is responsible for numerous decision makings such as the amount of raw material to purchase, production planning and inventory control issues, as well as transportation planning and warehousing decisions. In this chapter, SC is referred to as a production-distribution network in which the procurement activities are not incorporated and the SC network includes a set of manufacturers, warehouses and end-users.

SC planning is generally accomplished in 3 stages (Torabi & Hassini, 2009). The first stage is the strategic level or long-term planning where the SC configuration is determined (e.g. the location of manufacturing plants and warehouses). The objective at the second stage—tactical level or mid-term planning—is to determine the procurement, production and distribution quantities in order to minimise the overall SC costs while satisfying the customer demands. Finally, the third stage is the operational level or short-term planning where the day-to-day activities are managed according to the work plan drawn at the tactical level.

Over the last two decades, the importance of SC planning and optimisation at tactical and operational levels has been recognised as a competitive advantage for the growing production/distribution firms. There is also a growing recognition that these companies may not be able to compete without a global integration of all activities across SC (Sarmiento & Nagi, 1999). It is widely acknowledged that in order to achieve a globally

Figure 1. Configuration of SC network



optimised SC, manufacturing enterprises need to integrate and synchronise the activities in procurement, production and distribution networks for the coordination among the SC participants (Iannone, Miranda, & Riemma, 2007).

3. SIGNIFICANCE OF SUPPLY CHAIN PLANNING

Research indicates that SC planning and optimisation has raised significant interests for both researchers and practitioners over the past few years (Fahimnia, Luong, & Marian, 2008). There can be a number of major forces behind this trend, but there are two main issues which can perfectly justify the call for the implementation of effective and efficient integrated SC optimisation models (Fahimnia, Luong, & Marian, 2010). Firstly, the opportunity of an integrated management of a complex real-life SC positively affects the profitability of all the SC members (i.e. suppliers, manufacturers, and distributers). Secondly, effective SC planning reduces the lead-times and offers the quick response to market changes and therefore reduces the propagation of unexpected and undesirable events through the network (Guillén, Mele, Bagajewicz, Espuña, & Puigjaner, 2005; Persson & Olhager, 2002). These are the requirements of today's competition in order to stay in the market. This section discusses the two aforementioned factors.

3.1 Supply Chain Profitability

SC cost reduction has undoubtedly been one key issue why SCM has continually attracted much attention over the last few years. Optimising the supply chain performance is vital for the companies that are constantly examining areas where they can cut costs and improve profit margins while maintaining customer satisfaction (Koo, Adhitya, Srinivasan, & Karimi, 2008). Recently, manufacturing, distribution, and service industries have realised the cost savings that can be achieved by better planning and management of complex SC systems (Muriel & Simchi-Levi, 2003). Table 1 outlines some of the past success stories in the implementation of supply chain cost-saving plans (Aether-Consulting, 2009; Alloquor-Consulting, 2009; Bruss, 2005; Moduslink, 2009; The-cost-reduction-consultant, 2008).

Table 1 shows that the optimisation of complex SCs has become very attractive for both manu-

Table 1. SC success stories

Organisation	Overall cost savings achieved through the SC optimisation
Mazda Motor of America	$1.3M saving in annual SC costs through improving the logistics operation for the transportation of Mazda automobiles to the US dealers.
hp company	Savings of $24M per annum through the improvement of the SC transport management system
Nissan (North America Headquarters)	Annual cost reduction of 5%-10% through process and operations improvement
Pioneer Electronics	Annual savings of $1.5M (45%) through conducting a reverse logistics process improvement
Henry Schein	$1.3M savings in 6 months through the optimisation of the distribution network
Zara fashion store chain	28% rise in SC profits (equals to $621M) in nine month
Indiana Hospital	$3M cost reduction through cutting supply expenses
JLG Industries, Inc. (Producer of mobile lifts and excavators)	Potential savings opportunity of $11.4M identified (15.2% of total sourceable spend)
Advocate Health Care	$30M reduction (about 10%) in food, drug and supply costs in 18 months
Custom Building Products	12% reduction in annual transportation costs through reducing the number of carriers by 75%
Warner/Elektra/Atlantic (an AOL Time Warner company)	15% reduction in annual SC costs through logistics cost and service optimisation
Sur La Table	Reducing annual operating expenses by $1.2M through redesigning the distribution operation

facturers and service providers due to the opportunities it offers for improving the organisations' financial performance. It has been shown in the past that such financial enhancements are achieved when the decision-makings are integrated and coordinated among likeminded entities participating in the SC network (Pitty, Li, Adhitya, Srinivasan, & Karimi, 2008). In general, effective integration of procurement, production, and distribution activities across a SC network results in the following cost savings:

- **Reduction of production costs:** Production costs are the sum of fixed costs of opening and operating different manufacturing plants as well as the variable costs associated with production of various products at different plants. Implementation of integrated SC plans can contribute to the reduction of variable costs which may include regular-time production, overtime production, outsourcing as well as storage costs at stack buffers.
- **Reduction of distribution costs:** Distribution costs are the sum of fixed costs of opening and operating the warehouses and the variable costs of transporting finished goods from manufacturing plants to the end users through the warehouses. Implementation of integrated SC plans can contribute to the reduction of variable costs including transportation costs from plants to warehouses and from warehouses to end-users as well as penalty costs incurred for not being able to satisfy the customer demands at end-users.
- **Reduction of inventory costs:** In a complex SC, products and their components are manufactured in a number of different facilities and therefore inventory costs make up a significant proportion of total network costs (Fahimnia, Luong, &

Marian, 2009; Kaminsky & Kaya, 2008). Reduction of inventory costs through effective SCM contributes to a significant decrease in overall SC costs.

3.2 Quicker Response to Market Changes

The second issue on the significance of SC planning and optimisation is the quicker response to market changes and thus better customer satisfaction. To remain competitive by quickly responding to market changes, many companies started breaking traditional organisational barriers which has led to the high-level cooperation among different functional departments and introduced the concept of integrated SCM in 90s (Muriel & Simchi-Levi, 2003). Supply chain management which has attracted much interest thus far requires the effective use of information and communication systems to be widely implemented for providing data access to all SC participants (Muriel & Simchi-Levi, 2003). The result of this cooperation is appeared in form of lead-time reduction, an unavoidable element of today's time-based competitions. Sajadieh, Jokar and Modarres (2009) cites that an important benefit of the coordination is the more efficient and effective management of inventories across the entire SC which consequently leads to a shorter lead-time. In fact, the integrated management of a complex SC improves the SC information flow which naturally leads to an improved product flow (i.e. lower work-in-progress—WIP—inventories) and thereby shorter lead-time.

Two good examples of the application of SC strategies resulting in lead-time reduction are Seagate Technology and Intel Corporation (Alloquor-Consulting, 2009). Through the optimisation of SC plan, Seagate reduced its logistics cycle time by more than 50% and Intel reduced its WIP by over 35% while the average manufacturing cycle time was cut down from 10 to 4 days. In another case, a provider of communications products in United States could manage to create a 40% reduction in time to market (from 5 to 3 days), despite the production volume increases by more than 350% with a cumulative cost savings of $100M over 9 years (Moduslink, 2009).

The potential benefits of such lead-time reductions in SCM have been widely investigated and may include the following issues (Eskigun et al., 2005; Leng & Parlar, 2009; Ryu & Lee, 2003): (1) better responsiveness to market changes, (2) more accurate forecasts, (3) significant reduction of bullwhip effect throughout SC, (4) smaller order sizes, (5) reduction in WIP inventory and inventory of finished goods and (6) improved customer satisfaction.

4. REVIEW OF THE LITERATURE OF SUPPLY CHAIN PLANNING AND OPTIMISATION

The literature indicates that SC planning and optimisation has been an active research area over the last decade and many solutions have been made to solve the associated problems. The challenge in most of the SC planning problems at the tactical and operational level is to determine the operation policies to use so as to minimise the total cost or to maximise the profit of the SC while the SC configuration is assumed to be known. Mathematical techniques (e.g. linear programming, integer and mixed integer formulation) have been widely used to solve the small-scale SC planning problems and heuristics techniques, simulation and genetic algorithms have been recently applied to achieve near-optimal solutions with shorter computation time for larger-scale problems.

Many previous research works have attended the optimisation of a production plan in the supply chain context (Byrne & Bakir, 1999; J.-H. Chen & Ho, 2005; Ganesh & Punniyamoorthy, 2005; B. Kim & Kim, 2001; Pradenas, Penailillo, & Ferland, 2004; Tavakkoli-Moghaddam, Rabbani, Gharehgozli, & Zaerpour, 2007; Techawiboonwong & Yenradee, 2002; D. Wang & Fang, 1997; R.-C. Wang & Fang, 2001; R.-C. Wang & Liang, 2004). Many others have investigated the problems in the area of distribution planning (Amiri, 2006; Chopra, 2003; Jansen, Weert, Beulens, & Huirne, 2001; Liang, 2006; Lockett & Westwood, 1985; Raj, Nichols, Sterling, & Moynihan, 1992). However, in recent years simultaneous consideration of the characteristics and requirements of different functions in production and distribution networks to perform a global SC optimisation has attracted the attention of researchers and many models have been proposed in this direction. Sarmiento and Nagi (1999) cite that the basic idea behind all the proposed models in the area of SC planning is to simultaneously optimise decision variables of different functions that have traditionally been optimised sequentially (i.e. the optimised output of one stage becomes the input to the other).

Many reviews of the literature on the proposed SC models have been previously presented (Adrian E. Coronado Mondragon, Lyons, Michaelides, & Kehoe, 2006; Beamon, 1998; Donselaar, Kokke, & Allessie, 1998; Erenguc, Simpson, & Vakharia, 1999; Mary J. Meixell & Gargeya, 2005; Peidro, Mula, Poler, & Lario, 2009; Sarimveis, Patrinos, Tarantilis, & Kiranoudis, 2007, 2008; Sarmiento & Nagi, 1999; Thomas & Griffin, 1996; Van Donselaar & Sharman, 1997; Vidal & Goetschalckx, 1997). Despite the variety of the published reviews, our survey on the current literature indicates that there is no specific review on comparing the real world capabilities of the proposed SC models based on their level of complexity (multiplicity) and the solution approaches applied.

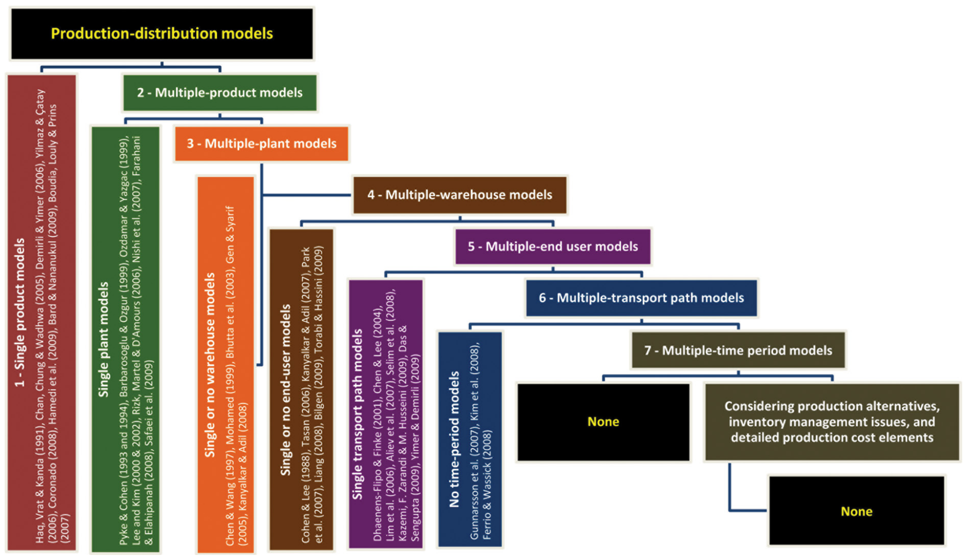
To evaluate the complexity of past research in the area, this section uses the following dimensions for classifying the past studies in the literature:

- Type of optimisation (i.e. total cost minimisation, profit maximisation, or multiple objective functions)
- Multiplicity of products to be produced at each manufacturing plant
- Multiplicity of geographically dispersed manufacturing plants
- Multiplicity of machine centres for the production of multiple products at each manufacturing plant
- A stack buffer at each manufacturing plant temporarily storing products prior to their shipment to the warehouses
- Multiplicity of transport paths from plants to end-users (direct/indirect shipment)
- Multiplicity of time-periods
- Multiplicity of production alternatives for each manufacturing plant
- Detailed production cost elements at aggregate level for each plant
- Inventory management issues considering the costs associated with WIP inventory and inventory of finished products at stack buffers and warehouses
- Shortage/penalty costs of not meeting demand forecast (also known as backlogging or backordering costs)
- Modelling and optimisation approaches

Based on the above-mentioned dimensions, all the published works in the context of SC planning and optimisation can be classified into the following 7 categories (refer to Figure 2).

1. Single-product models (Bard & Nananukul, 2009; Boudia, Louly, & Prins, 2007; Felix T. S. Chan, Chung, & Wadhwa, 2005; Coronado, 2008; Demirli & Yimer, 2006; Hamedi, Zanjirani Farahani, Husseini, & Esmaeilian, 2009; Haq, Vrat, & Kanda, 1991; Yilmaz & Çatay, 2006)
2. Multiple-product, single-plant models (Barbarosoglu & Ozgur, 1999; Elahipanah & Farahani, 2008; Lee & Kim, 2000, 2002; Nishi, Konishi, & Ago, 2007; Ozdamar & Yazgac, 1999; Pyke & Cohen, 1993, 1994; Rizk, Martel, & D'Amours, 2006; Safaei, Moattar Husseini, Z.-Farahani, Jolai, & Ghodsypour, 2009)

Figure 2. The classification of the literature of SC planning and optimisation



3. Multiple-product, multiple-plant, single or no warehouse models (Bhutta, Huq, Frazier, & Mohamed, 2003; M. Chen & Wang, 1997; Gen & Syarif, 2005; Kanyalkar & Adil, 2008; Mohamed, 1999)
4. Multiple-product, multiple-plant, multiple-warehouse, single or no end-user models (Bilgen, 2009; Cohen & Lee, 1988; Kanyalkar & Adil, 2007; Liang, 2008; Park, et al., 2007; Tasan, 2006; Torabi & Hassini, 2009)
5. Multiple-product, multiple-plant, multiple-warehouse, multiple-end user, single-transport path models (Aliev, Fazlollahi, Guirimov, & Aliev, 2007; C.-L. Chen & Lee, 2004; Dhaenens-Flipo & Finke, 2001; Lim, Jeong, Kim, & Park, 2006; Selim, Araz, & Ozkarahan, 2008)
6. Multiple-product, multiple-plant, multiple-warehouse, multiple-end user, multiple-transport path, no-time period models (Ferrio & Wassick, 2008; Gunnarsson, Rönnqvist, & Carlsson, 2007; Y. Kim, Yun, Park, Park, & Fan, 2008)
7. Multiple-product, multiple-plant, multiple-warehouse, multiple-end user, multiple-transport path, multiple time-period models (never studied in the literature)

Figure 2 illustrates the classification of previous works in the area of SC planning. Each level of this figure contains the related published works for that certain level of complexity. This figure can help identifying where the gaps are in the current literature of SC planning (refer to category 7 of this figure). Next section will discuss the research gaps identified.

5. IDENTIFIED GAPS IN THE LITERATURE OF SUPPLY CHAIN PLANNING

Despite the fact that the area of SC planning and optimisation has attracted much attention over the last few decades, there are still issues which have remained unaddressed. We classify the identified research gaps into two categories.

The first identified issue is "oversimplification" in the proposed models which is mainly due to the complexities associated with the optimisation of a complex real-life SC plan. Previous studies on the SC planning and optimisation focus on some SC principles, while pay less attention to the rest of the activities in the network. However, by actively pursuing only a subset of principles manufacturing/distribution firms will not succeed in achieving their expected improvements in the integrated SC performance (Muckstadt, Murray, Rappold, & Collins, 2001). Paying less attention to considering a realistic set of variables and constraints can preclude the previous models from functioning effectively in the real-life manufacturing/distribution scenarios. Therefore, there is a need to further extend the scope of the proposed studies in the way to develop real-world models concerning with the optimisation of complex integrated SC plans.

An evidence of oversimplification in the previously developed models is the scarcity of their real world implementation for solving complex large-scale SC planning problems. To demonstrate the applicability of a SC optimisation model, it is essential to test the algorithm on real world SC case problems incorporating a realistic range of variables and constraints (Blackhurst, Wu, & O'Grady, 2005). This helps analysing the impacts of various decisions on different SC entities (Biswas & Narahari, 2004). Although some of the former studies have shown the successful application of their models in the optimisation of simplified SC planning problems, the approaches have not been implemented in real-life large-scale case problems. in fact, a real world SC problem can be much larger in size and more complex in nature than the proposed models in the literature.

The second identified gap relates to the lack of appropriate and effective solution approaches for handling large-scale SC planning problems. Various techniques have been used in the literature to solve small and medium size SC planning problems ranging from mathematical programming, heuristics, simulation and knowledge based system to the latest fuzzy programming and genetic algorithms (Lair, 2008). Finding the optimal solution in a complex real-life SC planning problem with the use of the presented tools and approaches in the literature is almost impossible or subject to heavy computing overheads. Some of other presented approaches which might be able to handle larger-scale problems are not able to prove the optimality of the solutions found or do not have the potential to find the optimal solution on their own. Moreover, there is a wide range of tools and techniques available for the optimisation of SC models and a typical user may not be aware of the various tools available for solving a particular decision problem (Biswas & Narahari, 2004). Hence, there is a need to further enhance the quality and precision of the solution approaches for the optimisation of complex large-scale real-life SC planning problems.

The following 2 sections aim to address the identified research gaps in the current literature by developing a mathematical formulation for modelling a complex real-life SC planning problem and evaluating the alternative tools and techniques available for the optimisation of the developed mixed-integer non-linear model.

6. A COMPLEX LARGE-SCALE SUPPLY CHAIN PLANNING MODEL

The complex real-life SC planning problem considered in this research consists of a number of production plants producing a variety of product types during multiple time periods. The finished products are then distributed to a set of end-users through multiple transport routes in the sense that the products can be transported directly from manufacturing plants to end-users or indirectly through several warehouses. All the demand is to be satisfied at the end-users by the end of the planning horizon. The proposed SC plan aims the efficient utilisation of production allocation as well as transport, warehousing and material flow.

6.1 Key Performance Indicators

The first issue in developing a mathematical model is to identify the appropriate key performance indicators of the system. A vast amount of the literature has been published suggesting performance indicators for SC modelling and optimisation purposes (Bullinger;, Kühner, & Hoof, 2002; Gunasekaran, Patel, & Tirtiroglu, 2001; Lapide, 2000; S¨urie & Wagner, 2005; Stadtler & Kilger, 2005). However, all the proposed alternatives can fit within four main categories of *performance measures* that are applicable in most SC settings: (1) overall SC costs, (2) inventory management, (3) delivery performance (time-based) and (4) SC responsiveness (S¨urie & Wagner, 2005).

The literature on the SC planning models indicates that the cost-based value characteristics have been the most popular performance measures among both researchers and practitioners (Lair, 2008). These may include the minimisation of total cost, setup cost, delivery cost and penalty cost or the maximisation of overall SC profit. Obviously, the significance of cost value as the first SC performance indicator is due to the large interests of operation managers to observe the direct financial impacts on the overall SC performance (F. T. S. Chan, 2003). Likewise, the proposed model in this research aims to minimise the overall system costs as the main SC performance measure because cost-based optimisation can clearly reflect the SC efficiency due to its direct financial implication on the SC performance.

6.2 Model Assumptions

A set of assumptions are considered in the proposed SC planning model:

- Variety of products to be produced is known.
- Number, location and capacity of plants and warehouses are known.
- Number and location of end-users (customer zones) are known.
- Demand is deterministic and the aggregate demand for all types of products in the concerned periods is assumed to be known for the next planning horizon. The aggregate demand at each end-user is the total demand for each product which may be ordered by several individuals or retailers at end-users.
- Capacity limitations for regular-time and over-time production (capacity of machine centres), capacity of raw material supply, limitations in storage capacity at stack buffers and warehouses, and distribution capacities are known.
- All customer demands for each product have to be satisfied, sooner or later, during the planning horizon. A penalty cost will be incurred if the demand for a certain product at one period is decided to be backordered. The backordered demands are to be satisfied in the next periods before the end of the planning horizon.
- End-users or customer zones are the locations where products are delivered to the final customers with no holding capacity to store the products.
- Transportation costs are proportional to the transportation distances.
- Orders for subcontracting items are made by each plant at the start of each period and subcontracted items are sent directly to the stack buffer of the source plant (ordering plant) by the end of ordering period.

6.3 Parameters and Decision Variables

Before formulating the objective function, all the input parameters and decision variables must be clearly described. Indices used for mathematical formulation of the proposed model include product index (i), plant index (m), machine centre index (g), stack buffer index (b), warehouse index (w), end-user index (e) and time-period index (t).

6.3.1 Parameters

Parameters represent the input data for a system. Therefore, a parameter can be referred to as a variable with a fixed given value which is used as an input to the model (Lair, 2008). The parameters used for the purpose of mathematical modelling in this chapter are listed in Table 2.

6.3.2 Decision Variables

Decision variables are the outputs of the system or the variables in which the values need to be determined by the systems. The decision variables for the presented model in this chapter are listed in Table 3.

The integer variables are presented in Table 4.

6.4 Objective Function Formulation

This section describes the development of a mixed-integer nun-linear formulation model for a complex real-life SC plan. The proposed model deals with the trade-off between costs of inventories, production, transports and storage by integrating the Aggregate Production Plan and Distribution Plan. The objective function minimises the sum of the following costs: (1) production costs in regular-time, (2) production costs in over-time, (3) outsourcing costs, (4) inventory holding costs in plants, buffers, and warehouses, (5) transportation costs and (6) backlogging costs. The cost function (i.e. the objective function) is presented in Equation 1 (see Table 5).

The objective function in Equation 1 consists of 12 cost components:

- *Component 1 and 5* are the fixed costs of opening and operating plants and warehouses respectively. These are independent of the rate and quantities of production/distribution at plants/warehouses and may include hiring costs of building and facilities, amortisations of machines and tools, salaries of the managers, annual insurance payments among others.
- *Component 2* expresses the production costs in regular-time derived from Equation 2 (see Table 6).
- *Component 3* describes the over-time production costs derived from Equation 3 (see Table 7).
- *Component 4* is outsourcing or sub-contracting costs as an option for failing to manufacture the products in-house.
- *Component 6, 7, and 8* represent the inventory holding costs in plants, buffers and warehouses respectively.
- *Component 9, 10, and 11* express the transportation costs for the distribution of items from plants to end-users. This can be done directly from plants to end-users (expressed in component 11) or indirectly from plants to warehouses and from warehouses to end-users (expressed in components 9 and 10 respectively).
- *Component 12* stands for the shortage (penalty) costs incurred if backlogging occurs at the end-users.

6.5 Model Constraints

This section highlights all the realistic constraints faced in a real world SC plan including (1) the capacity constraints of manufacturing plants, buffers and warehouses, (2) the distribution capacity constraints of buffers and warehouses, (3) the demand satisfaction and backlogging constrains, (4) the inventory level constraints at the start/end of the planning horizon as well as (5) the variables constrains.

Table 2. Parameters

D_{iet}	Forecasted demand for product *i* at end-user e in period *t*
O_{mt}	Fixed costs of opening and operating plant *m* in period *t*
O'_{wt}	Fixed costs of opening and operating warehouse *w* in period *t*
H_{imt}	Unit WIP inventory holding cost for product *i* at plant m in period *t*
H'_{ibt}	Unit holding cost for finished product *i* at stack buffer *b* in period *t*
H''_{iwt}	Unit holding cost for finished product *i* at warehouse *w* in period *t*
HC_{ibt}	Holding capacity (maximum units) at stack buffer *b* for product *i* in period *t*
HC'_{iwt}	Holding capacity (units) at warehouse *w* for product *i* in period *t*
$Xmax_{imt}$	Maximum allowed WIP inventory for the finished product *i* carried in plant *m* at the end of period *t*
T_{ibwt}	Unit transportation cost of product *i* from buffer *b* to warehouse *w* in period *t*
T'_{iwet}	Unit transportation cost of product *i* from warehouse *w* to end-user *e* in *t*
T''_{ibet}	Unit transportation cost of product *i* from buffer *b* to end-user *e* in period *t*
RP_{imt}	Unit regular-time production cost of product *i* at plant *m* in period *t*
OP_{imt}	Unit over-time production cost of product *i* at plant *m* in period *t*
OS_{imt}	Unit outsourcing cost of product *i* ordered by plant *m* in period *t*
P_{igmt}	Processing time to produce a unit of product *i* on machine *g* at plant *m* in *t*
Q_{igmt}	Average time spent to produce a WIP unit of product *i* on machine *g* at plant *m* in *t*
L_{igmt}	Labour/hour cost for regular-time production of product *i* on machine *g* at plant m in period *t*
L'_{igmt}	Labour/hour cost for over-time production of product *i* on machine *g* at plant *m* in *t*
RM_{imt}	Cost of raw material for producing a unit of product *i* at plant *m* in period *t*
α_{imt}	Variable overhead costs of regular-time production of product *i* at plant *m* in *t*
β_{imt}	Variable overhead costs of over-time production of product *i* at plant *m* in *t*
SC_{iet}	Unit backordering (shortage) cost for product *i* at end-user *e* in period *t*
$Smax_{iet}$	Maximum amount of shortage permitted (maximum backorder) for product *i* at end-user *e* in period *t*
λ_{igmt}	Capacity hours for regular-time production of product *i* on machine *g* at plant *m* in period *t*
λ'_{igmt}	Capacity hours for over-time production of product *i* on machine *g* at plant *m* in period *t*
Y_{imt}	Capacity units of raw material supply for product *i* at plant *m* in period *t*
E_{ibt}	The distribution capacity at stack buffer *b* for product *i* in period *t*
E'_{iwt}	The distribution capacity at warehouse *w* for product *i* in period *t*
μ_{im}	WIP inventory level of product *i* in plant *m* at the start of planning horizon
μ'_{im}	WIP inventory level of product *i* in plant *m* at the end of planning horizon
η_{ib}	Inventory level of product *i* in stack buffer *b* at the start of planning horizon
η'_{ib}	Inventory level of product *i* in stack buffer *b* at the end of planning horizon
Π_{iw}	Inventory level of product *i* in warehouse *w* at the start of planning horizon
Π'_{iw}	Inventory level of product *i* in warehouse *w* at the end of planning horizon
$\rho_{bm} = \begin{cases} 1 & If\ stack\ buffer\ b\ is\ located\ in\ plant\ m \\ 0 & Otherwise \end{cases}$	

Table 3. Decision variables

I_{imt}	Quantity of product *i* produced in regular-time at plant *m* in period *t*
I'_{imt}	Quantity of product *i* produced in over-time at plant *m* in period *t*
I''_{imt}	Quantity of product *i* outsourced by plant *m* in period *t*
J_{ibwt}	Quantity of product *i* shipped from buffer *b* to warehouse *w* during period *t*
J'_{iwet}	Quantity of product *i* shipped from warehouse *w* to end-user *e* during period *t*
J''_{iwet}	Quantity of product *i* shipped directly from buffer *b* to end-user *e* during *t*
X_{imt}	WIP inventory amount of product *i* at plant *m* at the end of period *t*
Y_{ibt}	Inventory amount of finished-product *i* at buffer *b* at the end of period *t*
Z_{iwt}	Inventory amount of product *i* at warehouse *w* at the end of period *t*
S_{iet}	Quantity of product *i* backordered at end-user *e* at the end of period *t*

Table 4. Integer variables

$F_{ibwt} = \begin{cases} 1 & \text{If product i is shipped from bufer b to warehouse w at period t} \\ 0 & \text{Otherwise} \end{cases}$	
$F'_{iwet} = \begin{cases} 1 & \text{If product i is shipped from warehouse w to end-user e at period t} \\ 0 & \text{Otherwise} \end{cases}$	
$F''_{ibet} = \begin{cases} 1 & \text{If product i is shipped from buffer b to end-user e at period t} \\ 0 & \text{Otherwise} \end{cases}$	
$G_{mt} = \begin{cases} 1 & \text{If plant m operates in period t} \\ 0 & \text{Otherwise} \end{cases}$	
$G'_{wt} = \begin{cases} 1 & \text{If warehouse w is open in period t} \\ 0 & \text{Otherwise} \end{cases}$	
$d_{iet} = \begin{cases} 1 & \text{If demand for product i at end-uder e is not met at period t} \\ 0 & \text{Otherwise} \end{cases}$	

Table 5. Equation 1

$$
\begin{aligned}
MinZ = & \sum_t \sum_m O_{mt} G_{mt} + \sum_i \sum_m \sum_t I_{imt} RP_{imt} G_{mt} + \sum_i \sum_m \sum_t I'_{imt} OP_{imt} G_{mt} \\
& + \sum_i \sum_m \sum_t I''_{imt} OS_{imt} G_{mt} + \sum_t \sum_w O'_{wt} G'_{wt} + \sum_i \sum_m \sum_t H_{imt} X_{imt} G_{mt} \\
& + \sum_i \sum_b \sum_m \sum_t H'_{ibt} Y_{ibt} \rho_{bm} G_{mt} + \sum_i \sum_w \sum_t H''_{iwt} Z_{iwt} G'_{wt} \\
& + \sum_i \sum_b \sum_m \sum_w \sum_t J_{ibwt} T_{ibwt} \rho_{bm} G_{mt} G'_{wt} F_{ibwt} + \sum_i \sum_w \sum_e \sum_t J'_{iwet} T'_{iwet} G'_{iwet} F'_{iwet} \\
& + \sum_i \sum_b \sum_m \sum_w \sum_t J''_{ibet} T''_{ibet} \rho_{bm} G_{mt} F''_{ibet} + \sum_i \sum_e \sum_t S_{iet} SC_{iet} d_{iet}.
\end{aligned}
$$

Table 6. Equation 2

$$\sum_{i}\sum_{m}\sum_{t} I_{imt}\ RP_{imt}\ G_{mt} = \sum_{i}\sum_{m}\sum_{t}\left[I_{imt}\ G_{mt}\left(\sum_{g} P_{igmt}\ \ L_{igmt} + RM_{imt} + \alpha_{imt}\right)\right]$$

Table 7. Equation 3

$$\sum_{i}\sum_{m}\sum_{t} I'_{imt}\ OP_{imt}\ G_{mt} = \sum_{i}\sum_{m}\sum_{t}\left[I'_{imt}\ G_{mt}\left(\sum_{g} P_{igmt}\ \ L'_{igmt} + RM_{imt} + \beta_{imt}\right)\right]$$

Capacity constraints of plants:

- Restrictions on raw material supply:

$$I_{imt} + I'_{imt} \leq \gamma_{imt}\ G_{mt}\ \ \forall i,m,t \tag{4}$$

- Production capacity constraint for regular-time and over-time production:

$$If \quad \sum_{i}\sum_{g} Q_{igmt} = \frac{\sum_{i}\sum_{g} P_{igmt}}{2} \quad \forall i,m,t \text{ Then:}$$

$$\begin{aligned} &\sum_{i}\sum_{g} P_{igmt}\ \ I_{imt} + \sum_{i}\sum_{g} P_{igmt}\ \ I'_{imt} + \\ &\sum_{i}\sum_{g} Q_{igmt}\left(X_{imt} - X_{im(t-1)}\right) \\ &\leq \sum_{i}\sum_{g} G_{mt}\ \left(\lambda_{igmt} + \lambda'_{igmt}\right) \quad \forall i,m,t \end{aligned} \tag{5}$$

- Limitation on WIP inventory amount to be carried at each plant:

$$X_{imt} \leq X_{imt}^{Max}\ \ \forall i,m,t \tag{6}$$

Capacity constraints of stack buffers:

- Stack buffer capacity restriction:

$$Y_{ibt} \leq HC_{ibt}\ \forall i,b,t \tag{7}$$

- Inventory balance at stack buffers (see Table 8).

Capacity constraints of warehouses:

- Warehouse capacity restriction:

$$Z_{iwt} \leq HC'_{iwt}\ \ \forall i,w,t \tag{9}$$

- Inventory balance at warehouses (see Table 9).

Distribution capacity limits at stack buffers:

$$\sum_{w} J_{ibwt} + \sum_{e} J''_{ibet} \leq\ E_{ibt}\ \rho_{bm}\ G_{mt}\ \ \forall i,b,m,t \tag{11}$$

Table 8. Equation 8

$$Y_{ibt} - Y_{ib(t-1)} = G_{mt}\left[(I_{imt} + I'_{imt} + I''_{imt}) - \rho_{bm}\ (\sum_{w} J_{ibwt}\ G'_{wt} + \sum_{e} J''_{ibet})\right]\ \forall i,b,m,t$$

Table 9. Equation 10

$$Z_{iwt} - Z_{iw(t-1)} = \sum_{b} J_{ibwt}\, \rho_{bm}\, G_{mt}\, G'_{wt}\, F_{ibwt} - \sum_{e} J'_{iwet}\, G'_{wt}\, F'_{iwet} \quad \forall i,w,t$$

Distribution capacity constraint at warehouses:

$$\sum_{e} J'_{iwet} \le G'_{wt} E'_{iwt} \;\; \forall i,w,t \tag{12}$$

Demand satisfaction and backlogging constraints at end-users:

- Demand satisfaction constraint: The total amount of production and outsourcing for every product at all plants must meet the forecasted demand for that product at the end of planning horizon.

$$\sum_{m}\sum_{t}\left(I_{imt} + I'_{imt} + I''_{imt}\right) = \sum_{e}\sum_{t} D_{iet} \;\; \forall i \tag{13}$$

- Maximum allowed shortage at end-users:

$$S_{iet} \le S^{Max}{}_{iet} \;\; \forall i,e,t \tag{14}$$

- Inventory balance at end-users (see Table 10)

Constraints on the start/end inventory levels:

- Constraint on the WIP inventory level (Equation 16) and the inventory level of finished products at stack buffers (Equation 17) and warehouses (Equation 18) at the start and end of the planning horizon (t=0 and t=T):

$$\sum_{t=0} X_{imt} = \mu_{im} \;\; \& \sum_{t=T} X_{imt} = \mu'_{im} \;\; \forall i,m \tag{16}$$

$$\sum_{t=0} Y_{ibt} = \eta_{ib} \;\; \& \sum_{t=T} Y_{ibt} = \eta'_{ib} \;\; \forall i,b \tag{17}$$

$$\sum_{t=0} Z_{iwt} = \varphi_{iw} \;\; \& \sum_{t=T} Z_{iwt} = \varphi'_{iw} \;\; \forall i,w \tag{18}$$

Non-negativity restriction for all decision variables:

$$I_{imt}, I'_{imt}, I''_{imt}, X_{imt} \ge 0 \;\; \forall i,m,t \tag{19}$$

$$J_{ibwt} \ge 0 \; \forall i,b,w,t \tag{20}$$

$$J'_{iwet} \ge 0 \;\; \forall i,w,e,t \tag{21}$$

$$J''_{ibet} \ge 0 \;\; \forall i,b,e,t \tag{22}$$

$$Y_{ibt} \ge 0 \; \forall i,b,t \tag{23}$$

$$Z_{iwt} \ge 0 \; \forall i,w,t \tag{24}$$

$$S_{iet} \ge 0 \; \forall i,e,t \tag{25}$$

Table 10. Equation 15

$$\sum_{w} J'_{iwet}\, G'_{wt} + \sum_{b} J''_{ibet}\, \rho_{bm}\, G_{mt} = D_{iet} - S_{iet}.\, d_{iet} + S_{ie(t-1)}\, .\, d_{ie(t-1)} \;\; \forall i,e,t$$

7. TOOLS AND TECHNIQUES FOR THE OPTIMISATION OF COMPLEX SUPPLY CHAIN MODELS

All optimisation processes concern with the minimisation or maximisation of a function in which the values of the decision variables are selected systematically from a set of alternatives. The origin of many optimisation techniques which we use today dates back to the second World War (e.g. Simplex method) when the massive logistical issues raised by huge armies having millions of men and machines (Chinneck, 2004a; Dantzig, 2002). Today, optimisation methods are used almost everywhere from business, industry, and government to engineering and computer sciences because demand for optimisation modelling arise as regularly as they did during World War II (Chinneck, 2004a). In general, enterprises are continuously searching for new optimisation tools and techniques in order to obtain better results in terms of cost reduction, capital turnover, and quality improvement (Castro-Lacouture, Medaglia, & Skibniewski, 2007).

Over the last few decades, a large number of sophisticated optimisation problems have raised in the area of supply chain management to improve the decisions of SC planners. These types of optimisation promise the improvements in company's SC performance through reduced SC system costs, lower inventories, shorter lead-times, increased manufacturing throughput, as well as better return on assets. Among these, optimisation of complex SC models is one of the most popular problems (Paksoy, Kürsat Gules, & Bayraktar, 2007). The survey on the current literature indicates that several techniques and methodologies have been proposed in the past for the optimisation of integrated SC plan. Each of these techniques has strengths and weaknesses and can be helpful in solving limited types of problems. We classify these techniques into four categories: mathematical techniques, heuristics techniques, simulation, and genetic algorithms.

The essence of all mathematical techniques (e.g. linear programming, non-linear programming, mixed integer programming, and Lagrangian Relaxation) is to use the mathematical language for describing the essential aspects/functions of an actual system (Chinneck, 2004a, 2004b; Jordan & Smith, 2002). A range of mathematical techniques have been adopted in the literature to solve SC planning problems including *Linear Programming models* (M. Chen & Wang, 1997; Kanyalkar & Adil, 2005, 2007, 2008; Liang, 2008), *Mixed Integer Programming models* (Bhutta, et al., 2003; Bilgen, 2009; C.-L. Chen & Lee, 2004; Das & Sengupta, 2009; Demirli & Yimer, 2006; Dhaenens-Flipo & Finke, 2001; Ferrio & Wassick, 2008; Gunnarsson, et al., 2007; Hamedi, et al., 2009; Haq, et al., 1991; Y. Kim, et al., 2008; Mohamed, 1999; Paksoy, et al., 2007; Rizk, et al., 2006; Selim, et al., 2008; Tsiakis & Papageorgiou, 2008; H. Yan, Yu, & Edwin Cheng, 2003), and *Lagrangian Relaxation models* (Barbarosoglu & Ozgur, 1999; Jayaraman & Pirkul, 2001; Nishi, et al., 2007; Syam, 2002).

Mathematical programming models have been demonstrated to be useful analytical tools in optimising decision-making problems such as those encountered in SC planning (Geoffrion, 1976; Xu, He, & Gen, 2009). Proposed in 1947, Linear programming (LP) is only applicable when all of the underlying models of the real world processes are linear (Chinneck, 2004a; Dantzig, 2002). LP has been widely used in the past for solving constrained optimisation problems. In mathematical modelling, some of the variables may be real/fractional values and some others may only take integer values (0, 1). Mixed Integer Programming (MIP) is used when a combination of these two is required to be included in a model. MIP may be used in two forms: Mixed Integer Linear Programming (MILP) and Mixed Integer Nonlinear Programming (MINLP)—which is much harder to solve (Chinneck, 2004b). In Lagrangian Relaxation methodology, those constraints that make the problem hard to solve are removed from the model and are put into the objective function. A weight is then assigned to each constraint representing a penalty value when a constraint is not fully satisfied. In this way, the objective function value represents the solution feasibility in the sense that not only it includes the cost factors, but it is also a function of the constrain satisfaction. All the mathematical techniques are fully matured and are guaranteed producing the optimal solution for a certain problem types (Lair, 2008).

However, the following issues may restrict the application of mathematical modelling in solving complex real-world SC planning problems:

1. Developing a mathematical algorithm is not always easy. The complexity of formulating a mathematical model increases exponentially with the increase in the number of decision variables and model constraints (Lair, 2008; Méndez, Cerdá, Grossmann, Harjunkoski, & Fahl, 2006). Most of the SC planning problems are from a complex nature with a high number of variables and constraints involved and hence mathematical optimisation methods like LP and MIP may not be very effective in solving real-world SC planning problems (Jordan & Smith, 2002; Lair, 2008). In many cases, a complex SC planning problem may not even have a discrete feasible solution space to be searched by a mathematical technique (Chinneck, 2004b). Hence, mathematical techniques may be only suitable for solving small to medium size SC planning problems with limited number of variables and constraints.
2. Due to the exponential growth of the model complexity, immense mathematical models are NP-Hard problems which are very hard to solve (Lair, 2008; Park, et al., 2007). According to George Dantzig (2002), the father of linear programming, high computer memory and long CPU time is required in order to process complex mathematical algorithms. This can make it almost impossible to deal with a real-life large-scale SC planning problem using mathematical techniques unless the complex problems are simplified to a large extent in order to avoid the above-mentioned issues. This could have been one of main reasons for the oversimplification in the SC models developed in the past.

These restrictions of mathematical techniques have brought up the use of experience-based techniques known as heuristics for finding feasible solutions in large-scale SC planning problems. The primary advantage of heuristics methods is that they are able to rapidly find a solution that is hoped to be close to the optimal. One of the most popular heuristics which have been widely used in the literature is Simulated Annealing (Chinneck, 2004c). There have been some attempts for the use of heuristics methods in solving SC problems using other heuristics techniques (Cohen & Lee, 1988; Coronado, 2008; Ozdamar & Yazgac, 1999; Pyke & Cohen, 1993, 1994; Yeh, 2005; Yilmaz & Çatay, 2006).

There are, however, two reasons why heuristics techniques are not always the preferred technique for the optimisation of complex SC plans. Firstly, heuristics techniques cannot guarantee the optimality of the solutions found. Chinneck cites in his "Practical Optimization" book that as oppose to mathematical techniques, heuristics do not promise the optimal solutions but usually (not always) are able to give a good acceptable solution in solving complex problems (Chinneck, 2004c). Secondly, heuristics techniques are not effective tools in locating the global optimal solution when dealing with a complex problem with a vast search space, which is always the case in solving SC planning problems (Lair, 2008; Xing, 2006). Simulated Annealing, for instance, has limited capability in exploring large search spaces due to examining only one point of the search space at a time (Xing, 2006).

Simulation modelling in the area of supply chain management has been also used to monitor the performance of a real system so that the associated problems are diagnosed, SC activities are evaluated and possible solutions to the problems are suggested (Tarokh & Golkar, 2006). Based on these capabilities, simulation techniques can be ideal for reproducing the behaviours of complex systems (Tarokh & Golkar, 2006). Many previous studies have shown the capability of simulation modelling in SC modelling and optimisation (Jain, Ervin, Lathrop, Workman, & Collins, 2001; Jain, Workman, Collins, & Ervin, 2001; Lee, Cho, Kim, & Kim, 2002; Lee & Kim, 2000, 2002; Lim, et al., 2006; Moyaux, Chaib-draa, & D'Amours, 2004; Ritchie-Dunham, Morrice, Scott, & Anderson, 2000; Safaei, et al., 2009; Sarker et al., 2005; Williams & Gunal, 2003; T. Yan, Luh, Weidong, & Narimatsu, 2003). Due to the stochastic nature of today's SCs, simulation can be a highly effective tool in visualising the variations in uncertain SC factors and making effective and efficient business decisions (Williams & Gunal, 2003).

While simulation modelling is capable of describing various real and detailed situations, the two downsides of simulation modelling can demonstrate the limited application of this methodology for the optimisation of complex SC planning models (Lair, 2008; Park, et al., 2007). Firstly, simulation modelling is not able to guarantee the optimality of the developed solution. In many cases, even generating the near optimal solution cannot be promised using this method. Secondly, simulation software packages are in one hand expensive to purchase and on the other hand very time-consuming to analyse the auto-generated outputs.

Introduced by John Holland (1975), Genetic Algorithm (GA) techniques are based on the evolutionary ideas of natural selection and genetics. GAs are basically designed to simulate processes in a natural system necessary for evolution, particularly those following the principles laid down by Charles Darwin about the survival of the fittest (Ganesh & Punniyamoorthy, 2005). GAs are general-purpose search methods which are able to achieve a good balance between exploration and exploitation of the search space (Fahimnia, 2006). GA has been proven to be a highly effective and efficient tool in solving complex optimisation problems and some of their successful applications have already been reported in the context of SC planning (Aliev, et al., 2007; Altiparmak, Gen, & Lin, 2005; Altiparmak, Gen, Lin, & Karaoglan, 2007; Altiparmak, Gen, Lin, & Paksoy, 2006; Felix T. S. Chan, et al., 2005; Elahipanah & Farahani, 2008; Gen & Syarif, 2005; Kazemi, Fazel Zarandi, & Moattar Husseini, 2009; Liang, 2008; Park, et al., 2007; Syarif, Yun, & Gen, 2002; Tasan, 2006; Yeh, 2006; Yimer & Demirli, 2009).

The main advantages of using GA techniques for solving large optimisation problems are their robustness, searching flexibility and their evolutionary nature (Xing, 2006). GAs are capable of searching large and complicated search spaces in which the optimal solution is achieved by the convergence of the fitness function as the number of evolutions raises (Fahimnia, 2006; Holland, 1975; Lair, 2008; Marian, 2003; Sobhi-Najafabadi, 2002). The GA nature-based guided searching mechanism is well-structured and coordinated that enables this technique to produce the optimal solution for complex problems faster than any other optimisation tool; while for problems that are not overly difficult, other methods may find the solution even faster than GAs (Fahimnia, 2006; Haupt & Haupt, 2004; Lair, 2008; Marian, 2003; Sobhi-Najafabadi, 2002). However, the optimisation procedure (i.e. the evaluation of fitness function) in GA is performed on a large population of solutions (generally between 100 to 500 individuals) and this may require parallel processors when dealing with larger-scale SC planning problems (Haupt & Haupt, 2004).

Chapter 79
E-Government Clusters:
From Framework to Implementation

Kristian J. Sund
Middlesex University Business School, UK

Ajay Kumar Reddy Adala
Centre for e-Governance, India

ABSTRACT

The concept of industrial clusters has received much attention in the literature over the past few decades and many examples of clusters exist today in a variety of industries, from manufacturing to services. Within such clusters, competitive cost and innovation advantages are generated through co-location. Very recently several examples of e-government clusters have emerged. This chapter offers a conceptualization of what an e-government cluster is, and how it may be different from other industrial clusters. This chapter is an attempt to formulate a framework for e-government clusters and bring out the necessary conditions for policy decisions to support the creation of such a cluster. An attempt has also been made to validate the proposed framework on the basis of case studies and to derive some recommendations to sustain the operation of e-government clusters.

INTRODUCTION

Information and Communication Technologies (ICTs) are increasingly being used in government as indispensable tools, in an effort to transform them into efficient, effective, transparent and reliable organizations at national, regional and local levels. Electronic government (e-Government) has been defined as the application of ICTs in transforming the internal and external relationships of governments [UN World Public Sector Report 2003]. While many governments across the world have implemented e-government projects, many have failed to live up to expectations due to the design-reality gaps, which were often not considered during the planning stages (Heeks, 2001).

Since e-government is as much about government as about electronic ('e') (Riley, 2002),

DOI: 10.4018/978-1-4666-1945-6.ch079

its implementation is likely to involve active and shared participation of several players from private, public and social sectors. Often, governments face a shortage of the right expertise, right technologies and right solutions to successfully implement e-Government projects. This situation is similar to that faced by most industries during their initial stages, especially when they set-up in new locations or regions. Subsequently, the availability of right skills and technologies improves with several firms joining the region resulting in the formation of clusters.

The concept of industrial clusters has received much attention in the literature over the past few decades and many examples of clusters exist today in a variety of industries, from manufacturing to services (Porter, 1990). Recently, several projects have seen the light of day under the heading of "e-Government clusters". Examples of these include the e-Government cluster in Hungary, Ubiquitous IT (u-IT) cluster in Korea and the GAUDI e-Government cluster of the European Union. The e-Government Cluster in Hungary has been the initiative of the private sector with active support from the Government of Hungary at local, regional and national levels. The u-IT cluster of Korea is driven by the government and primarily focuses on the development of ubiquitous technologies for the implementation of e-Government at the local level. The GAUDI e-Government cluster is the result of the PRELUDE project initiated by the European Commission under the 5th Framework Program with an aim to establish 9 European Clusters for Innovations (ECI). The GAUDI e-Government cluster is a consolidation of the Lombardy cluster of Italy, Kouvala cluster of Finland and Catalonia cluster of Spain. Unfortunately, although the concept of industrial clusters has been widely examined in the literature, no framework has yet been developed within the context of e-Government, something from which e-government clusters such as those mentioned previously might benefit. This chapter proposes to develop such a framework answering the basic question '*What are the necessary pre-conditions for Government to support the creation of e-Government cluster?*' As a logical sequence to this question, an attempt has been made to address the question '*What can be the likely success factors which sustain the operation of e-Government cluster?*'.

Historically, different regional economies around the world had within them specialized industries operating in the form of so-called clusters. These clusters were composed of main firms, which produce industry output, and supporting firms which actively contribute to the efficient operation of the main firms. Through a mix of competition and cooperation, such firms tend to create sustainable competitive advantages within their industry and the cluster, as compared to other isolated players of the industry (Porter, 1990). Famous examples of such regional clusters include Silicon Valley of the United States, the pharmaceutical cluster centered on Basel in Switzerland, and fashion-leather cluster of Northern Italy. Such agglomeration of firms brings about improvement and innovation owing to the mutual reinforcement of cluster-based factors, subsequently leading to sustained competitive advantage. In other words, firms within such a cluster benefit from agglomeration economies with reinforced effects. The cluster becomes a vehicle for maintaining diversity and overcoming the inward focus, inertia and inflexibility that slows or blocks competitive upgrading and new entry (Porter, 1990).

It is with these advantages in mind that attempt have been made around the world to create e-Government clusters. However, it remains unclear whether the concept of cluster can be applied in the context of e-Government. Neither can one readily find a specific framework for e-Government clusters in the literature. Simply transposing the original notion of clusters, as defined by economic geographers, to the field of e-Government may not be the best way to plan or enhance such a cluster.

The most common formulation of industry clusters is probably that of Prof. Michael Porter of Harvard Business School, made famous by his 1990 book, “The Competitive Advantage of Nations”. In this chapter we adopt a similar approach, and analyze the Porter “diamond” model of clusters from the perspective of its application to the e-Government “sector”. The e-Government clusters in Hungary, Korea and EU have been critically examined through interviews, e-mail enquiries and secondary research.

The outcome of this chapter is a detailed framework on e-Government Cluster, adapted from the “diamond” model of Michael Porter, and a description of various factors to be considered when implementing e-Government clusters. Also, the importance of each factor and their role in e-Government competitiveness has been assessed. This chapter also provides insights on critical aspects of clusters which governments should carefully examine prior to its decision on supporting the creation of e-Government cluster. The validity and necessity of physical proximity of firms while forming such e-Government clusters has also been considered, given the possibilities for remote working offered by modern ICTs. The results generated not only would guide e-Government cluster investments, but also more generally the outsourcing of e-Government projects.

CLUSTERS AND e-GOVERNMENT

Clusters

Defining Clusters

Clustering, in broad generic terms, involves the grouping together of tasks or entities with similar goals and attributes. The subject of clusters is a traditional concept which is increasingly being used currently in diverse fields and areas to achieve goals in a collaborative and cooperative yet competitive environment. For example, a marketing cluster involves the segmentation of customer market based on the nature of the product, age of the customer, income level of the customer etc. Similarly, a research cluster involves the grouping of teams working on a particular subject, technology, device etc. Clusters, in general, may be categorized as marketing clusters, academic / research clusters, partnership / alliance clusters, industrial clusters, project clusters, knowledge clusters etc. With the rapid growth of information and communication technologies, online partnership clusters have seen the day in the form of online communities and online forums.

Today, the concept of industrial clusters is well known in management communities owing to the popular “diamond” cluster theory, published by Professor Michael Porter, explaining the reasons for growth or decline of competitiveness of a nation or region. The concept of industrial clusters has become so widely known in the management, research and industrial sector that the word “cluster” is quite often directly associated with the concept of industrial cluster. Prominent examples of industrial clusters include ICT cluster in Silicon Valley (USA), fashion leather cluster in Italy, wine cluster in California (USA), the forestry cluster in Finland and consumer electronics cluster in Japan.

The Formation of Clusters

It is very interesting to study the formation of clusters in various parts of the world. The forest cluster of Finland was more of a natural phenomenon owing to the ready availability of abundant and economically accessible natural resources (Rouvinen & Ylä-Anttila, 1999). The fashion leather cluster of Italy has been the result of the continued and sustained family business inheritance, whilst the consumer electronic cluster of Japan has been due more to the specific needs and wants of its citizens. Studies have shown that a strong home demand with favorable factor conditions positively influence the development of demand-related and input-oriented industries in a region (Porter, 1990). Furthermore, competitive advantage in the form of location becomes an important factor in determining the survival or exit of individual firms over the course of the industry life cycle (Sund, 2006).

The sustained operation of firms within clusters are said to induce the development of other firms operating in related and supporting industries, supporting the main firms producing the industry outputs. The intense rivalry among organizations in a cluster often leads to stiff competition forcing companies to enhance their product features and quality, through process improvement, technology upgrades or innovative solution deployment. The firms within the cluster tend to sub-contract their procurement and other activities to the related and supporting firms set-up within the cluster as they would be able to provide more efficient and reliable services. This would further attract firms aiming for market share in the demand for suppliers generated by the cluster.

The nature of firm strategy and structure is likely to have an influence on the competitiveness of firms within the cluster, leading to improved factor conditions and demand conditions. The companies not attempting to innovate, improve and upgrade, would gradually lose ground and disappear from the cluster.

The phenomenon of the formation of clusters is well explained by Michael Porter in his "Diamond" theory, which has the following four determinants.

- Factor conditions
- Demand conditions
- Firm strategy, structure and rivalry
- Related & Supporting Industries

The reinforcement among the determinants results in the cluster being competitive, thereby, enhancing the productivity and economic potential of the region. The Porter "diamond" is illustrated in Figure 1.

Factor Conditions

The factor conditions are those essential inputs accounting for the successful operation of an industry. They drive the economy of the industry and the growth of the region. They include natural resources, demographic conditions, location geography, production facilities, investment and capital potential, the presence of highly skilled and quality human resources, research infrastructure, universities present in the region, and so forth.

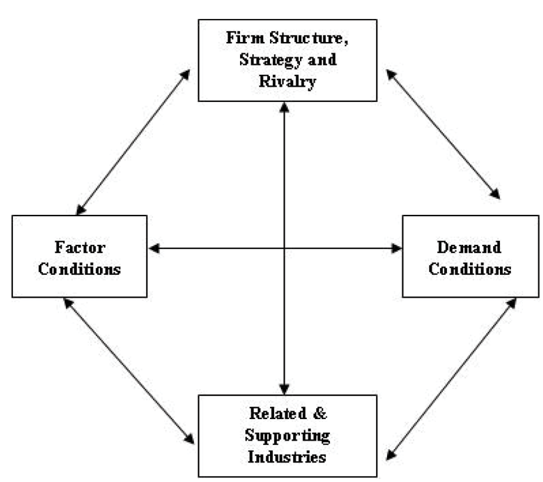
Demand Conditions

A strong home demand is usually considered a good driver to create competitiveness within the cluster and the region. The demand may be local, regional, national or even international. A strong home demand is not necessarily a question of quantity, but largely a question of the quality demanded. More demanding customers lead to better products that ultimately will be more competitive in the global market place. Thus, a sophisticated local demand is usually considered as a take-off point to stimulate the formation of clusters (Rychen & Zimmerman, 2008).

Related and Supporting Industries

Firms show an increased tendency to purchase from local suppliers if no compromise is seen in

Figure 1. Porter 'Diamond' Cluster Framework



quality and reliability of products and services when compared to purchases from established far-off suppliers. This would induce suppliers, which are specialized in a certain field, in setting-up their base within the cluster region. Subsequently, with time, these related and supporting firms tend to become a part of the overall value chain, enhancing the drive to innovate, improve and upgrade, strengthening their competitive position.

Firm Structure, Strategy and Rivalry

The attractiveness of an industry may not be reliably indicated by size, rapid growth or newness of technology, but rather by industry structure. The mechanism by which companies are created, organized and managed together with the approaches adopted by them to handle firm rivalry are known to have far-reaching and influential effect on the competitiveness of the cluster and, thereby, the economic potential of the region. It has been seen that healthy firm rivalry results in a local race to introduce new technologies, enhance productivity and lower costs.

Role of 'Chance' and 'Government'

The four determinants of the cluster as illustrated above are considered by Porter as internal sources of competitiveness. He further identified the external sources of cluster competitiveness as chance and the role of government. The external sources have a potential capability to change the dynamics of cluster and, thus, reorient it in different directions.

Chance

Chance events may be considered as occurrences with less accountability to the circumstances in a nation and are often largely outside the power of firms (and often national government) to influence. Possible examples of chance are acts of nature, major technological breakthrough, drastic changes in input costs such as an oil crisis, sudden shifts in financial markets, fluctuation in national or global demand, offset of war and so forth. Innovative and sustainable leadership often becomes a key word to drive competitiveness of the cluster in cases of such chance events.

Government

Government is quite often seen as a catalyst in the case of clusters. In some instances, governments become major buyers of the products produced in a particular cluster, for example in the case of defense goods, telecommunication equipment or aircraft. More generally though, the government is seen as a facilitator to effectively support various firms in their operations with a view to enhance competitiveness of the cluster and the region. Government policies on product standards, regulations, tax, anti-trust laws, education, and so forth, are seen to greatly influence the main forces of firm structure, strategy and rivalry, demand conditions, factor conditions and the health of related and supporting industries.

Cluster Benefits

The benefits associated with clusters affect competition in three broad ways – increasing productivity, driving the pace of innovation and stimulating the creation of new businesses. A cluster allows each member to benefit as if it had greater scale or as if it had joined with others formally – without requiring it to sacrifice its flexibility. In other words, it can be said a cluster is more than just the sum of its parts. The benefits of such a cluster are listed as follows.

e-Government

Defining e-Government

The concept of electronic Government (e-Government) has been defined in several ways by various authors and organizations. Some of them are as follows.

Information for Development Program (InfoDev 2002)

e-Government is the use of information and communication technologies to transform government by making it more accessible, effective and accountable

Organisation for Economic Cooperation and Development (www.oecd.org)

e-Government is defined as a capacity to transform public administration through the use of ICTs

World Bank (www.web.worldbank.org)

e-Government refers to the use by government agencies of information technologies (such as Wide Area Networks, Internet, Mobile Computing) that have the ability to transform relationships with citizens, businesses and other arms of government

European Union Commission (www.eu.europa.eu/egovernment)

e-Government is the use of ICTs in public administration combined with organizational change and new skills in order to improve public services and democratic services and strengthen support for public policies

United Nations (www.unpan.org, 'World Public Sector Report 2003')

e-Government is a government that applies ICTs to transform its internal and external relationships

Gartner Research (Gartner Group, www.gartner.com)

e-Government is the continuous optimization of government service delivery, constituency participation and governance by transforming internal and external relationships through technology, the internet and new media

Looking at the various definitions, the definition of e-Government seems to revolve around three important issues which are as follows.

1. Implementation of ICTs
2. Organizational change
3. Transformation in internal and external relationships

E-Government is thus typically seen as having a potential to optimize government processes, making them more effective and efficient. If e-Government is seen only to implement ICTs, it would be seen as an old car fitted with a new engine resulting in an inefficient and uneconomical drive. More than just the implementation of ICTs, e-Government involves the reform of government policies, relationships with various State and non-State actors, the re-engineering of operational processes, and innovation in service delivery mechanisms. Thus, the innovation involved has the power to change the relationship between levels of government and within government departments (Alberti & Bertucci 2006). ICTs need to be considered as tools to facilitate online transactions and achieve the broader goals of the government (Titah and Barki 2005). It is of course worth underlining the role of ICTs as a tool for development and not as a goal in itself (Misuraca, 2006).

e-Government Frameworks

E-Government frameworks have been designed in different ways by various organizations and institutions. Since countries vary in their political mandates, traditions, cultures, legacy systems, government working norms etc., it is a well accepted fact that one single e-Government framework may not be deemed fit universally.

This section contains some condensed examples of e-Government frameworks.

GePeGi (Korea) e-Government Framework

The e-Government framework designed by the Global e-Policy e-Government Institute (GePeGi), SungKyunKwan University, Seoul, Korea comprises of three factors: demand factors, supply factors and policy factors (Korea e-Government 2007). The supply factors are related to the development of ICTs and include network infrastructure, hardware infrastructure and application infrastructure. The demand factors are related to the maturity of civil society and include information management, e-capacity and economic support. The policy factors are related to the maturity of government and include IT policy, Institutional and Legal support policy and IT manpower policy.

NISG (India) e-Government Framework

The National Institute for Smart Government (NISG), India, is of the view that the full potential of e-Government can be realized only through a focused attention on people, process, technology and resources appropriately (Satyanaryana, J 2004), which are viewed as the four pillars of e-Government framework. The people pillar is related to the human element involved in e-Government and includes training, capacity building, change management, institution building, organization structure, governance structure, consultancy, monitoring, evaluation, awareness and communication. The process pillar is related to government workflows which need to be re-examined and includes process design and development, administrative reforms, process re-engineering, program / project management, procurement, and service levels. The technology pillar is related to the deployment of technologies in government and includes enterprise architecture, information infrastructure, standards and interoperability, security and privacy policies, identity management, biometrics, private key infrastructure and digital signatures. The resources pillar relates to the knowledge base on e-Government and includes public private partnership frameworks, service level agreement frameworks, business case analysis, mission teams, knowledge management, and user charges on services.

Singapore e-Government Framework

The e-Government framework designed for Singapore is based on different government interfaces with citizens (G2C), employees (G2G) and businesses (G2B). While the G2C and G2B services involve electronic service delivery as the main component, the G2G services are seen to involve knowledge management and education in information and communications (Altameem, T., Zairi, M. and Alshawi, S. 2006). The framework also suggests a strong focus on ICT infrastructure and operational efficiency in order to ensure a seamless interface and interoperability in the government interactions and transactions with employees, citizens and businesses.

Common to these three e-Government frameworks, it appears that the successful implementation of e-Government is likely to involve active collaboration among various e-Government actors, including political organizations, the public sector, business organizations, trade associations, training and research organizations, citizens and civil societies, deploying right resources at the right time and promoting productivity and innovation in government.

e-Government Success Factors

Many e-Government projects tend to fail owing to popular misconception of ICTs being ends rather than means (West 2007). It is important to realize the role of ICTs prior to any conceptualization of e-Government. ICTs are just a tool to provide an enabling environment to enhance efficiency and promote innovation (Misuraca, 2007). Several authors and organizations have suggested factors which account for the successful implementation of e-Government, some of which are as follows:

- Richard Heeks (2001): The success of e-Governance depends on building e-readiness and the closure of gaps (design-reality gaps, private-public gaps, country-context gaps).
- InfoDev (2002): Success factors for e-Government include process reform, leadership, strategic investment, collaboration and civic engagement.
- Jorg Becker (2004): The potential e-Government success factors can be viewed as organizational responsibility for Government, e-Government awareness, budgetary funding and organizational change.
- Altameem (2006): The critical success factors for e-Government can be categorized into governing factors, technical factors and organizational factors.
- Mila Gasco (2008): The key factors for the adoption of ICTs in government are political and personal leadership, strategic alignment between political strategies and IT initiatives, deployment of the encompassing institutionalization strategies, Information Technology to be a part of a more comprehensive strategy, and the management and architecture of corporate information resources.

DEFINING THE e-GOVERNMENT CLUSTER

An e-Government cluster may be defined as a '*group of inter-related and competing firms and organizations that offer products and services in the broad area of e-Government, and derive synergistic advantages from their co-location in a given region*'.

Typically, firms involved in e-Government services deliver hardware or software solutions to governments and government organizations with a view to enhance their efficiency, effectiveness, transparency, accountability and reliability (Mahapatra and Perumal 2006). Services range from the identification of system requirements, which is a pre-designing phase involving interactions and discussions with government and other stakeholders in order to identify the precise needs and requirements, all the way to servicing and advising government on the use of existing systems.

As e-Government is fast attaining the status of an industry sector in its own right, e-Government clusters can be thought of along similar lines as any other industry cluster, i.e. as a group of main firms operating in e-Government related software services and a group of supporting firms which operate in hardware, network, consultancy, training and research. As a necessary condition for an e-Government cluster to exist, strong demand from customers, in the form of government offices or agencies, need to be in close vicinity of the cluster.

The implementation of e-Government has been gaining momentum across the globe. Owing perhaps to a shortage of e-Government expertise, as compared to other IT expertise, it is often a difficult exercise for governments to identify the right partner who can conceptualize, initiate and implement e-Government projects for them. The choice of partner is often strategic in nature, and governments are sometimes seen to favor local partners. The common practice of issuing tenders or Requests-for-Proposals (RFPs), either nationally or globally, in order to select the right partner, is at times both costly and cumbersome, involving complicated pre-qualification criteria, technical criteria and commercial quote criteria. The selection of a wrong partner in the process is seen as a potential risk, in which case governments most often have to restart the whole process once again (Jaeger, Paul, Thomson and Kim 2003). It is perhaps with this in mind that efforts have been made in certain regions to build regional competence in e-Government solutions, through the creation of clusters.

A PROPOSED FRAMEWORK

Having defined the e-Government cluster and realizing the need for productivity and innovation in government, we hereby attempt to propose a framework which can serve as a basis for understanding such clusters. The proposed framework is based on Porter "diamond" framework, which was substantiated by several clusters across various countries in the world.

Since the Porter "diamond" framework is based on manufacturing industries like hardware, wine, chemical, fashion leather, consumer electronic etc., producing ready-to-use products, an attempt has been made to extend the "diamond" framework to illustrate the dynamics of e-Government cluster. Given the specificity of e-Government as a sector, the Porter "diamond" has been extended by including more constituents with a view to present a comprehensive framework for a specialized sector like e-Government.

As it is believed that favorable factor conditions and demand conditions are the likely initial drivers to attract organizations to establish themselves in a region, two additional "diamonds", the factor diamond and demand diamond, have been proposed, which would facilitate in creating favorable factor conditions and demand conditions. The factor diamond and demand diamond are based on networking dynamics among various e-Government actors. The proposed e-Government cluster framework is therefore a combination of three diamonds, the main diamond, the demand diamond and the factor diamond. The main diamond is the original "diamond" as suggested by Porter and serves as a parent framework for the other two diamonds.

The demand diamond is a framework involving various actors, whose active collaboration and cooperation is likely to generate favorable e-Government demand conditions. Unlike other industrial clusters where demand is mostly driven by the end user, the demand for e-Government is initially driven by the Government and its various agencies and organizations.

The factor diamond is a framework involving various actors, whose relationship with each other is likely to create favorable e-Government factor conditions, Unlike other industrial clusters where factor conditions are more focused on the availability of raw materials, transport infrastructure and so forth, the factor conditions for an e-Government cluster specifically include the availability of skilled manpower, network and broadband services, software solutions, hardware services and other related consultancy services.

The proposed framework is illustrated in Figure 2.

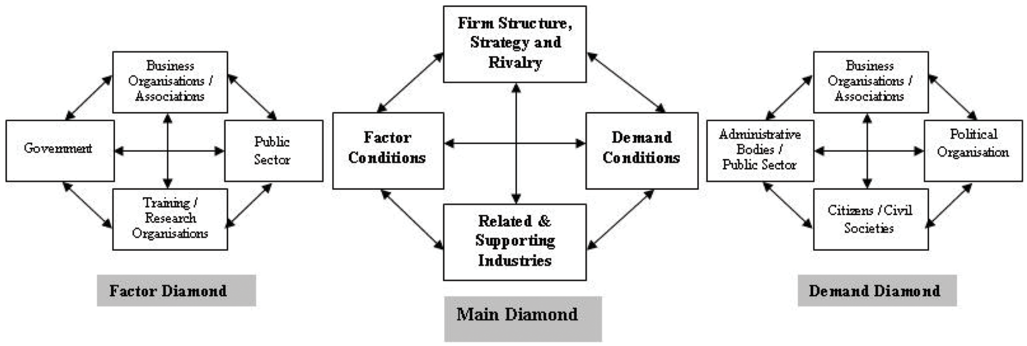
Main Diamond

Demand Conditions

The demand for e-Government services is seen as a necessary condition to enable the creation of an e-Government cluster in a region. Some of the factors which facilitate in generating favorable demand conditions are as follows.

1. Commitment to the implementation of e-Government in all government departments, agencies and organizations.
2. Adherence to e-Government strategies to achieve e-Government vision and objectives.
3. Intention to deploy high quality and innovative e-Government solutions with strong focus on reliability and sustainability.
4. Focus to improve democracy through provision of technology to citizens.
5. Implementation of citizen participatory mechanisms through online feedback system, discussion forums, citizen surveys, messaging applications etc.

Figure 2. Proposed e-Government Framework (based on Porter (1990))



6. Strong political will and leadership to transform labor-intensive methodology to technology-intensive methodology.
7. Partnerships / relationships with other State and non-State actors in order to utilize their knowledge, skills and expertise.
8. Right attitude and mindset among staff and officials at all levels of the government.

Factor Conditions

The factor conditions in a location / region may be categorized into basic factors and advanced factors. The basic factor conditions include availability of raw materials, power, land etc., and the advanced factor conditions include availability of expertise, skills, data storage centers etc. Both these factors need to be critically examined prior to setting-up of e-Government cluster. Some of the aspects which result in creating favorable factor conditions are as follows.

1. Easy accessibility of the region by various modes of transport.
2. Business-friendly environment at all levels of government.
3. Presence of strong telecommunication, broadband and network infrastructure ensuring reliable communication services.
4. Availability of skilled manpower (mainly engineers) in the region.
5. Willingness of skilled personnel to work in the region.
6. Presence of reasonably priced building infrastructure with basic facilities including power, security and broadband connectivity.
7. Possible presence of high capacity server infrastructure and data storage centers.

Related and Supporting Industries

The related and supporting industries like IT hardware, telecommunication and so forth, are likely to impact the sustenance of an e-Government cluster as these firms provide value-added services to the main firms of the cluster. A major driver attracting and retaining the supporting industries would be the strong home demand for e-Government services resulting from a strong commitment to implement e-Government strategies. Firms specialized in hardware, telecom, network infrastructure, training, academics, research, knowledge management and consultancy would add value to the overall value chain of the e-Government cluster.

Firm Structure, Strategy and Rivalry

The firm structure and strategy are often key areas to incorporate necessary changes needed to strengthen competitive position in e-Government market. Also, healthy firm rivalry is seen as an important mechanism to develop the attitude of continual improvement in delivering e-Government services. However, the presence of firm rivalry may not be seen in prominence during the initial stages of e-Government cluster formation. Subsequently, with the establishment of the e-Government cluster, firm rivalry would be seen as one of the prime factors enhancing the productivity and competitiveness among cluster members.

Demand Diamond

The Demand Diamond involves active relationships among four key actors of e-Government. These are the administrative bodies and public sector in general, political organizations, business bodies and trade associations and citizens and civil societies. These determinant actors and the nature of their relationship are likely to help generate sustained demand for e-Government services. Also, these relationships are likely to transform traditional-based governments into network-based governments utilizing the right skills and expertise, readily available within the network. The Demand Diamond in Figure 3 is therefore to be seen as a map of the key actors involved in forming demand for e-Government, and we would expect to see regions with strong collaboration between these actors as being more receptive to e-Government.

Factor Diamond

The advanced factor conditions needed for setting-up an e-Government cluster, apart from the basic factor conditions, may be categorized broadly as: ICT infrastructure, Capital infrastructure, Skilled personnel and Knowledge. The ICT infrastructure includes network infrastructure, hardware infrastructure, broadband connectivity, software facilities, data storage infrastructure, security infrastructure and other supporting components. The ICT infrastructure would be one of the influential factors attracting firms to the e-Government cluster owing to its capability in serving as a backbone supporting numerous IT-based solutions and services. The lack of basic ICT infrastructure is often seen as a hindrance in the realization of e-Government (Jaeger & Thomson, 2003).

The factor diamond of the proposed framework involves relationships among various actors involved in creating favorable factor conditions. The factor diamond is illustrated in Figure 4.

The Government through regular investment and through its e-Government projects can deploy elements like server infrastructure, network infrastructure, routing equipment and other related accessories, substantially improving the ICT infrastructure of the region (Chowdhury, Habib, Wahidul and Kushchu 2006). Likewise, the public sector contributes to the e-Government factor conditions through their strategies to implement IT solutions in their organizations. The presence

Figure 3. Demand Diamond

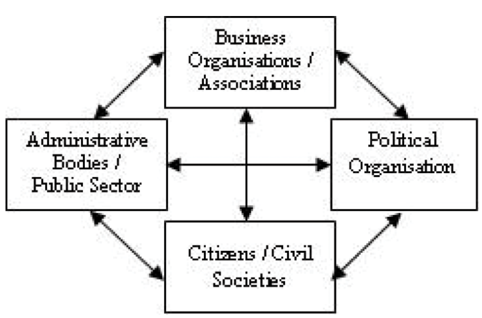


Figure 4. Factor Diamond

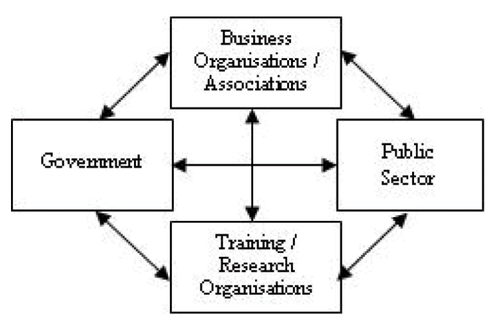

of business organizations and trade associations in the region may improve basic factor conditions and some of the advanced factor conditions, which include the generation of skilled personnel and creation of knowledge societies. Training and research organizations are of course instrumental in generating skilled personnel through education, work-related training programs and research projects.

CASE STUDIES

In order to examine the proposed e-Government Cluster framework, three case studies of e-Government clusters are examined: the Korean u-IT Cluster, the Hungarian e-Government Cluster and the GAUDI e-Government Cluster. The analysis is based mostly on the secondary research data collected from various sources, although some critical data was obtained through telephone interviews with concerned authorities and officials. A brief description of each cluster is as follows.

u-IT Cluster, Seoul, South Korea

The u-IT cluster plan has been framed for fostering industries of RFID and USN, which are the core technologies for construction of u-City and the next-generation growth drivers as clearly articulated in Korea's IT839 strategy. The u-IT cluster is planned to form an innovative cluster by attracting related leading companies and R&D centers. Furthermore, it will build a globally-competitive cluster that can continue to grow by facilitating technological innovations in the RFID and USN industries and by creating new businesses for different value chains and contribute to the formation of the IT hub in Northeast Asia. The main purpose of this master-planned cluster, which is being developed on 1,500 acres of reclaimed land along Incheon's waterfront, is to give opportunities to many leading RFID / USN companies around the world to complete RFID / USN products in the most efficient and cost-saving way.

The Ministry of Knowledge Economy and the Incheon Metropolitan City are in charge of the project and the cluster will be formed in the knowledge and information industry complex of Songdo area. They have made investments totaling $313.7 million to establish the "World's Best Infrastructure Facility for RFID / USN technologies" with the size of the building site amounting to 81,275 sq. mtrs. in the Incheon Free Economic Zone of Songdo from 2006 to 2010. The relevant public sectors shared the view that it was important to create a world-renowned RFID / USN industrial collective complex, encompassing research, production and services. The country believes that by establishing the u-IT cluster center, the government has sought to bridge the technological gap between Korea and other technologically advanced countries (Korea IT Times 2008).

Hungarian e-Government Cluster

The first Hungarian e-Government Cluster was founded in June 2007. It was a unique initiative and the only cluster Hungary has in e-Government, though plans are underway to create regional clusters in future. The e-Government Cluster aims to create an effective e-Government as well as to build a market by common enforcement of interests and harmonizing activities. The Cluster covers a wide spectrum with comprehensive specific competencies assuring the interaction of different views.

The cluster members include advisor companies, consultancies, universities, system integrator companies, knowledge centers, local government and alliances of towns. While members can function independently, their ability to develop synergistic relationships and cooperate in a network has enabled them to reap the benefits of working together. However, members' first priority has been to improve services significantly across the whole field of local government.

The managing agent of the Hungarian e-Government cluster is Albacomp Zrt., which is well known for its major network and system integration projects apart from operating Hungary's largest PC and notebook assembly plant. The company has been actively involved in several IT projects, some in part funded by the Hungarian government, and has played a significant role as an integrated IT solutions provider to local governments that are in the process of setting up their local e-Government services.

The cluster performed at least half a dozen projects and prepared proposals for more than a dozen projects. The cluster is looking forward to enter into partnerships with international firms and organizations to improve the competitiveness and productivity. The cluster will apply for an audit process to achieve "Accredited Polus Cluster" qualification. In the next 5-10 years, the cluster would be in a position to market itself on Pan-European level and possibly global level.

GAUDI e-Government Cluster: European Cluster for Innovation

The GAUDI e-Government cluster, which was a result of the PRELUDE project initiated by the European Commission under 5th Framework Programme with an aim to establish 9 European Clusters for Innovations (ECI), provided a critical bridge to the G2C aspects suggested by GUARANTEE and the G2B aspects of the digital economy being driven by EDEn (Zalisova 2006).

The GAUDI cluster was a consolidation of three regional clusters: Kouvola (Kymenlaakso) of Finland, Lombardy of Italy and Catalonia of Spain. The members of each regional cluster are shown in Table 1.

The activities of the cluster included the preparation of an e-Government Roadmap, e-Transaction projects, organizing the Internet Global Congress and facilitating the exchange of experiences, good practices, know-how and demonstration projects.

ANALYSIS

The main 'Diamond' as illustrated in the proposed e-Government Cluster Framework had been firmly established by Porter based on industrial clusters across various countries of the world. Since e-Government is fast attaining the status of industry sector, bearing most of the industry characteristics, the 'main diamond' of the proposed e-Government cluster framework has not been analyzed. The differentiating feature between e-Government clusters and industrial clusters is the role of demand diamond to generate demand conditions and the role of factor diamond to create favorable factor conditions. The demand diamond determinants like administrative bodies,

Table 1. Regional Clusters of GAUDI Cluster

Kouvala Cluster	Lombardy Cluster	Catalonia Cluster
• IT companies • National Land Survey • Population Register Centre • Helsinki University of Technology • Lappeenranta University of Technology	• 4 Lombardy Region General Directorate • 5 Public sector special agencies • CEFRIEL (Politecnico Milano) • 5 municipalities and provinces associations • 14 professional associations and enterprises associations • Lombardy Chambers of Commerce Union • 4 trade-unions	• Consorci Localret - 800 municipalities - Catalan association of municipalities counties - Federation of municipalities - 4 Catalan provinces • Generalitat de Catalunya • 4 provincial public administration bodies • 11 Catalan municipalities • 5 universities: UoC, UPC, UB, UPF, UdG • Cat 365

political organizations and civil societies may not be involved for industrial clusters but are likely to have an impact for e-Government clusters. Similarly, the factor diamond determinants like the government, public sector and training organizations may not be influential for industrial clusters but are likely to have substantial contribution for e-Government clusters.

The demand diamond and factor diamond have been analyzed in perspective of the three e-Government cluster cases elaborated in the previous chapter. The Demand Diamond Analysis and Factor Diamond Analysis is an attempt to examine the proposed e-Government cluster framework in the light of real-world examples, in particular its applicability for the creation and sustenance of e-Government clusters.

It needs to be mentioned here that the relevant data on the three clusters was collected through the following mechanisms:

- Websites, publications and journals
- Interactions with concerned officials during the modules of the Executive Master in e-Governance, EPFL
- e-Mail enquiries
- Telephonic interviews

Every attempt has been made to collect as much relevant information as possible so as to achieve near-real analysis.

Demand Diamond Analysis

The demand diamond analysis, which has been based on the level of involvement exhibited by each demand diamond determinant in the generation of demand for e-Government, for each of the clusters, is as follows.

u-IT Cluster, South Korea

The ubiquitous IT Cluster at Incheon is driven by strong demand generated by the Vision 2030 of Korea, which has e-Government as one of the core driving forces, along with the u-IT strategy, IT839 strategy and u-Korea strategy. The u-IT Cluster is a key initiative of the Ministry of Knowledge Economy and the Incheon Metropolitan Authority, with relevant public sectors sharing a common view. It can be derived that the political organizations, administrative bodies and public sector had a very high level of involvement in generating demand for ubiquitous services, which in-turn are directly linked to the generation of demand for e-Government services.

Korea had been implementing ICTs as early as 1980s with the active involvement of its ICT industries. The government was instrumental in establishing basic infrastructure through 11 key e-Government projects during 2002-03 and 31 e-Government Roadmap projects during 2003-07. It is likely that the successful implementation of e-Government projects, due to the active involvement of ICT industries, associations and other research organizations, would have stimulated government to visualize achieving a ubiquitous society. Business organizations had a high involvement while generating demand for future ubiquitous technologies like RFID and USN.

The role of citizens and civil societies in generating the demand for ubiquitous services seems unclear, indicating a possible low level of involvement, except for the mention in the Vision 2030 document to understand customer's needs and offer quality services in a timely manner.

e-Government Cluster, Hungary

The Government of Hungary published a document on 'Information Society' as early as 1999 and issued the first version of the National Information Society Strategy in 2001, which had the implementation of e-Government as one of the priority areas. The Hungarian Parliament launched the e-Parliament programme to support the modernization of Parliament. Also, the Hungarian Parliament adopted the Act of Freedom of

Information by electronic means in 2005, with a goal to establish the legal environment required to create a transparent Digital State. The Hungarian Government formulated the e-Administration Development Strategy 2007-13 which contains the e-Public Administration 2010 strategy. These series of events indicate a high level of involvement from the government (administrative bodies and public sector) in generating demand for e-Government services. Also, since the politicians from various political organizations approved the formulation of e-Parliament and other ICT projects, it shows that the political organizations had considerable involvement in initiating e-Government projects.

Hungary had been implementing e-Government projects since the year 2002 with the help of local and national firms. Due to insufficient domain knowledge within government, they often ended up purchasing expensive high capacity servers and computing equipments beyond their actual needs. The government seemed to greatly benefit from the e-Government cluster as it reduced unnecessary expenditure and enabled it to have a better view of the new system. The involvement of citizens and civil societies in generating demand for e-Government seems to be unclear, indicating a possible low level of involvement, as it was found unmentioned both in secondary research and telephonic interviews.

GAUDI e-Government Cluster

The GAUDI Cluster is a consolidation of three regional clusters (Lombardy Cluster of Italy, Kouvala Cluster of Finland and Catalonia Cluster of Spain) with IT companies, administrative bodies, universities, public sector, business associations, trade unions and other government agencies as members. Unlike the previous two clusters, the GAUDI cluster operates on partnerships among the regional clusters. The physical presence of an organization within a region was not treated as a necessary condition. The cluster had a focused objective to support, promote, contribute and lead e-Government in the European Arena, thus generating demand for e-Government. The administrative bodies and public sector are seen to have a high level of involvement in generating demand for e-Government services as they had prepared an e-Government Roadmap and submitted e-Government proposals to the European Union. The involvement of political organizations seems to be less as there was hardly any mention of such organizations, either in the literature or during telephone interviews.

The involvement of citizens and civil societies was not clearly defined while framing the objectives of the GAUDI cluster, indicating a possible low level of involvement. The only noticeable mention was in providing user-friendly personalized services and multi-channel access using advanced ICTs such as voice-enabled front-end public platforms. However, the need for citizen and civil society involvement was suggested for the 7th Framework Programme of the European Union.

The summary of the Demand Diamond Analysis is shown in Table 2, which gives the level of involvement by demand diamond determinants on each cluster.

From these case studies, it appears that citizen and civil society involvement was not necessarily a systematic feature in the planning of these e-Government clusters. This does not mean that the clusters, and the services and other results emerging from these, are not citizen-centric in themselves, but it does question our proposed framework in terms of what role citizens can realistically play in such clusters.

Factor Diamond Analysis

The factor diamond analysis below is based on the level of influence exhibited by each factor diamond determinant in creating favorable e-Government factor conditions, for each of the clusters.

Table 2. Demand Diamond Analysis

Determinants	u-IT Cluster South Korea	e-Govt. Cluster Hungary	GAUDI Cluster European Union
Political Organisations	High	High	Low
Administrative Bodies / Public Sector	High	High	High
Business Organisations / Associations	High	High	Medium
Citizens / Civil Societies	Low	Low	Low

u-IT Cluster, South Korea

The Korean government has established the basic IT infrastructure through its 11 key e-Government projects (2002-03), which in-turn helped the government to implement 31 e-Government roadmap projects. The government has planned to develop u-City infrastructure in major cities by putting in place 3 infrastructures viz., Broadband Convergence Network (BCN), Ubiquitous Sensor Network (USN) and Next-Generation Internet Protocol (IPv6). From the above, it can be deduced that the government played an important role in building the basic infrastructure. Since the State owned companies in Korea obtain direct contracts from the government, they are also believed to have a substantial role in providing IT infrastructure. Thus, the government and public sector are seen to have a high influence in creating factor conditions.

The premises to host firms in the u-IT cluster have been built by the government with rental costs reported as quite low. Facilities include convenience facilities like dormitories, dining rooms, fitness centers etc. This shows that the government and the public sector have been instrumental in providing adequate and reasonably priced capital infrastructure.

Korea reported in 200X that 77% of population had access to high-speed internet and 88% of population having mobiles. The presence of large corporates and SMEs in and around the cluster region has led to an increase in the skills and expertise of the people. It can be deduced that the business organizations have had a high influence on e-Government factor conditions.

Incheon is an hour drive from Seoul, which is host to numerous universities, training institutions and research & development organizations. These institutions have been operating since a long time and have proven to be a source of rich knowledge and experience. This aspect of readily available knowledge has induced firms to set-up their base in the u-IT cluster.

e-Government Cluster, Hungary

The Hungarian government launched the Electronic Backbone (EGB) in 2004, which is a secured government-wide communication network involving 600 organizations, in order to implement its e-Government 2005 strategy. The Hungarian government organized e-Government training courses for civil servants from 700 different offices in 2006 in order to enhance internal capacities and induce a change in their mindset. It can therefore be said that the government has played an influential role in establishing IT infrastructure and capital infrastructure in Budapest, enhancing the e-Government factor conditions and inducing the creation of e-Government cluster. The public sector seems to have a more moderate influence on e-Government factor conditions in Hungary owing to the fact that very few public sector organizations actively contribute towards infrastructure development.

Business organizations were influential in setting up the e-Government cluster in Budapest. The region had numerous SMEs involved in software development, which enriched the region with skilled manpower. Also, the presence of well-reputed training institutions made the region more favorable for the setting up of the e-Government cluster. The managing agent, Albacomp Zrt., is a leader in the supply of hardware and PCs in Hungary, and could easily enter into partnerships with various other organizations in order to market e-Government solutions as Services rather than as Products. Thus, it can be deduced that private business organizations influenced in a major way to create favorable e-Government factor conditions.

GAUDI Cluster, European Union

Since the GAUDI cluster is a consolidation of three regional clusters across Europe, it was difficult to analyze how the e-Government factor conditions at European level were influenced by the factor diamond determinants. Instead, it was thought to consider a single regional cluster to conduct the factor diamond analysis. The case of the Catalonia region has been considered.

The Catalonia cluster seems to have benefited from the IT infrastructure set up by the government to implement its e-Government strategies. However, the influence of the public sector on e-Government factor conditions seems to be low. The city of Barcelona hosts Scytl, a leader in developing e-voting solutions, and other numerous consultancy organizations, internet service providers and IT based training institutions, which has resulted in creating a pool of skilled personnel in and around Barcelona. It can be deduced that business organizations have been influential in enhancing the e-Government factor conditions, especially on manpower skills, IT infrastructure and knowledge.

The Catalonia region has numerous reputed universities, which are seen as a reliable source of information and knowledge on various areas. Some of these universities have initiated programs and research initiatives related to e-Government. These universities often become training institutions for providing customized training to various types of users. The creation of CAT365, a public-private joint venture, has enabled users to secure digital signatures locally, avoiding the time and effort in applying from firms located outside Barcelona. The formation of a consortium of 800 municipalities, called Localret, is again a boon to the region as it has enabled the region to develop skills and expertise on e-Government, thereby, enhancing the skills of the people.

The summary of the Factor Diamond Analysis is shown in Table 3, which gives the estimated level of influence by factor diamond determinants on each cluster.

The above analysis suggests that in the case of the clusters studied in this paper, each of the four actors played in important role in terms of factors of production. This being said, while government and public sector do play a considerable role in providing basic factor conditions, their influence does not seem to be as high as business organizations in creating favorable e-Government factor conditions.

Table 3. Factor Diamond Analysis

Determinants	u-IT Cluster South Korea	e-Govt. Cluster Hungary	Catalonia Cluster Spain
Government	High	High	Medium
Public Sector	High	Medium	Low
Business Organisations / Associations	High	High	High
Training & Research Organisations	High	High	High

CONCLUSION

Electronic Government can be a more productive version of government in general, if it is well implemented and managed [Riley, 2003]. The concept of clusters has become widely known to induce productivity, innovation and competitiveness, which are key factors to sustaining regional economic growth and development [Porter, 1990]. Since the policies and regulations framed by government have a proven impact on cluster operations, they require being cluster-friendly and innovation-oriented. The network-based governance approach in the demand and factor diamonds of the e-Government Cluster Framework proposed in this paper, appears to be important for the success of these clusters.

Clusters often emerge and begin to grow naturally, with little role of government policies [Porter, 1998]. It is after a certain stage, that local, regional or national governments can facilitate the growth of firms within the cluster, to help them improve their competitiveness. In the case of e-Government clusters, the role of government and the importance of collaboration between various private and public partners appear much more pronounced. The internet age has seen the birth of numerous virtual organizations and virtual partnerships wherein firms collaborate and compete using online tools on the internet. Although internet facilitates the efficient exchange of information, it appears that the geographical proximity of firms cannot be avoided as this proximity facilitates the information and knowledge transfer between partners, and enhances trust and confidence within the cluster (Torre 2008).

In this paper, we have extended and adapted Porter's (1990) cluster model to the specific case of the growing e-Government sector. In particular, we hypothesized that a specific and collaborative cluster governance model needs to be in place in order to successfully create favorable demand and factor conditions for the e-Government cluster. We then examined briefly three specific e-Government cluster initiatives to give us an indication of whether various stakeholders played an important strategic role in these clusters. Our findings suggest that this was not always the case. Given the nature of the analysis, this does not, however, confirm or disconfirm the role of these stakeholders.

In conclusion, the creation of e-Government clusters is strategic in nature as it facilitates the ready availability of domain experts, the rapid selection of partners, and prompt access to innovative technologies. The pre-conditions for the creation of e-Government clusters appear to include the level of involvement of both the demand and factor diamond stakeholders as this leads to more favorable demand and factor conditions.

KEY TERMS AND DEFINITIONS

Cluster: A geographic concentration of inter-related businesses and institutions active in a particular industry or field.

e-Governance: The use of information and communication technology as a tool to achieving better governance.

e-Government: The application of information and communication technology solutions by the government, particularly with a view to better serving citizens.

Framework: The structure underlying a system.

GAUDI: A European cluster project launched as a consolidation of three regional clusters.

Regional Development: The provision of guidance, aid and institutional structures to support the socio-economic development of a geographical region.

U-IT Cluster: The name given to a cluster initiative sponsored by the Korean government and Incheon Metropolitan City to create infrastructure in the Songdo District (Incheon) for the development of RFID/USN technology.

This work was previously published in Global Strategy and Practice of E-Governance: Examples from Around the World, edited by Danilo Piaggesi, Kristian Sund and Walter Castelnovo, pp. 443-463, copyright 2011 by Information Science Reference (an imprint of IGI Global).

Chapter 80
Hybrid Algorithms for Manufacturing Rescheduling:
Customised vs. Commodity Production

Luisa Huaccho Huatuco
University of Leeds, UK

Ani Calinescu
University of Oxford, UK

ABSTRACT

This chapter investigates manufacturing rescheduling of customised production and compares the results with those found for commodity production in earlier research by the authors. The hybrid rescheduling algorithms presented in this chapter were obtained by combining two key rescheduling-related elements found in the literature (a) rescheduling criteria (i.e., job priority, machine utilisation and right-shift delay) with (b) level of disruption transmitted to the shop-floor due to rescheduling (i.e., High disruption and Low disruption). The main advantage of hybrid rescheduling algorithms over individual rescheduling algorithms consists of their ability to combine the main features of two different algorithms, in order to achieve enhanced performance, depending on the objective of the organisation. The five hybrid rescheduling algorithms taken into account in this chapter are: Priority High, Priority Low, Utilisation High, Utilisation Low and Right-Shift. The authors' case study research in three manufacturing companies has identified the use of a set of these hybrid algorithms in practice. Each of the case studies is evaluated in terms of time-based performance in three main areas: suppliers' interface, internal production and customers' interface. This evaluation is carried out for both customised and commodity production, using the same hybrid rescheduling algorithms and performance measure the authors used in their previous research work, for comparability purposes (i.e. the entropic-related complexity). The findings show that customised production exhibits a lower entropic-related complexity than commodity production. Although this behaviour may seem unexpected, the entropic-related complexity analysis allows for an interpretation / understanding of its underlying reasons. For example, companies making customised products first agreed the specifications of the products with the customer, and then they mutually agreed

DOI: 10.4018/978-1-4666-1945-6.ch080

on a contract which would financially protect manufacturers (should last minute customer changes occur), by specifying analytically determined penalties or premium charges. Furthermore, a set of recommendations were made to the companies involved in this research study based on the analysis presented in this chapter, such as the need for manufacturing organisations of customised products to ensure they have dependable suppliers, and that, internally, they plan for and embed sufficient spare capacity to cope with internal or external disturbances.

INTRODUCTION

This chapter aims to assess the relationship between hybrid rescheduling algorithms, entropic-related complexity, and customised production, by using real-world manufacturing case studies. The paper thus makes a theoretical and applied contribution on these inter-related topics, which (to our knowledge) have not been previously studied in conjunction before.

The main research question explored in this chapter is: *In the context of customised production, how do hybrid rescheduling algorithms impact entropic-related complexity?* The following objectives guide this chapter: (a) To identify the typical hybrid rescheduling algorithms used in the context of customised production, and (b) To explain why and how hybrid rescheduling algorithms vary across organisations.

Given the current climate of increased global competition, manufacturing companies need to focus on customised production. It is important to consider the ever-increasing need for value-adding product design and manufacturing processes (Browning *et al*., 2002). Tu *et al.* (2001) argue that firms need to move from the internal efficiency maximisation mindset towards the emphasis on customer value. In the same vein, Professor ElMaraghy (ElMaraghy, 2009) states that one of the key challenges that manufacturing organisations face nowadays is "to satisfy the market need for products variations and customization, utilizing new technologies, while reducing the resulting variations in their manufacturing and associated cost" (p. v).

In order to satisfy the customization need of the market at a competitive price, it is necessary to understand that the above goals are neither straightforward nor easily achievable. Furthermore, the additional complexity that arises in trying to pursue them should be carefully managed. As Griffiths and Margetts (2000) point out: "customers want high quality products and services, at a reasonable cost, and they want them 'now'" (p. 155). Managing the complexity resulting from such a dynamic environment plays a key role in keeping costs under control. If organisations do not manage complexity through rescheduling or other complexity management approaches, they could face some of the following consequences (Huaccho Huatuco, 2003): customer dissatisfaction, which can then lead to losing customer demand and, related to this, less flexibility and product variety.

The type of rescheduling problem tackled in this chapter could be classified as a "stochastic scheduling problem" (Pinedo, 2008) where the disturbances were arbitrarily assigned, but the spare capacity of the original production schedule (processing times, number of jobs and number of loaded machines) varied according to a random probability distribution. These experiments were designed, run and tested in our previous work (Huaccho Hautuco *et al.*, 2009), so their detailed discussion is outside the scope of this chapter. The aim in this chapter is to provide manufacturing organisations that make customised products with recommendations on which hybrid rescheduling algorithms are more likely to be of effective use to them.

The hybrid rescheduling algorithms presented in this chapter combine priority dispatch rules with the disruption effects on the shop floor, namely: *Priority High*, *Priority Low, Utilisation High, Utilisation Low* and *Right-Shift*. These algorithms were previously studied by the authors (Huaccho Huatuco *et al.*, 2009) for commodity production. The novelty and thus contribution of this chapter consists of the extension of these hybrid algorithms to the context of customised production.

The remainder of this chapter is organised as follows. A literature review follows next, on three inter-related topics: hybrid rescheduling algorithms, entropic-related complexity and customised production. Then, the measurement methodology section gives details on the case-based research carried out. Next, the data analysis section is briefly presented. After that, the section on case studies for customised production covers the following results: entropic-related complexity, hybrid rescheduling algorithms, customised versus commodity production, and recommendations to case study companies. Next, the discussion of results section focuses on implications to Scheduling practice as well as Value-adding (VA) versus non-value adding complexity (NVA). Finally, some conclusions including some implications for theory and practice, together with some future work directions are provided.

LITERATURE REVIEW

This section discusses the links and dependencies among hybrid rescheduling algorithms, entropic-related complexity and customised production. Major, established and more recent publications in these topics include a diverse range of rescheduling methods (Ouelhadj & Petrovic, 2009; Silva *et al.*, 2008), as well as links with customised production (Da Silveira *et al*., 2001; Smart, 2009).

Hybrid Rescheduling Algorithms

There has been no shortage of hybrid algorithms reported in the literature for manufacturing systems. For example, Bierwirth & Mattfeld (1999) used Genetic Algorithms (GA) together with a tunable parameter (in terms of the length of machine idle time) to carry out hybrid scheduling, whereas Gao *et al.* (2009) also proposed the use of GA in combination with Ant-colony algorithms to determine the order of manufacturing jobs and machine assignment, respectively. Wang *et al.* (2006, 2010) focused on hybrid algorithms for the blocking flow shop scheduling problem, proposing a combination of genetic algorithms with local search algorithms. In relation to rescheduling, the work by Deblaere *et al.* (2010) combined exact reactive scheduling with Tabu search algorithms. Most of the work presented in previous literature uses simulations as a means to test the performance of rescheduling algorithms. This chapter analyses and discusses hybrid rescheduling algorithms using real-world manufacturing case studies, rather than computer simulations.

The hybrid rescheduling algorithms presented in this chapter were obtained by combining two key rescheduling-related elements found in the literature (a) rescheduling criteria (i.e., job priority) (Yamamoto & Nof, 1985; Jain and ElMaraghy, 1997, Smith 2002), machine utilisation (Jain & ElMaraghy, 1997) and right-shift delay (Yamamoto & Nof, 1985; Cheng, 1998; Holthaus, 1999) with (b) level of disruption transmitted to the shop-floor due to rescheduling (i.e., High disruption) (Yamamoto & Nof, 1985) and Low disruption (Smith, 2002). It is worth mentioning that Priority is normally assigned by order / job due date, but it could be also assigned by customer importance, by order value, or by a factor determined at the discretion of the scheduler.

The main advantage of using hybrid rescheduling algorithms is that they provide a better approach to rescheduling than if separate individual rescheduling algorithms were used, such as their ability to combine the best features of two different algorithms in order to achieve an enhanced performance, depending on the objective of the organisation. For example, while some organisations may strive on getting robust schedules (schedules that would remain valid for a long period of time), other organisations could be interested in getting near-optimal schedules which could be generated in a relatively shorter time. As mentioned before, the five hybrid rescheduling algorithms that have been used in our previous research are: *Priority High, Priority Low, Utilisation High, Utilisation Low* and *Right-Shift* (Huaccho Huatuco *et al.*, 2009).

Algorithms Description

Each of these hybrid rescheduling algorithms is briefly described next.

- *Priority High*: This algorithm takes into account the Priority of the jobs (e.g. each job's due date). Additionally, in the case of a disturbance affecting production (e.g., customer changes), the *Priority High* algorithm generates a new schedule (rescheduling) immediately. This causes high disruption to the shop floor (i.e., no threshold condition is used to filter down the disruption transmitted to the production shop floor).
- *Priority Low*: This algorithm includes a threshold condition (added to the *Priority High* algorithm) in order to filter down the disruption to the shop floor (Low disruption). In our previous research on the impact of machine breakdowns on rescheduling, the threshold condition was based on the *downtime* being greater than the *remaining* time of the disrupted job (Huaccho Huatuco, 2009). Once the threshold condition is fulfilled or surpassed (Pfeiffer *et al.*, 2007), rescheduling takes place.
- *Utilisation High*: The algorithm takes into account machine utilisation. In the case of a disturbance, it chooses the least utilized machine immediately (High disruption) to allocate the affected job.
- *Utilisation Low*: The algorithm includes a threshold condition (added to the *Utilisation High* algorithm), as explained for the *Priority Low* algorithm.
- *Right-Shift*: The algorithm delays the disrupted job until the disturbance has ended, right-shifting (delaying) all the remaining jobs accordingly.

The pseudocode for these hybrid rescheduling algorithms is provided next, where:

- **Active:** The processing time of the job before the occurrence of the disturbance.
- **Affected Jobs Downtime:** The procedure that checks that the arrival times of the jobs affected by the disturbance is right-shifted.
- **Alternatives:** The procedure that looks for alternative machines for the jobs affected by disturbances.
- **Knock-On Effect:** The procedure that right-shifts the jobs both on the affected machine and on the alternative machine, due to the occurrence of a disturbance.
- **Remaining:** The remaining processing time of the job that needs to complete after the occurrence of a disturbance.
- **Disturbances:** The procedure that writes the disturbance effect on the production schedule, in the form of unavailability of the affected machine.
- **Right-Shift:** The procedure that delays the jobs affected by disturbances.

The pseudocode for the main part of the High disruption algorithms (*Priority High* and *Utilisation High*) is given next.

The pseudocode for the Low disruption algorithms (*Priority Low* and *Utilisation Low*) is

Algorithm 1.

```
1.     Process schedule, part data and disturbance data
2.     Assign Excel data to VBA variables (This is how Arena 5.0 handles the
introduction of the analysts' own logic into the simulation package)
3.     For all jobs (i=1 to n, where n is the number of scheduled jobs)
If Job_i is affected by a disturbance, then
Rewrite arrival time of Job_i
Call 'Knock-on effect' procedure
4.     If disturbance affects a machine that is busy, then
Generate Schedule [Perform Rescheduling]
Go to (6)
5.     Process (run jobs) according to Process Schedule, then go to (10)
6.     If active_i>0, then
7.     If remaining_i>0, then
Rewrite Process Time of Part Data
Update schedule
Call 'Alternatives' procedure
Call 'Disturbances' procedure
8.     Else [remaining_i >0]
Process according to Process Schedule
Call 'Affected jobs downtime'
Call 'Disturbances'
Call 'Knock-on effect'
9.     Else [active_i >0] Call 'Alternatives' procedure
10.     End
```

given next. Note that only Step 7 changes in relation to the High disruption pseudocode.

The pseudocode for the *Right-shift* algorithm is given next. Note that Steps 7, 8 and 9 change in relation to the High disruption pseudo code.

Although disturbances can affect both customised and commodity production, the analysis of the performance needs to focus on the type of disturbance that is more relevant to the problem under study. Thus, the analysis in this chapter focuses on customer changes, which are more relevant to customised production than machine breakdowns (as studied previously). Customer satisfaction is one of the main targets of manufacturing organisations, which can be achieved by accommodating customer changes requests in their production schedule. As stated by Efstathiou (1996), schedules should retain flexibility (which could be achieved by allowing spare capacity in the production schedule, for example) in order to allow manufacturing companies attending to those requests, while at the same time companies should be able to estimate the inconvenience and the possible disruption to other orders. Customer changes include: changes in order specifications (e.g. quantity ordered [more or less], delivery times [earlier or later], cancellations, inserting new—ordinary or rush—orders) or in terms of customisation changes, modifying the product specifications. However, satisfying the customer has to be carefully balanced with production schedule stability. For example, in the case of rush orders (also called Fast Turn Around or FTA orders), Krajewski *et al.* (2005) suggested that

Algorithm 2.

```
7.     If remaining_i>0, then
Rewrite Process Time of Part Data
Update schedule
If Downtime_i>Remaining_i, then
Call 'Alternatives' procedure
Call 'Disturbances' procedure
Else [Downtime_i>Remaining_i]
Call 'Right-shift' procedure
Call 'Disturbances' procedure
```

Algorithm 3.

```
7.     If remaining_i>0, then
Rewrite Process Time of Part Data
Update schedule
Call 'Right-shift' procedure
Call 'Disturbances' procedure
8.     Else [remaining_i >0]
Process according to Process Schedule
Call 'Affected jobs downtime'
Call 'Disturbances'
Call 'Knock-on effect'
9.     End
```

suppliers can use their contracts to their advantage (e.g. charging a premium for them).

The decision element of the rescheduling model will be whether to satisfy a customer that requires a rescheduling action or not and, if so, to what extent (this is determined by the disruption threshold conditions). The threshold conditions are taken into consideration by the level of disruption to the shop floor (High or Low disruption) that the scheduler would prefer / allow to accommodate. As Monostori *et al.* (2007) expressed, finding the appropriate threshold, which ideally should be an informed and quantitative-based decision, may imply that there is a compromise between schedule stability and schedule quality. In another paper, Pfeifer *et al.* (2007) tested different levels of thresholds before rescheduling took place by evaluating the performance in terms of schedule efficiency and schedule stability. It is worth mentioning that the level of threshold can be determined either statically or dynamically (at run time). Examples of criteria which could be used for deciding which type of threshold to use include: the type of manufacturing environment, performance objectives, information availability and information processing costs.

With reference to customer changes, the following disturbances were derived from Jain & ElMaraghy (1997): (a) Increasing the priority of existing orders (as noted earlier, also known as rush orders or Fast turn around or FTA), (b) Decreasing the priority of existing orders, (c) Introducing new orders, which could be either rush orders or standard duration orders, and (d) Cancelling already placed orders. Each of these is explained in turn below. Assuming that a customer's order corresponds to a single machine job, then:

A. ***Increasing the priority of existing orders (rush orders or Fast Turn around or FTA)***: This disturbance involves finding the job corresponding to the order for which the priority is increased. If the job has not been loaded to any machine, and if the machine required to process it is free, then assign the job to start immediately on it. Otherwise, pre-empt the machine and start the job immediately, all the other jobs on that machine are right-shifted accordingly.
B. ***Decreasing the priority of existing orders:*** This disturbance involves finding the job corresponding to the order for which the priority is decreased. If the job has not been loaded to any machine, and if the machine required to process it is free, then recalculate the priority of the jobs and assign a lower priority to the job, depending on the revised due date. Otherwise, pre-empt the machine and start the next higher priority job on it, the remaining part of the job gets right-shifted accordingly.

C. ***Introducing new orders, which could be either rush orders or standard duration orders:*** If it is a rush order the highest priority is assigned to its corresponding job, then the new job is treated as in part (a) above. If it is a standard duration order, then priority is assigned accordingly, and the job is inserted into the current schedule.

D. ***Cancelling already placed orders***: This disturbance involves finding the job corresponding to the cancelled order. If the job has not been loaded to any machine and if the machine required to process it is free, then do not load it. Otherwise, pre-empt the machine and cancel the remaining completion time of the job from it. Advance any jobs that were due to be processed later on that machine to finish earlier too.

Entropic-Related Complexity

Entropic-related complexity is a measure derived from entropy (Shannon, 1949). This measure was adapted and applied to manufacturing systems in the "Complexity in the Supply Chain" project by Efstathiou & Frizelle (EPSRC Grant No. GR/M57842). This project was run jointly by the University of Oxford and the University of Cambridge, in collaboration with industrial partners including: Unilever, BAE Systems and ALPLA. Complexity, within this context, is defined as the uncertainty and the variety within a system. Hence the two main characteristics of complexity which we consider in this chapter are uncertainty and variety. Variety refers to the many parts of the manufacturing system that need to be managed, whereas uncertainty refers to the unpredictability of the behaviour of each of those parts (probability of occurrence).

Entropic-related complexity is quantified into indices that highlight high complexity areas and help focus management attention to examine their causes. The higher the index the greater the complexity displayed by the system. This can be measured in different areas or levels, for example in this chapter we focus on three areas: at the suppliers' interface, internal production, and at the customers' interface. The complexity index is evaluated based on Equation 1, which gives the fundamental form for describing entropy. Here, the entropy (H) is defined as the uncertainty and variety of the system associated with a set of n events (states), where p_i is the probability of the i^{th} event occurring. The complexity index units are given in bits per state (bps).

$$H = -\sum_{i=1}^{n} p_i \log_2(p_i) \quad (1)$$

For example, a machine can be in one of three states: "idle," "making product" or "broken down." Each state occurs with certain frequency in a given period of time, which can then be used to obtain its probability of occurrence. Assuming the machine is "idle" for 10% of the time, "making product" for 85% of the time and "broken down" for the remaining 5% of the time, then the Complexity index is calculated as follows:

$$H = -0.1 \times \log_2 0.1 - 0.85 \times \log_2 0.85 - 0.05 \times \log_2 0.05$$

$$H = 0.75bps$$

Several practical considerations need to be taken into account when taking the entropic-related complexity measurements. First, a series of observations are made of the production processes relevant to the research study. These observations include both qualitative and quantitative behaviour, in the form of managing information flows, applying formal and informal methods, such as generating production schedules, taking / making customer phone calls, or carrying out procedures in case of unexpected events. Counting the variations and weighting each by the likelihood of occurrence gives rise to the probability of each state. The overall complexity index is calculated using Equation 1, and represents the entropic-related complexity of the system or subsystems investigated.

The level of unexpected variation (which corresponds to the uncertainty) within a system, indicates the level of "out of control." A system that behaves totally predictably can be assumed to be completely "in control." As the uncertainty and thus unpredictability of the system increases, the level of control decreases. A greater understanding of the behaviour and level of controllability of a system can be achieved through measuring the deviations from what was expected to happen. The aim of the measurements is to record these variations, and to identify their causes. This method of measuring the variations can be applied to information, to material flows, and/or to monetary values. The variations can be analysed by employing a time-, quantity- or reason-based analysis, or a combination of these.

Entropic-related complexity methods can be used for analysing and understanding how manufacturing organisations behave within their supply chain. The main idea is that the delivery performance of suppliers impacts upon the manufacturing organisation, which in turn could affect its delivery performance towards its customers. In this connection, it is hypothesised that rescheduling plays a key role in managing complexity.

Customised Production

As stated by Duray *et al.* (2000), without some degree of customer involvement in the design process, a product cannot be called customised. At the customised end of the spectrum the following customisation levels are considered: Build-to-order and Make-to-order manufacturers (Gunasekaran & Ngai, 2005). They considered that responsiveness and flexibility were both the key objectives and enablers in the customised production environment.

Four quadrants were presented in Huaccho Huatuco (2003), which resulted from the combination of the X-axes: "functional product" and "innovative product" and the Y-axes: "efficient scheduling objective" and "responsive scheduling objective." The two quadrants of interest to the work presented in this chapter are: "functional product, responsive scheduling" and "innovative product, responsive scheduling." The former refers to commodity production, whereas the latter refers to customised production. In terms of managing complexity, companies belonging to either of these two quadrants were identified to manage complexity using "rescheduling." However, in the search for an alternative way of managing complexity, the emphasis shifts from using "decision-making," for commodity production, towards the use of "spare capacity" in customised production. So, ideally, the production schedules in customised production should embed higher spare capacity levels than the production schedules in commodity production. "Responsive scheduling" is related to the Just-in-Time (JIT) Operations Management philosophy by its aim to satisfy the customer by delivering the right product, in the right quantity and at the right time.

Duray *et al.* (2000) built upon Mintzberg's work (1988), and stated that customization can be pure (from the conception stage), tailored (at the fabrication stage) or standardised (at the assembly stage).

Summary of the Literature Review

This section has covered the three inter-related topics of interest for this chapter: hybrid rescheduling algorithms, entropic-related complexity and customised production. Hybrid rescheduling algorithms have been extensively used in the manufacturing context, since they are robust in providing solutions that could take the best features of each algorithm. The rescheduling algorithms considered in this chapter are: *Priority High, Priority Low, Utilisation High, Utilisation Low* and *Right-shift*. Entropic-related complexity has been presented as a holistic, comparable and useful measure to managers. They can use it to prioritise and direct their efforts in an informed and objective manner. Customised production was discussed in the light of the level of customisation, and the need to enable organisations to achieve flexibility and responsiveness. This can be done through a combination of "rescheduling" and "spare capacity" approaches to managing complexity.

MEASUREMENT METHODOLOGY

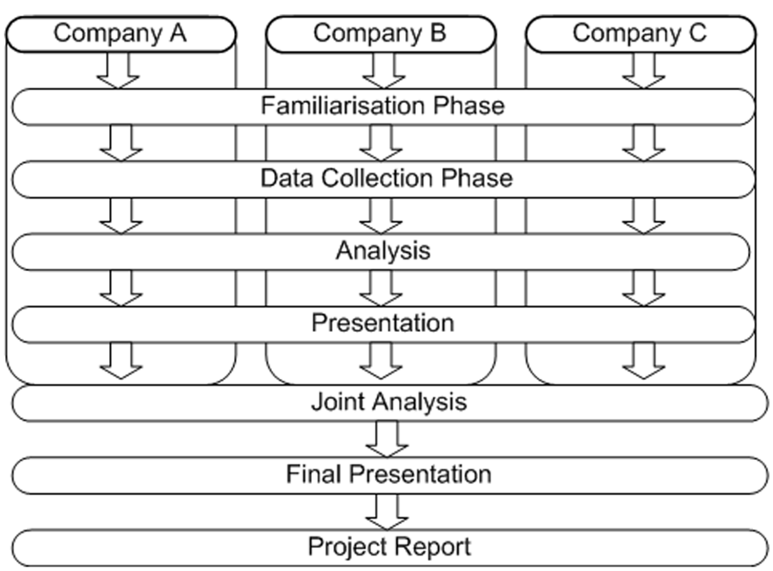
The measurement methodology used in this research was case-based research, with individual-companies case study analyses followed by a cross-case analysis. The case study protocol was followed (Voss *et al.*, 2002) with particular application of the stages proposed in Sivadasan *et al.* (2002), which are diagrammatically represented in Figure 1.

Company A, Company B and Company C participated in the "Rescheduling and complexity for customised products" project. The information flow complexity within these companies was evaluated by measuring the entropic-related complexity (i.e., the uncertainty and variety of the information transfers between suppliers and customers), for example. Data was triangulated using: (a) semi-structured interviews, (b) observations of the shop floor and (c) documents in electronic or hard copy form.

Familiarisation

Prior to conducting the actual complexity measurements, between two and three days were spent within each company for collecting preliminary information with people, information flows and processes. This involved an interactive process of semi-structured interviews with key personnel, to understand the operations and to map out the key material and information flows. In terms of plant familiarisation a tour of the plant sites was given by the companies, which provided a better understanding of the manufacturing processes such as process layout, and additional information about types of resources and their capabilities, at each organisation.

Figure 1. The case study methodology



Key Information Flows and Variations

The diagrammatic representation of the information flows studied is given in Figure 2, where the arrows represent the information flows.

The variations identified and investigated in this research are given in Table 1.

The Parameters Considered Prior to Data Collection

To ensure the effectiveness and accuracy of data collection, and the applicability of the complexity measurement method, the following parameters were determined prior to taking measurements:

- The variables to be measured (time-based, quantity-based or reason-based variables).
- The possible states of interest (using Equation 1) (e.g. at any given time a machine can be in one of three states: "idle," "making product" or "broken down").
- Frequency and duration of observations (e.g. once every hour, shift or day, for two weeks).
- Key information flows and variations (e.g. despatch notes and delivery requirements for the last three months).

The Variables to be Measured

For example, in the case of deliveries at the supplier interface, goods may not arrive on time and / or in full (OTIF) (i.e., time and quantity variations). The variables we chose were: time-based deliveries—for the suppliers' and customers' interfaces, and time-based production—for the internal production.

Additionally, the reasons for time and quantity variations were identified and recorded, in order to detect the instances of importing, exporting and absorbing complexity. Briefly, importing complexity consists of accepting complexity from elsewhere outside the organisation (e.g. suppliers or customers), whereas exporting complexity consists of transferring complexity to those organisations.

Figure 2. Information flows investigated

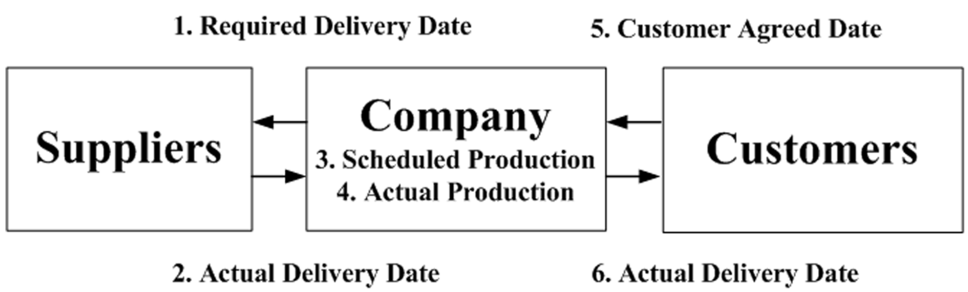


Table 1. Variations identified and measured

Area	Variation*
Suppliers' interface: Procurement	2. Actual Delivery Date – 1. Required Delivery Date
Company: Internal Production	4. Actual Production – 3. Scheduled Production
Customers' interface: Delivery	6. Actual delivery Date – 5. Customer agreed date

*Note: the symbol "–" refers to arithmetic difference.

Absorbing complexity is the way organisations decrease / minimise complexity internally. For a full discussion on complexity transfers please refer to Sivadasan *et al.* (2004). Also, the reasons for variations are useful in order to facilitate the understanding, interpretation and meaningfulness of the entropic-related complexity.

The Possible States of Interest

The results of this study focused on time-based analysis (i.e. the variations stated in Table 1). States were defined so as to accurately capture the investigated processes. They were kept the same across all case studies, whenever possible, for comparability purposes. The following states of interest were taken into account at the suppliers' and customers' interface:

- on time or early.
- < 1 week late.
- 1-2 weeks late.
- 2-4 weeks late.
- 4-8 weeks late.
- > 8 weeks late.

Frequency and Duration of Observations

The frequency of the information and material transfer was used as a guideline for the frequency of measurements. In the case of event-based activities (such as deliveries) the analyses utilise all the available data for each case study, which can be either live or historical. In terms of live data, two weeks were used for carrying out the data collection on site. In terms of historical data, it was determined that at least three months of weekly data would provide sufficient data points for the analysis.

Data Collection

Data collection consists of sampling information and material flows over time. In this study, information variations were investigated and recorded in terms of actual versus expected performance over the data collection period. Thus sufficient data (typically a minimum of 30 data points) should be gathered to ensure each state have been observed to give an estimate of its probability. As mentioned earlier, data consists of: (a) semi-structured interviews, (b) observations of the shop floor and (c) documents in electronic or hard copy form.

Data Analysis

The data analysis involved the calculation of the complexity indices, for the variations mentioned earlier, and the interpretation of the results thus obtained.

The computation of the complexity indices comprises five steps:

1. Calculate the arithmetic difference between the actual information flows and the scheduled information flows (e.g. if a delivery was expected on the 5th August, but it arrived on the 4th August, then the arithmetic difference would be: 4-5=-1 [a day early]).
2. Classify the difference calculated at step 1 using the pre-defined states (e.g. if a state is defined as "a day early") then, for illustration purposes, suppose 40 deliveries belong to that state.
3. Estimate the probability associated with each state. For the example above, if the total deliveries were 400, therefore 40 deliveries represent 10%, so the probability of "a day early" deliveries is 0.10.
4. With the estimated probabilities at step 3, use Equation 1 to calculate the entropy (e.g. continuing with the calculation from previous step: $-0.1 \log_2 0.1 = 0.33$ bps).

5. Add up all the entropy values to calculate the entropic-related complexity (e.g. 0.33+…=2.58 bps).

The subsequent analysis of the indices involves three more steps:

1. Compare relevant complexity indices calculated for the different areas being analysed, to identify high complexity areas. The rule of thumb used here was: < 1 bps: low; 1 to 2 bps: medium; > 2 bps: high. This rule of thumb results from considering that the maximum entropic complexity for a six-state system is 2.58 bps or bits per state (=$\log_2 6$), and a rough estimation of the low, medium and high values, respectively. It is worth mentioning that the specific state definitions have a direct impact on the results. However, the recommendations derived from the calculations in this chapter are robust, as they hold when tested with slightly different states, as in the case of Company B (Huaccho Huatuco *et al.*, 2010). For more details on the issue of state definitions for the entropic-related complexity, please refer to Sivadasan *et al.* (2001).
2. Identify specific reasons within each complexity area (e.g. suppliers' interface, internal production and customers' interface), and observe their frequency of recurrence throughout the flows, grouping them if necessary. For example, similar reasons can be aggregated into a state, "low materials quality" and "delays in suppliers' delivery" could be grouped into "suppliers-related reasons."
3. Provide recommendations to the manufacturing organisations about managing their entropic-related complexity. The key findings, such as high complexity areas and prioritisation of the areas that require managerial attention, were presented to each participating manufacturing organisation.

CASE STUDIES FOR CUSTOMISED PRODUCTION

This section is based on the "Rescheduling and Complexity for Customised Products" project involving three UK manufacturing companies in customised production (Huaccho Huatuco, 2006). The case studies are summarised in Table 2.

Both material flows (such as the raw materials and work in progress) and information flows (such as the production schedules) are important when rescheduling manufacturing systems. Details of the companies rescheduling practices were collected from interviews, direct observations of the shop floor and paper / electronic documents. These case studies are used to abstract the characteristics of the hybrid rescheduling algorithms as used in practice.

The following benefits to the participating companies were anticipated:

- Diagnosis and benchmarking of each company's rescheduling practice.
- Evaluation of the amount of entropic-related complexity they are handling when rescheduling.
- Recommendations as how to manage complexity to their advantage.

These companies are based in the UK and were chosen among different candidate companies due to their different levels of customisation. All three companies agreed to participate in the research project by providing access to their management staff in relation to scheduling and production.

The following good practice elements were gathered from all the case studies:

- People involvement and commitment.
- Frequent communications both formal (printed documents) and informal (phone and face-to-face conversations).
- Expertise coming from experience.
- Quality awareness throughout the process.

Table 2. Summary of the case study companies

Company (size)	**Product**	**Main disturbance(s)**	**Relative level of customisation according to Duray *et al.* (2000)**
A (Large, part of a multinational corporation)	Pumps for oil, water or waste	Suppliers do not always deliver on time. Bottlenecks exist in the production shopfloor (as a consequence, queues develop)	Each pump is a project on its own, depending on where the pump is to be installed. The customer determines the specification of the pump. Customisation is tailored (at the fabrication stage).
B (Large, part of a multinational corporation)	Paper chemicals manufacturer	Customers change their orders at the last minute, and innovative products are likely to fail in the shop floor. For example, new chemical products for paper to achieve particular properties, such as: allowing the quick drying of the ink printed on them.	Innovative paper chemicals with improved properties. Customer needs are gathered by the company's own dedicated customer service staff who work closely with customers. Customisation is pure (at the conception stage).
C (SME)	Industrial doors	None apparent	Each door is a project on its own, depending on where the door is to be installed. There is a limited range of door types on offer (four types), but the overall specifications such as size and location characteristics are unique for each door. Customisation is standardised (at the assembly stage).

Some of the issues identified at each manufacturing organisation are given in Table 3.

Table 4 shows the data collection details in terms of time period. It also shows that between 3 and 17 months historical data were collected.

The remainder of this results section is divided into: entropic-related complexity, hybrid rescheduling algorithms, customised versus commodity production, and recommendations to case study companies. These are discussed in turn next.

Entropic-Related Complexity Results

The results were shown to each manufacturing organisation by means of a Power Point presentation. Prior to this meeting, hard-copies of the presentation were distributed to the attendees to allow them to assess the confidentiality and sensitivity of the information. The attendees included key people within the organisation, people who had participated in the case study and people to whom the results would be most relevant. The participants provided feedback on their views and agreed with the results of our analysis. The most important point they made was in regards to being able to "quantify" the amount of complexity they were handling. Also, they acknowledged the fact that internal complexity does not exist in isolation and it is influenced by their suppliers' and customers' interfaces.

The results of the analysis have been classified, according to the type of entropic-related complexity handled due to rescheduling: Suppliers' interface, Internal Production, and Customers' interface. Each of these categories is discussed in turn next.

Suppliers' Interface

The complexity indices associated with the procurement or suppliers' performance are plotted in Figure 3. An example of the entropic-related complexity calculation is presented next. Company C's suppliers' interface was observed to be

Table 3. Issues identified

Company	Issues identified
Company A	• Difficult for the researchers to see the big picture (i.e. what is happening in other departments and the organisation as a whole). • Not much historical data recording. • Pressure on the scheduler for the individual projects to meet milestones / deadlines.
Company B	• Frequent rescheduling due to customer rush orders • No charge to customers for rush orders • Flexibility: strength or weakness? There is enough spare capacity to accommodate rush orders. However, the scheduler is finding increasingly difficult to manage the complexity associated with them. • Not enough operators – in the short term this is mostly because in the original schedule not many operators are needed, but in practice with the new rush orders coming in, shortage of labour becomes an issue.
Company C	• No extra charge to customers for rush orders or fast turnaround (FTA) deliveries. • Production earliness could become an issue when storage space is limited.

Table 4. Data collection details

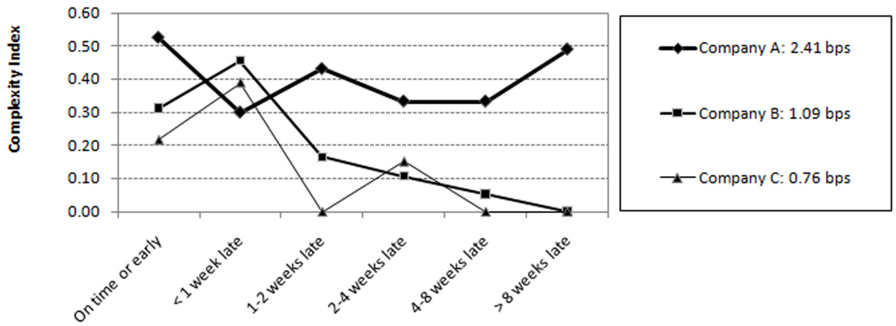
Company	Area of assessment	Time Period
Company A	Suppliers' interface	10 months
	Internal Production	3 months
	Customers' interface	17 months
Company B	Suppliers' interface	3 months
	Internal Production	9 months
	Customers' interface	3 months
Company C	Suppliers' interface	7 months
	Internal Production	4 months
	Customers' interface	4 months

in one of the following states: "on time or early," "< 1 week late" and "2-4 weeks late." There were: 21, 59 and 20 occurrences of each of these states, respectively. Applying Equation 1, they generate: 0.22, 0.39 and 0.15 bps, respectively. Adding these up, the complexity associated with the suppliers' interface at Company C is calculated at 0.76 bps.

In Figure 3, the horizontal axis shows the states of earliness or lateness associated with suppliers' deliveries to Company A, Company B and Company C, whereas the vertical axis shows the complexity index associated with those states. It can be seen that the average complexity associated with deliveries from suppliers to Company A is high at 2.41 bps (>2 bps), it is medium from suppliers to Company B at 1.09 bps (1-2 bps) and it is low from suppliers to Company C at 0.76 bps (<1 bps). All three results are within the limits of manageable complexity (Miller, 1956).

The complexity associated with the state of being "on time or early" could be regarded as value-adding complexity, which is the complexity that is needed to satisfy the end customer. However, early deliveries can cause some problems to companies, in terms of inventory, especially those working in a lean / JIT environment. The states of lateness are regarded as non-value adding complexity. Suppliers to Company A are most complex in the "on time or early" and the ">8 weeks late" states. This could be explained as due to the fact that suppliers' deliveries of common components are not a problem, whereas suppliers' deliveries of critical components such as pump motors are more prone to take longer than estimated. Suppliers to Company B and to Company C show a similar pattern of behaviour, with the highest source of complexity coming from the "<1 week late," and decreasing for the rest of the lateness states. This is because their suppliers are reasonably reliable and, if they missed the requested delivery date, they will deliver sooner rather than later. This is a direct consequence of the percentage of occurrence of states, which is presented in Table 5. As mentioned earlier, states are pre-defined in the analysis, so another way of analysing the data could consider two states: "on

Figure 3. Entropic-related complexity at the suppliers' interface



time or early" versus "late" deliveries. However, the six states used here have been defined taking into account the scheduler's decision making points as to whether to take action according to their implications on the shop floor production. For example, lateness of less than a week (i.e. "<1 week late") would not normally prompt as much managerial attention as lateness by a month or so (i.e. "4-8 weeks") would.

Internal Complexity

Although all three companies make customised products, they have their own individual production scheduling characteristics that make them different from one another. For example, their production lead time is 9 to 12 months, 1 to 2 weeks, and 4 weeks for Company A, Company B and Company C, respectively. Thus, the complexity results of their internal production are presented separately, in the next three sections.

Table 5. Percentage of occurrence of states (suppliers' interface)

State	Company A	Company B	Company C
On time or early	32	75	84
< 1 week late	8	19	13
1-2 weeks late	17	3	0
2-4 weeks late	10	2	3
4-8 weeks late	10	1	0
> 8 weeks late	23	0	0

Company A

Table 6 shows the percentage of occurrences for each of the areas which can be rescheduled in the order book. It can be observed that the schedule adherence ("OK" state) accounts for 17% of the total. The following processes contribute almost equally: factored, project equipment and materials (between 14% and 15%). Most importantly, it can be observed that rescheduling of the order book due to the assembly area accounts for 22% of the total. This is not surprising, given the nature of the product which is engineer-to-order pumps, and which implies that there is a high level of uncertainty when making one-off products.

Table 6. Order book rescheduling by production process at Company A

Production process	%
OK (production according to schedule)	17
Assembly	22
Factored	15
Project equipment	15
Materials	14
Machining	10
Fabrications	7

Figure 4 shows that the amount of complexity that is handled at Company A accounts for 2.80 bps, which is classified as high in this research. The value-adding complexity (represented by the black bar) accounts for 15% of the total, and the state that contributes the most to the non-value adding complexity is "assembly." Assembly consists of a series of steps, some of which are outsourced, so the performance is highly influenced by the performance of the outsourcees.

Company B

Table 7 shows that on time or according to the schedule production accounts for 46% of the total. The data used in the table corresponds to the combined live and historical data. Also, it can be seen that the percentages increase with lateness (i.e. once Company B has missed the production scheduled date, the customised product is expected to be made later rather than sooner). This can be due to technical issues, such as the different behaviour of the chemicals in the shop floor compared with the experiments carried out previously in the laboratory.

In Figure 5, we observe that Company B manages a high overall amount of complexity, at 2.16 bps, and that the value-adding complexity (represented by the black bar) accounts for 24% of the total. Then the non-value adding complexity states increase with lateness, with the biggest one coming from the ">8 days late" state. This can be attributed to technical errors during production and to knock-on effects in the production schedule.

Table 7. Actual versus scheduled production performance at Company B

State	%
On time	46
<2 days late	6
2-3 days late	6
3-6 days late	12
6-8 days late	12
>8 days late	18

Company C

During the period for which data were collected, which comprised both live and historical data, Company C's production was always on time or early. This was mainly due to the fact that the standard delivery time had been set to four weeks, which gave plenty of time to account for any unforeseen circumstances that could delay production. So, Company C's way of absorbing complexity consisted of allocating high spare capacity levels in their original production schedule. This also relates to the "spare capacity" identified earlier as another way of managing complexity

Figure 4. Internal entropic-related complexity at Company A (2.80bps)

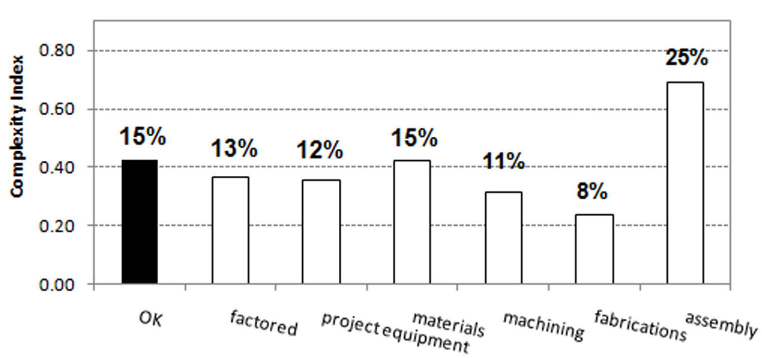


Figure 5. Internal entropic-related complexity at Company B (2.16bps)

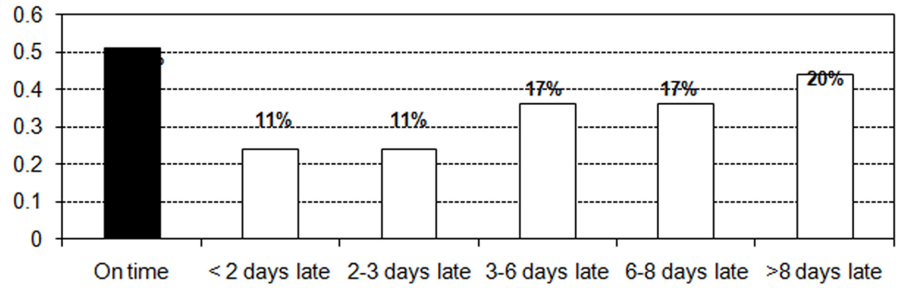

instead of "rescheduling." It was also noted that Company C placed a strong emphasis on fixed delivery dates with the customer, so once these are agreed with them, deadlines are quite firm, with the customer potentially bearing the costs for any rescheduling caused by them.

Further analysis was performed regarding the earliness of production, as seen in Table 8. It can be observed from this table that 50% of the doors were finished up to a week early; another observation is that the percentage of finished doors decreased with increased levels of earliness.

The overall amount of complexity handled at Company C, at 1.99 bps is in the medium range (1-2 bps), as seen in Figure 6. The value-adding complexity or "on-time" delivery accounts for 21% of the total. It could be argued that finishing products early is value-adding, since once the doors are completed the resulting spare capacity could be used for accommodating other orders. However, finishing products too early, such as the last three states ("9-11," "11-13" and ">13" days early) may be tying up capital that could be otherwise used, doors could become damaged or lost, and physical space may become an issue if the business were to expand. That is why those early states have been classified as non-value adding. This understanding was communicated to and validated by the company during the presentation of results.

Table 8. Actual versus scheduled production performance at Company C

State	%
On time	16
<7 days early	50
7-9 days early	19
9-11 days early	5
11-13 days early	5
>13 days early	5

It is worth mentioning that Company C's performance is remarkable, because no instances of late internal production were identified during the analysis period. This case is unusual among the other case studies carried out to date by the authors. The fact that 74% of Company's C requested deliveries were classified as fast turnaround (FTA) or rush orders makes its reliable performance even more surprising.

Customers' Interface

The entropic-related complexity was calculated at the customers' interface too. Table 9 shows the percentage of occurrences for each state at each company. It can be seen in this table that Company A and Company B exhibit about 60% on time or early deliveries to customers, compared with 98% from Company C. It is also shown that the last two lateness states ("4-8" and ">8 weeks" late) are heavily occurring in the case of Company A, but are hardly seen in Company B or Company C.

Figure 6. Internal entropic-related complexity at Company C (1.99bps)

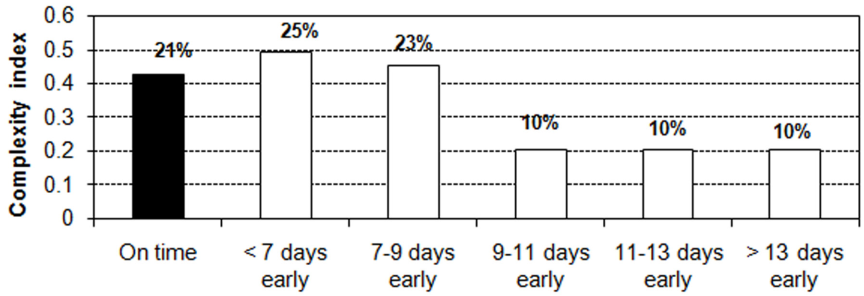

Table 9. Percentage of occurrence of states (customers' interface)

State	Company A	Company B	Company C
On time or early	61	62	98
< 1 week late	2	20	2
1-2 weeks late	5	9	0
2-4 weeks late	7	7	0
4-8 weeks late	10	1	0
> 8 weeks late	14	1	0

In this context, Figure 7 shows that Company A and Company B exhibit a medium amount of complexity (1-2 bps), whereas Company C transfers a very low amount (<1 bps). Company B and Company C show a similar pattern in terms of the states, with the highest being "<1 week late," and then decreasing complexity as the lateness increase. This means that once these companies have missed a promised delivery date they will try to deliver sooner rather than later. Company A's deliveries show a different pattern, with a distinctive increase of the complexity as lateness increases (Figure 7). The reason for this behavioural pattern is that, having missed the deadline, efforts are made to deliver as soon as possible, to avoid reaching and surpassing the penalties ceiling. Once this ceiling is surpassed, the efforts are then directed towards other projects (pumps) that may be in danger of becoming late, too.

Summary of Entropic-Related Complexity Results

Table 10 summarises the results presented so far in this chapter. The results indicate that the higher the complexity at the suppliers' interface, the higher the complexity handled internally. As mentioned earlier, the more complexity is imported by suppliers or customers into the organisation, the more complexity the company would need to handle internally. So, not surprisingly, good suppliers enable good internal performance. It was also noticed that all three companies handled less complexity at their customers' interface than the complexity they handled internally. This can be explained as the case study companies absorbing complexity (i.e., using ways of managing complexity such as "rescheduling" and the use of "spare capacity" in the production schedule to absorb it). It was suggested to companies that they should make their customers aware of this fact. By doing this, customers could become more amenable to pay a Premium (cost of peace of mind), as in the case of Company C; this approach could also help ease some of the pressure from Company A. These understanding and control mechanisms can be linked to the variety and uncertainty of processes, which in the case of customised products were prone to happen more often, as seen in Company B.

Figure 7. Entropic-related complexity at the customers' interface

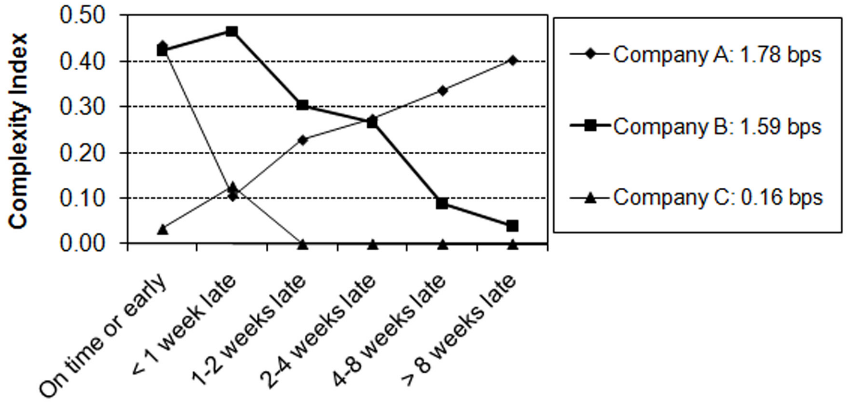

Table 10. Entropic-related complexity in bits per state (bps)

Case study	Suppliers' interface	Internal complexity (value adding %)	Customers' interface
Company A	2.41	2.80 (15%)	1.78
Company B	1.09	2.16 (24%)	1.59
Company C	0.76	1.99 (21%)	0.16

Note: <1:low; 1-2: medium; >2: high

Hybrid Rescheduling Algorithms Results

Company A

The emphasis of the production of the pumps at Company A was on the deadlines for achieving the milestones of each project (pump). If a need for rescheduling occurred, Priority was given according to the importance of the project (dictated by its monetary value). Company A operates in a highly regulated supply chain environment, with contractual clauses which will penalise it for not delivering on time to the customer. In terms of the level of disruption transmitted to the shop floor, the scheduler at Company A would consider the customer requests carefully against all the projects that were in the pipeline, and would just delay the jobs rather than pre-empt and interrupt the course of the jobs already running. So, Low disruption was transmitted to the shopfloor. Therefore, it could be concluded that Company A's preferred hybrid rescheduling algorithm was Priority Low (Figure 4).

Company A's poor performance at the customer interface is mostly the result of a knock-on accumulated effect of its suppliers' failure to deliver on time and in full, and of its own NVA internal complexity.

Company B

In terms of rescheduling strategies, it was observed that Company B was using Utilisation-based rescheduling strategies. This is because it was normally operating with large amounts of spare capacity, in the form of idle vessels. Thus, when a rush order was requested by a customer, Company B could easily accommodate it in its current production schedule by allocating the rush order to one of the vessels that was available. In terms of disruptions transmitted to the shopfloor, the objective of the scheduler was to satisfy the customer. As a result, the production schedule was updated quite often, on a shift-by-shift basis. So, it could be concluded that Company B's preferred hybrid rescheduling algorithm was Utilisation High (Please note that "High" refers to the high disruption transmitted to the shopfloor and not to high utilisation). See Figure 5.

In terms of the disturbances due to customer requests, Company B showed the following common requests: (a) increasing the priority of existing orders, and (b) introducing new orders, which were mostly rush orders. From the interviews at Company B it was found that it had verbal agreements with suppliers and contractual agreements with customers. This was because, as Company B's customers are a small set of paper mills (who may switch to another supplier if not satisfied), they had to pay extra attention to customer service. This could place Company B in a vulnerable situation in the context of its supply chain, since power can be imbalanced (New & Ramsay, 1997).

Company C

Company C did not need to carry out rescheduling at all (Figure 6) – the reasons for this are explained next. Firstly, at the suppliers' interface, Company C carefully selected its suppliers, such that they were highly dependable. It is worth mentioning that Company C was in a position to do so, as they focussed on a niche in the market, raising issues of costs versus added-value. Internally, spare capacity was built in the production schedule, so it remained mostly unaffected by disturbances (again a way of absorbing complexity). At the customers' interface, Company C used formal contracts with customers to protect itself against last minute changes. As a consequence, Company C did not need to reschedule its production at all during the studied period. This result was due to including spare capacity in its production schedule, and to its careful selection of suppliers and customers. This solution may be more suitable and feasible in the Company's C industry type rather than in other industries.

Customised vs. Commodity Production

Table 11 deals with the comparison between customised and commodity production results. Key differences between these two types of production on observed rescheduling practices are:

- The use of threshold conditions (associated with Low disruption rescheduling algorithms) for carrying out rescheduling is more common in customised production than in commodity production. Threshold conditions mean the use of decision making points in order to filter disruption transmitted to the shop floor due to disturbances (Low disruption). Typically companies of

Table 11. Rescheduling characteristics: customised vs. commodity production

Rescheduling characteristics	Customised production	Commodity production
Product unit cost (£)	High	Low
Product type	Specialised	Standard
Pace of production	Slow	Fast
Threshold conditions used for production rescheduling	More common	Less common
Spare capacity embedded in the production schedule	Medium to High	Low to Medium
Company protected by contractual agreements with customers	Very common	Not common
Preferred hybrid rescheduling algorithms for reducing entropic-related complexity	*Priority Low* (Company A) and *Utilisation High* (Company B)	*Utilisation High* and *Right-shift* (Huaccho Huatuco *et al.*, 2009)

customised production are protected by formal contracts against customer changes, with attached penalties / premiums for last minute changes or late deliveries.
- Spare capacity in the original production schedule is higher in the customised production than in commodity production.

A key similarity between the two contexts is that *Utilisation High* is a useful hybrid rescheduling algorithm in both customised and commodity production. Additionally, *Priority Low* (as observed in Company A) is better suited for customised production, and *Right-shift* is better suited for commodity production.

RECOMMENDATIONS TO CASE STUDY COMPANIES

The following recommendations were given to the case study companies; these are linked with Table 3, about the issues identified:

Suppliers' Interface (Figure 3)

- Company A (high complexity): Exercise tighter control over suppliers' performance, develop partnerships with key reliable suppliers, and allow the production schedulers to play a more important role in the process of purchasing materials or components. This approach will allow Company A to focus on managing its own internal complexity, by first reducing the uncertainty of suppliers' deliveries. However, it should be kept in mind that changing structures / responsibilities could be difficult in a large company such as this. Change should be driven by the top management with direct involvement of the shopfloor management and operators, and it should be carefully monitored and controlled to ensure that the overall objectives are achieved.
- Company B (medium complexity) and Company C (low complexity): Maintain the good planning of purchasing materials by the production scheduler, and further develop good relationships with reliable suppliers. These were identified through observations / interviews with the productions schedulers at these companies.

Internal Complexity (Figures 4, 5 and 6)

- Company A (high complexity): Synchronise production machining-assembly-test, in order to avoid bottlenecks, and improve forecasting of delivery dates (they were too optimistic) by allowing some slack in the production schedule, to cater for unforeseen problems (this recommendation also applies to Company B). This may allow the schedule to become more robust, therefore reducing the need for rescheduling. However, it is acknowledged that they may find allocating slack time in the schedule is too costly, if there are idle times when many jobs are waiting to be processed.
- Company B (high complexity): Continue monitoring the production system; rescheduling does help towards delivering the products on time.
- Company C (medium complexity): Improve forecast of delivery dates (they were too pessimistic), since most of the complexity is coming from earliness. This is a potential problem, and the company was made aware of this at the result presentation. This may seem to contradict the earlier "slack in the schedule" recommendation. However, it was noticed that Company C was overbuffering itself, and it could easily promise the customer and achieve "on time" deliveries of standard

products up to 3 weeks instead of 4 weeks, should they wish to do so.

Customers' Interface (Figure 7)

- Company A (medium complexity): Develop partnerships with customers, with especial review of the contractual agreements and the applied penalties in case of lateness.
- Company B (medium complexity) and Company C (low complexity): Develop threshold conditions regarding rush orders or fast turnaround products (FTA). This will allow Company B to achieve Low disruption transmitted to the shop floor because, during the period of study, the customers were taking for granted that their requests will be taken into account without penalty. For Company C, the threshold is so wide that it could risk becoming uncompetitive, should its competitors offer to provide the same product faster.

Although managers knew that certain areas were more complex than others, entropic-related complexity allowed them to measure and to compare the complexity levels. The ability to integrate and quantify complexity in a single comparable measure was considered useful by managers, and it provided a basis for fruitful discussions between researchers and practitioners.

DISCUSSION OF RESULTS

The counter-intuitive result in this chapter is that companies in customised production do not necessarily face high levels of complexity. This is because, as observed in the companies reported in this chapter, in practice companies in customised production ensure that they have formal contractual agreements in place for the delivery of the final products. Also, these companies ensure they have the resources to enable them flexibility, and to cope with the additional process complexity due to customisation. This can work in their favour, such in the case of Company C, which uses spare capacity as a buffer to protect itself from disturbances. Alternatively, it could work against the company, such as in the case of Company A, which tries to avoid the lateness penalties of its tightly arranged schedule. It could be argued that Company C operated in a niche market and could afford to place higher conditions onto its customers, than, for example, Company B, for which competition is more intense.

Table 12 compares the results previously reported in the literature by the authors (Huaccho Huatuco et *al.*, 2009) with the results of the case studies reported in this chapter. It can be seen that *Utilisation High* achieves lower levels of entropic-related complexity than *Priority Low*, in both customised and commodity productions. However, customised production shows, surprisingly, a lower level of complexity than commodity production for both identified hybrid rescheduling algorithms. In order to explain this, it is important to use the case-based research methodology to investigate entropic-related complexity, since it also captures the qualitative aspects through interviews and observations. Direct observations and historical data have been used to obtain meaningful results, by providing explanations from schedulers and managers about the reasons for rescheduling. Historical data can also help to smooth out any unusual performance into a more stable, and thus representative pattern.

Implications for Scheduling Practice

The more threshold conditions are embedded in the hybrid rescheduling algorithm, the less disruption is transmitted to the shop floor. So, this chapter encourages manufacturing organisations to be reactive to disturbances, whilst also taking into account thresholds for deciding when to re-

Table 12. Entropic-related complexity for each hybrid rescheduling algorithm: customised vs. commodity production

Hybrid rescheduling algorithm	Customised production	Commodity production*
Priority High	Not identified	2.731[b]
Priority Low	2.800	3.028[a]
Utilisation High	2.160	2.709 [b]
Utilisation Low	Not identified	2.713 [b]
Right Shift	Not identified	2.712 [b]

*Taken from Huaccho Huatuco *et al.* (2009): (a) The complexity associated with the information content of schedules and (b) The complexity associated with the variation between schedules (bps).

act. As discussed in the literature review section (Monostori *et al*., 2007; Pfeiffer *et al*., 2007), thresholds could be tested at different levels using computer simulations in order to test 'what if' scenarios and taking into account the studied organisation's objectives.

The High disruption algorithms (*Priority High* and *Utilisation High*) monitor the state of the system and react whenever there is a disruption. This is called event-based rescheduling. However, that reaction is constrained sometimes because the alternative machine is busy, but the effort to check alternative machine availability had already been made. Whereas the Low disruption algorithms (*Priority Low* and *Utilisation Low*) monitor the state of the system, they only react if the remaining processing time is greater than a threshold. When executing the *Right-shift* algorithm there is less need to update the schedule, as it only affects the jobs on the affected machine.

Value-Adding (VA) vs. Non-Value Adding Complexity (NVA)

Table 10 depicts the value adding percentage of internal complexity. In this chapter value adding is related to "on time or early" production, as it is assumed that these states will allow a manufacturing company to satisfy its customers. In this respect, Company B and C achieved over 20% VA complexity, whereas Company A achieved a 15% VA complexity.

It is worth mentioning that determining what is VA and NVA complexity depends on the company or industry sector under study. A trade-off of the potential benefits versus losses should be performed in order to give more general insights and to decide the VA and NVA states and complexity.

Even when a company is handling a high amount of VA complexity, this still needs to be managed by the company. However, a different type of action is needed for this. As mentioned in the Appendix: "Key Terms and Definitions," the manager would need to decide on the VA complexity level it could allow into the system depending on the company, sector and wider context.

The NVA complexity, which is the complexity that does not help with satisfying the customers, needs to be both monitored and controlled. NVA complexity could possibly not be entirely eliminated, but it can be reduced. In order to do this, the reasons that cause it in the first place need to be identified and analysed.

CONCLUSION

The conclusions section provides theoretical-based insights for customised versus commodity production, and it derives practical guidelines for production managers / schedulers about the hybrid rescheduling algorithms which are more likely to succeed in practice.

The main research question explored in this chapter was: *In the context of customised production, how do hybrid rescheduling algorithms impact entropic-related complexity?* The following objectives guided this chapter: (a) To identify the typical hybrid rescheduling algorithms used in the context of customised production, and (b) To explain why and how hybrid rescheduling algorithms vary across organisations.

For the research question, it can be seen from the results that *Priority Low* (originated from Company A) generates higher complexity indices than *Utilisation High* (originated from Company B). This can be dependent on the context of the organisations studied, for example production lead times were longer at Company A than Company B. It was also confirmed that the less rescheduling is carried out the lower the complexity, with Company C (SME making customised production) showing a level of complexity management that could serve as a beacon for other companies. As a reminder, Company C embedded flexibility into their manufacturing process by allocating spare capacity in their production schedule.

A counter-intuitive finding was that the entropic-related complexity associated with customised production was lower than that related to commodity production. This could be explained by the fact that commoditised production typically faces tougher competition; the customer could easily switch from one supplier to another and this can happen as late as already placed orders or production set into motion (Sivadasan *et al.,* 2010). By contrast, in the case of customised production, once the customer has made up their mind and agreed to the specification of their product (which had been discussed in order to match its specifications), then the company is protected (or bounded) by contract to provide what has been agreed. This leads to a more stable production schedule in practice.

Regarding the first objective, it could be argued that manufacturing organisations in customised production prefer the two hybrid rescheduling algorithms identified in this chapter: *Priority Low* and *Utilisation High*. However, this is dependent on the companies selected for the case studies, so different companies may use different hybrid rescheduling algorithms. With respect to the second objective, several other factors not included in this chapter could have an influence on the different choices of hybrid rescheduling algorithms by manufacturing companies, production lead times (e.g. weeks or months) or the type of competition (e.g. sheltered or competitive).

Implications for Theory and Practice

This chapter brings a novel and analytically-based insight into the effects of hybrid rescheduling algorithms on entropic-related complexity. An unpredicted result—of customised production leading to lower complexity than mass production—is highlighted and explained. The work presented in this chapter has shown the application of concepts derived from previous research carried out by the authors to real-world manufacturing companies. As stated earlier, the two quadrants of interest to the work presented in this chapter were: "functional product, responsive scheduling" and "innovative product, responsive scheduling" (Huaccho Huatuco, 2003). The former refers to commodity production, whereas the latter refers to customised production.

Organisations that belong to the "functional product, responsive scheduling" quadrant can manage complexity through decision-making and rescheduling. Here the key point is to be responsive to customer requests by adapting the current scheduled quantity. This was observed in previous case studies carried out by the authors (Sivadasan *et al.*, 2010).

Organisations that belong to the "innovative product, responsive scheduling" quadrant, which are made-to-order of customised products, can deal with complexity through spare capacity and rescheduling in order to become responsive. In this chapter it has been found that *Priority Low* and *Utilisation High* are the preferred hybrid rescheduling algorithms used by manufacturing organisations in practice. However, these results should not be taken prescriptively. Each company should identify its main objectives, and design and manage the system consistently with these objectives. The thresholds/ tolerance limits / trade-offs of spare capacity should be analytically investigated and linked with each company's ability to manage the additional complexity, either value- or non-value adding, associated with these decisions. In this line, companies should reserve spare capacity for products at greater risk of mismatch between their supply and demand, since additional spare capacity in the production schedule can be a detriment to internal performance measures and a drain on costs.

Future work should consider the possibility of carrying out extra case studies for customised production to see whether the other rescheduling strategies are used in practice: *Priority High, Utilisation Low* and *Right Shift* in the context of customised production environment. Another future work direction could be to design, set up and run computer simulations, which should include some spare capacity already built-in the Original Schedule (OS), a sign of robust and sound scheduling methods. Then, a comprehensive statistical analysis of results could be performed.

KEY TERMS AND DEFINITIONS

Commodity Production: Commodity production refers to the production of mass produced, standard or off-the-shelf products.

Customised Production: Customised production refers to the production where the customer's preferences for the configuration of a final product are taken into account.

Entropic-Related Complexity: Entropic-related complexity is defined as the expected amount of information required to describe the state of the system (Calinescu *et al*., 2000). It is based on "entropy," which was first proposed in the seminal work by Shannon (1949), and was later adapted to manufacturing systems by Frizelle & Woodcock (1995) and Efstathiou *et al.* (1999). As a result, a number of studies about the entropy measure in the context of manufacturing systems emerged (e.g. Sivadasan *et al.*, 2002, 2004, 2006, 2010 and Huaccho Huatuco *et al.*, 2009). Entropy captures two characteristics of complexity: the variety and uncertainty within the system, corresponding to the structural and operational complexity, respectively (Calinescu *et al*., 2000).

Hybrid Algorithm: Taking the separate definitions of "hybrid" and "algorithm" from the Oxford Dictionary (Hornby, 2000), and combining them, a "Hybrid algorithm" can be defined as the product of mixing two or more sets of rules that must be followed when solving a particular problem. In this chapter the problem refers to rescheduling manufacturing systems.

Non-Value Adding (NVA) Complexity: Non-value-adding (NVA) complexity is the complexity that is not helping the company achieve the satisfaction of its customers (e.g. in the form of late deliveries). This complexity needs to be both monitored and controlled, in order to reduce it and mitigate its possible consequences. For a paper on VA and NVA complexity, please refer to Huaccho Huatuco *et al.* (2001).

Rescheduling: Rescheduling, also known as "predictive-reactive scheduling" (Vieira *et al.*, 2003; Morton & Pentico, 1993), is defined in this chapter as changing the schedule in terms of time, quantity or product specifications in response to disturbances (Huaccho Huatuco *et al*., 2009). Disturbances can be of internal or external nature. Internal disturbances are those that occur within the manufacturing system, such as machine breakdowns; whereas external disturbances are those that occur outside the manufacturing system, such as customer changes (Calinescu *et al.*, 1998). Rescheduling affects the performance of manufacturing organisation(s) (Herrmann, 2001; Hermann & Delalio, 2001; Hermann & Pundoor, 2002). Previous research normally uses traditional measures, such as mean tardiness to evaluate the effectiveness of the rescheduling procedure (e.g. Bean *et al.*, 1991).

Value Adding (VA) Complexity: Value adding (VA) complexity is defined in this chapter as the complexity needed to satisfy the customers (e.g. in the form of "on time" delivery). This complexity needs to be managed too, with the manager judging the level that is suitable to allow into the system. This decision depends on the company, its industry sector and wider context where it operates.

Chapter 81
Negotiation Protocol Based on Budget Approach for Adaptive Manufacturing Scheduling

Paolo Renna
University of Basilicata, Italy

Rocco Padalino
University of Basilicata, Italy

ABSTRACT

The research proposed concerns the development of a multi-agent scheduling approach able to support manufacturing systems in different dynamic conditions. The negotiation protocol defined budget approach is based on a financial asset that each part obtains when it is released into the manufacturing system for processing. The part spends the budget to perform the manufacturing operations by the workstations; the virtual market in which part agent and workstation agents coordinate the decentralized system. A fuzzy tool is proposed to assign the budget to each part based on the objectives pursued. A simulation environment based on Rockwell ARENA® platform has been developed in order to test the proposed approach. The simulations are used to compare the proposed approach with classical dynamical scheduling approaches proposed in literature. The results show how the proposed approach leads to better results, and it can be selective among the different priority of the parts.

INTRODUCTION AND MOTIVATION

Nowadays, the competition is played in a market environment characterized by demand fluctuations, new product introduction, reduction of the products life cycle and random disturbances. Some disturbances can be: the failures of manufacturing machines or technological equipment; the importance of the parts can be modified; the objectives of the manufacturing system can change; etc. In this environment, a static scheduling approach leads to reduce drastically the performance of the manufacturing system when exceptions occur. Therefore, the manufacturing systems need

DOI: 10.4018/978-1-4666-1945-6.ch081

to dynamic scheduling to keep a high level of the performance when the conditions change. The dynamic scheduling concerns the possibility to take all decisions based on the current state of the manufacturing system. Ouelhadj and Petrovic (2009) classified the dynamic scheduling in three categories: completely reactive scheduling, predictive–reactive scheduling, and robust pro-active scheduling. (Mehta and Uzsoy 1999; Vieira et al. 2000, 2003; Aytug et al. 2005; Herroelen and Leus 2005). In briefly, the completely reactive scheduling is obtained taking the decisions in real time without a global scheduling in advance. The robust pro-active scheduling is performed building the scheduling in advance trying to capture the exceptions in advance. The predictive-reactive scheduling is a compromise between the two above opposite approaches.

The architecture to support the scheduling approaches in manufacturing systems can be classified in centralized and decentralized systems.

The centralized architectures are not flexible enough to adapt themselves to the dynamism and complexity needed in dynamic manufacturing system conditions.

The main requirements of a dynamic scheduling approach are the following:

- Agility: it is the ability to adapt quickly the scheduling to the dynamic conditions of the manufacturing system;
- Scalability: it is the possibility to add resources into the architecture and the expansion is possible without disrupting the entire architecture established
- Fault tolerance: the architecture can reduce the impact of failures occurred to any parts of the architecture.
- Computational efficiency; the problem of scheduling can be more complex to resolve in a single step.

The above requirements can be obtained by a decentralized architecture (Shen et al., 2001). The Multi Agent Systems are able to support the development of decentralized architecture. A MAS is an artificial system composed of a population of autonomous agents, which cooperate with each other to reach common objectives, while simultaneously each agent pursues individual objectives (Ferber, 1999). Among the several definitions agent, Woodbridge and Jennings (1995): "*an agent is a computer system that is situated in some environment, and that is capable of flexible and autonomous action in this environment in order to meet its design objectives. By flexible we mean that the system must be responsive, proactive, and social*". Multi-agent systems (MAS) have already demonstrated their potential in meeting such complex requirements (Monostori et al., 2006). In manufacturing, such as systems have demonstrated their ability to build up agile and reactive behaviour in various settings like enterprise integration and supply chain management (Swaminathan et al., 1996), dynamic system reconfiguration (Shen et al., 1998), learning manufacturing systems [Monostori et al., 1996), distributed dynamic scheduling (Chiuc and Yih, 1995; Váncza and Márkus, 2000), as well as factory control (Brennan, 1997).

A MAS to pursue a global objective needs to implement a coordination mechanism among the autonomous agents. The most common coordination mechanisms used are the Contract net protocol (Smith 1980), market based, auction based (Siwamogsatham and Saygin, 2004) and game theory (Zhou et al., 2009b).

In this chapter, a coordination mechanism based on market-like approach is proposed. The market like approach works like a classical marketplace where the increase of the demand for a product causes its price to rise, and vice versa, to fall. In the case of the manufacturing systems, the resources become the products and parts are buyers asking for these products. The parts have a budget to spend to perform the manufacturing operations buying a resource. The amount of budget allows the generic part to buy the resource that asks a price lower or equal the budget of the part. Therefore, the level of the budget defines what resources the generic part can buy and the related level of services of the resources (working time, efficiency, quality, etc.). The crucial activities of this coordination approach are the following: how the resources define its price and the budget assigned to the parts when they enter to the manufacturing system. The price of the resources outlines the mechanism of real time scheduling and control of the manufacturing system. The budget assignment to the parts interprets the objectives to pursue in terms of priority of the parts typology, due date, throughput, throughput time, etc.

The aim of this approach is to capture the dynamic conditions of the manufacturing system keeping a high level of performance and able to modify easily the objectives changing only one parameter: the budget assigned to the parts. A fuzzy tool is developed to assign the budget to each part based on the objectives of the manufacturing system. A simulation environment based on Rockwell ARENA® platform has been developed in order to test the proposed approach. In particular, the proposed approach is compared with a classical market like approach proposed in literature in order to highlight the behaviour in very dynamic conditions.

The chapter is organised as it follows. In Section 2 the discussion of the literature review is reported. In Section 3 describes the manufacturing environment and the main principles of our proposed distributed control method in Section 4. In section 5, the experimental environment is outlined. Finally, in section 6 the simulation test results are detailed while conclusions are drawn in section 7.

LITERATURE REVIEW

Many authors have addressed the problem of adaptive scheduling related to job shop with most of the approaches proposed based on heuristics and use dispatching rules.

Jeong and Kim (2005) have used simulation to evaluate the manufacturing system performance and selected an appropriate dispatching rule for scheduling the subsequent period. Chryssolouris and Subramaniam (2001) have proposed a dynamic scheduling approach based on a genetic algorithm (GA). At each event of the manufacturing system (machine breakdown, job arrival, mix change, etc.), the GA was run to select a new scheduling method. Trentesaux et al. (2000) proposed a distributed management system that selected the dispatching rule for an FMS based on the state of the manufacturing system. This research was rather focused on the design of a scheduling system. Maione et al. (2003) presented a MAS with a negotiation protocol using also fuzzy logic. As they found, this soft computing technique led to better performance but required more computational time in order to obtain acceptable results.

Cowling et al. (2001, 2003, 2004) and Ouelhadj et al. (2003a, 2003b) proposed a novel multi-agent architecture for integrated and dynamic scheduling in steel production. Each steel production process is represented by an agent, including the continuous caster agents, the hot strip mill agent, the slab yard agent, and the user agent. The hot strip mill and continuous caster agents perform the robust predictive–reactive scheduling of the hot strip mill and the continuous caster, respectively. Robust predictive–reactive scheduling generates robust predictive–reactive schedules in the presence of real-time events using utility, stability, and robustness measures and a variety of rescheduling heuristics.

Aydin and Fogarty (2004) proposed a parallel implementation of the modular simulated annealing algorithm for classical job-shop scheduling. A multi agent-system based on Java technology is proposed. The empirical results obtained show that the method proposed is scalable and decreases the CPU time compared with other approaches proposed in the literature.

Wonga et al. (2006) proposed an agent-based approach for the dynamic integration of the process planning and scheduling functions. The simulations show that the hybrid-based MAS, with the introduction of supervisory control, is able to provide integrated process plan and job shop scheduling solutions with a better global performance.

Zhou et al. (2009a) proposed an agent-based Decision Support System (DSS) for the effective dynamic scheduling of a Flexible Manufacturing System (FMS). The proposed DSS mainly includes six components: User Interface Agent (UIA), Criteria And Rules Selection Agent (CRSA), Performance Evaluation Agent (PEA), Scheduling Decision Selection Agent (SDSA), FMS database and Scheduling Knowledge Base (SKB). The functions of each component are discussed and a corresponding prototype system is developed. Finally, some examples are used to illustrate the decision process and to study the performance of the FMS under different dynamic disturbances.

Recently, some authors have developed coordination approaches inspired by the behavior of social insects like ants, bees, termites and wasp to. Valckenaers and Van Brussel (2005) presented the design of a holonic manufacturing execution system, that is an instantiation of the PROSA architecture (1998). The control and coordination mechanism is inspired by the ant colony foraging behaviour.

Zhou et al. (2008) proposed an algorithm based on Ant Colony Optimization in a shop floor scenario with three levels of machine utilization, three different processing time distributions, and three different performance measures for intermediate scheduling problems. The experimental results show that ACO outperforms other approaches when the machine utilization or the variation of processing times is not high. The procedure proposed is a centralized approach.

Renna (2009) developed two pheromone approaches for the job shop scheduling problem in a Multi Agent System environment. One is based on the past information of a part (throughput time of the manufacturing cell); and the other on the queue of the manufacturing cell. The proposed approaches are tested in a dynamic environment; the simulation results show how the approach based on the queue of the manufacturing cell performs better when the environment conditions are very dynamic.

Renna (2011) proposed a coordination approach for the multi-agent architecture based on the computation of internal and external indexes of the generic manufacturing cell. Several scenarios were considered: from static to very dynamic conditions for internal and external exceptions of the manufacturing system. The simulation results highlighted that the performance of the proposed approach outperforms the performance of a classical workload approach (benchmark) in all conditions. In the related FMS literature there are quite a few publications that deal with an extremely dynamic environment, where also the manufacturing system itself changes frequently. Most of the researches take a centralized approach and propose decision models that require intensive computations, hence are inadequate to control the job shop in real time. In this chapter, an adaptive scheduling approach is proposed that is capable to operate in a very dynamic environment. The proposed method is based on a budget that each job can spend on purchasing the service of manufacturing resources. The price computation of the cell is based on the evaluation of its local state as well as of the global state of the manufacturing system. The main motivations of our investigations are the following:

- Developing a simple methodology where only one parameter has to be set in order to keep a proper performance level of the manufacturing system

- Reducing the information communication among the agents of the architecture in order to obtain an approach to implement in real case applications
- Evaluates the performance of the proposed approach in a very dynamic environment where internal and external exceptions occur
- Integrating our model into a supply chain or extended enterprise. In fact, the only typology of information exchanged between the shop floor and the upper management levels is the importance of each job type that determines the budget assigned to the job

The principal advantage of our method is the possibility to adapt the scheduling approach to the change of the objective of the production planning level by setting only the parameter of the budget.

MANUFACTURING SYSTEM CONTEXT

The testbed for the proposed negotiation approach will be a production system consisting of a given number of cells. Each cell can perform any kind of manufacturing operations so that the resulting system is generic. The manufacturing system processes jobs, each consisting of operations to be executed sequentially. Jobs belong to various job types.

Scheduling decides about the assignment of a manufacturing cell to the next operations of running jobs, therefore it is a pure dispatching problem. If such decisions are made in a distributed way, the dispatching problem is to be solved through a negotiation between autonomous agents representing cells and jobs in a real time fashion.

A cell agent is associated to each workstation; it is an intelligent entity aimed at scheduling the cell's work with as high efficiency as possible. Moreover, when a new job arrives to the manufacturing system the corresponding job agent is created; it analyses the job's status locating the following operation to be scheduled. Dispatching problems for a given job are handled by negotiation between job and cell agents using a version of the well-proven contract net protocol (Smith, 1980). Accordingly, the negotiation process consists of the following steps:

1. Job agent analyses the job status and determines the job's next technological operation to be executed
2. Job agent sends a message to the cell agents informing them that an operation is pending for processing; afterwards, it remains waiting for the cell agents' answers
3. Each cell agent evaluates the workstation status at negotiation time t, calculates and provides a price
4. Job agent receives evaluations coming from all the cells and builds up an index for evaluating each cell's offer
5. Finally, the job is assigned to the cell that provides the best offer at the time t.

As the reader can notice, the above procedure is a simple auction based negotiation protocol. It defines the environmental relations of the autonomous agents involved in the work, but makes no assumption towards the agents' decision-making mechanisms. This means that the above protocol can be adapted to different objectives and decision mechanisms of the autonomous cell and job agents.

The assumptions of the Job-shop scheduling problem researched in this chapter are the following:

- There are n tasks, and each task consists of m operations.
- Each typology part has been given processing order, processing time and due date.
- Orders for production of different parts arrive randomly.
- Operations cannot be pre-empted.

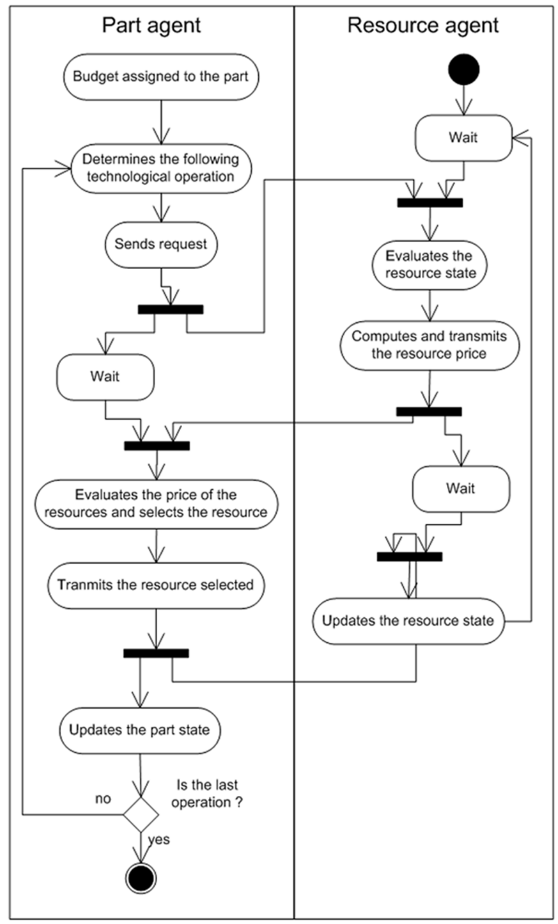
- Each machine can process only one task at once.
- Each machine performs the manufacturing operation with an efficiency, which sets the speed of the operation.
- The queues are managed by the First In First Out policy in order to investigate only the proposed strategy.
- Each machine can breakdown randomly.

In this research, the material handling time is included in the machining time, and the handling resources are always available.

BUDGET APPROACH

Our proposed approach is based on a budget level assigned to each job. The budget is an amount of fictitious money that the job can spend to acquire the manufacturing services. The financial aspects are not considered because we handle problems on the shop floor level where no real transfer of money is made. Essentially, the budget is used to coordinate the multi-agent system. The activity UML diagram in Figure 1 shows the process, with the following activities:

Figure 1. UML activity diagram



1. *Budget assigned to the part*. When a part enters to the manufacturing system, the amount of the budget is assigned to the part. In the following sub-sections is described the fuzzy tool proposed to define the amount of the budget.
2. *Determines the following technological operation*. The part agent determines the technological operation to perform based on the process plan of the part.
3. *Sends request*. The part agent sends a request to all manufacturing resources agent with the information related to the technological operation requested. The part agent waits for the answers by the resources' agent.
4. *Evaluates the resource state*. The resource agent evaluates the processing time of the technological operation requested, the queues of the parts, the failure state, etc.
5. *Computes and transmits the resource price*. The resource agent computes the price to submit to the part agent evaluating the resource state. As described in the following, a high price means high performance of the resource. Then, the resource agent submits the price to the part agent and waits for the part agent answer.
6. *Evaluates the price of the resource and selects the resource*. The part agent collects the price of the resources' agent and selects the price that the part agent can spend (based on

the amount of the budget). In particular, the part agent selects the higher price that can spend in order to buy the better resource. In order to avoid a deadlock, if the budget is not enough to buy any resources, the part is assigned to the worst resource (the resource with the lower price).

7. *Transmits the resource selected*. The part agent transmits the assignation of the part to the resource to the resources' agent.
8. *Updates the resource state*. The resource agent updates the state of the resource in terms of queues and technological operation to perform.
9. *Updates the part state*. The part agent updates the information of the parts and verifies if other technological operations are required. If the part needs another technological operation, the above process is repeated when the part ends the technological operation assigned.

PERFORMANCE INDICES AND PRICE COMPUTATION

The price computed by the resource agent is based on the state of the manufacturing resource.

Details of the price computation are given by the following expressions. The first expression computes a performance about the flow time of the parts, that is between 0 (worst performance) and 1 (better performance, no parts are in the queue).

$$NorFlowTime_m(t) = \frac{Max\Pr ocTime_{Type_{j,k}}}{FlowTime_m(t) + Max\Pr ocTime_{Type_{j,k}}} \quad (1)$$

where m is the index of the resource, $Max\Pr ocTime_{Type_{j,k}}$ is the maximum processing time for the technological operation k of the part of type j.

The effective service time $\left(EWT_j^k(t)\right)$ is obtained by multiplying this value with the resource's efficiency CTC_m, that is minor of one. A greater value of CTC_m, means that the generic resource is able to process the part with higher speed.

$FlowTime_m(t)$ is the expected throughput time of resource m computed by summing up the processing times of the parts waiting in the resource's queue plus the residual service time of the part being just worked in the cell at the negotiation time t. This index is the measure of workload of the manufacturing cell. The index value is one if no parts are in the queue and the resource is in the idle state, and decreases with the increase of parts in the queue.

Then, a Cell Failure Index, *RFI*, is computed as follows:

$$RFI_m(t) = 1 - \frac{FT_m(t)}{t} \quad (2)$$

where $FT_m(t)$ is the total time of failure status of resource until negotiation time period t. *RFI* above is the index of reliability of the manufacturing resource. This index value is one if no failure happens and decreases with the increase of the failure time.

A Resource Processing Time Index, *RPTI*, is computed as

$$RPTI_m(t) = 1 - CTC_m(t) \quad (3)$$

where $CTC_m(t) > 0$ is the efficiency of resource m at time t. The value of $CTC_m(t)$ multiplied by $TaskT_{Type_{j,k}}$ produces the expected working time of the resource. In particular, a lower value of $CTC_m(t)$ leads to lower expected time to manufacturing a generic part.

Then, an Internal Resource Index, *IRI* is computed by the following expression as a combination of the two above indices:

$$IRI_m(t) = \beta \cdot RFI_m(t) + (1-\beta) \cdot RPTI_m(t) \quad (4)$$

Finally, the External Resource Index, *ERI* is determined as follows:

$$ERI_m(t) = NorFlowTime_m(t) \quad (5)$$

The *IRI* is the average of the indices related to the cell, while the *ERI* is the index related to the manufacturing system status.

The so-called Resource Efficiency Index of the manufacturing resource is the following *REI*:

$$REI_m(t) = \alpha \cdot ERI_m(t) + (1-\alpha) \cdot IRI_m(t) \quad (6)$$

where α is a weight between the internal and external efficiencies. Note that the value of *REI* can assume the values in the interval [0,1].

The resource agent computes the price as follows:

$$Price_m(t) = K \cdot REI_m(t), \quad (7)$$

where the constant *K* is the maximum price of the cell.

Therefore, if the value of the *REI* index is one (the state of the resource is the better possible: no parts in the queue, no failures occur and higher speed of processing time), the resource agent asks the higher price K; otherwise the price reduces proportionally to the reduction of the *REI* index.

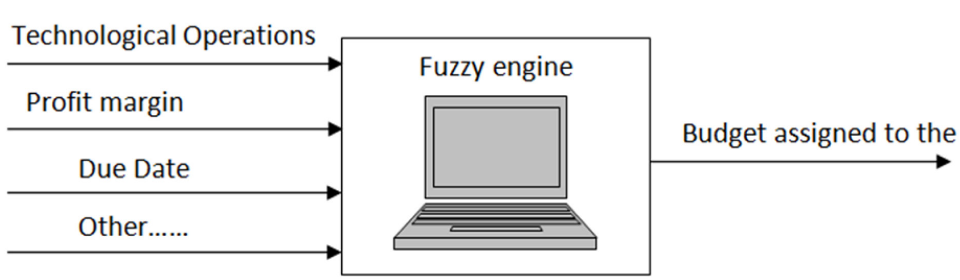
The job agent selects the resource with the highest price required, because high price involves a high level of performance of the manufacturing resource. If the job does not have the sufficient budget to pay the resource, it has to select a resource that requests a price compatible with the budget of the job. If all resources request such a price that the part cannot pay, the part is dispatched to the resource that requests the lowest price (deadlock avoidance). Finally, the part and resource agents update their budget for processing the subsequent operations.

Budget Allocation

A fuzzy approach has been proposed to assign the value of budget to each part type. Figure 2 shows this fuzzy engine whose inputs data are the following:

- Technological operations: the number of operations that the parts have to get processed by the manufacturing system. The increase of this number leads to increase the level of the budget (more resources to buy).
- Profit margin: the level of profit margin related to the product type. The increase of the profit leads to increase the level of the budget (greater importance of the product type).

Figure 2. Inputs and output data of the fuzzy tool



- Due date: a closer due date leads to increase the budget assigned to the part, so that the part can have a chance to get better manufacturing resources in order to minimize the delivery delay.
- Other: other inputs can be easily added to the fuzzy engine to include other characteristics of the part.

The only output of the system is the level of budget allocated to the job.

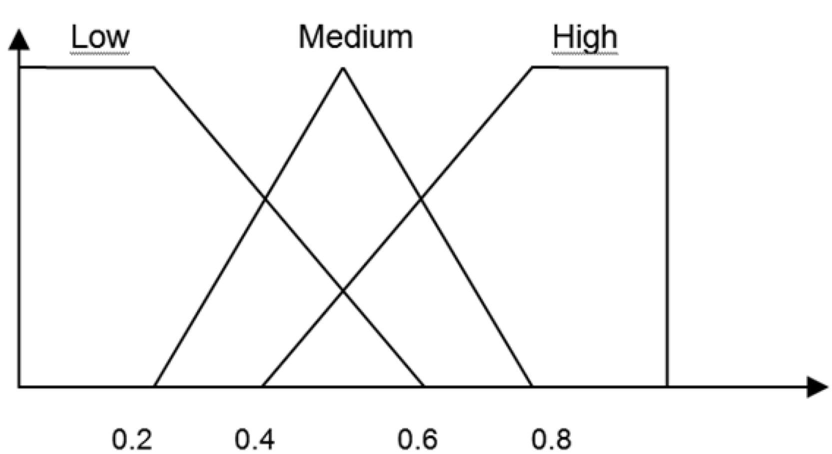
For each input there is defined the following fuzzy set (see Figure 3):

Table 1 shows the value of the inputs of the fuzzy systems for the test case where, as the reader can notice, the technological operations can assume values like 2, 3, 4 and 5. The profit margin of products is classified in three categories: 1 stands for low, 2 for medium, and 3 for high. Finally, the due date input depends on the value of the multiplier of the technological operation time.

Table 1. Fuzzy inputs value

	low	medium	high
Technological operations	2	3 - 4	5
Profit margin	1	2	3
Due date	[3-4]	[2-3)	[1.5-2)

Figure 3. Fuzzy sets



The fuzzy inference rules applied are the following:

no.	rule		budget
1	IF due date is High	THEN	High
2	IF due date is Medium	THEN	Medium
3	IF due date is Low	THEN	Low
4	IF number of technological operations is High	THEN	High
5	IF number of technological operations is Medium T	THEN	Medium
6	IF number of technological operations is Low	THEN	Low
7	IF profit product is High	THEN	High
8	IF product profit is Medium	THEN	Medium
9	IF product profit is Low	THEN	Low

The budget assigned to the part is obtained by activating the above fuzzy rules; among the rules with the same consequent is adopted the rule with higher membership. The rules are arranged by the "maximum" method and the de-fuzzification is done by the centre gravity method. The crisp value *z_out* leads to assign the budget to the jobs by the following expression:

$$Budget = \begin{cases} High & 0.625 \le z\_out \le 1; \\ Medium & 0.325 \le z\_out < 0.625; \\ Low & 0 \le z\_out < 0.325; \end{cases} \tag{8}$$

Alternative Solution Methods

In order to validate the operation of the proposed approach, it has been compared with other on-line scheduling methods; some of them taken from the literature (Jeong and Kim,1998; Smith, 1980). For all these solvers, the negotiation protocol is the same as presented in Section 3. Where they differ is the offer formulation and how the resource's choice is made. The following six methods have been experimented with:

- Budget: The Budget Approach, as described above.
- Budget+DIS: The Budget Approach is combined with the heuristic dispatching rule LowValueFirst: DueDate.
- Slack1: Each cell evaluates Service Time End (STE), the estimated finish time of the task subject to negotiation. STE is calculated in the following way:

$$STE_m(t) := \sum_{i}^{NQ} EWT_j^k(t) + Res_m(t) \quad \forall j \in Queue_m \tag{9}$$

where *NQ* is the number of jobs in the cell's queue, while Res_m is the estimated remaining operational time of the actual running job. The job agent calculates *SlackOp* in the following way:

$$SlackOp := \frac{DueDate}{\sum_{k=k^*}^{Ntask} Max\Pr ocTime_k} \tag{10}$$

where *k* is the task under decision. Job agent choices the cell which has the following minimum difference:

if *SlackOp* > 0, $\min_m (SlackOp - STE_m)$

If *SlackOp* < 0, $\min_m (STE_m)$ (11)

Slack2: As the previous one, but *SlackOP* is divided by 2, to compensate for system delays. Several values are tested and value 2 leads to better performance measures for the test case investigated.

Slack3: *SlackOp* is calculated in a different way:

$$SlackOp := \frac{DueDate}{\sum_{k=k^*}^{Ntask} TaskTime_k} - NQ \cdot MTD - AvTTR \tag{12}$$

where *MTD* is the maximal possible delay in each task execution and *k* is the task under decision; in this model *MTD* = 5. *AvTTR* is the mean failure length.

MinSTE: Each cell evaluates the *STE* (Service Time End), the estimated finish time of the request task as in *Slack1*. The job agent chooses cell *m* corresponding to $\min_m (STE_m)$.

SIMULATION ENVIRONMENT

The manufacturing system processes various parts that arrive according to an exponential distribution. A part type is specified by a sequence of tasks (so-called routing, see Table 2) to be processed and the maximum processing times (*MaxProcTime,* see Table 3) of the tasks. Tasks belong to various task types, each having a fixed routing.

Each *part* $Type_i$ has its $InterArrivalTime_i$, (exponential distribution is used) which can be easily set. Hence, the mix of jobs is determined

Table 2. Routings

Type	Tasks				
Type 1	2	1	3	4	
Type 2	3	2	1		
Type 3	1	4			
Type 4	4	3	1	3	2

Table 3. Maximum process times

Type	$Max\,ProcTime_{Type_j,k}$					TPT
Type 1	20	25	15	18		78
Type 2	30	25	19			74
Type 3	15	27				42
Type 4	20	25	30	15	20	100

TotalProcessTime(*TPT*) is the sum of the *MaxProcTime* for each job type.

stochastically by the *InterArrivalTimes* setting. An example is reported in Table 4. Each part has a *DueDate* that is set when the job arrives at the system. Each *DueDate* is calculated according to the following rule:

$$DueDate_i := CoeffDD_{Type_j} \cdot TPT_{Type_j} \tag{13}$$

The coefficient *CoeffDD* is characteristic to the job type (see Table 5); its actual value is taken from uniform distribution, according to the following rule:

$$CoeffDD_i = unif(CDDmin_i, CDDmax_i).$$

The resources are able to process various task types; in the following table the resource - task type assignment is marked. The system is reconfigurable, so these assignments can be changed. Value 1 indicates that the cell can execute a particular type of task, and 0 otherwise (see Table 6).

Table 4. Inter-arrival times

Type	Type 1	Type 2	Type 3	Type 4
Inter-Arrival Time	15	10	12	18

Table 5. CDDmin and CDDmax

Type	Type 1	Type 2	Type 3	Type 4
$CDDmin_i$	1.5	2	3	2
$CDDmax_i$	2	3	4	4

We assume a real dynamic environment, so we consider a production stage: in each production stage the characteristics of the manufacturing resource CTC_m (see Table 7) and the time between failures TBF_m are modified. So the Expected Working Time *EWT* depends on CTC_m and it is:

$$EWT_j^k(t) = CTC_m(t) \cdot Max\,ProcTime_{Type_j,k} \tag{14}$$

The *TaskDelay* is calculated according to the following rule:

$$TaskDelay := \begin{cases} 0 & P(p < \gamma) \\ unif(1,5) & P(p > \gamma) \quad where\ \gamma = 0.5 \end{cases} \tag{15}$$

p is a random number between 0 and 1 that emulates the probability that an unforeseen event causes a delay of the part during a manufacturing

Stage 5	6.30	3.27	3.40	5.20	6.00

operation. The value γ=0.5 means that the probability of this event is the 50%. The cells may break down, and this failure model is also included in the model. Failure is a stochastic event (see Table 8): each failure happens according to an exponential rate that is $30 \cdot TBF_m$.

Failure Length (FL) is a stochastic variable taken from an exponential distribution: $FL := exp(C)$ where C is a constant. Finally, there are no setup times and transport times, while buffers and the queues can be infinite.

Experimental Plants and Streams

This section describes how a simulation test-bed, model, and case study have been developed in the Arena® simulation environment in order to test the behaviour of the presented approach. All the solvers have been compared with different streams of jobs and experimental plans. The experimental plan is a particular configuration of the manufacturing system. The stream is a sequence of parts arriving into the system. The idea is to compare results in all possible configurations of the manufacturing systems, under different workload and/or production mix conditions. In this section, there are presented 5 different streams of part arrivals and 5 different experimental plants. Hence, there are 25 experiments for each solution method. Each experiment is a combination of a stream and a plant with 50 replications.

- Experimental Plan 1: Plant is deterministic; absence of failure; Number of cells is 10; CTC_m as in Table 7; Cell – Task Type assignment as in Table 6.
- Experimental Plan 2: Number of cells is 10; $CTCm$ as in Table 7; Cell – Task Type assignment as in Table 6; TBF_m as in Table 8; $FL := exp(30)$.
- Experimental Plan 3: Number of cells is 10; CTC_m as in Table 7; Cell – Task Type assignment as in Table 6; TBF_m as in Table 9; $FL := exp(15)$.
- Experimental Plan 4**:** Number of cells is 7; CTC_m as in Table 10; Cell – Task Type assignment as in Table 6; TBF_m as in Table 8; $FL := exp(30)$.
- Experimental Plan 5: Number of cells is 6; CTC_m as in Table 7; Cell – Task Type assignment as in Table 6; TBF_m as in Table 8; $FL := exp(30)$.

In Table 11 there are demonstrated the steam features.

SIMULATION RESULTS

The criteria used to evaluate the solvers are the Flow Time of the parts, percentage of parts in Delayed, Tardiness, Maximum value of Tardiness, Work-in-Process (WIP), and Throughput (see Table 12).

Initially, it has been conducted a sensitivity analysis of the parameters α and β together. The analysis of the simulation results highlight that the range of α and β that assures the better performance is [0.7-0.85];

In this range, the performance measures don't change significantly. Therefore, the parameters are set to the same value of 0.85 for the simulation experiments conducted.

In particular, it can be observed that the best two solvers are *MinSTE* and *Budget*. To improve these solvers it is necessary to combine them with a dispatching rule Earliest Due Date (EDD). In fact, *Budget+EDD* has the best performance crossing both plants and streams. In the following table, there are summarized the performances of all solvers compared to the *Budget* solver. The value is the percentage (%) difference between the solver written in the head cell and *Budget* solver. Except for the throughput, *Budget* approach improves all performance measures of *MinSTE*. The best improvement is in the percentage of delayed of jobs, while as regards throughput *MinSTE* is better than *Budget*. It is important to underline the *Budget* and *MinSTE* seem to work in the same way, independently from Streams or Plants instances. In fact, while *MinSTE* tries to find the faster cell to perform the subsequent task, *Budget* looks for the most efficient cell.

In most of the cases, the fastest cell and the most efficient one coincide; the different performances of these two solvers are thus due to only a small percentage of choices during one simulation. Performances of other solvers are very far from the aforementioned. This is because they are not able to predict the failure or delay of the system. In fact, their performances are acceptable only in the deterministic plant, even if always worse than *MinSTE* and *Budget*. The worst solver is *Slack1*

Table 12. Solver comparison results

Cell	Min STE	Slack 1	Slack 2	Slack 3	Budget + EDD
% Delay Jobs	6.04	1987	211	365	-10.6
Flow Time	1.33	171	87.2	132	-7.72
WIP	0.68	164	84.2	127	-8.39
Throughput	0.38	-2.91	-1.04	-1.72	4.13
Tardiness	4.96	64.2	29.3	30.7	-14.9
Max Tardiness	3.15	143	55.3	65.5	-17.5

because it makes no attempt to forecast delays or failures. However, the forecast of delays or failures is not always so useful, which is demonstrated by the case of *Slack2*. It happens that *Slack2*, where the forecast is made by a heuristic division of the *SlackOp* index, is better than *Slack3*, in which delays and failure forecasts are explicit.

The above simulations have been conducted with the same level of budget assigned to each job, in order to match up to other approaches in the same environment. Moreover, the value of budget is enough high (defined infinity) to avoid the case in which the part doesn't have a sufficient budget to acquire the best cell. The motivation is to compare the proposed approach with the other methodologies in same operational conditions and evaluate the difference of performance measures due only to budget approach.

Further simulations have been conducted in order to test the fuzzy tool that allocates budget to the jobs.

Therefore, three job types have been hypothesized, with three different levels of budget (low, medium and high). The price of each manufacturing cell is computed as in (7) where k=100.

The low value is always 20, while medium and high values change between 20 and 100 with a step of 10. Moreover, the simulations have been conducted with three values of inter-arrival time and two dimensions of the manufacturing systems. The experimental classes are reported in Table 13.

The 25 experimental classes of budget values are simulated for the values of inter-arrival time and number of manufacturing cell reported in Table 14.

The total number of experimental classes simulated is 150.

The simulation results are compared (basis of comparison) with the case of infinity budget assigned to each part typology (parts with same importance). The performance measures investigated are:

Table 13. Budget values combination

Exp. No	Budget – medium level value	Budget- high level value

24	100	80
25	100	100

Table 14. Inter-arrival and manufacturing cell classes

Exp. No	Inter-arrival time	Manufacturing cells
1	13	4
2	16	4
3	19	4
4	5	8
5	7.5	8
6	10	8

- flow time is the average throughput time of the parts.
- tardiness is the sum of the time in delay of the parts.
- number of jobs manufactured in delay is the total parts that are in delay.

Parts with three different importance level enter the manufacturing system, the performance are collected and reported for each importance level. The Figures 4, 5 and 6 report the performance measures for each product importance computing the average values over the inter-arrival time and number of manufacturing cells. There are reported the more significant results.

From the analysis of the aforementioned figures, the following issues can be drawn:

- The products with a high level can gain advantages only if the level of the budget assigned can be the maximum value possible: 100. Moreover, the improvement is better when the weight of medium importance product is the minimum value possible: 20. The advantages are the same for all three performance measures.
- In case of weight of 100 for high importance products, the products with a medium importance level have a very low difference between the weight of 20 and 40. The performance measure of parts in delay is the performance with minor deterioration. Also, the products with low importance have the same trend of the medium importance products.

The drastically reduction of flow time of the high important products is obtained with an increment of the flow time of the medium important products about 25 times, while for the low importance products the increment is about 36 times.

Moreover, the products with medium and low importance have a trend of increment of the number of jobs in delay minor than the tardiness performance.

The Figures 7, 8, and 9 report the performance measures for each product importance computing the average value highlighting the manufacturing system dimension (4 an 8) and the inter-arrival time (low, medium and high).

From the analysis of the figures, the following issues can be drawn:

Figure 4. Parts with high importance

	Flow time high 80	Flow time high 100	Tardiness high 80	Tardiness high 100	Delay high 80	Delay high 100
20	146,88%	-67,01%	887,72%	-70,30%	86,51%	-73,89%
40	161,23%	-54,05%	520,83%	-43,97%	123,88%	-52,64%

Figure 5. Parts with medium importance

	Flow time medium		Tardiness medium		delay medium	
	80	100	80	100	80	100
20	2837,24	2604,51	3536,95	3350,87	6,04%	32,05%
40	1844,75	2508,31	2295,30	3292,61	426,23%	143,31%

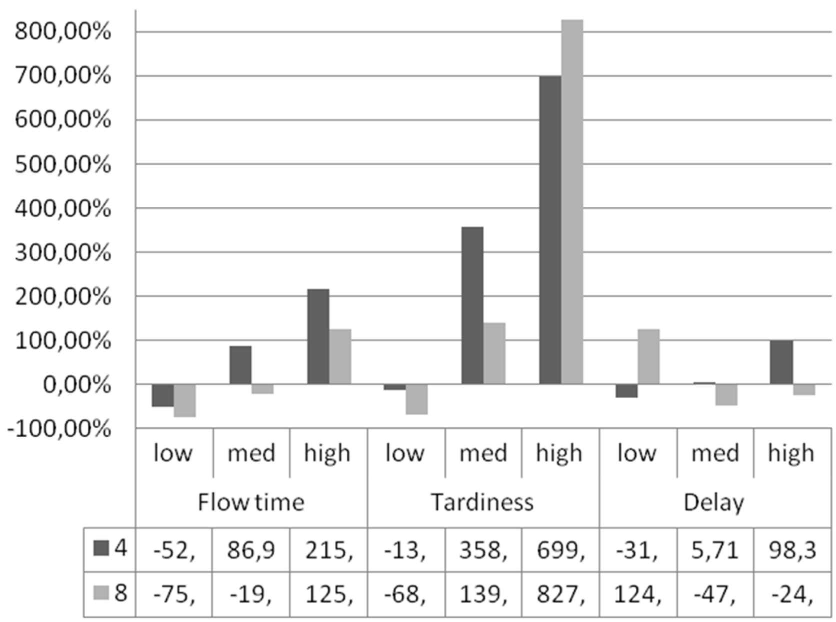
- The performance measures improve when the manufacturing dimension increases from four manufacturing cells to eight.
- From the point of view of manufacturing congestion, the performance measures are better when the inter-arrival is low, therefore with a high congestion level.

Though, the performance of the jobs with medium and low importance gets worse. The fuzzy

Figure 6. Parts with low importance

	Flow time low		Tardiness low		delay low	
	80	100	80	100	80	100
20	3930,80	3647,31	4579,02	4346,12	574,31%	604,17%
40	3380,03	3543,46	3941,34	4228,26	918,54%	639,93%

Figure 7. Parts with high importance



inference enables assigning a budget to each job correlating to the importance of the job. It can be adapted to the change of the importance of the jobs in real time and this leads to a selective and adaptable. Therefore, the fuzzy reasoning leads to a selective approach

Figure 8. Parts with medium importance

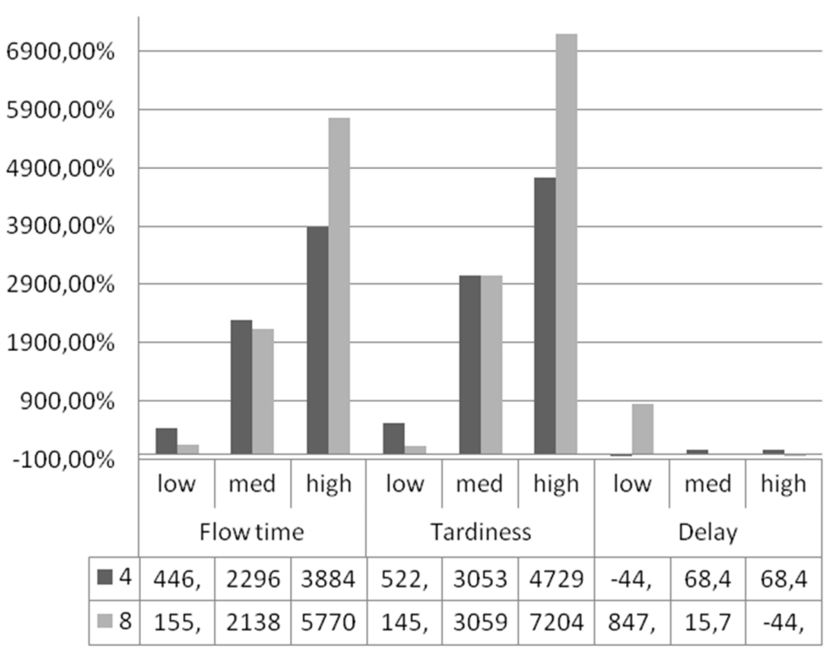


Figure 9. Parts with low importance

	Flow time low	Flow time med	Flow time high	Tardiness low	Tardiness med	Tardiness high	Delay low	Delay med	Delay high
4	693,	3270	5234	783,	4002	6262	-24,	278,	1290
8	342,	3473	8739	344,	4593	9656	2490	93,4	-22,

From the analysis of the simulation results, the following issues can be drawn:

- The budget approach proposed allows to discriminate the performance level by setting the importance of the jobs. The importance of the jobs is set by a fuzzy tool, therefore, defining qualitative parameters.
- The better performance for the high importance jobs is obtained when the configuration of the budget assigned to the part types is the following: HIGH=100, MEDIUM=20 and LOW=20. Then, the fuzzy tool works better when the classes are two.
- The performance measures are better when the congestion level is high (low inter-arrival) and the number of the manufacturing cells increases from four to eight.
- Finally, the extremely worst performance for medium and low importance performance have to be understood as a reduction compared to the case when all the parts have the same importance.

The fuzzy tool proposed allows to modify the performance level of different classes of job importance by setting only one parameter: budget assigned to the parts.

Moreover, the simulation results can be used to learn the opportune level of budget to assign at each typology part when the manufacturing conditions change.

The development of a hybrid approach, in which the proposed approach is activated when the congestion level is high and the selection of the products' importance, is necessary.

CONCLUSION

This chapter proposed an innovative scheduling approach for flexible manufacturing systems working in dynamic environments. Performance measures based on internal and external indices of efficiency have been elaborated. The negotiation protocol has been tested under different conditions of manufacturing system workload, with various numbers of cells and dynamic cell characteristics. The results show how the *Budget* approach leads to better performance, especially if it is combined with appropriate dispatching rules. Merits of the novel method are more characteristic when the manufacturing system is more dynamic. The *Budget* approach was also compared to other dynamic scheduling methods proposed in the literature. In particular, the *Budget* solver has performance much better than other solvers that try to estimate the next task slack because it considers also the possible failure state of cells; on the other hand, *Budget* is better than the *MinSTE* solver just because it is able to select dynamically the more efficient cell, not simply the fastest one. All in all, it has a high level of adaptivity without deteriorating performance. Overall system performance depends only on one intuitive parameter, the budget of the jobs. Several characteristics that define the priority of a part typology are combined by a fuzzy tool in an only parameter: the budget value of the part. The coordination approach is very simple, because the only parameter to set is the budget of the part. Moreover, if a new characteristic has to be added or modified to define the priority of the part, the coordination approach doesn't change, only the fuzzy tool needs to be modified to change the priority of the parts.

Hence, the overall system is well controllable and the approach can be extended towards production networks where the key to common competitiveness and efficiency is just the sharing financial risks and benefits. Future developments concern the application of the proposed approach in a real case study in order o validates the results obtained by the simulation experiments. Moreover, artificial intelligence approaches can be developed to learn the opportune level of budget. In particular, generic algorithms and neural networks can be integrated to learn and select the level of appropriate budget.

KEY TERMS AND DEFINITIONS

Agile Manufacturing System: It is a manufacturing system in which is the organization that has created the processes, tools, and training to enable it to respond quickly to customer needs and market changes while still controlling costs and quality.

Coordination: It is the mechanism how the agent exchange information and cooperate to purse a common objective.

Discrete Event Simulation: It emulates a real system by a chronological sequence of events. Each event occurs at an instant in time and marks a change of state in the system.

Distributed Approach: It is a system where independent cooperate to pursue an objective without centralized information.

Fuzzy Logic: It is a logic derived from fuzzy set theory to deal with reasoning that is fluid or approximate rather than fixed and exact.

Multi-Agent System: It is a system composed of multiple interacting intelligent agents.

Scheduling: It is a decision making process to allocate resources to tasks over a given time periods optimizing one or more objectives.

Chapter 82
Research Profiles:
Prolegomena to a New Perspective on Innovation Management

University of Maryland, USA

ABSTRACT

Despite the increasing importance of the management of research for innovation, the range of differences among types of research, as well as projects and programs, is not adequately captured in current theories of either project or organizational innovation. This chapter offers preliminary discussions for a new perspective about alternative styles of management for different types of research, whether basic, applied, product development, manufacturing, quality control or marketing. Based on these discussions, the chapter proposes a framework for a new perspective of innovation management, called Research Profiles, which is derived from a literature review and extensive field research. This new perspective delineates four research profiles on the basis of two dimensions of research objectives and two dimensions of research tasks. In matching the research objectives and tasks, we identify inherent dilemmas that managers must address and this developing perspective suggests some appropriate research management approaches.

INTRODUCTION

Despite the central importance of scientific and technological research, including product development, for national competitiveness and security, at present there is not an adequate theory about the appropriate managerial styles needed to address alternative kinds of research objectives at the research project, program or inter-organizational level. Organizational innovation theory stemming from Burns and Stalker (1961) typically focuses on the entire organization and, we would suggest, one organizational model (the organic organization), rather than recognizing the existence of differ-

DOI: 10.4018/978-1-4666-1945-6.ch082

ent kinds of research work. More critically, the organic model does not include either the concept of complexity (Brown & Eisenhardt, 1995; Hage, 1999) or external networks of expertise, which are precisely the ones that are increasingly important in the growth of knowledge network communities (Mohrman, Galbraith, & Monge, 2004; Shinn, 2002), and the spread of inter-organizational relationships (Alter & Hage, 1993; Hagedoorn & Duysters, 2002; Powell, 1998; Powell, Koput, & Smith-Doerr, 1996; Van De Ven & Polley, 1992). Indeed, in the organizational innovation literature there is only one study that examines the structure and performance of research laboratories and it does not include external relationships of any kind (Hull, 1988).

Although we are beginning to see an increasing number of studies of research labs (Brown, 1997; Joly & Mangematin, 1996; Jordan, Streit, & Matiasek, 2003; Menke, 1997), inter-organizational alliances (Gomes-Casseres, 1996) and a few studies of research consortia (Browing, Beyer, and Shelter, 1995), the fact remains that none of these studies have connected the measurement of scientific and technological research objectives, to the nature of the research tasks and their appropriate managerial styles. The research literatures cited above stand largely in isolation, often ignoring other kinds of research work. Specifically, the level of the project is overlooked, which is a smaller unit than the organization, the whole organization, and inter-organizational networks of various kinds. Indeed, what makes a proposed theory of management styles necessary is the considerable range in the ways scientific and technology research is organized. While many small research projects funded by the National Science Foundation (NSF) and the National Institutes of Health (NIH), such as those found in academia, tend to be the standard structure, a considerable amount of research is conducted in large-scale organizations and programs, such as mission agencies like the National Aeronautics and Space Administration (NASA) and the National Oceanic and Atmospheric Administration (NOAA), as well as large scale inter-organizational research programs such as the Human Genome Project. For the same reason, the new and growing literature on projects (Brown and Eisenstadt, 1995) overlooks what might be called "Big Science" as represented in the research conducted at the large national and international laboratories such as Argonne in the US and CERN in Switzerland.

Further, as Clarke (2002) has discussed in comprehensive detail, the management of a large number of researchers is very different from the typical management issues involved in contemporary firms or public bureaucracies. Among other differences are the oft-cited assertions that researchers are more motivated by intellectual curiosity than monetary compensation, the longer and more uncertain time horizons for successful objectives, and, perhaps most importantly, work that is seldom standardized and difficult to evaluate.

While a theory about the diversity of research management styles would necessarily differ from more general theories of organizations, the logic in the construction of our perspective is basically the same. First, one must specify particular kinds of research objectives and identify the potential trade-offs. Then one must also distinguish different kinds of research work and tasks. Finally, the management styles appropriate for the linking of the typology of research tasks with a typology of research objectives at the levels of project, program and inter-organization networks have to be determined. In this chapter, we present our argument for a diversity of research management styles in three sections. First, we provide a more detailed justification of the need for our perspective on of management styles. Second, we specify a typology of research work and a typology of research objectives and provide a theoretical linkage between the two. Finally, we offer our proposed view of Research Profiles and discuss the managerial styles necessitated by the kinds of management challenges that are presented in each profile's combination of research tasks and research objectives.

BACKGROUND: THE NEED FOR A NEW PERSPECTIVE OF RESEARCH MANAGEMENT STYLES

Essentially, we identify two lines of argument for justifying a new perspective of management styles. We take as a given that the central importance of scientific and technological research, not only for competitiveness but many other national goals, speaks to the need for greater attention. First, the closest appropriate specialty, namely organizational innovation research, needs to be altered in the light of new theoretical and conceptual developments (see Hage, 1999). Second, the literature on scientific and technological research is missing a conceptual apparatus that would allow for the accumulation of findings across a myriad of studies.

The first argument is based on the fact that most current and past innovation research continues to be dominated by Burns and Stalker's (1961) seminal work on the organic model. In many ways, this model has become outdated. For example, the model is largely focused on new product development by engineers, rather than scientific and technological research. This model also largely ignores the concept of complexity, which has proven to be fundamental when combined with the organic model and the strategy of risk-taking in explaining differences in innovation rates (Hage, 1999). Finally, as argued previously, the organic model is not designed to handle the varying sizes of units in which research is conducted, from the very small project within an organization to the very large mission agencies such as NOAA and NASA or a research consortium such as SEMATECH (Browning, 1995) or various strategic alliances (Gomes-Casseres, 1996).

More recently, the importance of both the organizational learning perspective (Grant, 1996; Kim & Wilemon, 2007) and the theory of idea innovation networks (Hage & Hollingsworth, 2000; Kline & Rosenberg, 1986) are implicitly calling attention to the importance of research as a mechanism for learning. Further, these perspectives suggest the importance of inter-organizational networks that connect two or more of the six arenas of research: basic, applied research, product development, manufacturing research, quality research, and commercialization research. In fact, the latter literature necessitates a considerable revision of the organic model, specifically to allow for external relationships.

In short, the organic model, and organizational innovation research in general, needs to be linked in various ways to the research project literature (Brown & Eisenhardt, 1995; Hobday, 1998; Shenhar, 2001) and the abundant literature on inter-organizational relationships cited above. One of the reasons for this is the dramatic changes that have occurred because of the explosive growth and globalization of R&D and the way in which science and technology are evolving (Hage & Hollingsworth, 2000). Furthermore, the linkages between arenas (for example basic and applied) of research are usually at the project/program level and therefore research projects and the problems of how to manage them should be the analytical focus.

The second line of reasoning that justifies the need for a theory of research management styles is that much of the social studies of science literature have emphasized concrete categories rather than general dimensions that would allow one to accumulate evidence about how best to manage research. For example, the outcomes of research are typically measured in concrete categories, such as papers, patents, peer review assessments, and citations. As we discuss below, we propose a reconceptualization of these ideas so that they can be used as general dimensions, such as the degree of radicalness of the outcome of the research or the scope of the research outcome, that can be applied to basic or applied research, product development research, manufacturing research, and so on. Similarly, research work is often described by such terms as scientific and technological research or the specific content, i.e. physics, chemistry, or biology. Again, there is a need for general dimensions of research tasks that can be applied across these various situations such as the degree of complexity or diversity in the research team and the size of the research program or inter-organizational network. Until these general dimensions are developed and linked, it is not possible to identify the correct managerial practices for linking the nature of the research task with the kind of desired outcome. In summary, the increasing importance of research and these two lines of reasoning provide a compelling case for the importance of our perspective of Research Profiles based on tasks, objectives, as well managerial styles and managerial challenges.

THE BASIC DIMENSIONS FOR RESEARCH MANAGEMENT STYLES

What characteristics might one desire in a categorization of research management styles? Ideally, one should encompass dimensions that tap into the fundamental dilemmas, tensions and problems of conducting research. Since our interest is in making meaningful distinctions, we want to isolate multiple dimensions of research objectives and tasks. Another concern is to connect choices about objectives as much as possible to the existing literature and, in particular, to the literature on innovation.

To provide new insights about research management styles across a wide range of different kinds of research projects, programs and inter-organizational networks, we conducted an inductively-based exploratory study, funded by the U.S. Department of Energy (DOE), to help identify the critical factors facing the research workers and managers. Utilizing the Competing Values Framework as an organizing framework for understanding the pursuit of research (Cameron & Quinn, 1998; Quinn & Rohrbaugh, 1983), a number of focus groups were conducted with scientific researchers to more specifically identify attributes of a research environment. The focus group discussions uncovered a number of unique tensions in managing research, which demonstrated not only that competing values exist in the research environment, but that these values differ depending on the research objectives and tasks. For example, a tension mentioned often in these discussions was between researchers' desire and need for autonomy and management's desire and need to focus research and meet deadlines. In their study of productive climates for scientists, Pelz and Andrews (1976), found similar tensions such as these prevalent and important to consider in managing scientists because of their significant impact on performance. The findings of the exploratory study and subsequent surveys suggest that the diversity of research projects, programs and organizations can be sorted according to two primary dimensions for research objectives and two primary dimensions for describing the nature of the research work or task.

The Research Objectives Dimension

We define the research objectives dimension as Degree of Radicalness in the Scientific or Technological Advance on a continuum from incremental to radical. In slight contrast to the Schumpeterian notion of the degree of radicalness, which focuses primarily on the competitive impact of an invention (Dahlin & Behrens, 2005), we would argue that the degree of radicalness in research includes the degree of change in the state of the art, the centrality of the research problem, and the discovery of a pattern that upsets existing theory or a technology that creates a market niche. For scientific research, the task environment is the knowledge world or "the state of the art," that is, how much is known, and what is considered to be an important scientific concern or requirement.

Radical advances in science sometimes occur when a central problem is solved, such as the identification of the structure of DNA (Judson, 1979). Sometimes this also happens when a major discovery is made, such as the observation of the first candidate black hole in 1971 (Cygnus X-1), or when a research finding challenges an existing theory, such as the discovery of skeletal remains in the Americas estimated to over 1,000 years older than it was theorized that the Americas were colonized or the discovery in China of fossils of dinosaurs with feathers.

The second dimension of research objectives is the Scope of Focus, a continuum from narrow to broad, defined by the number of variables or processes or components or the number of levels or systems involved, or the extremeness of the environments of the work. In product development, this includes the number of performances affected as well as the need to change supply chains and distribution chains and create idea innovation networks or strategic alliances, as discussed in great detail by Shenhar (2001) and Hobday (1998). The challenge is adapting these concepts of scope from the product development and industrial innovation literature for scientific and technological research.

As we have already observed, the question of the amount of the scientific advance can involve multiple outcomes, that is, the number of variables or processes that are being researched at the same time. Some disciplines have a systemic quality, that is, a large number of variables have to be considered at the same time. Further, not all scientific problems can be approached with small research teams; some of them require a large scale focus. While progress in mapping and sequencing the human genome could have proceeded with small research teams, it took a large-scale inter-organizational program to coordinate a range of efforts so that the time needed to complete the entire genome was appreciably lessened. Indeed, the systemic quality of some types of research is frequently overlooked as a critical dimension to the scientific problem. One example of what might be called a systemic problem is research on the weather, which encompasses both oceanic and atmospheric systems. NOAA was created in 1970 to unify and coordinate the government's research efforts on various aspects of the global environmental system, including the National Weather Service (NWS). Altogether, the scope of NOAA's mandate necessitates quite expensive and specialized equipment and teams to collect the relevant data, including satellites, ships, buoys, and planes. Indeed, one could argue that the choice to conduct large scale data collection represents one form of a broad scope focus.

Just as science has a systemic quality in some areas that cannot be easily divided into small projects, there are technical systems that necessitate a large program of product development that may last many years. Leifer and colleagues (2000) observe in a series of case studies that this is a common characteristic of radical product innovation. Further, the research involves not simply the program, but also supporting technologies as well. For example, research on high speed trains, hydrogen-fueled cars, or fusion research also necessitates accompanying research on infrastructure, distribution and delivery systems.

Taken together, these two dimensions of research objectives, or intended outcomes, can be cross-classified to generate a typology of research objectives (see Table 1). In this manner, the choice of the relative emphasis on the radicalness of the scientific discovery or technological advance and *focus* scope generates four distinctive kinds of strategic choices. In general, the research of Shenhar (1993; 2001) on engineering projects is suggestive of how these two dimensions of research objectives can be operationalized in scientific research, where both the idea of scientific or technological uncertainty and systemic scope are in effect. In science and technology, it is the combination of objectives such as superconducting at room temperatures that reflects a radical advance.

Table 1. A typology of research objectives

	Degree of Radicalness in Scientific or Technological Advance	
Scope of Focus	**Incremental**	**Radical**
Narrow	Minor advances in a limited area, a few performances or components	Major advances in a limited area, a few performances or components
Broad	Minor advances in a system or on multiple performances of a system; Changes outside of system.	Major advances in a system or on multiple performances of a system; Changes outside of system.

The Research Tasks Dimensions

Research tasks can also be characterized by two dimensions. The first, and most obvious, dimension is the relative size of the research project, measured by the number of researchers, the number of different instruments, the number of technicians that are involved, and the number of teams and organizations involved. Furthermore, as is obvious, as the costs increase--the movement from 10 million to 100 million to one billon—there is a need for significant changes in the organization and management of the research. These changes in organization roughly parallel the movement from research project to research program or research organization, such as a national laboratory, to mission agency or inter-organizational network, as in a research consortium. At the extreme is the cost of a space shuttle, with a price tag of over 20 billion dollars expended over ten to twenty years (Gelès, 1999).

Significant work can be accomplished in small projects, such as the theoretical advances involving DNA (the double helix structure) and RNA (the messenger), which were radical advances in scientific knowledge, involved relatively small and complex research teams working within a circumscribed knowledge community (see Judson, 1979). In contrast, the mapping of the human genome necessitated a large research program that required the coordination of multiple research teams and inter-organizational relationships since there were over 3,000 genes. In systemic research, it is the large number of variables or properties of the system that require large scale programs to test and develop theories. In large organizations, programs of research are frequently housed in separate divisions because they focus on a specific area of research.

This dimension of size is similar to the fundamental distinction in the Competing Values Framework between flexibility and controlled structures, with the idea that larger projects are those that are more likely to be controlled. But the dimension of size also encompasses a number of consequences that create tensions about coordination and control mechanisms that inevitably impact on project autonomy that are discussed at greater length below. Some would classify the cost of a project as an indicator of radicalness of the innovation (McDermott & O'Connor, 2002), but we would argue this should be kept quite separate from measures of revolutionary breakthroughs in science or in technology because the cost of these projects is variable. Beyond this, the issue of the cost leads naturally into the more critical question of the size of the research project.

The other dimension of research projects is the complexity or diversity of research on a continuum from specialized to very diverse, as represented by the variety of scientific and engineering disciplines involved. This dimension is equally well established in the literatures on organizational innovation (Hage, 1999) and contingency theory more generally (Lawrence & Lorsch, 1967), as well as in science more generally (Mote, 2005). In our research at Sandia National Laboratories, we have found that many research projects had only six to ten people but in some cases, this represented six or more departments; in other instances, it reflected only one or two departments (Jordan, Hage, Mote, & Hepler, 2005). Thus, even in relatively small research projects, there can be a considerable variation in the degree of diversity in the composition of the researchers and technicians. Above, we have stressed the importance of the technicians and the equipment as one aspect of the size of the project. These factors also represent an element of complexity that is frequently ignored. For example, one of the more interesting aspects of complex research projects is the variety of research equipment that is utilized. In Latour and Woolgar's (1979) well-known study of the research laboratory, they found ten different instruments used for the purposes of measurement.

Diversity or complexity in the number of researchers and technicians can change across time. Furthermore, as research findings develop, one begins to recognize the need for still other kinds of equipment or of other kinds of expertise, that is, knowledge areas. The changes in the knowledge composition of the research project or fluidity over time are yet another measure of complexity. Again, as our research on Sandia National Laboratories research projects and programs demonstrates, typically each year, new scientific and engineering specialties were added and in some cases, others were dropped. In other words, complexity has not only a static dimension but a temporal one as well.

This dimension of structure typically measures whether expertise exists within an organization or within external organizations. Since complexity is essentially a measure of the knowledge pool of the research effort, it is to be expected that not all of the necessary skills and attributes needed are to be found in the same research unit or even within the same research organization, even in large organizations such as the national laboratories or mission agencies. The literature has consistently demonstrated that as the complexity of the research effort increases, there is frequently the need for expertise outside the research organization (Alter & Hage, 1993). In this manner, the search for additional expertise or knowledge fosters a greater external focus within the research project or program.

The two dimensions of size and complexity (see Table 2) yield four distinctive types of research projects: (1) small complex research projects; (2) large complex research programs or research organizations; (3) large specialized research programs or research organizations; and (4) small specialized research projects. Earlier, we emphasized the importance of adding the external, inter-organizational dimension to the variations on the organic model. Small complex research projects are usually connected to knowledge or practice communities, but typically in a more informal manner, and perhaps one inter-organizational relationship. In contrast, large complex research programs are more likely to be connected to set of inter-organizational relationships and maybe even a consortium, as in global alliances (Gomes-Casseres, 1996) or research consortia such as SEMATECH (Browning, 1995). Again, these are general dimensions with a considerable range of variability.

The Amount of Choice Involved in the Selection of Research Objectives and Tasks

Although we have employed the word "choice", there still remains a question of the latitude that managers have in selecting particular research tasks. For instance, the choices may be dictated to them by the environment, whether because of the agendas of funding agencies, control exerted by the state, or certain socialization practices that create a distinctive world view (DiMaggio & Powell, 1983). An example is that the culture surrounding the peer panel review process in general creates a bias toward what is often termed "normal science," that is, toward incremental advances in knowledge (Braun, 1998).

Table 2. A typology of research tasks

	Degree of Complexity or Diversity	
Size of Research Effort	**Some**	**A Lot**
Small	Specialized research projects	Complex research projects; knowledge communities
Large	Specialized research programs or research organizations	Complex research program or research organization; inter-organizational relationships

Crises can also affect the choice of research objectives and tasks. For example, the cyclical nature of environmental concerns has been manifested in rising and falling pressures on public research laboratories and private companies and shifting choices of research objectives and tasks from incremental ones, such as minor improvements in gas mileage, to more radical ones, such as the hydrogen fuel car. As this illustrates, not all pressures are necessarily directed towards radical advances in knowledge. For instance, the pressing need for immediate improvements in national security after the events of September 11, 2001 in the United States might necessitate the need to place greater emphasis on incremental advances, that is, to quickly transfer current technology into security applications (Trajtenberg, 2006).

But the most interesting constraints on choice emerge from the nature of the research problem. Natural systems that are at the extremes of scale, from the very small (subatomic) to the very large (outer space), require quite expensive equipment, numerous technical personnel and many researchers to study them. It is the case that the research problem might be capable of compartmentalization so that it can be pursued as smaller research projects. Obviously, when this is possible, the pursuit of a smaller research project presents itself as a viable research choice. But if one wants to study the system in its entirety, then either a large research organization, mission agency or a research consortium becomes necessary.

Dilemmas in the Choice of Research Objectives and Research Tasks

The influence of the external world is not the only pressure that affects the choice of the research objectives and tasks. Other, perhaps more critical, pressures are the different kinds of management dilemmas that accompany each choice. These need to be discussed in some detail because they reflect important management challenges and provide examples of how management style could make a difference.

Two very common terms in the management literature, especially in discussions of innovation, are the terms “risk” and “uncertainty”. Both of these apply to the choice of the research objectives and reflect dilemmas, particularly in the notion of how much risk one should absorb and how much uncertainty. While the terms are frequently used interchangeably in the literature, we would propose making the following distinctions: risk is a measure of the degree of radicalness in the research objective, while uncertainty is a measure of the scope of the focus on possible outcomes. A review of the literature on the management of innovation indicates that when one shifts to the language of uncertainty, the issue becomes simply a matter of counting the number of uncertainties. In other words, there are not only technological uncertainties but market uncertainties and others, although the role of the market in many areas of basic and applied research are not readily clear (Clarke, 2002). And while it follows that a large number of uncertainties, almost by definition, translates to high risk, the converse is not necessarily true. Indeed, there might only be a few technological uncertainties but still the choice to pursue a radical outcome would entail high risk. For example, Shenhar (1993) and Hobday (1998) suggest that technological uncertainty is related to the degree in which new devices, knowledge or techniques are embodied in a product. But it could be the case that one seeks a radical research outcome, yet still utilize existing technology to do so.

In short, we propose the idea of using risk and uncertainty in somewhat different ways, while still recognizing that the combination of many uncertainties with high radicalness presents the most difficult management tasks. In this manner, we are suggesting that each dilemma flows from a different set of issues than that found in new product development and industrial organization. Attempting to make a significant advance in science or technology development obviously carries a large risk of failure. Uncertainty, however, flows more from the scope of the focus that one is desiring to achieve because as the implicit number of unknowns increases, it becomes more and more uncertain as to which set is the most critical. Stated another way, when the focus is on understanding an entire system, either large or small, especially at multiple levels, there are a large number of potential unknowns or avenues of research.

One might assume that the simple solution to reducing risk is by pursuing a greater number of smaller, incremental research projects. In one sense, this is a familiar dilemma faced by managers of research in risk-averse, budget-conscious organizational environments. But there are times when progress can only be made by taking a radical approach, and “failures” can still result in a scientific advance in the sense that learning took place. In this regard, one is reminded of Thomas Edison’s remark the he did not fail, he simply found ways that did not work. Similarly, one might assume that the simple solution for reducing uncertainty is to pursue a small-scale project that is highly focused on a smaller range of unknown factors, but this can result in losing what many might call the “big picture”, a problem in any systemic science or multiple component technology.

Managerial dilemmas are not restricted simply to the choice of research objectives but also exist in the selection of research tasks. Research projects of a large size require a significant investment in management control and coordination. Such projects also typically need a substantial support staff and support systems for required services, such as accounting, human resources, and library resources. Further, larger teams also need effective leaders who can allocate resources and maintain communication and focus among team members. Finally, management also must define and communicate clear goals and strategies in order to align large groups with strategies. Indeed, the success of a large research project often depends on management correctly positioning the research to fulfill a need or fill a niche. Overall, a unifying system-wide scope makes it possible to set specific goals and track progress. The dilemma is that in increasing size and, correspondingly, internal coordination and control, there is less and less research autonomy and more bureaucracy.

Clearly, the distinction between autonomy and internal control is one of the basic structural dilemmas. Therefore, given the tight connection between size and managerial control, we have included the degree of coordination of the research project or program on the vertical dimension of the typology of structure. The desired independence and autonomy of academics are well known, as is the fact that researchers are motivated as much by the recognition of their work and the intrinsic pleasure of doing their research as by extrinsic rewards. The tension between autonomy and control also manifests itself in another way, which is the need to search for expertise as complexity increases. In so far as one locates this expertise outside the organization, another structural dilemma emerges because it conflicts with organizational autonomy given that some external control comes with the external expertise. In this regard, coordination difficulties across organizational boundaries are a dominant theme in the inter-organizational literature.

We note that there is a certain irony in this dilemma. Those projects that are already more complex because of their revolutionary strategy are precisely the ones that are most likely to recognize the need for other pools of knowledge. This flows from their aspirations and thus makes the strategic choice so critical, as Zammuto and O'Connor (1992) argued in explaining the adoption of the radical process technology of flexible manufacturing. Meeus and Faber (2006) also observe this is true on the inter-organizational side of the structure as well.

In summary, we have identified a number of dilemmas attached to both the choice of research outcome and the choice of research task within the constraints of how the context—economic, political and scientific—constrain the choices that are made. And as we combine the choice of outcome with the choice of task, these dilemmas multiply, a subject we turn to in the next section.

Constructing the Research Profiles and Management Styles

A central idea in contingency theory is that structure must follow from strategy, thus the two basic dimensions of research objectives discussed above must dictate how the research tasks should be structured. The creation of general variables that is accomplished with the typologies describing both the research objectives and the research tasks allows one to develop several hypotheses about the match between task and objective or intended outcome, the equivalent at the project or program level to the match between structure and strategy. The heart of our perspective is connecting the typology of research objectives with the typology of research tasks, which results in four kinds of research profiles. And since each choice of outcome and of task also has a set of related dilemmas, it is also the case that there are four general areas of managerial problems.

Connecting Research Tasks to Research Objectives

As we stated above, the matching of research task with research outcome is the heart of the theory of management styles. The construction of the new perspective is based on a series of hypotheses that emphasize the range of each of the dimensions used to identify research objectives and research tasks. Of these hypotheses, we present two, both of which draw heavily on contingency theory.

1. The greater the emphasis on the radicalness of the outcome in science or technology, the greater the need to emphasize the complexity or diversity of expertise in the research project, program or inter-organization network.

The more that managers choose to pursue a radical breakthrough in science, then the research project itself must become complex, particularly in terms of different types of knowledge. As discussed before, this flows from the need to synthesize different perspectives as a way of achieving the radical breakthrough. In this vein, Shenhar's (2001) study of engineering projects provides at least some evidence for the fit between the choice of a revolutionary strategy and the need for expertise; projects coded as most uncertain had the highest proportion of academic degrees.

Research findings on the positive relationship between complexity and industrial innovation defined as new products or services have been accumulated over a forty-year time period. Damanpour (1991) summarized the first thirty years of work in a meta-analysis that explored the relative importance of complexity vis-à-vis other variables while controlling for a number of alternative possibilities. Hage (1999) updated this study and noticed the absence of research on complexity and radical innovation in science. For instance, in discussions about the importance of the discovery of the double helix structure of DNA, it is often overlooked that Watson had been trained as a biologist and Crick as a physicist (Watson, 2001). In a study of the Institut Pasteur, the relationship between complexity and radical innovation holds quite strongly at the level of project (Hage & Mote, 2008).

2. The greater the emphasis on a broad scope of focus, the greater the need to increase the size of the research project, program or inter-organizational network.

As the scope of research broadens, the specific expertise that is needed may not reside within the research organization and must be sought outside the organization, either informally, as in knowledge or practice communities, or formally, as in inter-organizational alliances or consortia. The search for expertise suggests that the research unit increases in size as a consequence, moving along the continuum from project to program to inter-organizational network. The movement along this continuum is driven by the notion that scope is a measure of the number of variables involved in the research and the choice to study multiple levels, components of systems or entire systems. Many of the national public laboratories in the U.S. were created to work on difficult and intractable problems. For example, the origins of both Los Alamos and Sandia National Laboratories reside in the Manhattan Project and the drive to construct the first atomic weapon. In response, the Europeans created CERN in 1954 to reverse the brain drain of physicists to the United States and to restore and rebuild European research in high-energy physics.

In general, these types of large national laboratories and mission agencies are quite different from the smaller academic research projects funded by the National Science Foundation (NSF) or National Institutes of Health (NIH). Furthermore, within these national laboratories and mission agencies, additional distinctions can be made between problems that can be approached with small projects and those that require a more extensive program of research. If the project focuses on a system, then almost by definition, one needs a large-scale research program to handle all the aspects of the system, if not a mission agency or national laboratory. Oceanographic ships, space shuttles, and radio astronomy observatories are all examples of quite expensive equipment needed to study particular natural systems, which in turn means quite large support staff and a large number of technicians for their operation.

Another aspect of scientific research is what might be called the difficulty of the research problem, that is, studying phenomena under extreme conditions. For example, consider the case of conducting research on flora and fauna at the bottom of the ocean or the difficulty of studying black holes at the other end of the universe. Again, the presence of extreme conditions often necessitates a large scale program of research.

With these two hypotheses, we can delineate four distinctive kinds of Research Profiles, each with their own distinctive management challenges and dilemmas. We now turn to a discussion of these four Research Profiles.

FUTURE RESEARCH DIRECTIONS: RESEARCH PROFILES AND MANAGEMENT STYLES

Combining the two dimensions generates four ideal-type Research Profiles, each of which can be used to define a particular management style. In addition, because we have suggested that there were a series of dilemmas associated with the choices of the degree of radicalness and the degree of scope and similarly with the degree of complexity and the size of the project, we want to explore ways in which these dilemmas can be managed.

In Table 3, we have combined the dilemmas associated with the strategic structural choices on the assumption that structure follows strategy as we have hypothesized above. Within each quadrant are potential solutions to the dilemmas associated with each Research Profile. It is critical that one interpret this figure as suggesting dilemmas in all four quadrants. While it is easy to argue that high risk or many uncertainties pose managerial problems that necessitate solutions, it is much harder to recognize that too little risk or too few uncertainties also pose managerial problems that require solutions. In particular, the combination of little risk and few uncertainties, which is part of the Small Incremental Research Profile, raises issues about the loss of competitiveness of the research organization in which the project of this nature are located, as well as lack of understanding even by research sponsors, of the importance of some of this work.

Two important general qualifications need to be made about the four Research Profiles. First, the dimensions on which the Research Profiles are based have considerable range. In other words, one must remember that the underlying dimensions are the degree of radicalness, the broadness of the focus, the degree of complexity, and the size of the project, program, *or* inter-organizational network. Of course, this means that the specific managerial problem discussed occurs in varying quantities accordingly. Second, we recognize that each of these dilemmas exists to a certain degree in each quadrant. For example, if we focus on the Small Radical Research Profile, the two primary managerial problems are to encourage risk-taking and integration of diverse perspectives. But these same issues exist in the Large Radical Research Profile, only now they are overshadowed by the larger number of uncertainties and the greater amount of coordination needed to conduct research. In contrast, in the Small Incremental Research Profile, the motivational problems are more centered on the issue of keeping abreast of the discipline or the competition. As a consequence, a very different set of managerial solutions are needed because of the greater research autonomy. In the Large Incremental Research Profile, the same motivational problems exist but now they emerge at the level of research teams within the program and thus necessitate a different set of managerial solutions. In this respect, we associate dilemmas and Research Profiles where the problems tend to be accentuated.

To help set the stage for future research on this perspective, we identify one managerial problem associated with the choice of the research outcome and one problem associated with the choice of the research task. Many of these examples arose from the discussions in the focus groups that were conducted in the development of the research environment survey instrument discussed earlier (Jordan & Streit, 2003; Jordan, Streit, & Binkley, 2003; Jordan, Streit, & Matiasek, 2003)

Table 3. Research profiles: Strategic and structural dilemmas and associated management challenges

Strategy		*Lower Risk/Payoff*	*Higher Risk/Payoff*
	Structure	*Less Integration*	*More Integration*
Lower Uncertainty	***Less Coordination***	Small specialized projects; Value the individual; Provide professional development.	Small complex projects Encourage exploration and risk taking; Integrate ideas externally and internally.
Higher Uncertainty	***More Coordination***	Large specialized programs; Good internal allocation of resources; Good technical management.	Large complex programs; Clearly defined vision, project goals; Build strategic relationships.

Small Radical Research Profile

It goes without saying that most, if not all, researchers would like to have a radical breakthrough in their scientific or technological research, and many often tend to think that their research is geared toward that end. However, as we have suggested, it is important to view this along a dimension with considerable range. In our work at Sandia National Laboratories, we identified several examples of small projects (under 10 million funding over five years) with complex research teams that achieved radical breakthroughs, such as the project that developed a particulate trap for diesel engines that reduced particulates by 400 percent as well a project focused on the development of semi-autonomous, modular robotic control technology that greatly decreases the necessity of human control. Within NOAA, we identified a project focused on new compression methods for satellite data which achieved compression rates of almost a factor of 3 over a current compression standard (Mote, Jordan, & Hage, 2007).

Two managerial problems associated with this Research Profile are encouraging researchers to take intellectual risks and to integrate them as a team. In other words, the motivation issue is how to encourage a team of researchers to think and act boldly. The managerial solution associated with the choice of pursuing radical objectives is to create enough time to think and to explore, encourage the willingness to take risks and also have an atmosphere of challenge. A potential solution is to provide sufficient flexibility, with the resources and freedom to pursue new ideas. This suggests that it is necessary to give researchers in this profile enough time while resisting the pressure of deadlines that may be coming from those higher in the hierarchy.

As we have discussed, increasing the radicalness of the outcome requires that one increase the complexity of the research team, adding multiple disciplines, specialties within them, and technicians and their specialized equipment. But here we face a critical managerial problem associated with this Research Profile: How does one integrate across the various disciplines and equipment so that there is access to tacit knowledge? Furthermore, as Nooteboom (1999, 2000) has observed, although one creates radical innovation by increasing cognitive distance, the tendency is for people to communicate less as the cognitive distance increases. Clearly, the managerial solution is to develop a number of mechanisms to encourage the sharing of tacit knowledge (Judson, 1979), that is to encourage integration across diverse perspectives. Furthermore within the context of science and smaller research projects that address only a component of a larger system or area, we would suggest that this requires more than the classical mechanisms suggested by Lawrence and Lorsch (1967), because this involves ensuring the cross-fertilization of ideas and managing the external collaborations with various knowledge communities.

Large Radical Research Style

As one moves from a project that costs less than ten million dollars over a five year period to a program that costs more ten million dollars, and even upwards of a billion as in the example of NASA's space program, a new set of problems emerge that necessitate a different managerial style. Indeed, the increase in scale magnifies the problems described above, but alters them in interesting ways.

One of the earliest examples of a large-scale program of research is the famous Manhattan Project that produced the first atomic weapon. Since that time, large-scale research programs have been initiated to pursue a number of high-profile topics, with recent examples being the Human Genome Project and the National Nanotechnology Initiative (NNI). On a somewhat smaller scale, Sandia National Laboratories has initiated a handful of relatively large projects under the category of Grand Challenges, which are designed to be first to solve a major technical challenge. One recent example has been a research project on the feasibility of wide-scale, mainstream use of light emitting diodes (LED), which requires advances in both semiconductor design and manufacturing.

In this Research Profile, not only does one want to encourage taking risks and to integrate diverse perspectives, but one also has to be concerned about handling the number of uncertainties and the multiple research teams, including teams that cross organizational boundaries. What are the solutions? To maintain an emphasis on a radical breakthrough in a larger scale program of research, one must put forth a clear and consistent vision that provides much of the motivation for the research teams. Part of this vision is the investing in future opportunities that may provide the breakthrough in either the knowledge or technology needed to advance. The problem of handling the many uncertainties is dealt with by developing a clear set of project goals and strategies so that the many different research teams and organizations that are cooperating together in this effort can understand their responsibilities. The clarity of the vision, such as Project Apollo's explicit goal to land a man on the moon and return him safely to Earth, is critical for the success of these large scale and complex efforts. Initially, the process of determining the right research strategy and achieving a consensus on that strategy can be both time and resource intensive. Hence, continued funding over long time periods is essential. Therefore, projects and programs in this profile often endure well beyond the shorter time horizon of smaller projects, as Leifer et al (2000) have observed.

But an increase in scope of focus also creates new difficulties with managing the complexity of multiple research teams in networks of organizations, all of which have to be integrated. And in large programs and research organizations, it is important to maintain coordination and control over the research efforts. As research autonomy is reduced in this manner, so too are the opportunities to create a radical breakthrough. One of the ways in which this reduction in autonomy impacts on the creativity of the research is the inherent conflict between creativity and maintaining progress and schedules—an important issue in large complex programs. While measuring and tracking progress is an essential part of the solution to this managerial problem, it must be done in a way that does not force researchers to focus on shorter term, incremental, measurable products, benchmarks, or milestones, or take too much time away from research.

Small Incremental Research Profile

The managerial problems shift dramatically in small scale research projects designed for incremental improvements in science and technology, which, of course, are the most common ones in academia, government and in industry. Interesting examples from our work with NOAA include the ongoing, incremental improvements in the calibration of satellite data, as well as the identification of a new type of hurricane that maintains its intensity for a longer time period. A project from our work at Sandia National Laboratories also helps to illustrate this profile. This research project seeks to understand the nature of soot formation from unsteady, "dirty" flames; previous research primarily focused on the properties of steady flames generated by simple, pure hydrocarbon fuels. As these examples demonstrate, as well as many of the research projects funded by the NIH or the NSF, the research is not necessarily aimed at radical advances but at incrementally pushing the knowledge boundaries.

Since the projects in this profile are relatively smaller, the effectiveness depends much more upon the individual researcher and, at most, a small team. Therefore, one of the managerial problems in this profile is to ensure continued professional development, particularly with regard to maintaining and improving skills. Left to their own devices, researchers often tend to focus on the same set of problems across much of their professional life. In this regard, a kind of human capital decay sets in because not enough new issues are being considered to really continue to master a particular specialty. Professional development, such as continued education, seminars, and conferences, becomes a key mechanism for increasing their human capital. Individual growth is also encouraged when there is an atmosphere of cooperation rather than competition among diverse research projects in an organization. Under these circumstances, individuals are more willing to interact and talk with others about their research, particularly scientific challenges they might be facing and need help in overcoming.

Unlike the Small Radical profile, the problem here is potentially too low a level of aspiration rather than one that is too high. Again, the managerial solution to this problem is in various ways to indicate to the individual that they are valued and their work is valued even if it does not need to take intellectual risks or a broad focus. This can be accomplished by providing respect for the individual and valuing their ideas and opinions which can be achieved by allowing autonomy in decision-making, as well as more latitude in choosing areas of research. While this may appear to be quite simple, it is, in fact, often more difficult because typically the rewards are given to those scientists and research teams that make the big breakthroughs. Therefore, part of the solution includes providing greater recognition to the contributions of researchers who have not experienced similar achievements.

Large Incremental Research Profile

The combination of less radical and broad scope of focus research is frequently found in the various national laboratories and mission agencies funded by federal governments. This profile is characterized by large-scale and functionally specialized teams. For example, NOAA maintains separate research programs on both the atmosphere and the oceans, each of which encompasses a number of integrated research projects. Further, the development and implementation of a new weather satellite typically entails a substantial program that includes teams from a number of mission agencies, such as NOAA and NASA, the military and private contractors. This type of research is focused largely on incremental advances and poses different managerial challenges than research efforts focused on radical advances, such as hydrogen fuel-based cars or unmanned aerial vehicles.

Paradoxically, the large scale of research in this profile poses two managerial problems that are also observed in small, specialized projects discussed above, that is, professional development and individual respect. Given the larger scale of research, however, the existence of these two problems in this profile reflects the need to overcome the impersonality of layers of bureaucracy and, hence, suggests different management strategies. A major difference in which the handling of motivation in this profile differs from that above is that rather than value the individual or the few individuals in the team, here the problem is proper recognition of each team. Unlike the Large Radical Profile, which also emphasizes teams and teamwork, this profile emphasizes the pursuit of incremental advances, primarily on components of an overall system and use of functionally specialized teams. It goes without saying that coordination among these teams relies not only on management that is well informed about the research and rewarding and recognizing individual merit, but also on good internal allocation of funding. Cultivating well-informed, technically adept management within the research project is always difficult, for it requires skill in administration and management of people as well as knowledge and skills in the research area. This is particularly important given that the research expertise may lie in separate departments not under the immediate control of the program manager. Indeed, it is this kind of profile that led to the creation of matrix authority structures and, as is well known, this particular structure has not always functioned well because employees find it difficult to serve two masters, discipline (or department) and project (Tushman & O'Reilly, 1999; Tushman & O'Reilly, 1996). For all of these reasons, the need for clear cut measures of technical progress for each team is essential so that progress can be measured carefully and appropriately.

As indicated in the Large Radical profile, one of the major issues for large projects is the lack of research autonomy. Shenhar (2001) provides a vivid description of how managers in this profile attempt to bureaucratize the coordination of the disparate parts of the research program or teams. But, in fact, this solution is what creates many of the problems within this research profile. In addition to the impersonal effects, bureaucratic control also has negative impacts on technical management in requiring time for administrative tasks that can detract from time spent on research. Indeed, in this situation, team leadership becomes very desirable as a solution (Hage & Mote, 2008).

CONCLUSION

In summary, our argument is that the management of different types of research, including basic, applied, product development, and quality control, necessitates an adaption of existing theories of innovation and R&D management in the current literature. The Research Profiles should help with portfolio level decisions because it proposes general categories of research objectives and tasks that can be applied across various arenas of research from basic to manufacturing research to inform strategy decisions and to judge progress and effectiveness. Thus, our perspective about the diversity of research projects, contained in the Research Profiles, has an incredible spread of potential impact. Of course, a test of this assertion is the number of insights that one obtains from the perspective and below we identify and discuss three such insights.

One of the insights is the revision of the organizational learning perspective. In this respect, we would argue that the Research Profiles represent four different kinds of learning. The strategic choice of pursuing a radical breakthrough is probably going to lead to more learning than the pursuit of an incremental strategy. This corresponds to the notion of competency destroying innovation and competency enhancing innovation, which largely looks at the impact on other organizations. The Research Profiles perspective suggests that the organization that has the radical breakthrough is learning a great deal and building its capabilities in the process. As has been indicated in our discussion of each of the four profiles, whether the organizational structure and management style match the research strategy will determine if the desired scientific and organizational learning actually takes place. In each instance, different obstacles to learning present themselves. A second insight is the revision of organizational innovation theory, particularly the emphasis on the organic model, and the integration with the inter-organizational literature. The diversity of research projects shifts the attention in organizational innovation to the study of where the research is largely accomplished, while recognizing that there is not just the organic model but four profiles of research activity.

The third insight is the discussion of inherent dilemmas and problems. Rather than perceive low risk and low uncertainty as presenting no managerial dilemmas, we have suggested that they do. And unlike traditional contingency arguments that assert that the correct fit ameliorates any managerial problems, we are suggesting quite the opposite. Even with a good fit, there are still managerial problems associated with each of the four types of Research Profiles. These problems flow from the dilemmas that have been delineated. We have suggested what some of the solutions to these dilemmas are and then indicated that these define specific management styles. This is clearly not the usual perspective in either contingency theory, or management theory in general, but we would argue it is critically important given the central importance of research for both economic competitiveness and national security.

KEY TERMS AND DEFINITIONS

Competing Values Framework: The Competing Value Framework is a theoretical framework for assessing an organization's culture. The framework consists of two dimensions, organizational focus and decision making control, from which one can derive four distinct organizational cultural archetypes: Clan, Adhocracy, Hierarchy, and Market. (Cameron & Quinn, 1998; Quinn & Rohrbaugh, 1983)

Idea Innovation Network: The idea innovation network theory is a conceptual framework for understanding the generation of innovations across organizations. The theory posits that research is differentiated among six arenas reflecting basic, applied, product development, production, quality control and commercialization/marketing (Hage & Hollingsworth, 2000).

Innovation: Involves the creation of a new idea, method, process or device. One of the earliest contributions on organizational innovation was the concept of the organic organization (Burns

& Stalker, 1961). In recent years, a great deal of attention has focused on radical innovation (Leifer et al, 2000, McDermott & O'Connor, 2002).

Networks: A network is a pattern of relationship among actors, from individuals to organizations. Within the innovation literature, the types of networks studied have included intra-organizational networks (Mote, 2005), knowledge communities (Mohrman, Galbraith & Monge, 2004; Shinn, 2002), interorganizational networks (Alter & Hage, 1993; Powell, Koput & Smith-Doerr, 1996), and strategic alliances (Hobday, 1998; Shenhar, 2001).

R&D Organizations: Research and development (R&D) organizations are public or private organizations, or subunits of these organizations, focused on the development of scientific or product innovations (Trajtenberg, 2006). Many have argued that such organizations have unique work environments (Clarke, 2002), which require different approaches to management (Geles, 1999).

Harris, pp. 408-427, copyright 2012 by Business Science Reference (an imprint of IGI Global).

Section 7
Critical Issues

This section contains 13 chapters, giving a wide variety of perspectives on Industrial Engineering and its implications. Such perspectives include reading in privacy, gender, ethics, and several more. The section also discusses new ethical considerations within social constructivism and gender gaps. Within the chapters, the reader is presented with an in-depth analysis of the most current and relevant issues within this growing field of study. Crucial questions are addressed and alternatives offered, and topics discussed such as creative regions in Europe, ethos as an enabler of organizational knowledge creation, and design of manufacturing cells based on graph theory.

Chapter 83
Cultural Models and Variations

Yongjiang Shi
Institute for Manufacturing, University of Cambridge, UK

Zheng Liu
University of Cambridge, UK

ABSTRACT

This chapter provides the models and variation of culture. Specifically, the following concepts will be introduced: an understanding of the original of culture and how culture is studies in the academic field; the most influential culture theories which are adapted in business and management research. A detailed exploration on the methodology, dimensions, and implications of each model will be provided. An understanding of culture's impact on manufacturing systems which stems from traditional factory-based model to inter-firm network with the increase of collaboration in globalization is given Some understanding of culture's variation in the fast growing inter-firm collaboration with case observations are also elucidated.

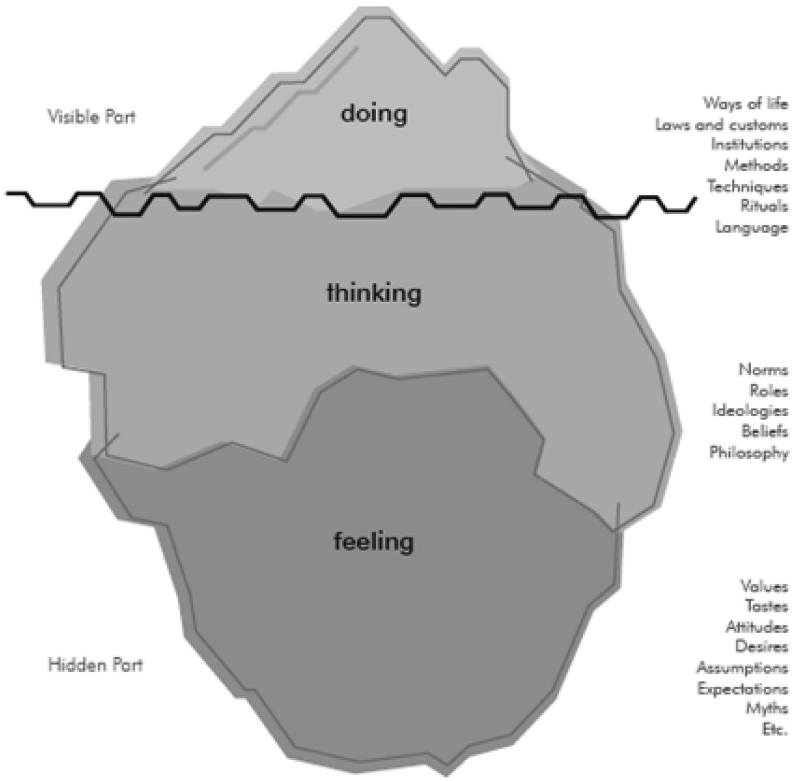
CULTURE AND ITS NATURE

Today business practices have experienced an increasing amount of collaboration as companies seek strategies to grow, restructure, and become globalized (Shi, 2005). Instead of traditional in-house production, many companies choose to collaborate as networks, particularly as international networks. The networks often include firms in different countries, and thus the interaction with companies from different national culture backgrounds becomes important. Culture influences the way companies operate. Cultural differences and conflicts become more obvious as increasingly more international outsourcing, Mergers and Acquisitions (M&As), and collaboration are developed. Culture can be defined as a system of values and norms "shared among a group of people, and when taken together constitutes a design for living" (Hill, 2000). It can be used to explain human and organizational behavior (Hofstede, 1980).

To illustrate and visualize the constructing elements of culture, several models have been developed. One of them is the "iceberg" model (French and Bell, 1979). As shown in Figure 1, it

DOI: 10.4018/978-1-4666-1945-6.ch083

Figure 1. Iceberg model of culture[1]



describes culture as an iceberg. The majority of culture, meaning to values and norms, is hidden below sea level. The top, visible area consist of behaviors, ways of life, laws and customs, institutions, techniques, rituals, language. They represent the impact of culture in daily life.

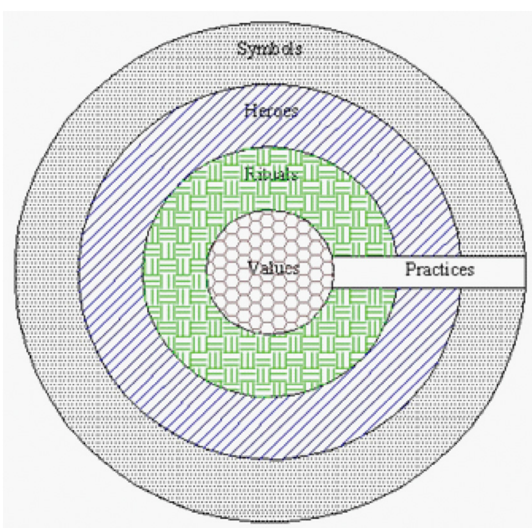
The "tree model" is another way to explain culture. As shown in Figure 2[2]. It provides the historical roots of culture—unwritten expectations, values, and norms. These factors can lead to the type of rites, stories, rules, language and behaviors, control system, and symbols.

The third model, known as "onion" (Figure 3) (Hofstede, 1994), indicates that culture, like an onion, can be peeled layer-by-layer to reveal the content. Symbols – words, pictures, or objects that carry a special meaning – are the most superficial layer. The core part of a culture is formed by the tangible symbols, heroes, story, and rituals. However, the real culture meaning of the practice is intangible. It is revealed only when the practices are interpreted (Hofstede, 1994).

In terms of cultural studies, the multi-discipline approach can be seen from perspectives of psychology, anthropology, sociology, politics, management, economy, and religion. The study of culture in psychology begins from individuals to groups and organizations, as individuals grow up within a particular culture and the accumulation of individual actions changes culture over time (Smith, 2002). Anthropology is a field of humanity starting from a group to a nation. According to anthropologists, culture is human nature. Cultural sociology is the study which uses culture analysis to interpret social life. In political science, culture is originally related to political sociology. A practical cultural approach is to identify the establishment of politics, to explain how symbols can produce political meanings, and to find out why some policies work better than others (We-

Figure 2. Tree model of culture[3]

Figure 3. Onion model of culture (Adapted from Hofstede, 1994)



deen, 2002). There are other disciplines which also explore culture factors. For example, from an economics perspective, national culture influences economic performance through institutions.

Culture as a system of values has many levels. Some typical levels are national, regional, gender, and organizational levels. These levels can overlap with each other. For example, an organizational culture can contain different regional cultures, and inside a region there can be several types of organizational cultures. In general national culture and organizational culture are most frequently studied as influential factors in business practice.

CULTURAL THEORIES AND DIMENSIONS

National culture is a frequent research in the context of international management. It is believed national level differences have a large impact on people's values as a group (Ford & Honeycutt, 1992). Many researchers try to define and measure national culture differences by establishing different sets of dimensions. Some of the most influential national culture theories are Hall's classic patterns (1959, 1969), Hofstede's cultural dimensions (1980, 1994), Hampden-Turner and Trompennars' cultural dilemmas (1993, 1997, 2000), and Schwartz value inventory (1992, 1994).

Hall's Classic Patterns

Hall is one of the earliest researchers on intercultural issues. Based on his own experience in foreign services and communication, he published two books – "The Silent Language" (1959) and "The Hidden Dimension" (1969), in which he identified two dimensions – "high vs. low context", and "polychronic vs. monochromic time orientation".

The first dimension – high vs. low context – describes the way information is transmitted. High context transactions feature pre-programmed information that is in the receiver and in the setting, with only minimal information in the transmitted message. In low context transactions, most of the information must be in the transmitted message". In this concept, countries such as the United Kingdom belong to low context culture, where information is clearly transmitted. France, on the other hand, is a high context culture, where hidden language is also used behind a conversation. Many Eastern countries also share features of high context.

Hall's second concept, "polychronic vs. monochronic time orientation", deals with the way people look at time. The monochronic time concept follows the notion of "one thing at a time", while the polychronic concept focuses on multiple tasks being handled at one time. In the culture of the UK and the USA, monochronicity is emphasized where people do tasks according to schedules, plans, and appointments based on first-come-first-serve principle. In Eastern cultures, schedules can sometimes be much more flexible. People tend to deal with emerging issues together with settled tasks. As one of the early culture studies, Hall's dimensions are very useful; however, the lack of empirical data and quantitative indications makes the concept difficult to apply.

Hofstede's Cultural Dimensions

From the 1980s, Hofstede began a survey to develop cultural models by using a large sample of IBM employees from 50 countries. Hofstede initially identified four key dimensions – "power distance (PDI)", "uncertainty avoidance (UAI)", "individualism vs. collectivism (IDV)", "masculinity vs. feminity (MAS)" – to define the differences between culture in different countries (Hofstede, 1994). Later on, the fifth dimension – "long vs. short-term orientation (LTO)" – was created in a study among students in 23 countries (Hofstede, 1994).

Power distance is defined as "the extent to which the less powerful members of institutions and organisations within a country expect and accept that power is distributed unequally" (Hofstede, 1994). It describes the hierarchical structure of a society and an organization. Uncertainty avoidance is "the extent to which the members of a culture feel threatened by uncertain or unknown situations" (Hofstede, 1994). High uncertainty avoiding countries prefer structured situations, whereas people from low uncertainty avoidance cultures are tolerant of different opinions. In individualism societies, "the ties between individuals are loose". Collectivism, on the opposite, describes a society in which "people are integrated into strong, cohesive in-groups" (Hofstede, 1994).

Hofstede defines the fourth dimension as "masculinity pertains to societies in which social gender roles are clearly distinct (Men are supposed to be assertive, tough, and focused on material success whereas women are supposed to be more modest, tender, and concerned with the quality of life); femininity pertains to societies in which social gender roles overlap (Both men and women are supposed be modest, tender, and concerned with the quality of life)." (Hofstede, 1994).

The fifth dimension was first termed as "Confucian Dynamism", and later was renamed as "Orientation" (Hofstede, 1994). Values associated with short-term orientation are thrift and perseverance. Long-term orientation is related with tradition, and fulfilling social obligations. In Hofstede's revised and expanded edition of his previous work (2010), another dimension "the nature of subjective well-being" was added to his original findings. As a societal dimension, it indicates to what degree people pursue leisure and feel happy. Hofstede's work was widely implemented in management studies. However, there is also debate that Hofstede's work is entirely based on an attitude-survey questionnaire, and it is questionable whether this is an appropriate way to find out about a nation's culture (Tayeb, 2000). The sample is also highly specific – a single industry and even a single company (Tayeb, 2000).

Trompennaars & Hampden-Turner's Cultural Dilemmas

Trompenaars and Hampden-Tuner's research is based on a ten-year period with questionnaires to 46.000 managers from 40 countries. They used a 7-dilemma model to explain culture from the perspectives of rules, individual, emotion, involvement, status, the approach to time and attitude toward the external environment. A series of seven cultural dilemmas are identified (Hampden-Turner & Trompenaars, 2000).

Universalism vs. Particularism

Universalism searches for the common similarity and standardization in a community, whereas particularism highlights the differences and uniqueness (Hampden-Turner & Trompenaars, 1993). American culture is universalism because of its "stable democracies and global cooperation – they assume that techniques can be applied universally" (Hampden-Turner, 1991). Most Catholics, Buddhist, Confucian, Hindu, and Shinto countries tend to be particularism – concerning more about personal relations (Hampden-Turner & Trompenaars, 1993).

Individualism vs. Communitarianism (Collectivism)

Individualism is associated with competition, personal growth, and fulfillment, whereas communitarianism is linked with cooperation and social concern. Most pioneer capitalist countries favor individualism, and seek personal goals and responsibilities, whereas other countries highlight team spirit (Hampden-Turner and Trompenaars, 1993).

Affective vs. Neutral Cultures

In an affective culture, people do not object to a display of emotions. In a neutral culture, people are taught that it is incorrect to show one's feelings overtly – they are aware of feelings, but keep them in control (Hampden-Turner & Trompenaars, 1993).

Specific vs. Diffuse Relationships

Cultures vary in the how specific they are. Most Protestant countries are specific. They like action, research, problem analysis, and competition. However, Catholic countries are regarded as diffuse, passionate, and romantic – they stress relationships (Hampden-Turner & Trompenaars, 1993).

Achieving vs. Ascribing Status

In a culture of achieving status, people believe there is fair atmosphere. By making efforts, one can achieve his/her goal. In ascribing culture, people are determined by their birth or origins (Hampden-Turner & Trompenaars, 1993).

Sequential vs. Synchronic

Sequential time is described as an "irreversible sequence of seconds, minutes, hours, days, months and years" (Hampden-Turner & Trompenaars, 1993). The contrast is synchronous time, which is circular or cyclical. USA people regard time as money, and race with the clock, whereas eastern people do many things simultaneously.

Inner Directed or Internalist vs. Outer Directed or Externalist

Inner direction is measured by virtues inside people – souls, wills, principles, and core beliefs. Outer direction is featured by external virtues in natural rhythms, environments and relationships (Hampden-Turner & Trompenaars, 1993). For each dilemma, according to Hampden-Turner and Trompenaars (1993), the aim is not to choose between the options, but to manage and achieve integrity.

Schwartz Value Inventory

Another theory in national culture studies was established by Schwartz (1992, 1994). Using Schwartz Value Inventory (SVT), Schwartz asked respondents to assess 57 values as to how important they felt these values were as "guiding principles of one's life". Analysis was separated into an individual-level and a culture-level. From data collected in 63 countries, with more than 60,000 individuals participating, Schwartz categorized 10 distinct values at individual-level analysis: power, achievement, hedonism, stimulation, self-direction, universalism, benevolence, tradition, conformity and security. Based on this structure, four value dimensions were finalized as: openness to change, self- enhancement, conservation, self- transcendence.

Seven types of national values were also found from the survey as – conservatism, intellectual autonomy, affective autonomy, hierarchy, egalitarian commitment, mastery and harmony, which were further summarised into three dimensions.

Embeddedness / Autonomy

This dimension concerns the relationship between the individual and group. Embeddedness culture emphasize group values and people's commitment to the group. In autonomy culture, people have their own uniqueness.

Hierarchy / Egalitarianism

This dimension concerns about the hierarchical structure of a society. Hierarchy represents a cultural emphasis on obeying to the unequal distribution of power. Egalitarianism emphasizes self-interests and equal opportunity.

Mastery / Harmony

Mastery refers to a culture which prefers competition and self-achievement. Harmony represents an emphasis on maintaining the world as it is, keeping a relationship rather than to change it. The SVI mentioned earlier represents a different way from previously studies in terms of methodology. It is based on a conceptualization of values and is developed with systematic measurement and analysis tools (Drogendijk & Slangen, 2006). However as a relatively new theory, the framework has not yet been tested through empirical applications enough (Drogendijk & Slangen, 2006).

Other Studies

Besides the above four key theories, there are other studies on national culture. Kluckhohn and Strodtbeck (1961), and Triandis (1972) created seven dimensions: hierarchical nature, individualism vs. collectivism, attitudes towards work, time orientation, approach to problem solving, fatalism, view of human nature. Additionally, other large scale of culture survey were taken in House et al., (1994)'s GLOBE project, and Minkov's World Values Survey (WVS) (2007). Lewis (2000) classified nations into three groups: linear-active, multi-active, and reactive, whereas Tayeb (2000) also developed seven main categories and 55 items of cultural characteristics.

Organisational Culture (Corporate Culture)

The study of organization or corporate culture has similar methodology and vision with national culture. From the foundations, culture aspects of an organization are observed through collective behavior, or the manner in which to strengthen member commitment (Durkheim, 1965). The broad studies of anthropology, sociology, political science all contribute to the literature of organizational culture. The level of analysis includes organizational level – viewing culture in its societal context, and "micro" level – concerning about individual participation and problem solving inside the organization (Fryxell, & Van Cleave, 1989).

Two general approaches of studying can be observed in organizational culture studies. The first stream views culture as "implicit in social life". The second stream views culture as "an explicit social product from social interaction as a consequence of behaviors, which contains observable forms such as customs, methods of problem solving and use of technology" (Baker, 2002). In the second approach, more practical issues are considered, such as the control power of the management groups (Martin et al., 1985), leadership, and culture change.

In terms of classifications of organizational culture patterns, Deal and Kennedy (1982) identified four key dimensions of organizational culture as: 1) values - the beliefs that lie at the heart of the corporate culture; 2) heroes - the people who embody values; 3) rites and rituals - routines of interaction that have strong symbolic qualities; 4) the culture network – the informal communication system or hidden hierarchy of power in the organisation. Denison (1990) created four types of organisational culture as: "(1) the consistency hypothesis, (2) the mission hypothesis, (3) the involvement / participation hypothesis, (4) the adaptability hypothesis". Using the four types of leaders from Greek mythology, Handy (1995) characterized organizational culture types as Zeus, Apollo, Athena, and Dionysus, and classified them into three types (Handy, 1995): 1) role cultures "Apollo"; 2) task cultures "Athena"; 3) existential design cultures "Dionysus"; 4) club culture "Zeus". Cameron and Quinn (1999) categorized organizational culture into four types – hierarchy, clan, market and adhocracy, Schein (1992) developed dimensions of organizational culture into: 1) external environments; 2) managing internal integration: 3) reality, truth, time, space, human nature, activity, relationships.

The issue of culture change is also highlighted in qualitative studies. Trice and Beyer (1993) pointed out the basic types of culture change such as the revolutionary, comprehensive, and gradual efforts. In Schein (1999)'s view, the strategies are: (1) unfreezing the old culture and creating motivation to change; (2) capitalizing on propitious moments; (3) making the change target concrete and clear; maintaining some continuity with the past; (4) creating psychological safety through a compelling positive vision, formal training, informal training of relevant groups and teams, providing coaches and positive role models, employee involvement and opportunities for input and feedback, support groups, and addressing fears and losses head on; (5) selecting, modifying, and creating appropriate cultural forms, behaviors, artifacts, and socialization tactics; (6) cultivating charismatic leaders; (7) having a realistic and solid transition plan; and, (8) exercising risk management by understanding and addressing the risks and the benefits as well as the potential inequitable distribution of these risks and benefits.

MANUFACTURING SYSTEM AND CULTURE

The linkage between culture and manufacturing system has drawn attention in both research and business practice. Culture is formed by nature forces such as environment change, and human force including war, immigration, trading, and technology (Hofstede, 1980). It influences the way people behave within a family, community, organization, region, and nation. On a system level, it also forms the way of education, family patterns, political structure, business routines, legislation, and communication within a nation and society (Hofstede, 1980). These systems will eventually influence business practice such as innovation pattern and relationship management. Figure 4 provides a framework to indicate culture's origins and its impact.

Figure 5 is the conceptual framework of manufacturing systems. Traditionally, culture influences operations in a single factory in terms of quality management and human resource management. For example, the Lean concept from Japan is much related with the Japanese culture of collectivism, and high uncertainty avoidance. The designing of shop floor layout can also reflect individual or collective culture. More studies are carried out on the impact of national culture on the using of Manufacturing Resource Planning (MRP) and Total Quality Management (TQM). As factories disperse among various countries, to some extent national culture differences can determine the coordination of new product development and production management in different locations. The issue of cross-border Mergers & Acquisitions (M&A) also includes many culture elements as host country and home country can differ in many ways. There are many studies on the relationship between the preferences of foreign investment mode, local management, innovation patterns with culture differences by using the scores provided in Hofstede's culture theory.

Figure 4. A system of culture (Compiled from Hofstede, 1980)

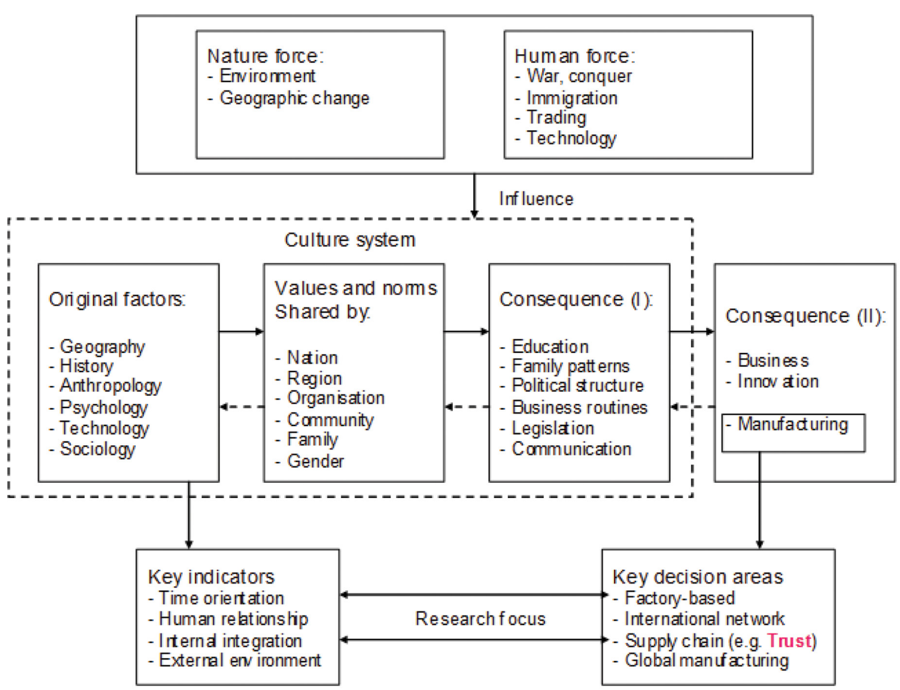


Figure 5. International manufacturing system framework. Adapted from Shi, 2005.

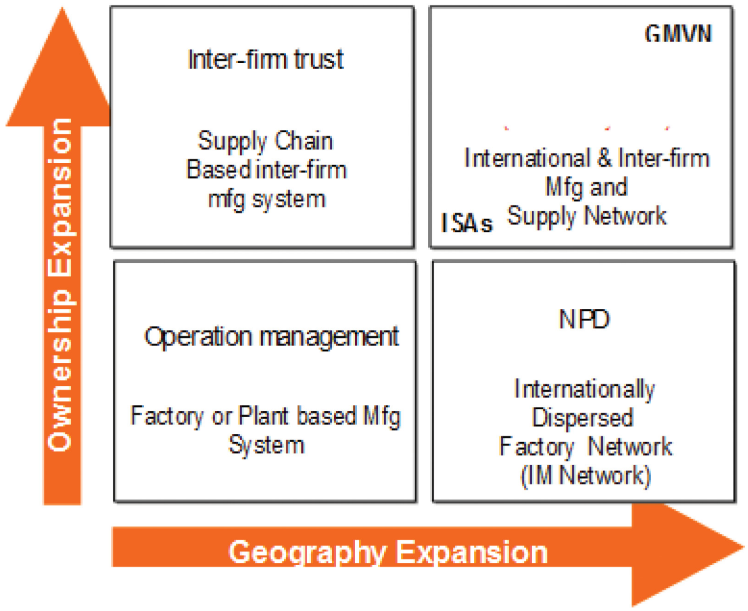

In the vertical axis of Figure 5, the supply chain requires for understanding and coordination of different firms who have different values and culture background. Among the inter-firm issues are trust, technology transfer, and learning. Culture differences can result in different understanding and evaluation methods of trust. For example, the inter-firm trust in western culture rely more on competence and clear contract, but in China, personal relationship is more important. To combine the inter-firm and intra-firm issues, globalization and the global manufacturing virtual network have much interaction with culture in terms of information management, network structure, coordination and control.

INTER-FIRM RELATIONSHIP AND CULTURE WITH INDUSTRY OBSERVATIONS

The impact of national culture on inter-firm relationship becomes an important issue as companies now operate within a network. There is much collaboration between firms from different national backgrounds. Understanding cultural differences can help to solve problems, and failure to do so may cause misunderstanding, conflicts, and difficulty reaching an agreement. This happens not only in traditional industry sectors, but also in new industry sectors. For example, using the creative industry in the past, the product of animations was done primarily via in-house production. Since the 1980s, there has been a trend towards outsourcing and international collaboration. In China, due to the lack of original design capability during the 1980s, most animation companies are studios which focus only on production. As a result, many western and Japanese animation designing companies choose to collaborate with Chinese studios to enter the Chinese market, and to cut down production cost. When studying into these Chinese animation companies, it is found that they are experiencing culture differences between the Chinese and western culture.

One case company from China collaborates with both Chinese and USA partners; however, the collaboration followed different processes.

One chief executive said: "In China, we first find friends; then perhaps we choose the most capable partner within that community. Sometimes we do not establish any contract at all. It is more about personal interaction." In this way, they join animation industry clusters, keeping close to other partners, and getting to know more friends through the intermediate introduction. They build up with many Chinese partners who may not be capable enough to design a full animation production. However through co-learning and sharing resources, they develop a competence together.

Meanwhile, through 10 years of international outsourcing collaboration, they also realize that "when we collaborate with western partners, we should always focus on our capability. No matter how well people know us, we must show them evidence that our technology and skills are satisfactory. There is a strict process and a standard contract to identify roles, responsibilities, technology issues, cost, IP." In order to attract more western clients, this company pays much attention to competence improvement by:

- Using the latest 3D drawing software and train employees with skills
- Developing a IP protection system in terms of hardware and software
- Exchanging staff overseas to learn cross-culture management
- Other training program such risk management
- Continuously improving knowledge and new production technology

This case shows the different approaches of the Chinese and USA way of developing inter-firm trusting relationship. Chinese companies prefer relationships first, and then co-develop a competence, whereas companies in the USA highlight the competence and standard contract first, and may develop long-term interaction later. To trace back the national culture root of Chinese and USA companies, several features can be learned through previous culture theories. A comparison can be made as in Table 1.

In general, Chinese culture has the feature of long-term orientation, polychronicity, high power distance, collectivism and diffusion. It emphasizes group goal, teamwork, and personal relationships. When developing inter-firm relationships, it tends to develop personal interaction with a long-term orientation. Additionally, tasks may not be allocated clearly. Instead, co-evolution and sharing is more desired. In contrast, the USA has the culture of short-term-orientation, mono-

Table 1. Culture differences in China and USA

Culture dimensions	China	USA
Long vs. short-term	Long-term (118) (Hofstede)	Short-term (29) (Hofstede)
Monochronic vs. polychronic	Polychronicity (Hall)	Monochronicity (Hall) Sequential (Trompenaars)
Power distance	High (80) (Hofstede) Particularism (Trompenaars)	Slightly low (40) (Hofstede) Universalism (Trompenaars)
Individualism vs. collectivism	Collectivism (20) (Hofstede)	Individualism (91) (Hofstede) Individualism (Trompenaars) Autonomy (Schwartz)

Uncertainty avoidance	Low (30) (Hofstede)	Slightly Low (46) (Hofstede)
Specification vs. diffusion	Diffusion (Hall)	Specification (Hall)

chronicity, low power, individualism, masculinity and specification. It highlights the clarification, transparency of documents (in the case of contracts), a clearly defined technology, and individual responsibility. Therefore, companies in the USA may visit their partners directly to make sure that a real competence exists. It may also have a standard process of sample making, technology definition, and partner selection.

The success of this Chinese company gives a good example of handling the culture differences between the East and the West. It focuses on conflicting values and adapts itself to the new context. The company does well because it keeps the culture differences clearly in mind and respects the values from its partners. To achieve effective communication, it sends people to learn American culture in USA, and invite partners to experience Chinese culture. Other companies may still struggle with cross-culture relationship. Sometimes they turn to professional consultancy or local agency for help. A comprehensive understanding of culture theory is foundamental. Furthermore a real practical knowledge of how culture influence business behavior can be enriched through international management experience.

CONCLUSION AND FUTURE AREAS FOR CULTURAL STUDIES

This chapter first introduces the concept of culture from the perspectives of typical models, disciplines, and levels. Then particularly some most influential studies on national culture and organizational culture are provided with details of definition, dimensions, and meaning. From the literature review, it is clear that researchers explore culture mostly from aspects of national culture and organizational culture with dimensions. To finalize the similarities among the dimensions by its meanings, three types of culture can be summarised as time orientation, internal integration, and external adaptation (Table 2).

1. **Time orientation:** related with people's attitude towards time. Dimensions include the "long vs. short term orientation"; "monochronic vs. polychronic", which are combined from Hall, Hampden-turner, and Hofstede's dimensions.
2. **Internal integration:** refers to the issues related to the relationship in human organizations, such as the hierarchical structure, the emphasis on competition, and group relationships. Dimensions are the power distance, individualism vs. collectivism, and masculinity vs. feminity.
3. **External adaptation:** focuses on the interaction between human society and the outside environment. Details are uncertainty avoidance, and the content of communication (specification vs. diffusion) can also be included as external issue.

The later section of the chapter discuss how these dimensions can be adopted as national culture variables when assessing the interaction between culture and issues of business management. Particularly an industry observation was given to show the culture factor in inter-firm relationship management in the context of the USA and Chinese collaboration. The values and processes indicate different priorities of Chinese and American companies.

Following the literature, this chapter also provides preliminary thoughts on the impact of

Table 2. Dimensions of national culture

Types of culture	Key dimensions
Time orientation	Long vs. short term orientation
	Monochronic vs. polychronic
Internal integration	Power distance
	Individualism vs. collectivism
	Masculinity vs. feminity
External adaptation	Uncertainty avoidance
	Specification vs. diffusion

culture on manufacturing system, which grows from individual factory based system towards inter-firm and intra-firm international network. Some industry observations on the cross-culture inter-firm relationship issues are also explored.

There are some future research areas for culture, which are closely related with the emerging issues of business. One important phenomenon now is the emerging countries MNEs. In the past decade, many of these companies have emerged from China and India. They develop quickly, and extend resources quickly through M&A. However, some of the companies failed to conduct local people management, while others may still struggle with local adaptation. Culture differences between the host and home country contribute a lot to the problem. How to use culture dimensions to help those emerging countries MNEs to integrate resources after M&A, and build up local relationship effectively can be of much practice values in the current business climate. Also, as manufacturing nowadays aims to achieve a more sustainable system, the issue of green management, which involves the interactions with environmental and societal factors become important. Different countries may view differently towards green issues, and thus conduct different practices. There is a need to link current culture theories with sustainability dimensions. The topics of "what are the new requirements for culture" in this sustainable system will also be of great value in future research.

In terms of culture studies itself, a multi-discipline is needed. These can help to enrich the existing theories with a broader view. More qualitative research is also required to understand the process of cross-culture management in the current international business climate.

Chapter 84
New Design Paradigm:
Shaping and Employment

Vladimir M. Sedenkov
Belarusian State University, Belarus

ABSTRACT

The multiple shortcomings of the current Design paradigm manifest the need of its modification. Our objective was to find out an appropriate mechanism. But such a mechanism could not be revealed without assistance of a Design theory. The emergent dilemma – to use one of the available theories or develop a new one – was resolved by choosing the third way: rearrangement of the material at hand on modularity principles with initiation of fundamental (systemic) Design theory module via identification of its paradigm. While doing this, we had to overcome a number of delusions ingrained in engineering design, concerned firstly with design problem, process and design representation. To push these efforts forward, a scientific base named Continuous Process Theory had been developed. Systemic module initiation enabled to define a paradigm of the second Design theory module – the sought-for Design practice paradigm. Discussion on the outcomes of this definition rounds off this chapter.

INTRODUCTION

The Way to Reveal an Adequate Design Paradigm

The title of the chapter declares generation of a new design paradigm – the set of practices that define and drive (implements and manage) design process (*DPR*). This assumes that a certain version of the paradigm is available. Indeed, it cannot be out of place because of many decades of everyday designing. Design paradigm ("applied theory") is crystallized by design practice and is needed for practitioners in each design field – whether it be mechanical engineering, information science, architecture, chemistry, nano-technology or something else. Design paradigm is the base of design methodology within a given domain and the benchmark for developers of computer-aided design facilities.

DOI: 10.4018/978-1-4666-1945-6.ch084

In Design theory absence, Design paradigm formation was spontaneous: the values of its descriptors mirror a specialized empiricism, intuition, experience, borrowings, parts of theories possessed by other disciplines, etc. This has stipulated a number of weak points of the paradigm. With the reference to design in mechanical engineering, recall some of those:

- it employs semi-intuitive design language;
- supports mainly adaptation design;
- generates ill-observable, non-holistic *DPR*, which is equally insufficient for learning and teaching and for the most part implicit;
- has no ideas how to keep the *DPR* complexity to a manageable level;
- structure synthesis problem remains unsolved;
- the role of computer in designing is obscure and insufficient;

Thus, modification or replacement (radical modification) of design paradigm is anticipated and in demand. However, there is no a regular mechanism of paradigm improvement, which should concurrently be a mechanism of paradigm identification forgoing to its change. Let us try to find out such a mechanism.

To be analyzed, evaluated and modified, the paradigm should have a sort of representation. We associate with any Design paradigm representation a set of descriptors or *paradigmants* – the certain characteristics of a paradigm, which take on one or another value. Thus, paradigmants characterize via their values this or that paradigm during a certain period of time. For instance, Design paradigm is concerned with such paradigmants as *notion base of design language* (formalized ∨ intuitive ∨ semi-intuitive), *the mode of structure synthesis problem realization* (explicit ∨ implicit), *design system architecture* (an hierarchy of subsystems ∨ another) and others.

If paradigm representation is available, we define a paradigm modification as the change of values for one or a subset of its paradigmants. To regularize the way of paradigm change, we distinguish within its representation a minimal subset of paradigmants sufficient for a unique paradigm identification – call it *design paradigm signature* (*Sg*). Then change of values for paradigmants, which are beyond the signature, would signify the paradigm modification, while the change of value for at least one signature's paradigmant replaces the paradigm. A signature considered without its paradigmants values is called a signature platform or *meta-signature* (*mSg*). Choosing different variants of *mSg* attribution, the produced signature alternatives (paradigm identifiers) could be compared and paradigm assessed as a whole.

It should be noted that the outlined mechanism of paradigm identification and modification has a heuristic base – the choice of both paradigm representation and modification rests mainly on experience, intuition and experiment. This does not make the mechanism reliable. Besides, it generates only paradigm clones according to given representation – this deprives the mechanism of practical value. Generation of paradigm versions becomes possible after changing the course of identification for an opposite one. This means that paradigm representation initially is unavailable and its deriving begins with identification of Design paradigm meta-signature and signature. Then the paradigm representation will be obtained by deployment of its signature. But such a systematic way of Design paradigm handling needs for feeding it by a resource of paradigm *mSg* generation. Such a resource could be provided by a Design theory only.

TOWARDS DESIGN THEORY PARADIGM IDENTIFICATION

Requirements to Design Theory

Does the stated need for Design theory signify development its new version or sampling from the list of currently available Design theories is also possible? To make decision, let us lay down three clue, in our view, requirements to Design theory.

1. First of all, the theory has to have a base of scientific principles. "The teaching of engineering subjects such as thermodynamics, mechanics, and materials are based on established principles like the first and second laws of thermodynamics, Newton's laws, and atomic and molecular theories of matter… Engineering design lacks sufficient scientific foundation, and without an adequate base of scientific principles, engineering design education and practice are too much guided by specialized empiricism, intuition, and experience" (Dixon, 1988, p. 145).
2. To be accepted by practice, a theory should answer its questions, solve its problems, and uppermost provide a regular mechanism of Design paradigm identification (attribution of *mSg* paradigmants) and modification. In case of design practice, its *mSg* is invariant and fixed a priori: i) constructive design definition; ii) a priori described process that provides the sought-for design, i.e. *meta design process* (Sedenkov, 2008, p. 93); iii) a system that supports meta process run or *design system*. Combining the requirements 1 and 2, we assert that the base of scientific principles should be aimed firstly at beneficial identification of Design paradigm (a proper *Sg* of Design practice paradigm).
3. The requirement of a viable theory organization is the last one in the triple. The origin of this requirement needs for comments.

We have in focus a Design theory, which should have its own paradigm – a set of ideas that define a scientific discipline during a particular period of time. This theory should identify an adequate design paradigm that is the part of itself, as the identified paradigmants of Design paradigm signature will become paradigmants of Design theory paradigm. This separation of Design theory and Design paradigm in their unity gives rise to the idea of modular structure of Design theory where paradigms of two main modules – Design theory and Design practice – define accordingly fundamental and applied aspects of a single theory.

Indeed, distinct components of Design theory may have substantially different dynamics of development. For instance, there are highly dynamic divisions aiming at knowledge handling. Next, market dynamics of computer aided design facilities and value dynamics of Design paradigm paradigmants, which are beyond the signature, interrelated closely and stimulate each other. Besides, the status of interdiscipline accepted by designing (Cross, 2002) obligates it to interact with a dynamic list of contractor disciplines. In this situation, a single Design theory has been either substantially loose or inflexible. The first variant makes a theory be of little use for design practice while the second one entails its frequent revisions and disintegration into a number of short-lived mini-theories supporting particular design stages (DfX). Between one-piece ("General") and mini-theories, there is a class of "heuristic" theories for particular design fields.

In case of modular structure of Design theory, the paradigms of modules get the autonomy in the sense of possibility to vary within the values of their current signatures. The paradigm change of Design theory itself (replacement of its signature value) occurs either on a signal "underneath" (when the paradigms of modules are not sufficient any more), or "from above" (with gathering new knowledge about signature's paradigmants possessed by Design theory paradigm and/or with alteration of scientific principles). It seems of importance to reserve the space for paradigmatics variations in each of modules as it should ensure simultaneously both the theory stability and its progress without strong conflicts between them.

Choice Testing

Let us see, whether some of the available theories could be suited for our objectives. To avoid single analysis (it is beyond the scope of this chapter), we shall manipulate the two above mentioned classes testing those for compliance with the stated requirements.

The class name "heuristic" indicates not only the origin of theories "from practice" but the domination of heuristics in their statements as well. The prevalent method of such theories creation is induction, which begins with generalization of design experience. With the terminology introduced, one may state that this class of studies (Lossack&Grabowski, 2000; Eder&Hosnedl, 2008) is characterized by the attempt to elevate applied aspect of design theory to the rank of fundamental. In other words, Design paradigm signature should become a core of Design theory paradigm signature. But as initial component is not reliable, the result proves to be artificial as well. In so doing, the weak points of design paradigm (for instance, the transfer of concepts related to representation and analysis of available products to synthesis of nonexistent products) turn to be weak points of Design theory.

The alternative class of theories ("General Design Theories") stresses the fundamental aspect putting off the handling of applied one to the end of theory formation. But when the theory comes to the focus of practice, it turns out that the applied aspect of the theory does not suit for complete and consistent use (Yoshikawa, 1981; Hatchuel, 2003). Thus, though the maxim "a theory will help advance the practice of design" (Dixon, 1988, p. 148) became a generality, it does not follows from the theory itself *how* and *by which* the advancement should come.

Having compared the properties of Design theory classes with the triple of requirements (sound scientific foundations, aimed at Design paradigm identification, and modularity), we have to conclude that the choice in the space of available Design theories could hardly be resultant to our end.

What Then, a New Theory?

However, the conclusion about necessity of new Design theory creation would be premature as well. In the light of modular structure and relative autonomy of both – modules evolution and its rate, theory shaping and its validation is the issue of time and efforts of the entire design research community. On the other hand, odd parts of a theory are in existence (Design paradigm, design methods, design knowledge, etc.) but those are either inadequate (like Design paradigm) or technologically imperfect in practical use (as knowledge or design methods).

Under this situation, it seems rational to rearrange the available material on the principles of modular theory organization. Then the first module should be established. It has doubling the parts of an attractor for odd elements of the theory and a platform for creation and synergetic operation the rest of the theory modules. This gives grounds to consider not a theory creation but its *initiation*, that is shaping a module of fundamental theory aspect or, hereinafter, a *theory platform*.

The Platform Based Design Theory Organization

The Design theory platform should provide a mode of Design paradigm signature identification and so is initially aimed at establishment and support its applied aspect. To develop the platform means firstly to propose a meta-signature of its paradigms. Then we have to initiate an adequate signature via attribution *mSg*'s paradigmants. The signature of Design theory platform will ensure the Design paradigm signature identification. The latter also has *mSg*, which is known a priori and was mentioned above.

We complete to plan a modular structure of Design theory by introduction of its third module.

It will be a meta knowledge base that involves design methods, design knowledge, computer software, contractor disciplines, multidiscipline models and will be provided with control facilities to support knowledge access, knowledge storage and knowledge maintenance. We call this module "Design knowledge management system". Its meta-signature consists of three paradigmants: knowledge structuring, knowledge storage and knowledge access.

Thus, the only way to obtain Design paradigm signature (attribution of *mSg* paradigmants) is the initiation of constructive version of Design theory via identification of paradigm signature for the main module of the theory. In turn, Design paradigm signature has been a trigger for shaping the third module of the theory via identification its signature. Such a "modular-trigger" concept of theory development removes from agenda the necessity of General Design Theory. The latter can be changed for the new entry – a unified Design theory platform. On the other hand, it has been doubtful to have internal Design theory for each particular design field – with the use of master module they can adjust two other modules from the triplet and get a required version of Design paradigm for the domain.

The reminder of this chapter is organized as follows. In the next part we briefly review the proposed science base for design – Continuous Process Theory and the mode of problems tackling when those have the same insolubility (of the second kind) as a design problem. The third part addresses to establishment of Design Theory platform that paves the way to adequate design paradigm identification. The proper design practice paradigm revealing is the content of the forth part, while the main outcomes are discussed in the fifth part.

TOWARDS DESIGN THEORY PLATFORM: THE BASE OF SCIENTIFIC PRINCIPLES

Continuous Process Theory

Dixon (1988) states that "design is a process, and processes are not the usual subject of theoretical formulations" (p. 146). A process is a continuous entity and therefore it should have a continuous representation. Discrete representation of a process – by an hierarchy of sub-processes, for instance – mostly inefficient. *Continuous Process Theory* (*CPT*) is just intended to serve for the part of adequate scientific principle for design theory development. Here are two of the most important applications: (1) with the help of *CPT*, we shall show a design problem membership of the class of problems with insolubility of the second kind and outline the way to get an answer to such problems; (2) structure synthesis problem realization needs for continuous representation of a design, and we shall get it using (continuous) representation of *operation process* of the required product.

The starting point of *CPT* is representation of any process *PR* by its scheme:

$$PR=(D, P), \tag{1}$$

where *P* stands for a *processor* that performs transformation of energy, raw materials, information or products entering its input (I^P), and *D* stands for a *procedure* that describes the function of *P* over its I^P. *D* and *P* are referred to as a process *object* and *subject* respectively. Thus, the *subject matter* of *CPT* is a representation of complex process in a continuous mode. The *CPT method* – the scheme technique of process – is characterized by the following:

- A set of process schemes is added with a number of binary relations;
- Process schemes linked by distinguished relations make up a *structure*;

- The rules for structure shaping and conditions for its operability are stated.

The *CPT goal* is a constructive proof for a process (induced, for instance, by a declared problem and represented by the scheme) its runability through building up upon its scheme an operable continuous structure of processes.

There are two relations appropriate for making up the structures: providing relation or **p**-*relation* and relation of determination or **d**-*relation*. PR_1 and PR_2 are linked with **p**-relation $(PR_2 \xrightarrow{p} PR_1)$ if the output of PR_2 serves for the input of PR_1. If the output of PR_2 becomes a scheme component of PR_1 (*D* or *P*), these two processes are linked by **d**-relation $(PR_2 \xrightarrow{d} PR_1)$.

A set of processes (or their schemes) continuously linked by **d**- or **p**-relation forms an *elementary structure* of processes (or process schemes). This structure is represented by a plain graph, the nodes of which serves for the processes and each arc is a cross-linking relation. Elementary structures have an *order n*, equal to *1* (Figure1).

Each processes structure has a *core* (PR_1), a *tail* (PR_n) or *multitail* (PR_2, PR_3) and a *body* (the part between the core and tail). Elementary structures generated by one of the relations can form a new structure by the alternative (orthogonal) relation. The new structure gets $n=2$ and is represented by a *super-tree* (*S*-tree) – an arc bichromatic (2D) tree where each node is an ordinary graph (Figure 2*a*). Relations between members within such non-elementary structure of processes are relations between the members' cores.

The structures with $n=2$ may serve for the members in a structure of the next order. A usual motive for the third order structure generation is the synthesizing a required process from scratch. To this end, let us associate with each process scheme a level of its *uncertainty* (*UL*) as *UL* of the scheme's components.

Figure 1. First order process structures on **d**- *and* **p**-*relations*

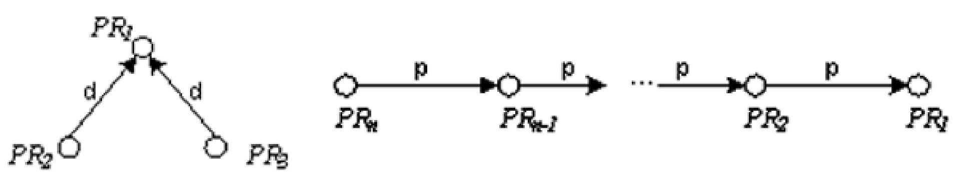

Figure 2. The second order S-tree by **p**-*relation (a) and the third order S-tree by* **d**-*relation (b)*

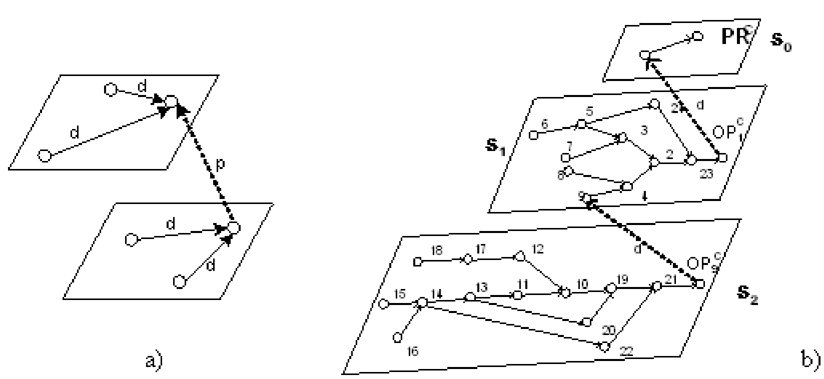

- A process, which has *UL=0*, is called *physical*: its *D* and *P* are real.
- *UL=1* corresponds to a *logical* process: its *D* and *P* have descriptions sufficient for their physical implementation.
- A *virtual* process has *UL=2*: its *D* and *P* exist only as mental images.
- *UL=3* is assigned to a *conditional* process (PR^C): its result has been declared but its *D* and *P* are presented by their symbols only.

Constructive proof of logical runability for PR^C consists in stepwise reduction of its *UL*. A step of reduction is referred to as *determination* of conditional, virtual or logical process. Each step of $PR^C=(D, P)$ determination is modeled by the search on appropriate sets for its *D* and *P*. Thus, each search assumes the run of two processes – *search for D* (*SD*) and *search for P* (*SP*):

$$SD \xrightarrow{d} \mathrm{PR}^{C} \xleftarrow{d} SP \qquad (2)$$

While the two-stroke determination of PR^C (Table 1), the objective of the *virtu al* (downward) determination is the reduction *UL=3→UL=2*; during the second or the stroke of *logical* (upward)

Table 1. Constructive proof of logical runability for a conditional process

Down stroke	**Up stroke**
$SD^V \xrightarrow{d} PR_1^C \xleftarrow{d} \mathrm{SP}^V$ **1**	PR_1^L =(D, P) **8**
PR_1^V $p\uparrow$ PR_2^c **2**	PR_1^L $p\uparrow$ PR_2^L $\Uparrow$ I^P **7**
PR_1^V $p\uparrow$ $SD^V \xrightarrow{d} PR_2^C \xleftarrow{d} \mathrm{SP}^V$ **3**	$SP^L \xrightarrow{d} PR \xleftarrow{d} \mathrm{SD}^L$ $p\uparrow$ PR_2^L $\Uparrow$ I^P **6**
PR_1^V $p\uparrow$ PR_2^V $\Uparrow$ I^P **4**	PR_1^V $p\uparrow$ $SP^L \xrightarrow{d} PR_2^V \xleftarrow{d} \mathrm{SD}^L$ $\Uparrow$ I^P **5**

determination, the reduction $UL=2 \rightarrow UL=1$ will take place.

This two-stroke cycle of PR^C determination results in *S*-tree (Figure 2*b*) where each node is the second order structure (2). Thus, while representing a complex process in *CPT*, the underlying principle is not a *D* decomposition with shaping a hierarchy of sub-processes, but making up a continuous structure out f process schemes.

Realization of Problems with Insolubility of the Second Kind

Let the structure (2) be elementary, i.e. when PR^C has a defined input (I^P) and does not need a generation of providing process:

$$SD \xrightarrow{d} \underset{I^{P\uparrow}}{PR^V} \xleftarrow{d} SP \qquad (3)$$

Reduce (3) to the form (4) assuming **d**-relation between the contents in brackets:

$$PrB = \langle SD, SP \rangle \xrightarrow{d} \langle \underset{I^{P\uparrow}}{PR^V} \rangle \qquad (4)$$

Following (Polya, 1965) while generic problem tackling, we distinguish a "*problem solution*" (the determined *D* and *P* from PR^L – the results of <*SD, SP*> performance) and an "*answer to the problem*" (the output of PR^L). The activity consisting in problem solving (<*SD, SP*> execution) and answer computing (PR^L run) is referred to as *problem realization*.

But expression (4) does not meet the structure precondition – the two processes in <*SD, SP*> are linked by empty relation. To restore for (4) the structure status, divide it into two schemes of processes where the relation between them is **d**-relation between their cores (the first scheme has no tail):

$$PrB = \langle SD \rangle \xrightarrow{d} \langle SP \xrightarrow{d} \underset{I^{P\uparrow}}{PR^V} \rangle \qquad (5)$$

Next, making **d**-relations implicit, we get two expressions named *problem schemes*:

$$PrB = \langle SD \rangle \langle SP, \underset{I^{P\uparrow}}{PR^V} \rangle$$

or (6)

$$PrB = \langle SP \rangle \langle SD, \underset{I^{P\uparrow}}{PR^V} \rangle$$

Thus, problem schemes like (6) get $n=2$ as each component scheme is the process structure with $n=1$. Incidentally, a structure made out of problem schemes (upon **p**-relation) should have $n=3$. Problem realization analysis in terms of problems schemes and their interrelations is named *problems schematics*. The use of this or that scheme from (6) depends on problem's specificity.

The problems that have both solution and answer are *soluble*. But, there are many more problems (posed usually directly upon a required result), which have an answer but have no solution. Those are referred to as insoluble of the *second kind*. (The problems that have neither solution nor answer have insolubility of the *first kind* – "perpetuum mobile" creation, for instance.) For all that, the answer availability to the problem with insolubility of the second kind indicates that instead of original (insoluble) some another problem is actually realized, the answer to which coincides with the answer to the initial problem. This another problem is said to be *conjugate problem* (*CP*) with respect to original one. Knowledge engineering gives the classic example of such a pair of problems: insoluble original – diagnosis problem, and soluble conjugate – knowledge inference problem. Answer deriving to a problem through realization of its *CP* is called *quasi*- or *q-realization* of the initial problem.

Turn now to design problem (*DP*), which has the reputation of ill-defined (Simon, 1970) or even wicked (Rittel & Webber, 1979), and write down its scheme:

$$P\ rB =< SD >< SP, PR^{V} >$$
$$\llcorner I^{P} =_{\text{needs and requirements}} \quad (7)$$

Any problem can be presented by "what is given" and "what is required". In case of *DP*, the "given" is a description of needs and a set of requirements, while the "required" is a sought-for product design. As the needs and requirements cannot be directly transformed into a goal design (the former and the latter belong to different conceptual worlds (Meijers, 2000), *DP* has no solution. Formally, there is no *D*∈*DPR*, so *DP* is a phantom problem. At the same time, an answer to *DP* (a design) is possible. Answer deriving to *DP* through realization of a conjugate problem (CP^{DP}) is referred to as *q*-realization of *DP*. Thus, the replacement, in respect to *DP*, of ambiguous "ill-defined" for constructive "insoluble of the second kind" means searching for CP^{DP}.

DESIGN THEORY PLATFORM: THE PARADIGM SIGNATURE IDENTIFICATION

A Conjugate Problem for a Design One

AXIOM 1

"There is no a priori DPR: DPR shaping comes to an end concurrently with design obtaining".

Let us begin the search for CP^{DP} with the search for a process conjugate to *DPR*∈*DP* and preliminarily named "not *DPR*" ("¬*DPR*"). Restore upon ¬*DPR* the scheme of CP^{DP}:

$$CP^{DP} =< SD >< SP, \neg DPR > \quad (8)$$

Virtual (or top-down, see Table 1) determination of ¬*DPR* by *D* requires generation of this or that virtual inputs for the process. For instance, any available design theory, which unavoidably employs some CP^{DP} by default, uses for the ¬*DPR* input a future product representation. The latter may have different levels of abstraction – a product during redesign or its abstract idea – and was called "context description" (Braha&Reich, 2003); such input refines ¬*DPR* to quasi-*DPR* (*qDPR*) or a process of product representation transformation. In this case the CP^{DP} problem scheme changes its view for (9) being ready for logical (bottom-up) determination of *qDPR*:

$$CP^{DP} =< SD >< SP, qDPR >$$
$$\llcorner I^{P} =_{\text{"contect description"}} \quad (9)$$

Explicit *qDPR* determination upon its object *D* (the result of *SD*>) is generally either impossible or restricted (*D* proposed in (VDI, 1987) or intended for Suh's model (1990, 2001)). Meanwhile, most of available design theories present this *D*∈*qDPR* as a "*DPR* model" (*qDPR*=(*D*, *P*)=(*"DPR model"*, *P*)), though inexistent entity, particularly *DPR*, cannot have a model by definition. Next, the performance of <*SP*> results in a "human master processor" (*H*) because "*DPR* model" realization is only within human's depth. Thus, completeness and quality of CP^{DP} solution depend on what is entering the ¬*DPR* input. How tear oneself away from the circle of mythic *DPR* modeling since a product representation could hardly be recognized as adequate input of ¬*DPR*?

Axiom 2

"Just as a physical product is the outcome of product design processing, so a product design has been an outcome of design process design implementation (processing)".

The stated axiom defines both generative process conjugate to *DPR* – call it *meta-DPR* or *mDPR* – and this process input, i.e. *DPR* design. *mDPR* should both generate *DPR* and produce a required product design through *DPR* performance. The new conjugate problem restored on *mDPR* is the problem of *DPR* design realization:

$$CP^{DP} =< SP >< SD, mDPR > \quad {}^{\Lsh} I^{P} = \text{DPR design} \tag{10}$$

It remains to construct *DPR* design and proceed with the search of solution to CP^{DP} when the latter is represented by the scheme (10). In the course of this problem solving, we have to identify a signature for the platform (systemic module) of Design theory. The solution per se is required to be triply independent: of a master processor, design task and design domain. We call such independence "3D independence (3Di). 3Di solution to CP^{DP} will be called also *systemic* solution. To obtain the latter, the main input of *mDPR* – *DPR* design – is required to be represented in 3Di form as well. *mDPR* platform or $mDPR_3$ will undertake the realization of 3Di *DPR* design. The input data of initial design problem serves for the second input of *mDPR*. We have not recalled it after (7) but it will serve for control data for the sought-for $D\in$ *mDPR*. Thereupon we refine the scheme of CP^{DP} under solution as in (11).

$$CP^{DP} =< SD >< SP, (D_{\in} mDPR, P_{\in} mDPR) > \quad \text{needs and requirements} = I^{P\Rsh} \quad {}^{\Lsh} I^{P} = \text{DPR design} \tag{11}$$

DPR Design Construction

Design Progress Concept

A product design does not emerge in a single-step action – it evolves over time. It is not desirable to have this evolving chaotic. Hence, any design process should realize some *design progress concept* (*DPC*). For instance, the famous model of engineering design process (Pahl & Beitz, 1984) mirrors *DPC*, which may be called stepwise refinement of design abstract description (conceptual, embodiment and detail design). Another example of *DPC* is the *evolution of population* (selection, mutation, recombination), presented in numerous papers on evolutionary design, e.g. (Vajna et al., 2005). For our project, we have taken the most natural, in our view, concept named *evolution of individual* – adaptation of the current product design state to a new state of *operation environment design* related to the sought-for product. This *DPC* is fixed in (10) by I^P-input of *mDPR*. In compliance with this *DPC*, the (operation) environment, which will accept a product after its physical implementation, is under design concurrently with a product. The initial state of environment is mirrored in (11) by I^D-input of *mDPR*.

Dynamic Design Representation

Thus, we should have to deal with representations of three designs – a product design, environment design and design process design. The idea of some unification of these representations (via a platform, for instance) knocks at the door, as they say. But yet more earlier by the same door, another idea stands in the wings – dynamic design representation, which is integral to design synthesis. Lastly, the all design representations within systemic module of Design theory, inclusive of the unified, should be 3D independent.

In point of a (physical) design itself, the listed concepts are unrealizable. Though the following axiom brings about a possible solution to the problem.

AXIOM 3

Just as a product is obtained via implementation of a product design, so a product design should be *obtained via implementation of product's design of design:*

design of design → design → artefact. (12)

An extension of string (12) to the left (design of design of design, etc.) is replaced with the sequence of design of design maturity levels (ML_i, $i=1,2,...$). Thus, the possibility of a unified, dynamic and 3Di representation is associated now not with a design but with a design of design or, as we shall call it in what follows, *logical design* (*L*-design) of a product, environment or design process.

We shall say that the sequence of *MLs* names reflects a *diachronic* (*dh*) or "historical" structure of *L*-design. Componentization of a single ML_i will be referred to as *synchronous* or *sh-structure* of a respective item from the *dh*-structure. At the same time, diachronic structure reflects only design *quasi-dynamics*, if synchronous representations of *dh*-items (description of componentization) are static, e.g. drawings. If we manage to impart dynamics to *sh*-representations, we shall obtain the corresponding representation for the *L*-design in whole.

Dynamics signifies a process. Hence, the case in point is a representation of each *dh*-structure item in terms of processes. This is possible if the content of any such item, from the very first one, should be the determination of the process scheme – namely, the scheme of *operation process* of the sought-for product. In that case, each *sh*-component will be specified by the structure of processes. This opportunity is provided by continuous process theory. Thus, with the assumption that designer perceives the future product in terms of its operation processes, we shall try to display his reasoning by:

1) shaping the sequence of *L*-design states (design *dh*-structuring),
2) dynamic representation of these states (by the structure of processes),
3) choosing the number of states that provides designer with a comfort design increment ("the quantum of evolution").

Successful virtual designing of a product comes to an end with deriving of a final *L*-design state – dynamic representation of the last item's (within $ML_1, \ldots, ML_n$) *sh*-structure. This sequence is given the name of *approximate model* (*AM*) of *L*-design. Incident ML_i and ML_{i+1}, $i=\overline{1, n-1}$, are linked with *embedding relation* ($\prec$).

Let us divide the *AM* into its *structure St* (*dh*-structure of *L*-design) and *semantics Sm* (the *sh*-content of each *dh*-structure item). If *Sm* of each ML_i is determined, we have *approximation model* of *L*-design: *AM=(St, Sm)*. Otherwise, it will be a *quasi-approximation* model – *qAM=(St, Sm*)*, where *Sm** is an abstract semantics. Then logical explicit designing is defined as *AM* construction for *L*-design or transformation of *qAM* into *AM* via refinement of *Sm**∈*qAM*. This *qAM* is called *L-design platform*.

Thus, the way to *DPR* design assumes construction of a unified *L*-design platform, refinement it till *L*-design and transformation the latter into a sought-for design. The role of objects to be unified will be performed by *dh*-structures of *L*-designs for a product and its operation environment, which design process should have to deal with. Those have to be obtained.

Primary dh-Structure for a Product L-Design

In compliance with the declared *DPC* (evolution of individual), we link by $\prec$-relation the following four product design states (*design goals*): *Prototype* (PRT), *Market version* (ITM), *Manufacturing version* (COM) and *Artefact* (ART).

$$PRT \prec ITM \prec COM \prec ART \quad (13)$$

To smooth the discrecity of design representation in terms of its states, split the development of each state into four stages. Each stage results in *design subgoal*: *quasi-system* or qSYS (a minimal set of product units that validates the concept of goal attainment), *system* or SYS (the extension of *q*SYS with control functions), *quasi-design* or *q*DES (space layout of the SYS constituents) and *design* or DES (the *q*DES components assigned with shape, materials, grades of finish and all necessary joints):

$$\text{qSYS} \prec \text{SYS} \prec \text{qDES} \prec \text{DES} \qquad (14)$$

Combine all design states into its diachronic representation – the data structure named *quasi-hierarchy* (*q*-hierarchy) – by closing the nesting hierarchy, i.e. making the latter actual across horizontal as well. The resulted *dh*-structure is shown in Figure 3.

Primary dh-Structure for Operation Environment L-Design

OE is a family of processes **{PR$_q$}**, which a product deals with throughout its lifecycle. There are only three kinds of relations between a product and a process from the family: a product can play the role of the *input*, *disturbance* or *processor* with respect to any process from **{PR$_q$}** (Figure 4*a*). Hence, we can break **{PR$_q$}** up to three constituent sets: {PR$_{q1}$}, {PR$_{q2}$} and {PR$_{q3}$} (Figure 4*b*).

Processes from {PR$_{q1}$} place on their input a number of *requirements* (*Rq*); this set is shared by the product life cycle stages (six, as in our case, or more). Processes from {PR$_{q2}$} impose *constraints* (*Cs*) on their disturbance. Processes from {PR$_{q3}$} specify for their processor the *operation conditions* (*Cn*). In turn, each constituent set is divided into motivated (we drop the details) number of subsets – the hierarchy in Figure 4*b*.

Figure 3. Primary dh-structure for a product L-design

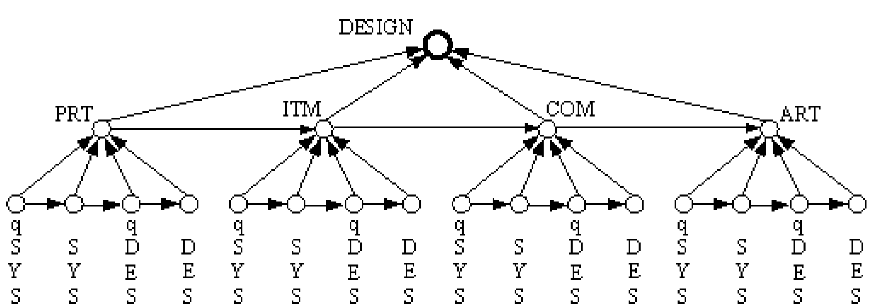

Figure 4. OE design dh-structure construction

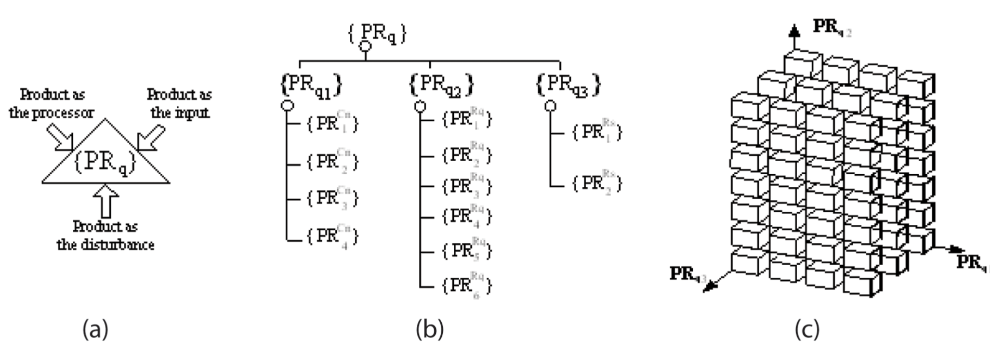

As product-oriented *OE* should also be under design, it needs *P*-independent diachronic representation (hierarchies are *H*-oriented structures). Having taken the members of each set of processes (Figure 4*b*) for the vector of 3D space, we shape *dh*-structure of *OE* design. The latter is referred to as *&-cube* (Figure 4*c*).

Embedding relation links incident cells of &-cube along the *track* of its scanning. This track leads from the starting cell of &-cube – ($X_0Y_0Z_0$) – to its end cell – ($X_{max}Y_{max}Z_{max}$). Here are examples of tracks (brackets signify elements' iterations along the track up to their depletion):

- *(X(Z)(Y(Z)))* – layer-by-layer &-cube scanning along axis *Y*;
- *(X(Y)(Z))* – all *Z*-vectors, except the last one, are omitted in vertical layers (reduced layers);
- *(X)(Y)(Z)* – reduced &-cube (all *Y*-vectors are omitted, except the last one);
- *(X)(Z)(Y(Z))* – only the last vertical layer is taken wholly;
- *(X)(Z)(Y)(Z))* – the layer from the previous track is reduced.

Thus, the choice of &-cube scanning track defines both relevant power of {$\mathbf{PR_q}$} and variants of its structuring. These variants are also valid for the sets {Rq} and {Cs}, generated by {$\mathbf{PR_q}$} members (*OE* processes), and consistent with the concurrently derived design properties and characteristics. Incidentally, the obtained structuring for properties and characteristics is more insightful than in (Eder & Hosnedl, 2008).

From Design Platform to DPR Design.

The unified *dh*-structure is obtained by substitution of &-cube (Figure 4*c*) for terminals in the above *q*-hierarchy (Figure 3). After that, design *dh*-structure is valid for both product and *OE* designs, taking the status of $St \in qAM$. Whereupon, it takes only to refine $Sm^* \in qAM$ to come from *qAM* to approximate model of a product design (AM^P) and approximate model of *OE* design (AM^{OE}). The notion of design platform $qAM=(St, Sm^*)$ is completely pertinent for *DPR* design as well; the only difference is that "*L*-design" is used in this case without prefix because a physical representation for *DPR* design (a structure out of processes) coincides with the logical one.

Approximate model for *DPR* design is labelled as AM^{DPR}, and we come to it via refinement of $Sm^* \in qAM$. This refinement results in iterations of two processes (Figure 5) – synthesizing a new product design state (SPR^P, determination of the product operation process) and synthesizing a new operation environment design state (SPR^{OE}, changing for an increment the current set of conditions, requirements and restrictions, related to the sought-for product, and further paretization of this set).

Eventually, the obtained 3Di *DPR* design is represented by *AM*, in which every element of its *dh*-structure includes one iteration of the two processes mentioned above. Now when 3Di *DPR* design – the main CP^{DP} input (Figure 6) – has been obtained, we can proceed to CP^{DP} solving or determination of $mDPR \in CP^{DP}$ with respect to its subject (*P*) and object (*D*).

Figure 5. AM^{DPR} semantics

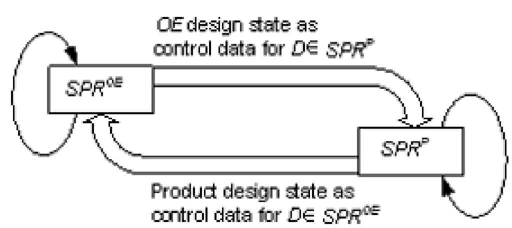

Figure 6. Input specification for the meta design process of 3Di

$$mDPR_3=(D, P)$$
P = 3Di *DPR* design

Systemic or 3Di solution to CP^{DP}

P-Solution to CP^{DP} or mDPR Determination on P

To get *P*-solution to CP^{DP} means to determine *P* from *mDPR=(D, P)*. Thus, the search for CP^{DP} solution on subject will proceed upon the expression (11) where <*SP*> means the search for *P*∈*mDPR*. To compile *P*, we have in general case: a) two types of processors – *H* and *C*; b) a list of members within a type; c) the kinds of relations between the types and members within a type (hierarchical subjection, cooperation and others).

We come to a virtual definition of the sought-for *P* in the following way. While *P*∈*PR* is a *physical* processor of some *PR*, *D*∈*PR* could be viewed as the *logical* processor with its own input – the processed control data (I^D). Then realization of any *D*∈*PR* is performed in general case by a pair of processors – a *master* one (P_w), which deals with the input of *P*∈*PR* (I^P), and *reference processor* (P_I), providing I^D for *D*∈*PR*. Let us consider the two as a single dual-core *P*. We call the latter a *diprocessor* (d*P*) – $P_w^{P^I}$. Diprocessor plays the role of action system (*AS*) platform, i.e. the base for shaping a real *P* for a particular *mDPR*. There are four variants for d*P* to be concretized: H^H, H^C, C^H or C^C. A process, which has the subject identical to one of the listed variants, will be referred to as *manual*, *computerized*, *automated* or *automatic* respectively.

Thus, CP^{DP} (virtual) solution on subject has been a d*P* with relation of interchangeability between *H* and *C*. This relation signifies that *P* of any type (*H* or *C*) is able to realize both work and reference function. Aiming at automated *mDPR*, we choose (logical solution) for the role of its *P* just d*P*=C^H. Then design automation gets under way from *mDPR* subject, and we have proposed instead today's intuitive design automation the more precise treatment of the notion. There are two ways of expanding d*P* to a real subject. First, each type of processors (*H* or *C*) has a number of instances that may be used. Secondly, P^I∈d*P* serves for the gateway to descendants whose action systems can take for the base any of the four d*P* types. Lastly, we assign to each member of d*P* the equal ability to perform both functions (master and reference). Thereby determination of *mDPR* upon subject gets the status of 1Di *P*-solution of CP^{DP}.

D-Solution to CP^{DP}

3Di *D*∈*mDPR* has been a procedure, which traverses the cells of &-cubes relevant to qAM^P and triggers in each of those the pair of processes (Figure 5). The corresponding meta-design process is designated as $mDPR_3$.

The Paradigm Signature for the Design Theory Platform

We call it Sg_1. The list of signature's paradigmants with their values is as follows:

1. Design Progress Concept = *evolution of individual*.
2. Conjugate Problem for a design one = *design process design implementation*.
3. Design (states) Representation = *dynamic*.
4. Fundamental definition of designing = *logical feedback synthesis*.

DESIGN PRACTICE PARADIGM IDENTIFICATION

Design process could not be other than domain-specific and task-oriented. At the same time, we retain it independent of a master processor type in d*P*, that is the aim of *mDPR* run is obtaining of 1Di design process.

In the light of the stated, the above obtained systemic solution to CP^{DP} (causing 3Di *DPR*) is out of practical sense as 3Di *mDPR* cannot transform entering its input 3Di *DPR* design into 1Di *DPR*.

To get 1Di *DPR* as a result of CP^{DP} realization, we need the lDi status either for *mDPR* object and subject or for its I^P-input – *DPR* design. The choice of this or that variant will be defined by a strategy of design system construction. We shall dwell on the variant of successive concretization of 3Di solution to CP^{DP} that is deriving 1Di solution from a preliminary obtained 2Di solution. The corresponding *mDPR*s will be denoted as $mDPR_1$ and $mDPR_2$ respectively.

2Di Realization of the Conjugate Problem

2Di D-Solution to CP^DP^

This solution consists in determination of $mDPR_2$ upon its subject (*P*) and object (*D*). Given the problem scheme – CP^{DP}=<SP><SD, $mDPR_2$> – let us feed the $mDPR_2$ input (Figure 7) with *DPR* design approximate model (AM^{DPR}) and design task (a sought-for product description and design goal).

CP^{DP} solution on subject, i.e. $P \in mDPR_2$, has been the above obtained *AS*. CP^{DP} solution on object (*D*) is a procedure that will allow to adjust the qAM^P structure to design goal and design subgoals. This adjustment consists in: i) selection of a required design goal (PRT, ITM, COM or ART) and terminal subgoal (qSYS, SYS, qDES or DES) for each inclusive goal; ii) elimination of irrelevant life cycle phases in subgoal's &-cube; iii) assignment of &-cube scanning path. Just the appropriate meta design process, designated as $mDPR_2$ with 2Di object (*D*) and 1Di *AS* in a subject (*P*) capacity, is taken as relevant for systemic module of design theory.

Figure 7. Input specification for the meta design process of 2Di

$$mDPR_2 = (D, P)$$

design task $= I^D$ ↰ ↳ $I^P = AM^{DPR}$

2Di CP^DP^ Realization

We assume here a logical realization of CP^{DP} – making arrangements for $mDPR_2$ rendering. The facilities for $mDPR_2$ implementation (a special purpose OS) have gotten the name of domain-independent *design machine* (Sedenkov & Guziuk, 2004).

1Di Realization of the Conjugate Problem: Design system

To obtain 1Di solution to CP^{DP}, there is a need for information about design domain. In the general case, such information is represented by a collection of domain-specific procedural and declarative knowledge: domain-specific SW libraries, theories, gained experience, design methods, etc. Acquisition, representation and assignment of such knowledge are the functions of the third module of Design theory, which gets the name of Domain Knowledge Management System (*DKMS*). A complete study of this module is beyond the scope of this chapter, while the outline of its signature looks like: 1) knowledge structuring; 2) knowledge storing; 3) knowledge access.

Starting 1Di solving of CP^{DP} (determination subject and object of $mDPR_1$), we claim the following input to $mDPR_1$ (Figure 8).

Then we take *P=DM* to be solution to CP^{DP} on subject, while the problem solution on object is taken of a procedure that couples in each &-cube's cell from qAM^P and qAM^{OE} structures the pair of processes (Figure 8) with *DKMS*.

Figure 8. Input specification for the meta design process of 1Di

$$mDPR_1 = (D, AS)$$

$DKMS = I^D$ ↰ ↳ $I^P = qAM^P \,\&\, qAM^{OE}$

The Paradigm Signature for Design Practice

Paradigm signature of the second design theory module (Sg_2) consists of the following three paradigmants:

1. Applied definition of designing = *transformation of design platform (qAM) into design.*
2. *mDPR$_1$* = (Subject: *DM*, Object: *The procedure coupling DM with domain knowledge*).
3. Design system architecture = *Platform (DM) based Design System*.

SUMMARY: THE OUTCOMES OF NEW DESIGN PARADIGM REVEALING

Design Theory Rearrangement

In search of a new Design practice paradigm, it was imposs ible to avoid to refine some basic aspects of Design theory – design problem and process, design representation, constructive definition of Design. Available Design theories do not consider these issues in their close relationship. At the same time each theory gives its own definition of Design, that is claims a conjugate problem to solve. The adequacy of this problem is called by Design practice in question, as a rule. Besides, the proposed theories virtually do not take into account the participation in designing the formal processor (computer) though its expansion into the process will only grow. The next challenge is the steady increase of design process complexity. In sum, these circumstances cause considerable confusion, discordant opinions and chaotic tendencies in research (Hundal, 1990; Tomiyama, 1990). To take this situation for the reference point in search of adequate Design paradigm was as recklessly as to propose a regular new Design theory.

We decided to rearrange the current design theory through partition it into three conditionally independent units and their content revision. The unit of Design theory basic principles was named *systemic module* or a platform of the theory. Solutions to the problems related to this module are required to be independent of domain, design task and a type of processor – *C* or *H*. Systemic module is followed by a module of applied design aspects where the solutions produced at systemic level are coupled with design domain and design task. In turn, the applied module initiates the third module that provides designing with procedural and declarative knowledge. Each module was attached with the established signature of its paradigm.

Incidentally, the auxiliary (modular) concept of design theory reorganization has proved to be tempting as the concept of its initial arrangement as well. It seems a promissory alternative to both attempts to develop a General Design theory and tendency to have specific theory in every design field. Modular approach works in the best way also for theory consolidation, the calls for which sound ever more insistently (Birkhofer, 2006). This approach define three main lines of the theory development – fundamental, applied and design knowledgemation aspects – and distinct directions (upon signatures' paradigmants) within the bounds of each module. The relative autonomy of modules enables them to progress independently and at own rate.

In the course of systemic module establishment (design theory platform), we have considered the main, in our view, delusions ingrained in engineering design – design problem, design process, and product representation. The first among those is the design problem. It does not exist as a soluble problem. Instead of *DP* there is realized a conjugate problem (quasi-realization of *DP*). The choice of the latter will define the paradigm of the applied module, as well.

Design problem quasi-realization crosses the positivism of H. Simon (1970, designing as problem solving) and constructivism of D. Schön (1983; 1992, the study of designer's activity). In addition to the Simon's concept, we have changed the coined characteristic of design problem ("ill-defined") for the more promising one – "un-solvable of the second kind". This resulted in realization of the conjugate problem relative to the phantom *DP* – the problem of design process design implementation. In addition to the Schön's concept, we have proposed the proactive model of interaction between a product design and product operation environment ("evolution of individual") embodied in design process design.

The next modification was concerned with a design. Instead of misleading but widely discussed *product* representation (Ariyo et all., 2008), we have proposed continuous (dynamic) representation of a *product design*. This made possible explicit structure synthesis of both designs process and product.

It was now a design process turn. The latter a priori does not exist though it has been the current focus of design research community. Within the limits of Continuous Process Theory and its pivotal formalism – process scheme *PR=(D, P)* – the notion "(design) process model" becomes pointless. There are levels of uncertainty introduced for a process, pursuant to which it can be conditional, virtual, logical or physical. Hence, *DPR* model (Pahl & Beitz, 1988) has been an abstract procedure in the scheme of virtual process – *DPR=(DPR model, P)*, the refinement of which comes to end only when designing is over. In reality, there is in operation just a meta design process, which composes the design process proper part-by-part, supports these parts performance and, eventually, provides through this performance a required design. 3D independent meta-*DPR* (*mDPR* platform) is also defined within systemic module of design theory. Then a unified design platform had been constructed that enabled to represent design process design entering meta-*DPR*.

Thus, renunciation of the listed delusions shifts the focus from design problem to its conjugate problem, from design process to meta-design process, and from representation of a product to representation of a design – particularly continuous representation. But the all denoted innovations within systemic module would have been out of place without the proposed formal tools – Continuous Process Theory. While other design theories address to external facilities (which entail external problem as well) – for instance, issues in set theory or logic (Tomiyama & Yoshikawa, 1987; Hatchuel & Weil, 2003), we have used the ad hoc tooling. *CPT* meets a lack of scientific principles in engineering design and shifts the latter to a discipline in its own right.

The Impact of the New Design Paradigm on Design Practice

Design paradigm signature consists of three paradigmants. The names and values of the new one in comparison with the current design paradigm (based on German systematic model (Pahl & Beitz, 1984) are given in Table 2.

Within the new Design paradigm, *mDPR* deals with not a model but design of *DPR*, realizing it initially at systemic and then at applied level in line with constructive definition of Design for each theory's level – "Design as *DPR* design implementation" and "Design as transformation of design platform into design" correspondingly. Thus, with the account of Axiom 1, the quotation "Most researches and practitioners recognize that design process cannot be fully formalized mathematically" (Braha & Reich, 2003) gets a new sense: there is no such a necessity. Henceforth, exactly $mDPR_i$ ($i=1,2,3$) is intended to attract main activities directed to resulted *DPR* perfecting.

In whole, new Design paradigm paves the way to new technologies in design computerization, design automation and design knowledgemation. For instance, the use of *design system platform* (design machine, *DM*) leads to the new efficient and effective technology of design computerization (automation): the compilation a wind range of domain-, product-, user-, and media-oriented design systems, via replication of domain-indepen-

Table 2. The comparison of two design paradigm signatures

Paradigmants **Design Practice Paradigm**	**Conjugate Problem under solution**	**Conjugate Problem Solution** (*mDPR* input, its subject and object)	**The system that supports *mDPR* run** (Design System)
Current	Stepwise refinement of a prototype abstract description.	I^P = *(prototype, conceptual, embodiment) design description.* I^D = *design task.* *mDPR* subject = H^C. *mDPR* object = = *substantially implicit.*	Whole-cut and high-value item with long-term development but short durability. Supports Computer Aided Design (CAD).
New	Transformation of design platform into a product design.	$I^P = qAM^P \& qAM^{OE}$. I^D= *DKMS.* *mDPR* subject= *DM.* *mDPR* object= *D that supports interface between DM and DKMS.*	Platform based, holistic and product (domain, user, media)-oriented. Supports Computer Urged Design (CUD).

dent *DM*, and further extension of each specimen with domain-specific knowledge (design knowledgemation) via design knowledge management system. Design knowledge structuring within *DKMS* is guided by the structure of the unified design platform (*qAM*).

Due to *P*-independent theory of the systemic module, it is clearly stated the partner but not merely instrumental role of computer in Design: action system of $mDPR_1$ employs C^H platform, whereby we may identify the new paradigm as *Computer Urged Design* (CUD) that replaces CAD.

And one more benefit of the new design paradigm: it eliminates the problem of design process complexity: the realized $mDPR_1$ does not critically depends on complexity of a product under design.

CONCLUDING REMARKS

Any design theory should begin with propositions concerning the way of unavoidable design problem (*DP*) realization. To this end, it should have not involved but an ad hoc scientific base. In our case, the role of the latter is performed by Continuous Process Theory and Problem Theory.

(As for available design theories, most of those avoid to focus on design problem as such and begin just with design process modeling. The appropriate tooling is borrowed from other disciplines. This results in a doubtful resolving power of the tools and some extra problems for designing borrowed from the donor disciplines together with tools.)

Insolubility of design problem validated by *CPT* entails the search for a conjugate problem (CP^{DP}). For the role of CP^{DP}, Axiom 2 has identified the problem of design process design implementation. The process of such implementation was called *meta-DPR* (*mDPR*). *mDPR* dynamically generates design process, supports it performance and concurrently becomes the part of the process.

(Available design theories also realizes a conjugate problem but does this by default. Mostly it is one and the same problem of transformation a future product representation, which may have different level of abstraction. Thus, design theories with such CP^{DP} differ only in their input representation, involved tooling for the input transformation, and appropriate procedure. Schematic or concrete description of the latter is inconsistently called "*DPR* model", though inexistent entity, in particular *DPR*, cannot have a model – the only primary description of inexistent entity is a design. Due to the common CP^{DP}, these theories share such characteristics as catering for adaptation design, indispensable availability of a prototype, the luck of a structure synthesis problem solution, an obscure way of design automation, inability to manage the growth of design process complexity, and exclusive *H*-orientation as well. The latter prevents efficient usage in design a computer, reserving for it the role of instrument on demand. And though theory's human orientation is natural, we propose the trade-off decision – to have in the three-module theory structure a processor-independent systemic module.

Next, available design theories used to deal rather with *product models* than design representations. As inexistent entity cannot have a model, we considered the way of *product design* representation, particularly *dynamic* design representation required for explicit design synthesis. When designing, we have to deal with three designs – a product design, its operation environment design, and *DPR* design. So, the partial unification of their representations seemed both necessary and beneficial. The result of such unification has manifested itself in *design platform*. The latter gave rise to constructive definition of designing in the new paradigm: successive semantic attribution of each design platform cell.

Generally, the platform concept is also in the focus of the new design paradigm. Except design platform, it has defined generative *DPR* platform (*mDPR*), action system platform (diprocessor, d*P*), design system platform (design machine, *DM*) and design theory platform (systemic module). Besides, the bulk of facilities used for the platform technology description may shape one more platform – *design language platform*, which should allow to change from the current substantially intuitive notion base of designing to the more rigor one and thereby to serve for design coordination over distance and across professions. In whole, the platform-based reasoning paves the way for domain-independent approach to theory and research in design.

And one more point is noteworthy. There are an impressive number of questions, induced over time within design discipline, that still remain without answers (Sedenkov, 2008). The modular structure of Design Theory with identified signatures of modules' paradigms, the base of scientific principles in the form of *CPT* and platform-based technology enable to field these questions.

The main benefit of the new design paradigm for education is that it makes the primary design related processes ($mDPR_i$) observable, teachable and learnable. Incidentally, a pilot version of design system platform (design machine) is already in use for students training.

In whole, development of design practice paradigm contributes to shaping Design as "a coherent discipline of study in its own right, based on the view that design has its own things to know and its own ways of knowing them" (Cross, 2007, p. 3).

KEY TERMS AND DEFINITIONS

Meta Design Process (*mDPR*): The process intended to implement design process design. Through this implementation, *mDPR* dynamically generates design process, supports its performance and supplies the final product design state. Splitting a virtual design process into the real *mDPR* and a pair of synthesis processes (for the product and environment designs) has proved to be a promising deed.

Paradigm Signature (*Sg*): A number of paradigmants sufficient for a unique identification of a paradigm.

Paradigmant: Distinguishing feature of the paradigm descriptive of its certain property.

Problem Quasi-Realization: A situation when instead of initial (insoluble) problem another problem (conjugate) is under realization. The answer to the conjugate problem coincides with the answer to initial one.

Problem Scheme: The structure of the second order made up of process schemes names by relation of determination: *PrB= <SD><SP, PR>*. Each delimiter (angle brackets or comma) indicates **d**-relation (from left to right) by default. *SD* – search for *D*, *SP* – search for *P*, *PR* – performance *D* by *P*.

Process scheme: A simple formalization for a process *PR* intended to represent the latter by the pair – a procedure *D* and processor *P*: *PR= (D, P)*. *D* describes the function of *P* over its input I^P. Process scheme is a basic unit for shaping process scheme structures – continuous representations of complex processes. To this end, a set of process schemes is provided with two initiating structure relations (**p**- and **d**-relation).

Quasi Design Process (*qDPR*): The process intended to transform some initial representation of a future product design into a final state of the design.

Chapter 85
Dynamics in Knowledge

Shigeki Sugiyama
University of Gifu, Japan

ABSTRACT

Since the idea of "artificial intelligence with knowledge" had been introduced, so many thoughts, theories, and ideas in various fields of engineering, science, geology, social study, economics, and management methods have been proposed. Those things have been started as an extension of modern engineering control theories and practices. Firstly, expert system by using IF-Then rules came up to at a production spot in manufacturing, and then agent system method by using intelligent software programs for design, planning, scheduling, production, and management in manufacturing. And then after, the idea of "Knowledge" burst into the artificial intelligence field as a real aid for getting any purpose to be accomplished by having augmented the past key knowledge in terms of management (controlling). However, those augmented knowledge methods used to have usages only in a limited small area. In addition to this, lots of works have to be done before making the systems work for a target problem solving. And what is worse, lots of parts of systems have to be customized for a new application. This chapter introduces a new direction and a method in "Knowledge" by inaugurating the brand new idea of "Dynamics in Knowledge," which will behave more flexibly and intelligently in real usages.

INTRODUCTION

As an introduction, here briefly touches upon the conventional methods for engineering controls, an expert system, an agent method in term of management, which will be related with the future advancements.

DOI: 10.4018/978-1-4666-1945-6.ch085

History of Management Method in Control

One of the earliest open-loop control systems was seen by Hero's device for opening and closing the doors of a temple in the first century at Greece. The opening and closing required inputs to the system were by lighting and extinguishing of the fire of the altar. By the expanding the hot air under the fire made the water transfer from the container into the bucket. As the result of this, the bucket became heavier because of the incremented and fulfilled water, so that the bucket naturally caused to descend because of its gravity. And so its movement made the door spindles turn by means of a rope, and which could open the door. On the other hand, the door could be closed by moving the water of the bucket back to the container again by cooling the container with extinguishing the fire of the altar so as the pressure was being reduced. Thus the bucket became lighter, and then the bucket was moved down so as the door was closing.

The first significant work in automatic control was James Watt's centrifugal governor for the speed control of a steam engine by controlling the vapor pressure of the tank in stable.

And the frequency-response method made it possible for engineers to design linear feedback control systems that could satisfy lots of the engineering requirements. And then, the root-locus method in control system design was developed, which was working more intimately.

These methods are the major control methods. And then, because of necessity to treat many inputs and outputs, these methods became less significant. And then modern control theories have been developed. In modern control theories, linear control method, non-linear control method, and discrete control method have been developed by using a computer more and more even for complex systems.

After the classical control methods had been developed, the application of modern control theories expanded quite rapidly even in the fields of geology, economics, medicine, and sociology, etc. What is more, with developing of the micro processors process speeds and those software, it has become possible to have a discrete control and an expert system which is able to mimic human skills in manufacturing and management (thought of thinking).

Almost in the same period, Petri Net, Neural Networks, Fuzzy Logic by L.A. Zadeh, GA, Immune Control Method, Chaos, Complexity theory, and others have come up to the world as Intelligent Management Methods. And nowadays these methods are tried to be used in more complex and huge systems as a total management system.

PAST, PRESENT, AND FUTURE SITUATIONS IN PRODUCTION AND MANAGEMENT

Technologically Speaking, It has the Following History and the Future

1. One skilled person production
2. Power assisted by the nature (water) that helped a skilled person production
3. Power aided by artifacts that promoted a skilled person's production
4. Jobs Distributed System for Production
5. Worker Assisted by Mechanics Production for a tiny spot
6. Worker Assisted by Mechanics Production for a spot
7. Worker Assisted by Mechanics Production for an area
8. Worker Assisted by Machine Production
9. Worker Assisted by Mechatronics Production
10. Worker Assisted by Semi-Automatic Machine Production
11. Worker Assisted by Automatic Machine Production
12. Worker Assisted by Robot Production
13. Worker Assisted by Expert System
14. Manager/Worker Assisted by Artificial Intelligent System, (at present.)
15. Manager Assisted by Information Technology and Artificial Intelligent Management System, (in the future.)
16. Manager Assisted by Artificial Intelligent and Information Technology Management System

17. Manager Assisted by Dynamic Knowledge Base System
18. Semi-Autonomous Artificial Intelligence Management System
19. Autonomous Artificial Intelligence and Knowledge Management System
20. Management System assisted by Autonomous Artificial Intelligence

In these thirty years, especially, we had the drastic change in production and management. That is to say, the assisted parts in production have shifted from Power to Human Knowledge as shown below.

Power Assisted Skill → Replace Part of Skill by Knowledge → Replace Part of Job by Knowledge → Job Assisted by Knowledge → Human Assisted by Knowledge.

These phenomenon are observed by the facilities that we have been using now as shown below.

1. Exclusive Use of Computer Assisted Machine
2. Group Controlled Machine System
3. Semi-Automatic Machine and Automatic Machine
4. AGV
5. Robot
6. CIM
7. Process Control by GA, Fuzzy Logic, Neural Network, and Artificial Intelligence
8. Total Control and Management System
9. Knowledge Base
10. Management System in Complexity
11. Data Mining (Sort)
12. Total Management System for various fields

Through observing these developments in production (management) and in facilities, it is obvious to say that many kinds of production and management systems and facilities including computer have been developed in order to assist a manager/worker, physically, in an effective way. And now it is a small and tiny phenomenon, but Human Assisted System by using Knowledge Base or Artificial Intelligence with Knowledge is beginning to come up for real use.

Problems in General

Here, the general phenomenons in the management systems are discussed in terms of problems.

Because of the social needs/changes or because of the restrictions in the production and the management methods, we have the major four key difficulties and problems as mentioned below.

1. **Agile Production/Management (AP):** Firstly, in general, the most important thing for industries to be existed is to offer desired production goods at the places wanted, on the time desired with the highest quality and the necessary quantity. This is the only way to satisfy Need (Desire) in a society (Sugiyama (Ed) et al. 2002c). There are many kinds of facilities and many kinds of management systems that will facilitate these kinds of productions and managements quite easily, but these are the things that money can buy. So under this situation, those can be bought from anywhere in the world if there is a greedy person to do so. This means that those management systems can be constructed if there is a person to do so with money. In another words, once a good system is invented, there must be someone who is going to use the same system for lowering a cost production at somewhere in the world. So the companies will have been always facing this kind of the problem (Sugiyama (Ed) et al. 2002c) that is never ignored.
2. **Huge and Complex System (HC):** Secondly, in order to improve productivity and efficiency in a total production and management, the control areas of fields have been expanding more and more from a tiny spot of a machine to a whole company. So the system to be treated will become so huge

and complex. After all, the conventional methods in a production and management system will have become less effective in sense of getting the profits.

3. **Networking Allover (NA):** Thirdly, management in production and in sales, the globalization comes up, so that the functions of a company have been distributed at various places in the world geologically, but those distributed places always need very intimate and close relationships one another in order to create the most profitable output. So they need to behave as if they are very close and near geologically, in another words, they need to behave as if they are one unit of function.
4. **Intelligence like Human (IH):** Fourthly, it is quite important to watch the system closely whether it goes well or wrong even though a system is controlled automatically. Because a system easily goes wrong by a disturbance or by miss usage of systems. And to get it back to the normal situation it usually needs the proficiency of human to do. But ideally it would be the best if a system can do them intelligently. So in order to reduce this burden by human, the system needs a kind of intelligence to do this autonomously in replace of human.

RELATED WORK AND DIFFICULTY

Here examines how the today's methods including the conventional methods work and are working in order to reduce the problems (AP, HC, NA, IH) mentioned above. And also if today's methods do not work well, here shows what sort of difficulties they are facing.

Conventional Method

For controlling a motor, a machine, a transportation, etc., we have a method of continuous control method. But as every behavior of the control targets has to be written mathematically in detail, it is not easy and tough thing to do. As the result of this difficulty, the control areas are very limited within the special fields. If it is failed to express the target system mathematically in detail, lots of optimization have to be made. And as the result of this, it may cause to loose the accurate control.

In the early days of controlling and management, we have the following types of control methods, which are Open-loop control system and Closed-loop system. Open-loop control system (Bertalanffy 1950) is the one in which the control action is not influenced by the results of that action. Some desired or reference input is sensed and amplified and then operate on by the controller.

So this control method has a difficulty in that Open-loop control can be used in practice only if the relationship between the input and output is known and if internal and external disturbances are not much concerned.

A closed-loop control system (Saucedo et al. 1968) is the one in which the output quantity is in feedback for comparison with the input, and the difference, or the error quantity, is applied to the amplifier in order to reduce the error and it cause to bring the output of the system to a expected value. This is better off than the open-loop control system in terms of the accuracy, and what is more, this system is more robust under the disturbance.

Mathematically, generally speaking, the above two control methods can be shown in the simplest expression as shown below.

$[O] = [G] \times [I]$ (1),

where,

[O]: Output,
[I]: Input,
[G]: Transfer Function.

So as the results of these discussions, it is quite obvious to say that, for applying these methods, the target object of the whole system needs to be defined mathematically with continuous functions (linear or non-linear functions). That is to say, however large and complex the target system is, it should be clearly defined mathematically all through the system. And once the system has been defined, it should keep the system structure whatever happens. What is more, the variable numbers to Input are limited to certain values, that is to say, we cannot input arbitrarily number of variables.

As the results of these, we face the following difficulties;

1. It is hard to apply these methods in an excessively complex and huge system.
2. It is quite hard to use an irrational function.
3. It is impossible to use a graphically and experimentally expressed data.
4. It is hard to put an intelligence into the system.
5. It is quite hard to modify the system to the continuous change of the conditions.

So the problems of (AP), (HC), (NA), and (IH) are left as the difficulties.

Discrete Control Method

Discrete-time systems, or sampled-data systems (Saucedo et al. 1968), are dynamic systems in which one or more variables can change only at discrete instants of time. These instants may be the performing time at which some physical measurement is performed or the time at which the memory of a digital computer is read out, etc. The time interval between two discrete instants is taken to be sufficiently short so that the data for the time between these discrete instants can be approximated by simple interpolation. Discrete-time systems differ from continuous-time ones in that the signals for a discrete-time are in sampled-data form, so that the basic idea is almost the same as the methods mentioned above section, but only the mathematical expression is different.

Mathematically, generally speaking, the above control method can be shown in the simplest expression as shown in the equation below.

[O]* = [G]* x [I]* (2),

Where,

[O]*: Discrete Output,
[I]*: Discrete Input,
[G]*: Discrete Transfer Function.

Some of the advantages of digital method comparing with very conventional analogue ones may be summarized as follows.

1. Digital method is able to perform complex computing with a constant accuracy at high speed.
2. Digital method makes possible to use a larger system compared with the analogue method.
3. Digital method is very flexible in applications.

So as the results of these, this method is better than the conventional methods in a sense of treatment in the system operation, however there are almost all the problems of (AP), (HC), and (IH) that the other conventional methods have.

BACKGROUND

Artificial Intelligence Method

Artificial intelligence is a growing field that covers many disciplines as stated by Nick Cercone and Gordon MacCalla in the paper "Artificial Intelligence."

Artificial intelligence is an interdisciplinary field. It is related with Artificial Intelligence derives, including contributions from psychology, *philosophy, linguistics, electrical engineering, and computer science. The intersection between psychology and Artificial Intelligence centers on the sub areas known as cognitive psychology and psycholinguistics. Philosophy and Artificial Intelligence come together in the areas of logic, philosophy of language, and philosophy of mind. Intersections with linguistics include computational linguistics, psycho-linguistic. Philosophy and Artificial Intelligence come together in the areas of logic, philosophy of language, and philosophy of mind. Intersections with linguistics, include computational linguistics, psycholinguistics, and socio-linguistics. Mutual concentrations between electrical engineering and Artificial Intelligence include image processing, pattern recognition, and robotics. Computer science overlaps Artificial Intelligence proper and the related field of adaptive system.*

So there are so many ways to define the field of Artificial Intelligence as Nick Cercone and Gordon MacCalla are mentioning. That is to say, as a science, it will be essentially part of cognitive Science, and the goal of Artificial Intelligence is to understand principles that will make intelligence possible to work. As a technology and as a part of computer science, the goal of Artificial Intelligence will be to design intelligent computer systems that will show the characteristics associated with intelligence in human behaviour; that is to say, understanding language, environment, behaviour, learning, reasoning, solving problems, and so on. Especially Artificial Intelligence including knowledge representations, problem solving, learning, natural-language understanding, computer vision, robotics, Artificial Intelligence languages, expert systems, and several others is for studies. Many of these areas are related to one another theoretically and technically.

Knowledge Representation and a fundamental element of Artificial Intelligence were how to express information of a target object, a treatment in action, and processes into data structures and procedures. The most popular current approaches are rules, definitions, and basic logics without inferring, and production mechanisms. Knowledge representation schemes can be classified into declarative and procedural ones. In a case of a declarative one, it generally requires wasteful searching of data. And a procedural one base is relevant with programming methods.

From here on it is described a little bit more in detail about the typical areas of researches related with Artificial Intelligence.

Natural Language

Unit of "word" is not difficult to treat and to understand for various usages. But "sentence" cannot be treated like "word" as mentioned. And what is more, if it is treated in a context, we have much difficulty in some cases. So an ultimate purpose of natural language study is to learn "understanding of any sentence." It is said that studies of natural language in understanding has three categories: syntactic, semantic, and pragmatic. Syntactic is to structure and to make the grammatical relationships between words in sentences. Semantics is termed with assigning meaning within various syntactic contexts. Pragmatic is to relate individual sentences one another in the whole context category. So the problems of (HC), (NA), and (IH) are still left as the difficulties.

Computer Vision

The purpose of computer vision is to find and to understand a target object in the surroundings. This is initiated in a production spot in order to find a target object and to treat (examine, grasp, fixing, etc.) purposely. And this study comes further to understand an environment by recognizing objects by edging of the objects individually in order to recognize an individual object. And this tendency goes beyond further up to recognition of environment itself including road, tree, moving objects, etc.

So the problems of (HC), (NA), and (IH) are still left as the difficulties.

Expert System

Expert systems is initiated by an idea of imitation a professional expertise behaviour of management and production. A professional behaviour of expertise is ruled out of examining their behaviour one by one in detail. And then those behaviour are programmed in a computer in order to use by anyone needed. But to rule out of behaviour is not an easy task to do at all and the core problem is to understand a professional expertise behaviour by another. So the problems of (HC), (AN), and (IH) are still left as the difficulties.

Theorem Proving and Logic Programming

Theorem proving refers to the process of making logical deductions starting from a non-contradictory set of axioms specified in the predicate calculus. Robinson (Robinson 1995) showed how it was possible to totally automate this process by using a method called resolution. The idea and principle of resolution method is based upon theorem-proving research. And he says further on: "Any assertion that is to be proved using resolution theorem-proving techniques is first represented as a formula in the predicate calculus and then its negation is added to the set of axioms. A purely mechanical set of transformations can then be carried out by the theorem-proving program to put the axioms and negated assertion into so-called 'clause' form. Any pair of these clauses can be 'resolved' against one another in a matching process that results in the creation of a third clause that logically follows from the previous two clause. The resolution method automatically performs a series of such resolutions, eventually building a tree of clause, resolute, resolute of resolute, and so on. If eventually two clauses resolve to 'nil', then the two clauses are contradictory which, in turn, implies that the initial set of clauses is contradictory and this implies, finally, that the assertion has been proved since its negation caused a non-contradictory set of clauses to become contradictory." So the problems of (HC), (NA), and (IH) are still left as the difficulties.

Knowledge Representation

For a system to be able to behave intelligently it must have knowledge of expertise as mentioned in Expert System in the above. In a sense, Knowledge Representation is a process before ruling out of behaviour in terms of logical steps that are related with semantic networks by nodes and combinations. One of a common nodes and combinations in semantic networks is "ISA" link which is able to make facts to be attached to classes of objects and then inherited by specific objects in the class.

So the problems of (HC), (AN), and (IH) are still left as the difficulties.

Learning

At first, learning had not been a major concern for Artificial Intelligence and Knowledge Base. Most Artificial Intelligence researchers seemed to even ignore this kind of study. But after an idea of autonomous behaviour in artificial intelligence came up to as a current issue, leaning has begun to take on ever increasing significance in Artificial Intelligence. So the problems of (HC), (NA), and (IH) are still left as the difficulties.

Dynamic Knowledge Base

Simply to make an artifact like a certain kind of human knowledge which is able to understand a matter, a knowledge, and a figure is being done with various methods. For example Sugiyama (Sugiyama 2004, 2006, 2008) is introducing, the ideas that some kinds of human knowledge are able to be represented and be stored into a computer by using the back propagation neural networks (BPNN). And he proved that these kinds of the knowledge include "Remembering," "Retrieving," "Deducing," and some kind of logical "Thinking-out." However, the abilities achieved by those methods are quite different from the human knowledge that is able to Think-Out dynamically. But this is the main and the most important issue for getting the mechanisms of Artificial Intelligence by using a computer. So this will be the one of the key field in Artificial Intelligence studies.

However, the study itself is under way and no direction for study has been even acquired yet. So the problems of (HC), (NA), and (IH) are still left as the difficulties.

Distributed Computing Method

Distributed computing creates the foundation for manufacturing mediated via intranets of the Internet. In its simplest form, distributed computing having tens and thousands or more computers connected by a network that is working to solve the same problem. Real manufacturing is more complicated, that is to say, machines at a factory have got each computer and the machines should be coordinated/collaborated. The coordination collaboration pattern is not unique but it depends on the type of manufacturing and the company. So usually it is hard to manage the whole system. However, the Internet and intranets are used for getting them work together.

So the problems of (AP), (HC), and (IH) are left as the difficulties.

Agent Method

The Agents are intelligent knowledge bases that can be connected through intranets or the Internet to gather information on purchasing, designing, planning, production, marketing, planning, etc. But it is quite hard to make a proper agent that is able to satisfy the demands and needs because an agent is expected to behave like human. And it seemed that there would not have clear picture and clear definition to an agent logically.

So the problems of (AP), (HC), and (IH) are left as the difficulties.

Holonic Method

The word "HOLON" is firstly used in the book called "The Ghost in the Machine" by Auther Keostler. And he introduced the idea of "Self-regulating Open Hierarchic Order (SOHO)." This can be expressed as "YANUS."

And it says that SOHO has characteristics as;

1. The same as the living creature, it consists of sets of parts and does not consist of uni-motivated chains.
2. The whole of each creatures is branched into sub-wholes one after another autonomously and itself has a hierarchy of multi-levels.
3. It has Self-regulating Open Hierarchic Order; YANUS.
4. It has an autonomy and an integrality.
5. It has hierarchy and networking.
6. It has regulation and it is targeted.
7. The hierarchy has its own ordering regulations.

The studies have started first in Europe, and then Australia, then USA, and in Japan. HOLON is defined in the Consortium in Europe as follows.

HOLON: An autonomous and co-operative building block of a manufacturing system for transforming, storing and/or validating information and physical objects. The HOLON consists of an information processing part and often a physical processing part. HOLON can be a part of another HOLON.

Autonomy: the capability of an entity to create and control the execution of its own plans and/or strategies.

Co-operation: A process whereby a set of entities develops mutually acceptable plans and executes these plans.

Holarchy: A system of HOLONs that can co-operate to achieve a goal or objectives. The holarchy defines the basic rules for co-operation of the HOLONs and thereby limits their autonomy.

Holonic Manufacturing System (HMS): a holarchy that integrates the entire range of manufacturing activities from order booking through design, production, and marketing to realize an agile manufacturing enterprise.

Holonic attributes: attributes of an entity that make it HOLON. The minimum set is autonomy and co-operativeness.

In Europe this is still under the development and study for the aim of application in industrial companies. They have a prototype model of idea of HOLON, but it is that only the idea of HOLON is taken philosophically and the model behaves holonically under only a few conditions. That is today, it does not have a mathematical expression at all. In Australia, US, and Japan, the situation is almost the same as Europe, which means that the philosophical ideas have been implemented in systems, and there have not been introduced usual way of control methods.

By using the idea of HOLON, any complex system or organism is able to be expressed and so this idea can be applied to an engineering control field for a huge and very complex system. But this idea is still in need of a mathematical investigation and study in order to treat it logically and systematically. And the problems of (AP), (HC), (NA), and (IH) are still left for refinement and for constructing a basic idea for real usages.

Chaos; Complexity Theory

"Chaos" by James Gleick became a best seller in 1987. Since then, this world seemed to be caught up by this idea. And many kinds of the phenomenon in this world have been explained or expressed or described by this idea. Since then, mathematical explanations have been given to this idea, but it is still under-going theme to solve as Stuart Daw who is a researcher at the Oak Ridge National Laboratory in Oak Ridge said at the fifth annual conference on "Chaos in Manufacturing" in Santa Fe, N.M., 1997.

"No one can yet define complexity or say exactly how to manage a company in accordance with its principles. But computer tools exist to predict explosions and metal fatigue where once the timing of such a failure was anybody's guess...."

Now we have got the general algorithm (the typical steps) in building a simulation model of Chaos.

Simplify the problem as much as possible while keeping what is essential.

1. The program which simulates many components following simple rules with specified interactions and randomizing elements.
2. Run program many times with different random number seeds, collecting data and statistics from the different runs.Attempt to understand how the simple rules gave rise to the observed behaviour.
3. Perform parameter changes and "lesions" on the program to locate the sources of behaviour and the effects of different parameters.
4. Simplify the simulation even further if possible, or add additional elements that were found to be a necessary.

But this idea is still in need of a mathematical investigation and study in order to treat it logically and systematically. And the problems of (AP), (HC), (NA), and (IH) are still left for refinement and for constructing a basic idea for real usages.

As seeing from the above discussions on an expert system, an agent method, a knowledge base, and an intelligence system in a management system, and as we can easily notice from the focused problems in the above discussions, it is quite important thing to use "Knowledge" for solving the problems (AP, HC, NA, and IH).

MAIN FOCUS OF THE CHAPTER

Here discusses on the main issue of the problems' (AP, HC, NA, and IH) solving by giving some definitions about Knowledge, Knowledge Base, and Artificial Intelligence (Sugiyama 2004e, 2005g, 2006h, 2008i, 2009k). Especially the discussion will be focused on the dynamic behaviour (Dynamics in Knowledge) in processing of Knowledge by using a neural networking (Sugiyama 2008j, 2009k) in order to solve the problem facing.

Firstly here discusses on Artificial Intelligence, Knowledge, and Knowledge Base in General.

Even though in the above Sections there explained and discussed on Artificial Intelligence, Knowledge and Knowledge Base, they are very ambiguous "words" to explain and to define in detail. It may be related with abilities for actions; knowing, understanding, thinking, familiarity gained by experience, and doing things, or it may be related with a behaviour for actions. And also Artificial Intelligence, Knowledge, and Knowledge Base have a very ambiguous "structures" to explain and to define in detail although there are some explanations for those. These facts will show that the present techniques can only be applied to an individual target in certain limited areas within nonflexible technical and system limitations although those system and technique sometimes work such and such individually in very limited usages.

So at present, we may conclude to say that we do not know yet and do not have yet a clear picture of it although it has been challenged to make Artificial Intelligence, Knowledge, or Knowledge Base by using a computer for many years.

So, it is very important and necessary to know more about what Artificial Intelligence, Knowledge, and Knowledge Base are meant to mean. And also it is quite important to find a description method of Artificial Intelligence, Knowledge, and Knowledge Base as a system.

Core Factors and Definitions of Dynamics in Knowledge

As we can easily notice from the above discussions, it is quite important to use Artificial Intelligence, Knowledge, and Knowledge Base for solving the problem (AP, HC, NA, and IH). Because the direction of the behaviour for those is to behave like human. So here further discusses on this key matter in detail.

Artificial Intelligence, Knowledge, and Knowledge Base

All the knowledge of human intelligence has not been fully studied yet, but those have been rationally applied in many fields to bring about an intelligent artificial creature for solving a problem. This clearly shows that the researchers know the limit of an artificial intelligence as a narrow sense of intelligence. And there is small doubt among some researchers that an artificial intelligence will be capable of creating an intelligent thought even in the near future.

At this stage we can say that there are many different approaches to Artificial Intelligence, Knowledge, and Knowledge Base, and that none of which are either completely right or wrong. Some are obviously more suited than the others in some cases, but the others do not.

In the past, Artificial Intelligence research has mostly been focused on solving specific problems. And this phenomenon makes the field of Artificial Intelligence split into many branches; from a pattern recognition to an artificial Life, including Evolutionary Computation, Soft Computing, Fuzzy Logic, and Neural Networking.

Here, we look at Artificial Intelligence, Knowledge, and Knowledge Base from a point of meanings.

A dictionary briefly says about Knowledge/Intelligence as follows.

1. Understanding.
2. Familiarity gained by experience.
3. Within a range of information.

So, in another words, we can interpret the above expression such that “Knowledge” or “Artificial Intelligence” means to understand what is going to do, is doing, and has done for a purpose to be accomplished in a range of information.

However, this is a knowledge statement for Humankind, we need to restate and to redefine for Artificial Intelligence, Knowledge, and Knowledge Base as follows.

“Artificial Intelligence, Knowledge, or Knowledge Base is a mechanism for accomplishing a desired purpose to be done by getting a necessary information one by one from an environment facing through the sensors or by communicating among entities (Artificial Intelligence, Knowledge, Knowledge Base, Data, Objects, etc.) within a range of information.”

At this stage, we can easily understand about the Artificial Intelligence, the Knowledge and the Knowledge Base as the same kind of entity because of the behaviour. So from now on, Artificial Intelligence, Knowledge and Knowledge Base will be written just as “Knowledge.”

Next, we will look at this matter from a point of view in “structure.”

Generally speaking, as it is mentioned in the above, we have a problem in a structural uncertainty. And they are as follows.

1. Not easy to describe and to control a whole system (Environmental Uncertainty; (EU)).
2. Many pre-processes are needed before inputting data onto Knowledge (Data Uncertainty; (DU)).
3. Not easy to understand a rough environment (Functional Uncertainty; (FU)).
4. Poor for a system to understand what Knowledge is doing (Knowledge Uncertainty; (KU)).
5. Not easy to communicate among agents (Communicational Uncertainty; (CU)).
6. No way to re-examine an output quality (Self Recognition Uncertainty; (SU)).

If we look at the uncertainties above (EU, DU, FU, KU, CU, and SU) more closely, they will be focused onto a rigidity of Knowledge. Because we are able to have a nice Knowledge that will behave nicely for solving a problem only if we have a usage within a very limited condition with a very stable environment. That is to say, on the contrary, “Dynamics” in Knowledge is the key matter in order to let Knowledge work appropriately. And so, here gives some discussions and studies on Dynamic Behaviour in Knowledge.

Piaget (Piaget 1999) has given us two views about ‘Knowledge Acquisition’ from a psychological stand point of view. And they are as follows.

Assimilation → “Passive Modification”

1. The modification of an incoming stimulus by the activity of a pre-existent mental structure. Such structures are denoted ‘schemes’, and represent the regular structure of an action.

Example. The general method involved in catching a ball:

The ball catching scheme, producing ‘the catching action’, assimilates the unique circumstances in which the person and the ball may start moving within a very limited behaviour.

Accommodation → “Active Modification”

2. The active modification of the structure – scheme – itself, so as to adapt to the situation.

Example. Catching the ball from different directions:

An initial attempt is made to assimilate the object into a general ball catching scheme. If this fails – the object cannot be caught by the method of assimilation – then an accommodation takes place. The catching scheme is adapted, for instance, by adjusting an arm form by twisting the arm for the glove to face the ball, and then re-applied and happily could get the ball. It may be retried again if it does not go well by collecting another scheme of catching the ball.

So from the facts about the human knowledge acquisition mechanisms from Piaget, we can conclude to have the following views about Knowledge.

1. Passive Modification would cause a problem when Knowledge faces an unexpected situation.
2. Active Modification would be better off in behaviour for Knowledge to overcome an unexpected situation.

Here looks at the case of living creatures what will happen for problem solving as behaviour in action. The following shows about functions of brain what to do in action. In general, a living creature's brain will be functioned as follows.

1. At first stage, there is stimulation from the world to the five senses of a living creature, or from an internal brain itself.
2. Next, capturing the stimulation through the senses or by the frontal cortex. The stimulation will be transformed into 'a semantic form' in a sense of words or a real image or an abstraction in order to understand what it will be.
3. Taking an action according to this understanding.
4. If the input (the requirement) is satisfied by the action, it completes the process and ceases to activate the group of neurons.
5. If it is not satisfied, taking a next action for the input accomplishment by introducing a next related group of neurons or a next related knowledge within the numbers of co-related group of knowledge. This process will be able to go on and on until it reaches to some limitation that makes the process cease to act as "Active Modification" in a case of satisfaction to the input, or in a case of the nature of neurons.

In the above events, there are several events ((2), (3), (4), (5)) that are not good at processing for the present "Knowledge" system.

From the weak processing events shown above, we can extract Core Properties existed to show below.

A. A General Expression in Description of Knowledge.
    1. System - Knowledge - Action - Event - Core Factors - Group of Processing.
B. Forming Co-related Group of Knowledge with a semantic form.
C. A method of Active Modification within the co-related groups.

Solutions

In the above section, we look at the core factors of "Active Modification" in Knowledge, which will assist and solve a problem facing.

Here shows the core factors for solving the problems [(AP, HC, NA, and IH), (EU, DU, FU, KU, CU), (a, b, c)], and SU by introducing "Knowledge" as "Notion."

Notion 1: (Primitive Element)

As we know about human brain mechanism, input information to eye, ear, etc. are broken (transformed) into pieces at one mediator to another in brain in order to get very primitive elements of those. With those very primitive transformed elements, human brains can recognize and understand things from outer world.

We can use this mechanism of human brain (primitive element) in order to make a system communicate with others (entities).

Notion 2: (Hierarchy of Multi-levels)

Hierarchy of multi-levels (a finite set of whole U, finite sets of parts {∑Pi} and finites sets of subparts {∑SP1j},.., finites sets of sub-subparts,.. {∑SPnk}) of system of organization) is defined mathematically. And the structure of the system's elements' connection at each layer is defined by {U⊇∑Pi⊇∑SP1j⊇...⊇∑SPnk}. And these U, Pi, SP1j,..., SPnk are correspond to each layer; Layer-1, Layer-,2 Layer-3,.., Layer-(n+2) in the system of organization, where i∈[0, m0], j∈[0, m1], k∈[0, m2], n∈[0, m3], m0, m1, m2, m3 are positive integers. Hierarchy of multi-levels is made arbitrarily by grouping in terms of a function's mechanism, a function's attribute, and a function's physical figure together.

We can use this mechanism of Hierarchy of Multi-levels in order to make a system transformed into very primitive stages.

Notion 3: (Networking, Regulation, Targeted)

The system of organization that has Networking, Regulation, and Targeted factors of being themselves networked with one another in a regulated way. For targeted has a characteristic of independent itself as well as dependent to another.

We can use these functions of Networking, Regulation, and Targeted in order to make a system combine one another in elements of all over the system and multi-levels.

Notion 4: (SOHO)

Self-regulating Open Hierarchic Order (SOHO) is defined by a property that each of U, Pi, SP1j,..., or SPnk has its own independent system of organization. And those of U, Pi, SP1j,..., SPnk are independent themselves and also dependent one another as well. And each of those is self-regulating.

We can use this mechanism of SOHO in order to make a system flexible to changes.

Notion 5: (Interchange of Whole and Part)

Every factor of U, Pi, SP1j,..., or SPnk in a system has a moment to be the whole of it and at another instance the whole may become a part of it. This topological interchange of the whole and a part can occur when U∩Pi∩SP1j∩...∩SPnk =Φ. When the interchange between the whole {U} old and an arbitrarily Ψ⊆{U}old is made, the topological transformation from the old hierarchy {U⊇∑Pi⊇∑SP1j⊇...⊇∑SPnk}old to the new hierarchy {Unew⊇{Ψ, ∑Pi∩Ψ}new occurs.

We can use this function of Interchange in order to make a system simple and targeted.

Notion 6: (Mathematical Expression for Knowledge)

Let X denote the set of arbitrary primitive data through the preprocessor from the outside world and assume there are (m x n) real valued functions. X is mapped into R, which is the set of relevant knowledge. It is defined as below.

Φij(x):X→R, i=1,...,m,

Ωj(r):X→R, j=1,...,n.

Each element of X is producing a primitive data through the preprocessor for each pattern and each element of R is producing an output to X.

Writing Φj(x) to denote the value of the ith primitive data of pattern x, the vector Φj(x) is shown as follows,

Φj(x)=[Φ1j(x),.., Φmj(x)]T.

Writing Ω(r) to denote the value of jth knowledge base of entity r related with Φj(x), vector Ω(r) is shown as follows,

$\Omega(r) = [\Omega 1(r),.., \Omega n(r)]T$.

The above are feature vectors description of x and r.

There are no restrictions on the forms of the functions Φij; they can be linear or non-linear functions of X.

This makes possible to express the above Notions mathematically and logically in order to treat Knowledge as an entity that will be implemented in a computer system.

Notion 7: (Select Any Part)

Let the whole universe {U} consists of

$\Psi = \{\Psi 1,.., \Psi n\}$

as shown below.

$U \supseteq \Psi$.

Ω(r) is correspond to Ψ each other as shown below.

$\Omega 1(r) \rightarrow \Psi 1$,

$\Omega n(r) \rightarrow \Psi n$.

The Reflex Transformation is defined as,

$U \rightarrow \Psi k \supseteq \{U \cap \Psi \cap \Psi k = \varphi\}$.

This also makes possible to express the above Notions mathematically and logically in order to treat Knowledge as an entity that will be implemented in a computer system.

Notion 8: (Dynamics in Knowledge)

It was possible to organize "Knowledge" in a conventional method within a very limited behaviour and actions with very much rigidity by using Back Propagation Neural Networking (BPNN). And by adding the ideas of "Dynamics in Knowledge" (Sugiyama 1994a, 2001b, 2002d, 2004e, 2005g), we can make "Knowledge" that will behave dynamically in order to select a related knowledge out of the related group of Knowledge.

This is shown by using a simple example by using BPNN as shown below.

Firstly, "Knowledge" in conventional sense is shown. That is to say, whenever a complex Knowledge is made, the behaviour is simply to produce the output even though the output is not an expected one as illustrated in Figure 1.

This Knowledge does not behave properly when unexpected event occurs. As mentioned in the previous sections, the reason is that this Knowledge is lack of flexibility in change.

But the Knowledge shown in Figure 2 below has a flexibility to select desired and related group of Knowledge in a category by Linker from the content related database of accumulated Knowledge, which is able to search and to form a related kinds Knowledge as a group. The group is selected by the value of Co-Relational Factor, which is given by BPNN output value.

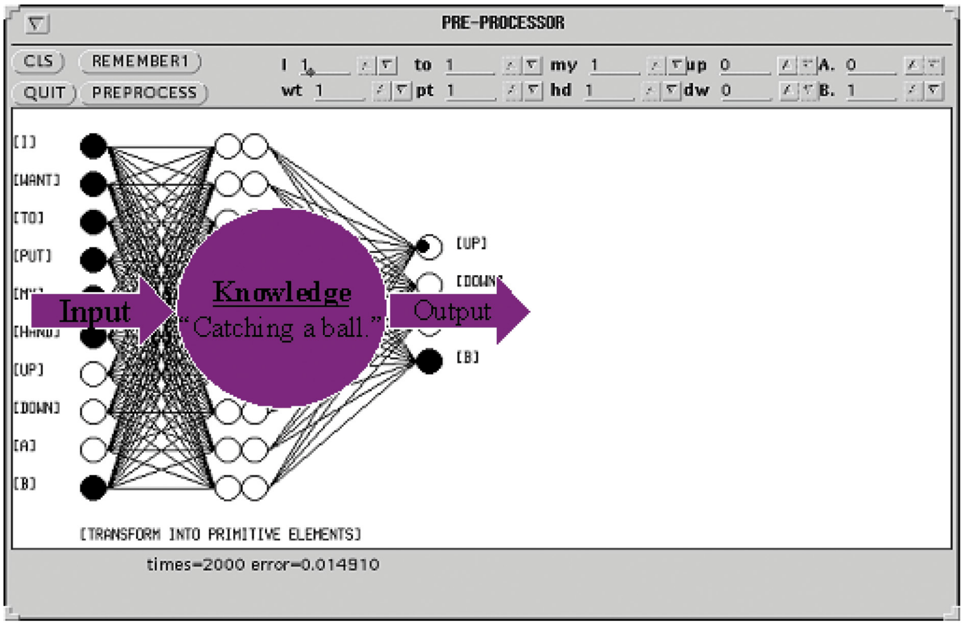
By using the group of related Knowledge, a system can select the most appropriate Knowledge from time to time. That is to say, if there is a problem that goes good in a certain situation, the system tries to find another most appropriate Knowledge for this situation as shown in Figure 3.

This example showed that this Knowledge could behave like in a case of living creatures what will happen for problem solving as in action. That is to say, the system is able to select a proper Knowledge from a group of the related Knowledge in order to face to a problem solving.

Notion 9: (General Behaviour)

By using these Notions, "Knowledge" is able to have a hierarchical structure and is also able to reconstruct for targeted, so that a necessary knowledge is able to be given one after another for

Figure 1. Conventional knowledge presentation in general



re-processing in order to get an improved output through communication.

This says that any necessary knowledge Ψk can be extracted, can be targeted, and can be concentrated in order to get the desired output.

So by using Notions 1 to 9 stated above, we can expand any system (system, agent, organization, etc.) hierarchically with multi-levels of layers, linked and networked. And also each element at each layer can easily communicate with another because of its primitively hierarchical structure.

Figure 2. A group of related knowledge

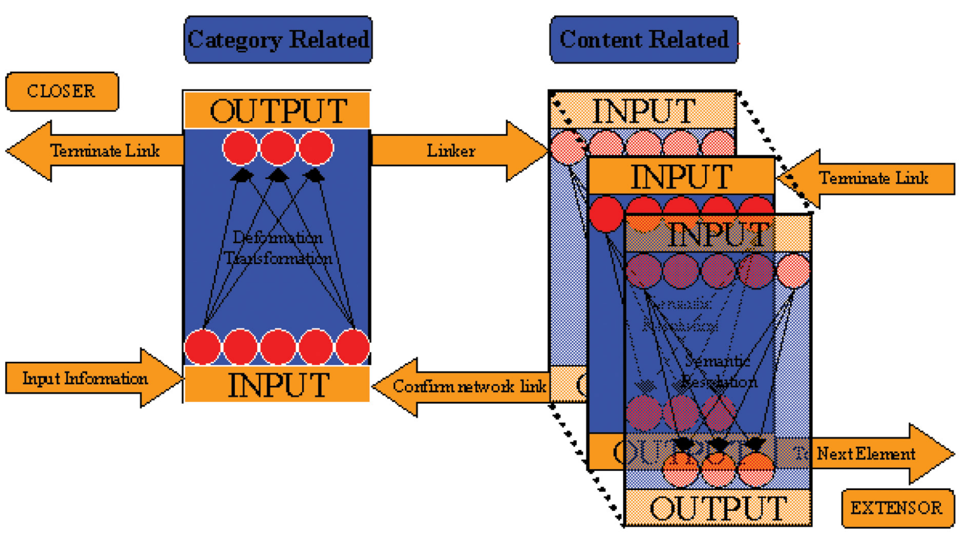


Figure 3. Active modification for new knowledge

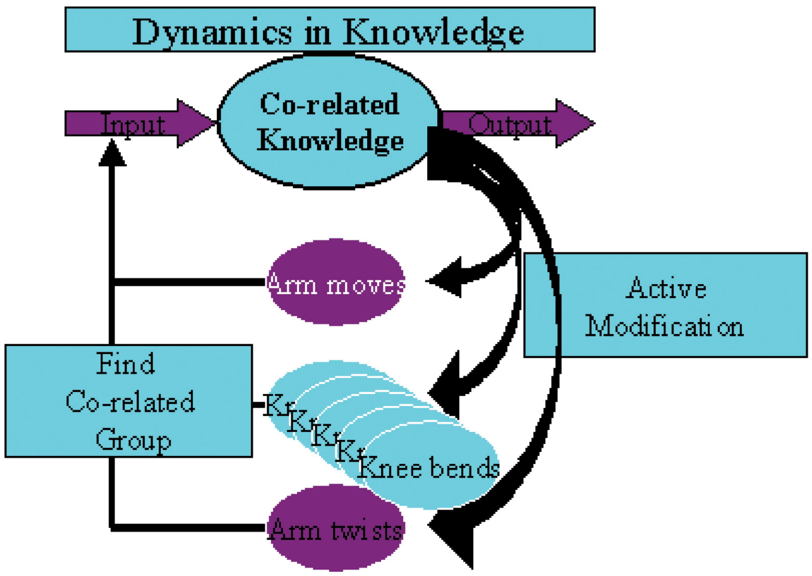

FUTURE RESEARCH DIRECTIONS

Here shows issues left for studies on Dynamics in Knowledge in order to get further developments.

A flexibility of Knowledge is given by the ideas shown above sections. But it goes better in the behaviour of Knowledge if Knowledge can communicate each other like human. The Knowledge studied here consists of primitive elements by BPNN, so that some kind of communication between Knowledge is capable to make but it is quite a primitive level of communication in the behaviour. One tip for solving this issue is to make a general Knowledge for each category that will understand a whole context of each category.

The flexibility for each primitive Knowledge (atomic Knowledge) in a sense of structure is also important matter. That is to say, each Knowledge that will be able to change its structure as describe in the Notion 5 is also very important matter to have. Because it is quite easy to get a proper output if Knowledge is transformed into the figure of Knowledge that is most suitable one. For example, if there is the Knowledge of searching an object, it would be better to transform the figure for a particular object. Because "Searching a pen" and "Searching the meaning of Pen" is different from each other.

And it is strongly expected to study on data structure for Knowledge. That is to say, whether or not it would be better to have data for each Knowledge or for the whole Knowledge or to be unified?

CONCLUSION

Through the examinations and discussions in this paper on Knowledge related matters and Knowledge itself, the following results have been given as shown below by touching upon a basic level of control, management, knowledge base, and artificial intelligence.

1. Basic idea of the Hierarchical Multiple Knowledge method has been introduced.
2. General mechanism of dynamic behavior of Knowledge through communication that behaves more intelligently than before has been introduced.

3. Overall system description method in complexity and hugeness by using the idea of Hierarchical Multiple Knowledge has been introduced.
4. A new direction and a method in "Knowledge" is logically expressed by inaugurating the brad new idea of "Dynamics in Knowledge," which will behave more flexibly and intelligently in real usages.

Chapter 86
Tool and Information Centric Design Process Modeling:
Three Case Studies

William Stuart Miller
Clemson University, USA

Joshua D. Summers
Clemson University, USA

ABSTRACT

A new design process modeling approach focused on the information flow through design tools is discussed in this chapter. This approach is applied to three long term mechanical engineering design projects spanning 24 months, 12 months, and 4 months. These projects are used to explore the development of the new modeling approach. This is a first step in a broader effort in 1) modeling of design processes, 2) establishing case study research as a formal approach to design research, and 3) developing new design process tools. The ability of engineers to understand the dynamic nature of information throughout the design processes is critical to their ability to complete these tasks. Such understanding promotes learning and further exploration of the design process allowing the improvement of process models, the establishment of new research approaches, and the development of new tools. Thus, enhancing this understanding is the goal of this research effort.

INTRODUCTION

This chapter begins with a general discussion on the design process and approaches to capturing and modeling the design activities. It is not intended to be a comprehensive review of the literature, but to provide a frame of reference with respect to the critical issues associated with design processes. This is followed by a discussion of case study research in engineering design. Again, this section is used to provide the reader with a broad understanding of how current case study research has been undertaken in engineering design and how it can contribute to our understanding of the

DOI: 10.4018/978-1-4666-1945-6.ch086

design process. Next, the reader is introduced to the relevant issues associated with representing the information flow through the tools used throughout the design process. Finally, three industry focused case studies are used to illustrate the application of this tool, demonstrating how it can be used to highlight issues such as iteration, information dead-ends, and tool function duality.

THE DESIGN PROCESS

The design process is a flexible, high level, logical network of activities to be performed and/or design tools to be used for the entire act of designing an artifact, formed by choosing desirable candidate(s) from a set of viable activities/design tools based on certain objectives (Hazelrigg, 1998). The design process is the collaboration of scientific "know how" with mental and physical steps being taken toward the goal of arriving at a satisfying solution (Simon, Kotovsky, & Cagan, 2001). It is a social activity which allows the generation of physical and intellectual property from mental organization and physical tasks (Leifer & Tang, 1988). Engineers perform design processes often with varying degrees of success. The goal of the research presented here is to enhance the ability of designers to understand and therefore complete design processes.

Design Process Modeling

Several approaches have been proposed in the literature for modeling design processes and activities. This section is not intended to review exhaustively the different approaches to modeling engineering design processes, but to highlight a fundamental limitation that appears to be common in most approaches. This limitation is their inability to easily capture the activities executed by the engineering designers in larger design projects outside of artificial academic environments. The goal of this research is to overcome this limitation by focusing on the actual engineering design tools that are used and to model the flow of information through these tools. This modeling approach will be discussed in the following sections.

One example of a design process modeling scheme is to view engineering design as a series of transformative steps that can be modeled as state transitions (Reymen, et al., 2006). In this approach, each state of the design, captured as the complete collection of the description of the design product, is modeled with a transition activity linking the initial and final state. A limitation of this approach is that the granularity of defining the transition activities is extremely coarse and there is no clear demarcation between states, as these are an artifact of the process modeler, rather than the design process itself.

Ullman presents a different approach to modeling the design process based on his empirical studies in the early 1980's (Ullman, Dietterich, & Stauffer, 1988). This approach seeks to define the task episode accumulation (TEA) model as a sequence of tasks that are essential information processing activities. The different activities are classified to include such actions as gather, synthesize, and decide. In this manner, the TEA model looks at sequencing the actual actions taken by individual designers as opposed to capturing the transition states between the entire collection of design product information. This model has been used to capture designer thought processes in controlled environments, but not in larger design projects as it would quickly become too unwieldy to process each task.

Another transformation based modeling approach to engineering design is that of the Function-Behavior-Structure model (Gero, 1990). In this model, there are eight basic steps that transform a function objective into a structure to realize that objective. While this model suggests that there is a distinction between different types of information and defines different design activities as formulation, synthesis, analysis, evaluation, documentation, and three types of reformulation, this model does not adequately capture all of the details of the design activities and it does not include other design information types, such as requirements.

Requirements tracing and design rationale capture is the basis for the design process model that has been proposed by (Burge & Brown, 2002). Essentially, this model creates a decision tree where design solution options are explored. At each branch, a criterion for success is selected and a branch is chosen. The rationale for selecting the option branch is defined. These three steps form a design task that is sequenced together to form a design plan. These tasks are used to define the value of the specified engineering design variables, thus linking the design requirements with the final design product. This model of engineering design provides for explanations as to why and how decisions are made. However, in large design projects, this level of documentation is not typically available thereby causing gaps in the modeling of the complete design process.

A different approach to modeling engineering design processes is to view the entire "space" of the possible design activities that can be used to achieve the artifact (Grabowski, Lossack, & Weis, 1995). In this model, the order of the design decisions leads to a path through this process space to the concretion of a design artifact. The activities, or directions, that can be chosen to explore this space include: concretion, abstraction, detailing, combining, varying, and limiting. These are similar to the activities defined by Ullman. This model provides, perhaps, an interesting theoretical view of the design process, it is not clear how this model could be constructed to capture a large scale design project.

Finally, Ostergaard and Summers present a model of engineering design from the perspective of the flow of engineering information through a series of design resistances that are the collaborative design situations (Ostergaard & Summers, 2007). In this model, the design information is represented as the current and each stage where information is passed between human and computer reasoning agents is treated as a resistance to this flow. This resistance is overcome through the application of external knowledge, termed design voltage. While this approach begins to capture the concept that information is accumulated throughout the design process through transformations, it has proven difficult to quantify and model actual engineering design projects.

These examples of different approaches to modeling the design process have been developed for many different purposes, including understanding how designers think, defining how computational reasoning support tools can be developed, how states of engineering design products evolve, and the flow information through collaborative situations. Unfortunately, none of these approaches have been easily applied to capturing the activities within realistic industrial engineering design projects. A model engineering design activities that can be used for studying large scale design projects.

Metrics of Design Processes

The design community has several measures of design success (Yang, 2007). One of these, product functionality, relates to how well the design solution accomplishes the tasks it has been given (Pahl & Beitz, 1996). Another common metric is customer opinion, a subjective measure. This metric can vary with aesthetics, comfort, appeal, or market trends (Kirschman, Fadel, & Jara-Almonte, 1996). Another more quantified success metric is the designer efficiency (Atkinson, 1999). This measure is used to find the time and cost to design. This could be measured as the time the designers take in the design process to develop the final product. It is recognized that many different methods of success evaluation in design exist (Ulrich & Eppinger, 2008). However, discrepancies exist in the academic community about which success measures are valid (Sobek II, 2007). Ultimately, only a handful of success metrics for design processes exist and there is no consensus which should be used.

All success metrics can be used by a variety of users. Designers, managers, and researchers all use success metrics of processes. Naturally, each user has their preferred success metric which caters best to their particular area of interest. However, each category of the metrics can be evaluated independently and used to highlight the most desirable traits within the options given. An absolute metric would be beneficial over a relative metric because any ambiguity about the results would be eliminated. A direct measure of the design process is desirable because directly measuring the process leaves less room for interpretation errors that are present when the products are evaluated.

For design processes to be comparatively evaluated through different metrics, the processes and their goals must be clearly defined and then related to each other. To fully explain the process, it should be broken down into sections or stages which can give more detailed understanding of the change of information throughout the process. Doing so not only gives designers understanding of what the process accomplishes, but also how it is accomplished. Each stage can be further analyzed to determine the individual steps taken within that stage to achieve the deliverables and how those interact with subsequent stages. Each of these steps can be evaluated to determine the information that enters from the previous step and the information that exits to the next step. The tools used within the design step can be identified as well as their fundamental function.

Decomposition of the Design Process

Design steps can occur in loops, repeating and converging on information vital to success. Each design tool or method receives information from other sources, and transmits its exiting information outward to another step. Steps can possess singular and multiple information units which can enter and exit specific process steps. The information produced by any design step should have value greater than the sum of its components. The same can be said regarding the design process and its subordinate stages. Figure 1 illustrates a design process that has design stages decomposed into design steps. This notion of decomposition of the general design processes into constituent elements has been the focus of research efforts that yield ontologies of design activities at the atomic level (Kumar & Mocko, 2007; Sim & Duffy, 2003; Whitfield, Duffy, Coates, & Hills, 2002). From a pragmatic perspective, engineers and practitioners would likely prefer the granularity of resolution that focuses on design tools rather than atomic cognitive and information manipulative activities. This view through the design tools is the focus of this research.

In order to quantify how well a design process has been executed, the process itself must be analyzed (Lockledge & Salustri, 2001). Analyzing processes can be done with various levels of detail resolution. A low detail resolution of the process allows the researcher to retain focus on the overall process goals. It does not lend detailed insight to information interactions within the process. Figure 2 shows a low resolution approach to process analysis. This type of analysis builds on the establishment of what is entering and exiting a specific boundary to the process. The result is a coarse representation of the process.

Conversely, in Figure 3, a higher detail resolution analysis of processes consuming more time and effort in detailing each step is shown. The work becomes tedious and can go into increasingly deeper detail, which may or may not be needed. This intermediate resolution of detail shows how increasing detail requires increasing effort as well, because the entities being considered increases, thus increasing the work required to analyze.

This type of analysis permits the researcher to identify information interactions within the process, thereby identifying additional information

Figure 1. Design process hierarchy

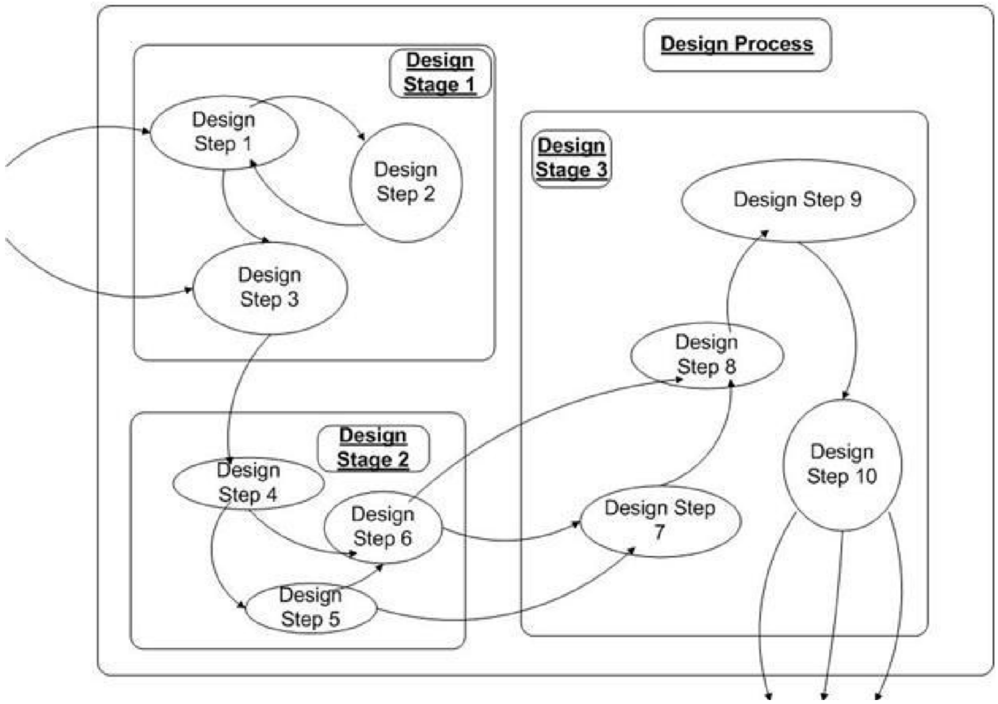

Figure 2. Low detail resolution

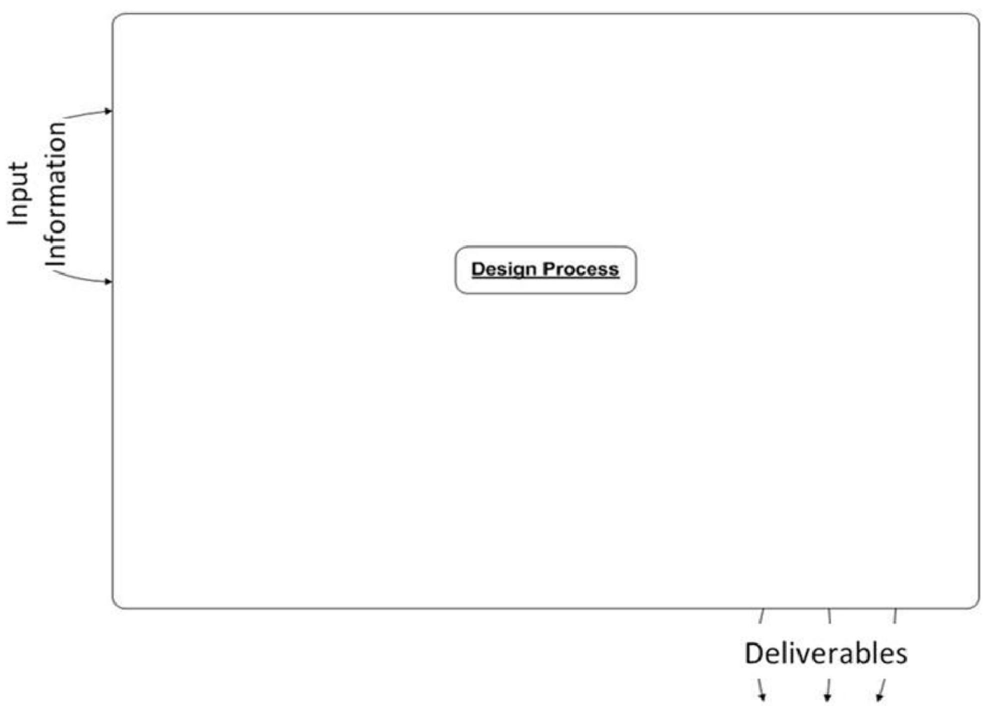

Figure 3. Intermediate detail resolution

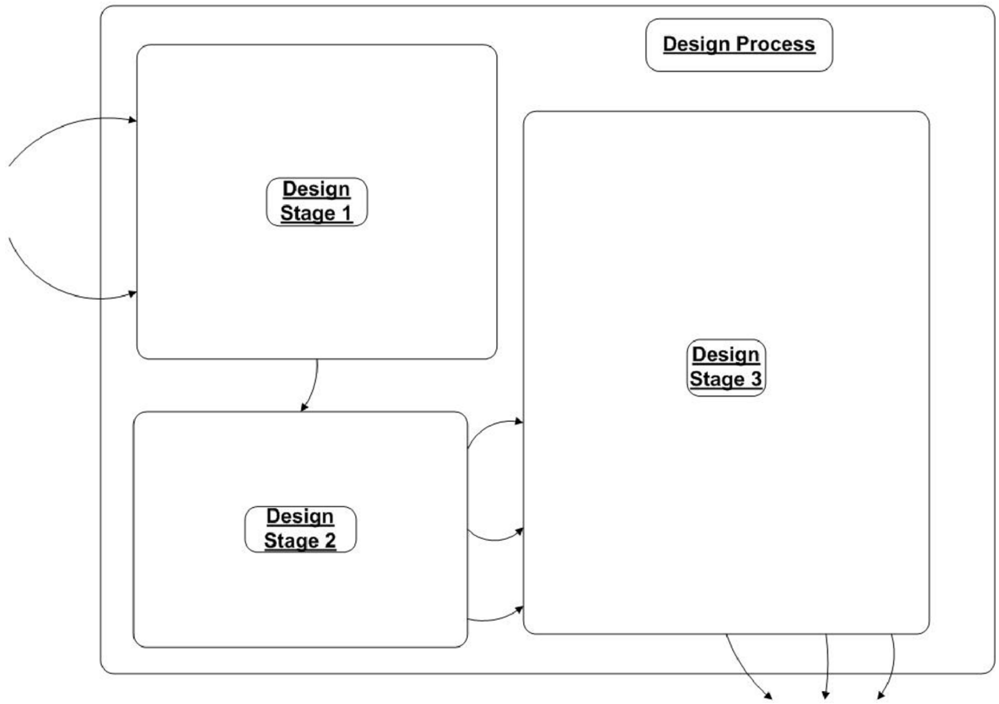

Figure 4. High detail resolution

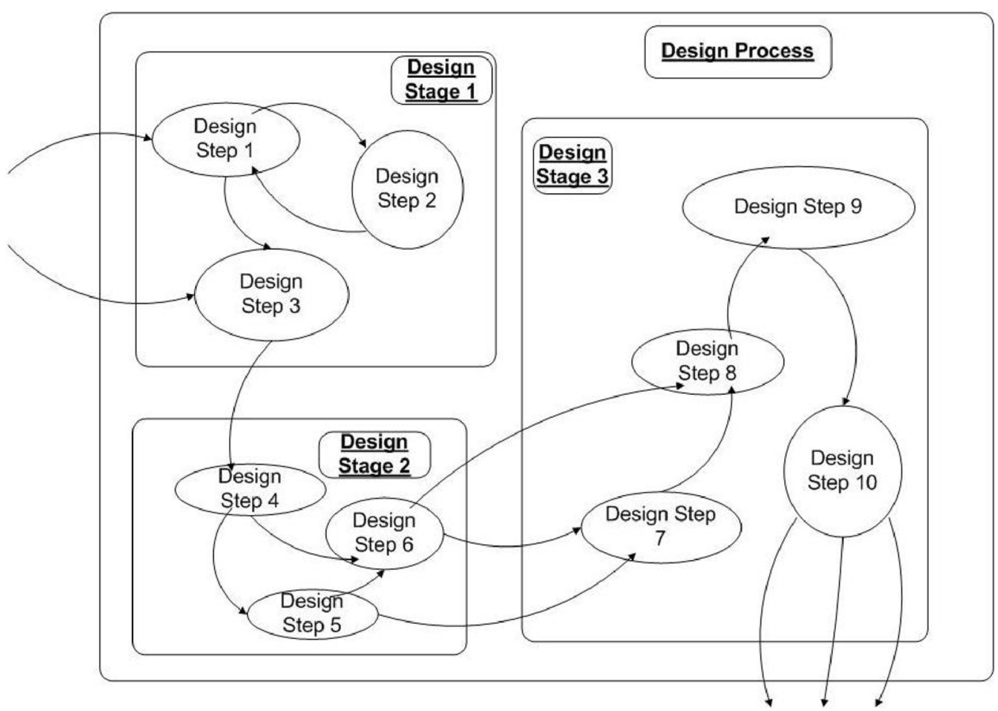


within the process that was initially overlooked. A high detailed resolution analysis of the design process is shown in Figure 4 which is an extension of the hierarchy defined above. This breakdown of the process is considerably more "incremental" than a low detail resolution analysis can give. It is the designer, or as previously discussed, manager or researcher who must be capable of specifying appropriate detail to consider in the evaluation that will not consume enormous processing power yet still yield a sufficient analysis.

Design Process Tool Support

Design tools can exist in two different forms; product support and process support. Product support tools are used within the design process to complete and achieve the design solution. Process evaluation tools are used to evaluate and observe the design process itself, thus giving some measure of goodness. These tools may or may not be used to arrive at a solution, but they are frequently used to manage and monitor the design process either en route or after a solution has been achieved.

Analysis of design can be accomplished with several existing tools, albeit with limitations. Program Evaluation and Review Technique (PERT) is a design tool which is used in scheduling and planning processes (Battista, Pietrosanti, Tamassia, & Tollis, 1989). PERT is best used to evaluate singular project management entities, such as time. Gantt Charts are another project or process management tool. They are used to present time related information of processes in relevant timeline domains (Maylor, 2001).

The ability of the user to modify the evaluation tool for their specific needs does exist, but is often tedious due to evaluation tool restrictions of formatting and application. A process evaluation and analysis tool is needed to allow the users to track the critical information that is important to their individual research. The ability to decompose processes and evaluate each sub-system should prove beneficial for designers, by increasing their understanding of the design process.

Such a tool should facilitate information tracking and evaluation for each step within the process and should display the information produced by performing the specified tasks within that process. If units of information, such as design documents, are generated by a design task, they must either be useful or considered waste. Wasteful information means that the information is not useful in producing a solution and should not be created. If information is created and used later on, but not part of the original intention of that step, the requirements should be revised to include the newly discovered information. This analysis should enable researchers to better understand design processes. Researchers can analyze design projects to use the information available to learn about the process while using the process to learn about the applied case as well.

CASE STUDY RESEARCH IN ENGINEERING DESIGN

One of the most significant tools for design process analysis is case studies (Yin, 1994). Remarkably, case studies are often misunderstood when used as a design process analysis tool (Ahmed, 2007). Case studies are the empirical extraction of data from real world events that are used to view relationships and examine results about design (Teegavarapu & Summers, 2008). They provide relative, fact-based results to qualitative questions (Eisenhardt, 1989). Case studies focus on real world practices to develop theories and methodologies (Teegavarapu & Summers, 2008). They generate straightforward data from results which apply to a group of design variables, but cannot lend themselves to distinguish the effects of each variable individually.

Collecting data from case studies can laborious and can take place in a variety of manners, but tradeoffs of collection cost, collection effort, collection time, and influence on the results exist (Yin, 1994). The researcher must select what information is needed as well as how to extract it and do so without skewing the data. To extrapolate the conclusions to a theoretical application, properly constrained studies must be established (Yin, 1994). Developing such a bank of studies is difficult and resource consuming because the similarity of multiple cases is subjective and not easily compared.

Using case studies is said to be an all encompassing method which covers the problem definition, hypothesis formation, and collection and analysis of data stages. Case studies enable the designer to answer how and why questions about the specific occurrence. They do not allow the user to control variables, however, which would classify the study as an experiment. Case studies possess tremendous power in analyzing design processes, but wielding such power requires care. Despite the informational gain potential, case studies are easy to execute incorrectly. This reduces validity of the results as well as the beneficial experience gained by the researcher who executed the case study.

In order to enhance the use of case studies within design, one should be able to visualize the design process, without affecting the products of the process. This would allow the researcher to know how to construct the case study without corrupting the data. The visualization, as well as the results generated from it must be easily observed and understood. The information gained from visualizing the design process should not require exhaustive effort to generate or comprehend thus reducing the probability of erroneous case study design and extrapolation. The identification of multiple similar cases should not require exhaustive efforts but should rather be an observation of the two cases. By improving the use of case studies, engineers can focus more on what can be learned rather than doing tasks correctly.

The Need for a Case Study Research Tool

A design process model is needed. If a design process model existed which could communicate the information that the user needed, universally, understanding and manipulating design would require much less work. A way to communicate requirements of design processes as well as the way information transforms and flows throughout the design process is needed. Designers have product support design tools at their disposal. Using this as a starting point, a design tool based approach to modeling the design process could prove beneficial. Since design tools cannot compose a design process alone, the information which flows throughout the tools must also be considered. Using this approach, the information that enters and exits design tools could be connected to plot the design process evolution as it progresses.

Representing design processes with both product support and process evaluation tools could lend an advantage over other process models when representing design processes. With a model of design processes showing the importance and function of design tools, researchers could increase their understanding of design processes. Furthermore, the design process can be analyzed in individual portions as well as a whole to reveal fundamental relationships that are hidden within the design process.

A visual design tool based representation of design processes would enable researchers to modify the design process. When the design process is completely disassembled, the components and relationships within the process can be studied, thus allowing thorough understanding of the effect of each part of the process. This deep understanding could expose quantitative data about the effect of each design parameter and allow designers the ability to critique the design process. Having this concrete data would allow design process construction to be done on rules and facts which are easily quantified.

Observing and measuring precise rules and facts about design processes has been subjective for decades, but with the ability to "see" design, one could predict performance of designers engaged in design processes (Tufte, 1986). Engineers and designers are typically visually oriented people (Henderson, 1999). It is logical that if design processes could be illustrated with visual images, then the designers and engineers who use them so frequently would be able to better understand and manipulate the process to suit their needs.

Such a visualization of design should be capable of representing many if not any design process model. Researchers should be able to construct such a representation in context with their own domain of information. The users should be able to locate and follow any specified entity through the entire design process with ease. This model would enable performing visual and content based comparisons of multiple design processes. With such enhancements in design analysis, future researchers can build experiments to control design process outcomes. Such experiments would prove useful for design education as well as research projects. All of this could be applied to case study research, giving engineers a more powerful tool to advance the understanding of design. By observing the information flowing through each activity within the design process, bottlenecks can be spotted and addressed to streamline efficiency.

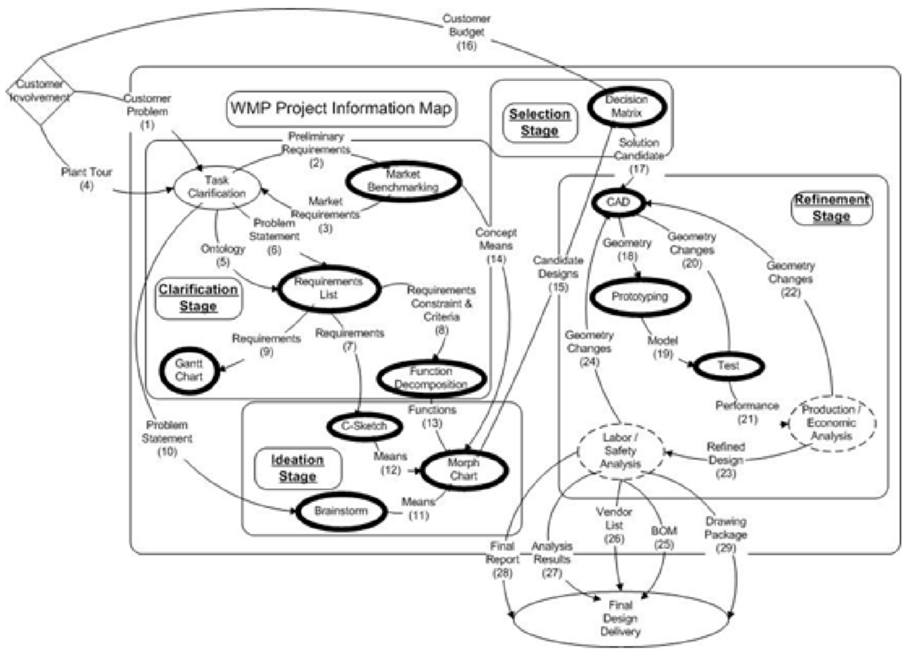
Fully understanding the design process and what happens within the context of design would allow engineers to improve the design process to suit the resources that are available to the designer. The design process itself could be manipulated intentionally to control the design process and learn about the effects that each component has on the final solution, thus blurring the line between experiments and case studies. With this improved understanding, the process can be used to improve the use of case studies in analyzing design processes. By implementing the aforementioned visualization method, case studies can become commonly used by many researchers and something that can work effectively to guide the design processes for engineers.

Thus, the development of a new process visualization tool is warranted. Here, we propose a visual representation scheme to illustrate information within design processes. This visualization method would enable the designer to see information that is of interest throughout the design process. As the process representation is constructed, the information of interest will develop from the first step of design to the final delivery of the product. Once complete, the process maps will allow researchers to follow critical information through the process as well as plan ahead to ensure that the current design process will yield something of sufficient value to the customer.

Development of a Design Process Visualization Tool for Case Study Research

A survey of process models is used to compare the differences between current design process model approaches and the limitations of each with respect to value gained by the executor. Inspired by IDEF0, an altered process model is presented in an attempt to increase the information captured by the designer when using and constructing these process models. The graphic representation proposed is applied to three case studies to illustrate the benefit of case study use in design tool development. Through applying this suggested representation to the case studies, it is shown that the Design Enabler Information Map (DEIM) allows researchers to create a visualization of design processes that can illustrate the needed information and be easily readable. By doing this, it is the goal of the representation to enable designers to understand, execute, analyze, and modify design processes in more effective ways than were previously available. By enabling design, the means of understanding, representing, modifying, and completing the process of design is permitted, or in this case, enhanced. Thus, this

Figure 5. Generic design enabler information map (WMP)



tool will be called Design Enabler Information Map (DEIM). Since information is the critical element of design, and the representation shows how information flows into and out of specific entities, these representations are called information maps. A design tool information map for the welding cell for metal frame construction project is shown below in Figure 5. Design activity sequencing is captured in the labeled arcs, along with the type of information that is flowing between design tools and activities. The design activities are grouped together into general design phases, such as *clarification stage*. The design activities are represented as formal tools (bold), general activity (thin), and unstructured (dashed).

Visualizing the design process traditionally falls into one of a handful of formats. Each of these formats has benefits and limitations to its use. Understanding what each can and cannot do is critical to proper application within the design process model. Fundamental methods to presenting the information contained within design process models exist and are commonly used widely; IDEF0, PERT, and Network schemes are typically the most commonly used (Dorador & Young, 2000; Shenoy, 2000).

Representation schemes for design processes are methods which present the information contained in the model to the reader. However, not all design process models are represented similarly. Some are represented via text and others are graphic with some being capable of using both. Words can be formed and sentences constructed to that communicate the information needed (Nanard & Nanard, 1995). While the text representation can give accurate and descriptive detail, the text is often lengthy and laborious to edit. Ideally, the detail will be maximized when writing the description and then filtered after the reader has deemed a specific portion unnecessary (Lockledge & Salustri, 2001).

A graphic representation may or may not give the same explicit detail as a text document, but can allow the user to observe the information that is pertinent to their present work. This can greatly reduce both the size of the representation as well as the volume of information that must be processed in order to obtain the required description of the image. A variety of graphic representations exist, and each performs a specific function appropriate for its own use. Graphics such as diagrams, pictures, and icons are the most abstract. These have the least structure and can appear in almost any different form. Other forms of graphic representations are charts, graphs, and plots. These often, but not always, relate directly to mathematical entities allowing great detail to be communicated in a relatively small form. Charts are typically used for comparison of few characteristics. Matrix or table representations also utilize visual stimulus to communicate. However, these combine the visual principal with traditional text to relay information. Understanding a matrix requires the reader to associate the row and column of the specified entity to the characteristics of that entity.

A comparison of Design Structure Matrices (DSM) to an image diagram in representing design processes has been evaluated against design research criteria (Keller, Eckert, & Clarkson, 2006). In this evaluation, the DSM is compared to a Node Link diagram. Both of these methods are used to predict changes in process modeling and are a form of connectivity modeling which in turn introduces coupling complexities (Summers & Ameri, 2008). In order to generate a method of representing design processes, a form of graphic representation must be selected; being either a matrix or node-link graph.

In evaluating matrices against node-link diagrams, measures needed to be established to give a level of goodness. The ease of locating a specific information unit or node is of interest. Likewise, identifying and locating a specific relationship, or link between two information units is also needed. The ability to count the number of links entering and exiting a node should be possible. The identification of any adjacent nodes should be available to the user with minimal effort.

It was discovered that matrices lend favor to sorting information, thus aiding in selection (Keller, Eckert, & Clarkson, 2006). Matrices are organized tables which can present large quantities of data in a clear fashion. However, matrices do make selection and counting of connecting links difficult. Identification of a relationship between two items is tedious to recognize meaning that identifying nodes adjacent to the current one is troublesome. Identifying the shortest process path via matrices is laborious if being analyzed manually.

Node-link diagrams present different benefits and challenges. They allow for identification of specific links easily. Determining the direction of the process links is easier with node-link diagrams, as is locating adjacent nodes. Following process paths is simple with node-link representations thus making the identification of the shortest possible path easy (Keller, Eckert, & Clarkson, 2006). The act of following paths, and shortest path identification were proven to be better represented with node-link diagrams for all datasets. This is believed to be due to the physical display of a path, which makes following easier. Since path following is critical to understanding information generation, flow, and change, node-link diagrams will be used to represent design processes.

IDEF0 is used to model functions of a system (Dorador & Young, 2000) and is similar to node-link diagrams. It represents the relationships and data which support the connection of those functions. The models are composed of hierarchal diagrams that show increasing levels of detail as the hierarchal level is reduced. IDEF0 is traditionally used to relate function to information of systems. The functions are traditionally shown as the nodes or entities. The information units or data which combine functions are shown as arrows leading from one function to another.

While IDEF0 diagrams allow designers to improve processes by describing critical information relationships, the traditional form of the tool is not optimal for representing process flows due to difficulty in tracking link flows. IDEF0 diagrams are suitable for showing activities and some connecting information. However, showing multiple domains of information flowing through nodes is something IDEF0 cannot easily communicate to the diagram reader.

An ideal scheme would combine the beneficial qualities of each of these into a single representation that researcher can use to illustrate design processes. The researcher should be able to specify the fundamental information of interest which is related to the specific information that flows through the process. The designer should also be capable of specifying the modifying bodies, or nodes, that exist so that the representation will be applicable to their specific area of work. The goal is to be able to determine the appropriate steps and expectations of design processes given the available information. The use of text should be available but not required and should not be limited to specific formats. This representation would be flexible to the researcher to use how each particular process needs it to in order to communicate the information that the designer desires to see.

The Case Studies

Three independent design projects were modeled after completion using the DEIM approach. The first project, designing a robotic welding cell, was a four month industry sponsored undergraduate design project for a small manufacturing firm. The second project was sponsored by another small company that is developing a combined trash and recycling collection and processing vehicle. The final project was to develop a tire testing system and was sponsored by a larger company. A brief comparison of the projects is found in Table 1.

These case studies are used to demonstrate the feasibility of using the DEIM to capture the type of information flow in the design projects. This quick and qualitative design research tool can allow engineers to visualize how different information is related throughout the design process. Coupling this visualization tool with formal ontologies for describing design information and activities is the next step in creating a formalism for conducting engineering design case study research.

For each of these projects, a visual design process map will be constructed representing the actual information and actions taken within the real life design project to develop a process representation and analysis tool. It is believed that throughout the development of these maps, the ability to represent design processes can be enhanced. Through these projects, the maps will be developed and tested, to show that visualization of design processes is possible and beneficial to researchers.

The graphic representation proposed is applied to three case studies to illustrate the benefit of case study use in design tool development. Through applying this suggested representation to the case studies, it is shown that DEIM allows researchers

Table 1. Case Study Comparisons

	EAI	WMP	Michelin

# of Participants	6	6	8
Review Frequency	4 Weeks	1 Week	1 Week
Professors	1	0	2
Graduates	4	0	5
Undergraduates	1	6	1
Deliverable	Revised Vehicle CAD	New Work Cell	New Equipment and Testing Procedure
Time from project to mapping	5 Months	20 Months	1 Month

to create a visualization of design processes that can illustrate the needed information and be easily readable. It is the goal of the representation to enable designers to understand, execute, analyze, and modify design processes in more effective ways than were previously available. By enabling design, the means of understanding, representing, modifying, and completing the process of design is permitted, or in this case, enhanced. Thus, this tool will be called Design Enabler Information Map or DEIM. Since information is the critical element of design, and this representation shows how information flows into and out of specific entities, these representations are called information maps.

By intent, DEIM is to promote illustrative flexibility in what is represented as well as how it is represented for the case studies modeled. The main consideration when building a DEIM is to structure each connection in the context of what is being tracked, the information of interest. However, some formalism is required to enable logical perception by readers (Kim & Jang, 1999). The ability to freely position nodes and links within the map remains, but the net flow of the process should extend from the top and left to the bottom and right of the map. Additionally, the method of representing information types cannot be shared by multiple types. These are requirements that permit the process to be modeled flexibly yet with organization.

DEIM's consist of a few components which are connected together to create the representation of the process. These are the information links, the accompanying nodes, and any specific borders which are an extension of the nodes. Information is represented in the form of arrow links, which may have specified thickness, color, line style, length, labels, and direction (Kim & Jang, 1999). The nodes can consist of various shapes, sizes, colors, and labels. Any graphical property of the maps can be defined as a characteristic key of the map, thus representing some specific information unit. Borders shown within DEIM perform the same function of nodes, establishing detail limits to the investigation of the process. Borders are shown on the highest level as the design process boundary allowing initial information to enter and the solution information to exit.

Each component in DEIM represents some sort of information that is important to the overall representation. Information links represent the most elemental component of the process representation. The nodes represent the transformation of the information from one state to another. The borders that exist in the DEIM are expansions of higher level nodes. They serve to group information links and action nodes of specific relation together.

The goal of constructing a DEIM is to sufficiently track the initial information given to the designer through each step it is transformed through until the desired exiting information is reached. This will allow the designer to understand how information changes, how information flows, and how information is related to specific operations within a process.

DEIM can be used to represent actual complex design processes, consisting of a multitude of information domains, and including an assortment of active entities which work together to illustrate a design process in a clear and concise manner. The information contained within a DEIM can be low if the mapper desires, resulting in a DEIM showing a single type of information throughout the process. Additionally, DEIM can show many different types of information while still remaining readable by the user. Ultimately, they show what happens in a process as well as how it happens by illustrating the connectivity and transformation of links through nodes.

To test the use of and verify the benefit from DEIM, three design projects were represented using the DEIM method in a manner similar what others have used in validating their case study work (Hernandez, et al., 2001). For the DEIM case studies, the author was involved with each of these projects thus lending firsthand experience to the events as they occurred, giving the author the ability to map the events of the design processes into DEIM. These DEIM models were constructed after the project was complete, although the time span between project completion and map development varies for each example shown.

For each of the examples shown, the information links are generic design process information that may range from Requirements Lists to Concept Performance. A formal ontology for the type of information exchanged between the design tools has not yet been adopted. The nodes selected are the combination of design methods and tools (instantiations of tools). The author recognizes the difference in these two, but the distinctions are not of interest, therefore they will be used collectively. These serve to transform the information from its entering state to some other form via work.

In these maps, several generic design stages exist such as, Clarification, Ideation, Selection, and Refinement. These were chosen based on a traditional systematic engineering design process (Pahl & Beitz, 1996). Each respective map may or may not show the explicit stage boundaries, depending on the type of work being done. An example of this is the EAI project which consisted of three separate and concurrent detail refinement stages. The baler, trash compactor, and structure systems all were designed independently, at the same time. Rather than show a single refinement stage, the EAI map shows each separate system refinement stage of the design process.

THE EAI PROJECT

The Environmental America Inc. (EAI) project was a privately sponsored endeavor. The company, EAI, had an idea to patent and prototype an integrated recycling center on board a common trash collection truck. EAI approached designers with a fourth generation prototype and asked the researchers to "streamline" the truck by reducing cost, mass, and complexity. This project relied heavily on the task clarification stage of design. Significant work was done to justify implementation of such a product into the infrastructure of local cities and residual plans had to be made that would affect the performance of the end product. Once appropriate justification of such a device was found, work began on ideation of concepts and product breakdown. The fundamental requirements of the truck were developed and used to eliminate excess systems on the current prototype. Once certain systems were eliminated, work began to improve efficiency and performance of the needed systems to conduct the truck's tasks. This work was segmented into three areas; Trash collection, Baler Design, and Structure Design (Smith, Johnston, & Summers, 2007).

The first of these is the design of the Trash handling equipment. This involved conceptualizing equipment to compact the trash and eject the load once at the land fill. Significant difficulty was encountered in modeling the behavior of trash, therefore, the project funding ceased before sufficient information about this could be collected. The baler design was more productive. The testing phase of this design proved instrumental in the generation of both concept ideas and Loading Conditions for the simulation. The superstructure design was also completed. Specification information was gathered from benchmarking existing vehicles and reproducing the functionality of those designs. The safety of the concepts was checked via FEA and the loadings gathered from market research.

Representation of the EAI Project

The DEIM of the EAI project was completed five months after the design project was finished. The DEIM representation of the EAI project is shown below in Figure 6. The information links vary in content but are primarily generic process information. Notice that each of the nodes is a design tool or design method which was used to transform the information to some other form. The line style of the node signifies what that node is. A bold node outline represents formal design tools. A thin node outline represents an informal action which can possibly be a design tool or method. Finally, the dotted outlines represent a fuzzy definition of that particular node. For these, the intent may be common, but the way in which the action was taken may constitute some modified version of a standard task definition. Thus these types of nodes are classified as "Fuzzy" and shown with a dotted line.

For this example, the information links can be related back to physical design documents or files. The Requirements List is a document that was printed and presented to the client. The geometry generated from the solid modeling (SolidWorks) step is the *.prt file for each respective part that was then analyzed in finite element analysis (Cosmos).

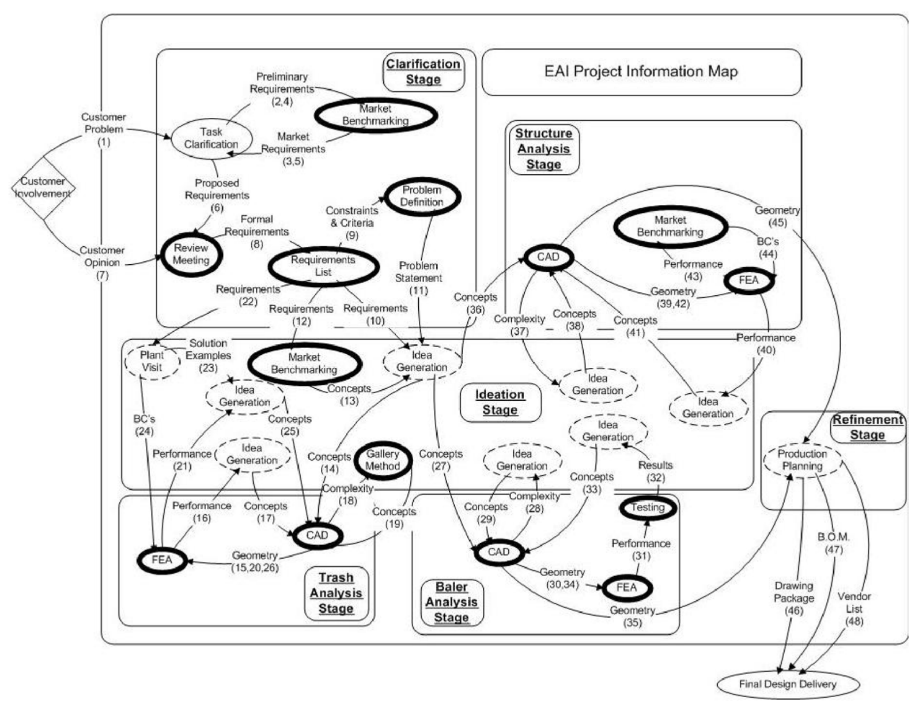
Observations of EAI DEIM

By constructing and examining the EAI DEIM, it can be concluded that:

- DEIM construction iteration improves readability
- Existing labeling of DEIM does not support parallel node sequencing
- DEIM readability can benefit from using cognitive tendencies
- DEIM construction iteration improves process content accuracy
- DEIM enables researchers to identify non-value adding nodes within a process
- DEIM enables researchers to identify information critical to a specific process

DEIM can allow the researcher to identify the critically needed steps within a process. By starting at the final design delivery, each subsequent step can highlighted. This can propagate all the way

Figure 6. Final EAI DEIM



up to the initial customer input. By doing this, connection of each part of the DEIM to the final design delivery can be determined. In doing so, non-value adding steps are identified, revealing to researchers the wasteful steps within the process.

By studying the following maps, Figure 7, Figure 8, Figure 9, and Figure 10, it can be seen that the Trash Analysis Stage along with Idea Generation Steps connected to it produced no work that contributed to the final design. This occurred because the effort required to model compacted trash behavior is extensive and the client decided to purchase an existing unit rather than consume resources to develop a new one. The identification of non-value adding nodes begins in Figure 7, with the final product. The required input information to that node is identified and then the source nodes of that information are then highlighted. This process propagates back through the process until the initial step is reached. Once a complete path of value adding nodes reaches from the final solution to the initial link, the process evaluation is complete. At this point, any remaining nodes are non-value adding.

THE WMP PROJECT

The Wright Metal Products (WMP) project was a four month long, sponsored design project. The client had purchased a welding robot, and wanted the designers to develop an efficient work area to use the robot in their facility. The client manufactures steel shipping crates out of pre-cut parts which are then welded manually in the facility. The goal of this project was to improve efficiency and production by using the robot along with manual workers. The client gave freedom to the designers to specify all needed layout, equipment, and fixtures that would be needed.

Figure 7. Back propagation step 1

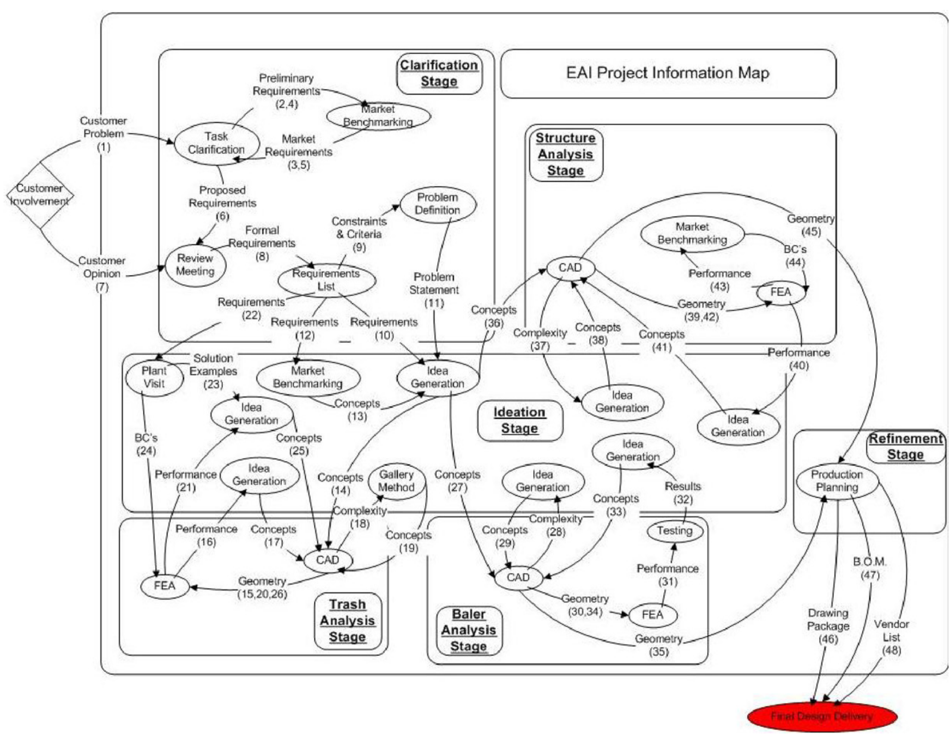


Figure 8. Back propagation step 2

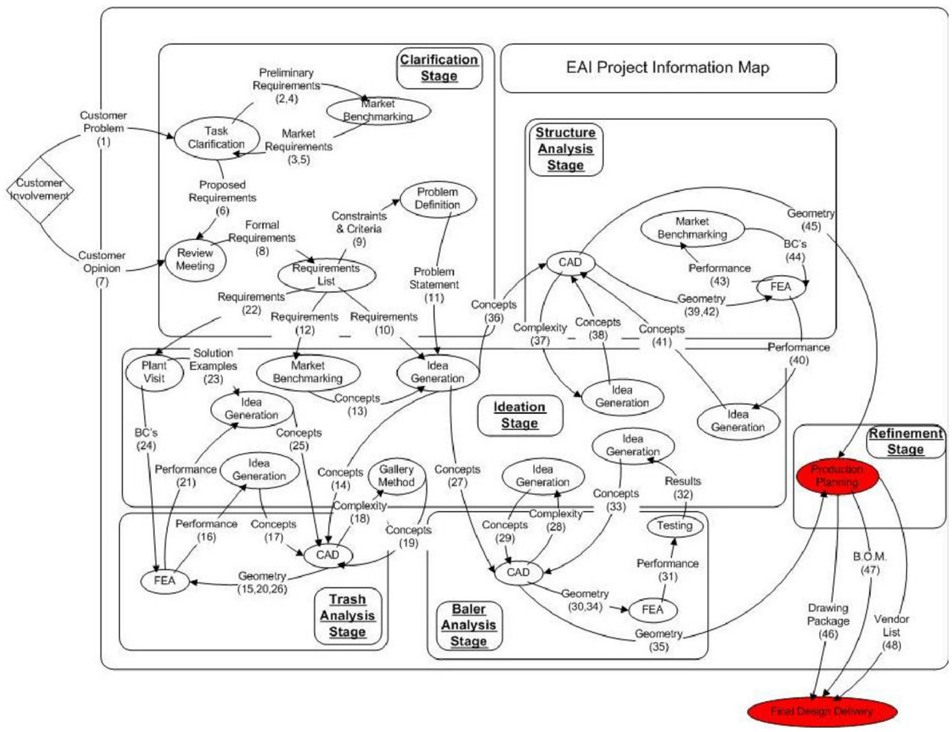

Figure 9. Back propagation step 3

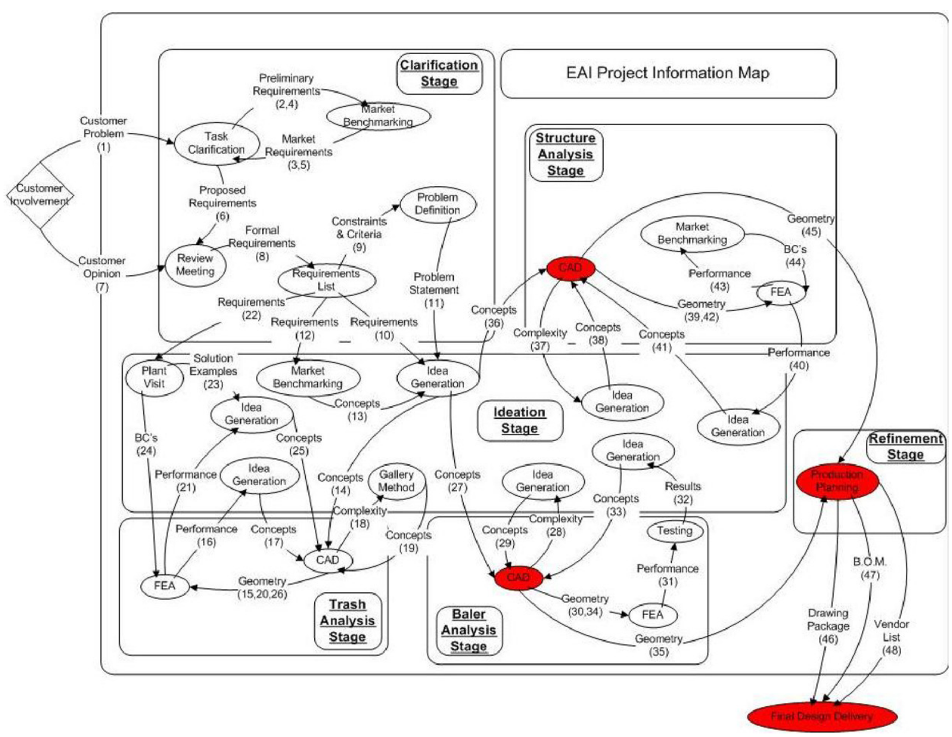

Figure 10. Back propagation complete

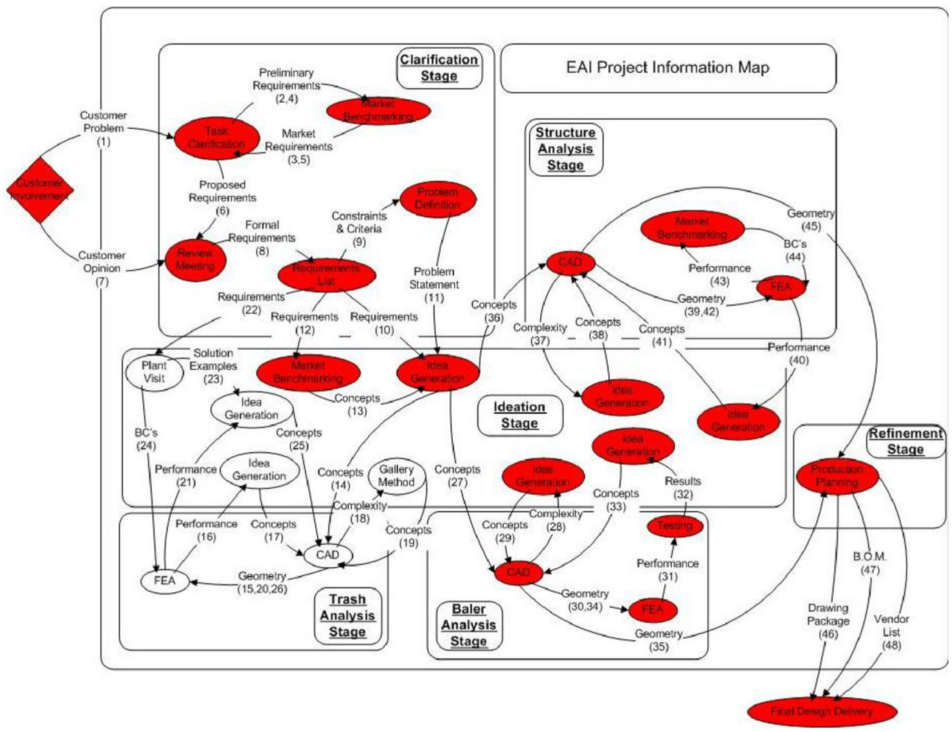

Figure 11. WMP DEIM

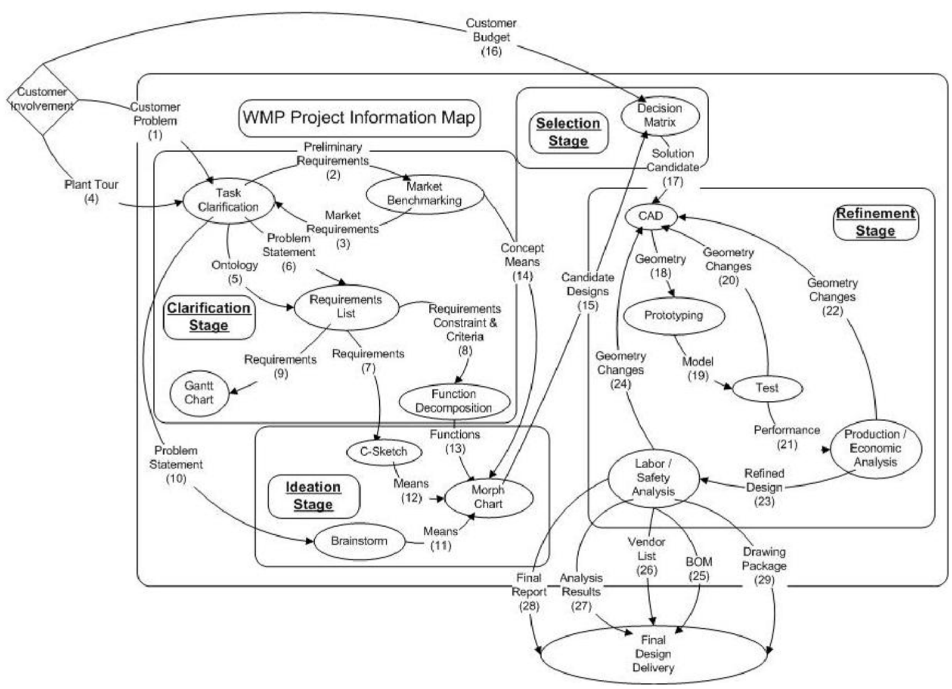

Representation of the WMP DEIM

The DEIM for the WMP project is shown below in Figure 11.

It can be seen that this map does not contain the bold, thin, and dotted node outlines. That representation scheme was used in the EAI map to differentiate the different classifications of nodes that were used. For the WMP map, most of the nodes were formal design tools, therefore adding the different node formats would only serve to add information to the map which is not desired.

This project consisted of four main stages, starting with the Clarification, proceeding to the Ideation, then to the Selection, and completing the process with the Analysis. The Clarification stage served to properly define the problem and develop forma Requirements that must be met by the solution. The Ideation stage encompassed three idea generation techniques and the formation of a Morphological Chart to aid in concept organization. The Selection stage was the shortest in duration and consisted of the use of a Decision Matrix to rank solution candidates allowing the designers to choose the better concepts from all the ones generated. The final stage was the Analysis stage, where the solution was tested, analyzed, refined and validated into a suitable solution.

Observations

By constructing and examining the WMP DEIM, it can be concluded that:

- DEIM is flexible with respect to node classification and formality
- DEIM is flexible with respect to node grouping
- DEIM can enable researchers to identify non-value adding nodes
- Nodes can alter information and channel information

Some of the nodes in the WMP map accomplish dual functions. The first is that the node functions as the modifier of the information. Initially, this feeds back into the previous steps for iteration. However, when the information again reaches the same node, a different "check" may occur, thus allowing the information to "pass" through the node on to the next. An example of this occurrence is shown below in Figure 12.

THE MICHELIN PROJECT

The Michelin project was a twelve month long project that began when representatives from Michelin Tire Co. approached the engineers with the topic of test procedure development. They were interested in understanding a soil and tire interaction and wanted to investigate the possibility of the designers developing an economic solution to their need of testing.

Representation of the Michelin DEIM

The DEIM of the Michelin Project is shown below in Figure 13.

Tires are a complex machine, and the construction and simulation of their behavior is not a

Figure 12. Dual function nodes

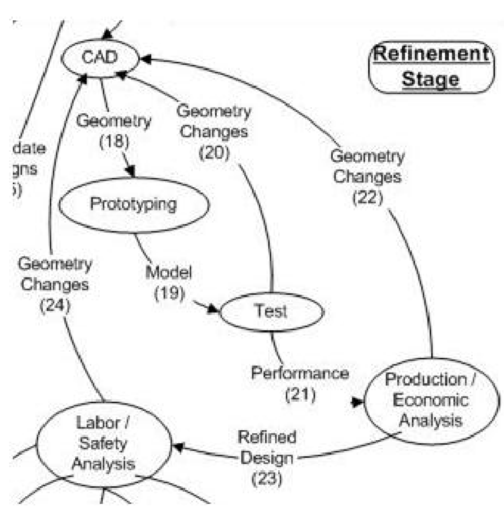

Figure 13. Michelin DEIM

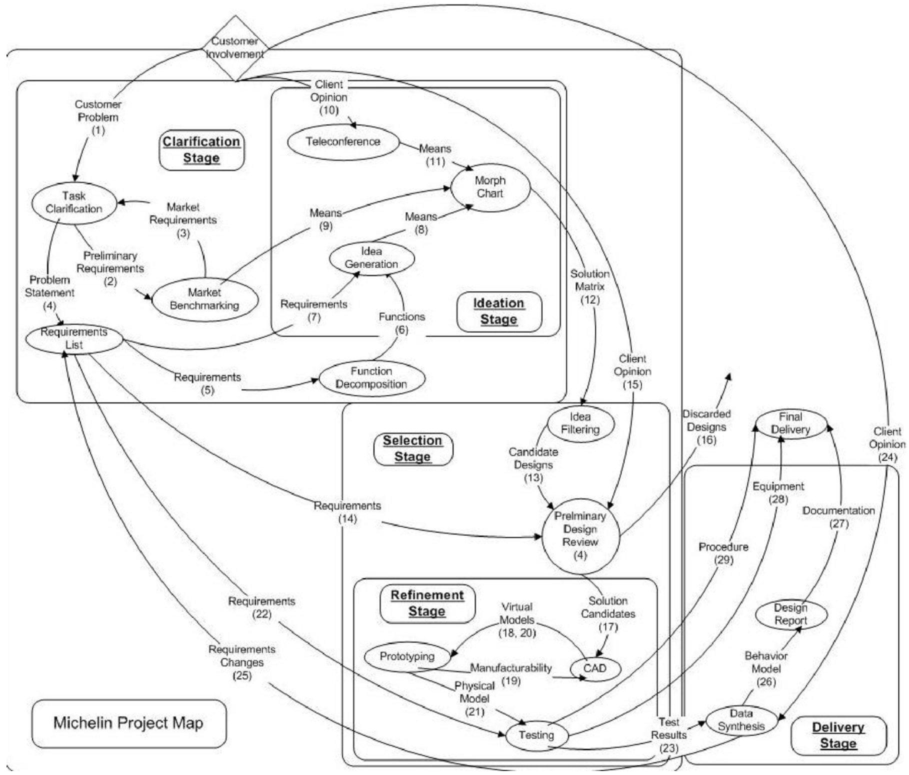


simple task. To test specific behaviors, tires are generally constructed, and used to examine the performance of certain parameters. The engineers will then specify changes, and will need to manufacture a new set of tires. This is costly due to tire mold manufacturing cost. The testing cost limits the ability of the tire engineers to learn about the behaviors, so the need of a simulation protocol with more economic operational cost is warranted. This was the goal of the designers, as specified by the customer.

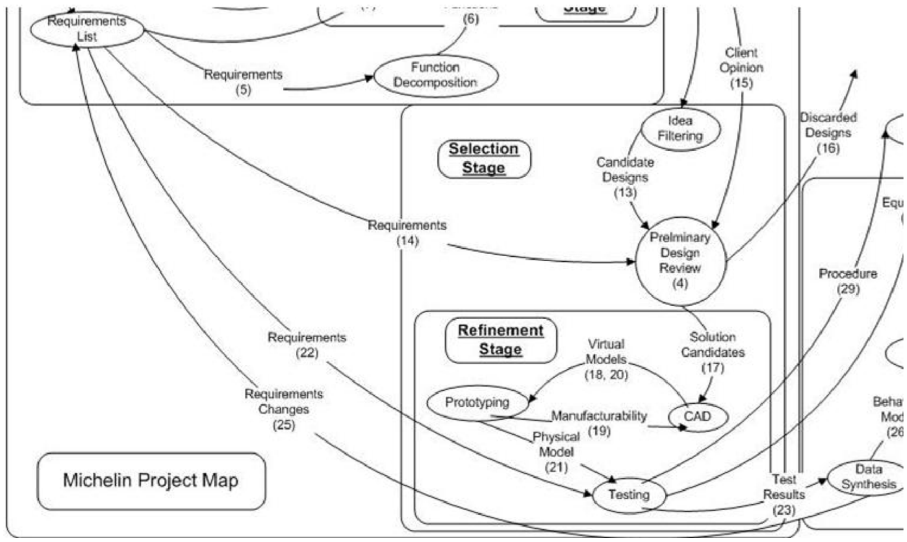
Observations

By constructing and examining the Michelin DEIM, it can be concluded that:

- DEIM can show non-critical information if the mapper wishes
- DEIM is flexible with respect to node grouping
- Link length may be proportional to specific information properties
- Node connectivity may be proportional to specific information properties
- DEIM can show the result of insufficient information
- DEIM can show the effect of making long iterations

It can be seen with this map (Figure 14) that the length of the links is proportional to the goodness of the design process. As mentioned above, early and often iterations make for better design processes, whereas the links representing those iterations would be spaced close together and in stages rather than in long sweeping curves. The link length in this DEIM varies greatly from node to node. This communicates some information

Figure 14. Michelin DEIM link length



about the process such as time required to iterate and percentage of time wasted by the iteration.

The Michelin DEIM shows relationships of node connectivity to the difficulty of that part of the process. If a node is highly connected such as the Requirements List or the Customer Involvement, then accurate and precise information from that source is needed for the design process to proceed properly. Accordingly, incomplete or inaccurate information from highly connected sources works against the productivity of the design process. As mentioned above, the lack of exhaustive requirements by the customer hindered the progress of the design project. If the significance of the Requirements List been known initially, the designers may have urged further clarification and development of the Requirements List before proceeding on to the next step of the design process.

The Michelin DEIM also shows the effect of insufficient information being used in a process. Fault of this deficiency cannot be given, but the effect of completing most of the process without it can be shown with the map. As the design data is being synthesized, discoveries were made that amended the requirements of the process. DEIM shows this by connecting a late node to an early node, thus initiating an almost complete process repetition.

CONCLUSION

By representing information within design processes, researchers can model complex processes graphically. Doing so gives researchers a better mental connection between what is perceived and what is real. With better understanding comes improved ability to analyze design processes with case studies. These improvements were shown through the application of a newly developed design process model in three case studies. Each case consisted of different deliverables, different experience levels of the designers, and project durations. The use of case studies to develop design tools and conduct design research has been proved beneficial by the successful application of and evaluation with DEIM to the case studies.

Through conducting these case studies, observations about the DEIM representation of design processes can be made and are:

- DEIM construction iteration improves readability
- Existing labeling of DEIM does not support parallel node sequencing
- DEIM readability can benefit from using cognitive tendencies
- DEIM is flexible with respect to node classification and formality
- DEIM is flexible with respect to node grouping
- DEIM can show non-critical information if mapper wishes
- DEIM is flexible with respect to node grouping

These observations illustrate ways that researchers can benefit from a graphic representation of design processes and that design processes can accurately be represented graphically while containing sufficient detail and promoting readability.

Observations about the cases studied through the application of DEIM were also made here are:

- DEIM construction iteration improves process content accuracy
- DEIM enables researchers to identify information critical to a specific process
- DEIM can enable researchers to identify non-value adding nodes
- Nodes can alter information and channel information
- Link length may be proportional to specific information properties
- Node connectivity may be proportional to specific information properties
- DEIM can show the result of insufficient information
- DEIM can show the effect of making long iterations

Information paths can be easily traced with DEIM. From the initial problem of the client to the documentation or artifacts that are physically delivered to the client, the type, quantity, and change of the information present at any given stage of the process can be displayed. This gives designers an ability to determine "Next Steps" for each process as well as determining information that may be needed to complete a specific task.

The critical path of information flow can be determined from reading DEIM. This can be done via back tracking the preceding nodes or any other means desired. The representation of links and nodes allows a holistic understanding of the process to advance into a detailed understanding of information that enters and exits any specific node.

The connectivity of the nodes within a DEIM can also be seen. It was shown that DEIM nodes that are highly connected tended to be significant contributors to the design process. The concept of this metric can be used to build DEIM in respect to other characteristics such as production dependencies, or information management. In the case studies shown, the connectivity relates to both the affect that the particular node has on other nodes as well as the difficulty that can be encountered when constructing DEIM containing that specific node.

More importantly, the development, application, and evaluation of new design tools and methods through the use of case studies has been proven. The three cases used show the benefit of the developed representation through the information revealed about the cases. The cases served to test the new representation, and allow the author to discover information about the representation that was previously unknown. These observations have been mentioned in the previous section. Furthermore, the application of the new tool to case studies has also shown that case studies can be used to evaluate design processes, in attempt to understand the process meaning that future endeavors of modifying and improving the process are possible.

Certain limitations were encountered when using DEIM to represent tools used in processes. These difficulties came from constructing the DEIM as well as reading and understanding the process being represented. The first difficulty is the difficulty to search for specified objects (links or nodes). With other representations such as DSM, readers can search for a specified entity in a one dimensional, linear manner by scanning either a column or row heading. DEIM expands the representation into a full two dimensional space, thus making searching more difficult. This was addressed by Keller et al as well in their Matrix vs. Node Link evaluation (Keller, Eckert, & Clarkson, 2006).

The layout of the nodes is also a cumbersome and tedious process. It is difficult to position the nodes of highly connected processes in a manner such that the links do not intersect. In fact, sacrifices must sometimes be made when constructing the maps to show some information and alter others. DIEM is a user defined representation of the process. It could be beneficial to allow link intersection sometimes, thus creating another entity which can represent additional information about the process.

The work presented in this chapter leads to some areas of future investigation such as the exploration of domain representation methods. They ways in which information domains can be shown within a map cannot currently be counted. The ability of DEIM to illustrate the sequence of operations within a design process is also of value to researchers. Future work could be focused on how to represent time and process sequence within the DEIM. DEIM contains complexity that could greatly benefit from computer integration. Implementing the theory presented in this chatper into a software package could prove to generate a useful and powerful tool for designers. Design disciplines such as project management could use such a program in researching and developing their own principles. More case studies should also be completed using DEIM to model the processes. These case studies give specific context to issues revealed in each map and allow researchers to relate the fundamental elements of DEIM to the details of design processes. The theory of information mapping reveals issues that could prove beneficial to process representation schemes. The application of the Conservation of Energy principle into information mapping could prove beneficial. By theorizing that "information cannot be created nor destroyed, but can only change form", researchers may be able to enhance the way that design processes are understood and completed. Similar benefit may also be had by investigating the integration of Boolean Logic into information maps. By identifying non-value adding steps, DEIM opens opportunity of integration with lean manufacturing process models. This can also be an extension of a software package. By exploring the theory of both lean manufacturing and DEIM, researcher may be able to discover similarities, thus enabling the design community to gain a broader and applicable model to understanding processes.

Finally, the expansion of design process models away from verbal descriptions into visually grounded renderings should be continued. This research has formed two dimensional representations of complex and real world design processes. A lofty future goal of this research is to enable designers to use complex and detailed scientific visualization tools similar to CAD software packages to represent design processes in a multi-dimensional virtual environment. This would give greater capability and freedom in information mapping and process modification to the researcher by representing design processes in virtual three dimensional spaces.

ABSTRACT

This chapter presents dynamic analysis of a model of a centralised supply chain. The research was conducted within the manufacturing sector and involved the breathing equipment manufacturer Draeger Safety, UK A simplified model of the Draeger Safety, UK centralised supply chain is developed and validated. Simulation and analysis are performed using System Dynamics, control theory, nonlinear dynamic and chaos theory. The findings suggest that destructive oscillations of inventory could be generated by internal decision making practices. Bifurcation diagram is plotted to indicate the bifurcation status of the model with different internal decision policies. A management microworlds is developed for managers to experiment with different decision scenarios and learn how the supply chain performs.

INTRODUCTION

The contemporary business environment is characterised by an acceleration of the process of change due in part to improved communication and analytical capabilities brought about by modern Information and Communication Technologies (Sterman, 2000; Terzi and Cavalieri, 2004; Ortega and Lin, 2004). This poses an ever increasing demand for periodical review of strategies and organisational processes, and for faster and more effective learning to deal with problem situations more quickly. Furthermore, companies increasingly need to react to customer requirements (Hong-Minh, Disney and Naim, 2000). Naylor et al (1999) suggested the principles of

DOI: 10.4018/978-1-4666-1945-6.ch087

agile manufacturing, i.e. responding to customer requirements with very short lead-times can be applied to supply-chains. Global companies are realising that the efficiency of their businesses is dependent on the collaboration with their suppliers and customers (van der Zee, 2005; Yusuf, Gunasekaran, 2004; Adeleye and Sivayoganatahn, 2004; Cox et al, 2004). The concept *of supply chain management* (SCM) is concerned with the strategic approach of integrating producers, suppliers and customers in a collaborative network with the objective of improving the overall responsiveness of the network, but at the same time preserving the organisational autonomy of each unit (Terzi and Cavalieri, 2004). More accurate data and better information available to all nodes of the supply chain are considered crucial in improving its performance. Thus, companies invest heavily in intra-company information and communication platforms and E-collaboration tools, such as data warehouses or Enterprise Resource Planning (ERP) and Manufacturing Resource Planning systems (Lyneis, 2005; Li & Li, 2005; Marquez, Bianchi and Gupta, 2004).

Contemporary Manufacturing Resource Planning (MRP) is a structured approach to manufacturing management in which a suite of integrated computer software covering the main operational business functions is used to assist the planning of materials, capacity and cash flow, in accordance with company policy, to meet customer delivery requirements (Ackermans & Dellaert, 2005). It is a total approach to managing a business (Li & Li, 2005). It includes inventory control data, purchasing and accounts payable, suppliers' data, master schedules, production schedules, resource capacities, manufacturing orders, and so on. MRP systems are developed under the assumption that more data and better information lead to better decisions. The quality of this data is believed to be accurate or at least good enough to be reliable (Ackermans and Dellaert, 2005). However, even with the introduction of resource planning systems, the performance of the supply chain often remains problematic (Lyneis, 2005; Fowler, 1999). The weakness of such systems is that when used on their own they fail to address the complexity of management situations for two reasons: firstly, they do not take into account the inherent 'messiness' of situations that contain human decision making within the process that is considered problematic (Maturana & Varela, 1987; Beer, 1979, 1994); secondly, such tools do not promote learning (Senge, 1984, 1996; Venix, 1994; Morecroft, 2007) or effective decision support as they do not include simulation facilities to allow what-if analysis on alternative strategies (Terzi and Cavalieri, 2004).

After reviewing more than eighty scientific papers on the role and application of simulation in the supply chain, Terzi and Cavalieri (2004) show how simulation is successfully adopted in different studies of logistic networks. Their findings ascertain that simulation allows evaluation of performance prior to the implementation of the system since: 1) it enables companies to perform powerful what-if analyses leading to learning and improved planning decisions; 2) permits the comparison of alternative strategies in a safe virtual world, without interrupting the real system; 3) permits time compression that allows for timely policy decisions to be made. These findings are also supported by Chang and Makatsoris (2001).

The suitability of simulation as an approach to studying supply chains does not guarantee its adequate decision support (van der Zee, 2005) as simulation relies on a heuristic search for good decisions strategies led by people. The success of the simulation study depends on the joint work of the analyst and the chain managers and actors, as well as the facilities offered by the modelling and simulation tools. Van der Zee (2005), Sterman (2000) and Senge (1996) suggest that it is important to consider the simulation model as a communicative tool between analysts and chain actors. System Dynamics (Forrester, 1961; Sterman 2000) as a modelling and simulation framework has been developed for such a purpose.

This research uses a combination of System Dynamics, control theory and bifurcation analyses to address the issues of decision support and learning in the supply chain. It acknowledges the insights of non-linear dynamics and chaos theory in exploring the system's behaviour (Sice & French, 1998; Mosekilde, 2002).

When used in a management context *Systems Dynamics* is 'a framework for thinking about how the operating policies of a company and its customers, competitors and suppliers interact to shape the companies performance over time' (Forrester, 1961). It is an approach that allows practitioners to explicitly model perceived delays, bounded rationality and goal setting and explicitly discuss systems' boundaries (Ackermans and Dellaert, 2005). To do this System Dynamics uses metaphors drawn from control theory to provide tools for mapping and simulation, and metaphors from behavioural decision theory to describe decision making processes (Morecroft, 1985, 2007).

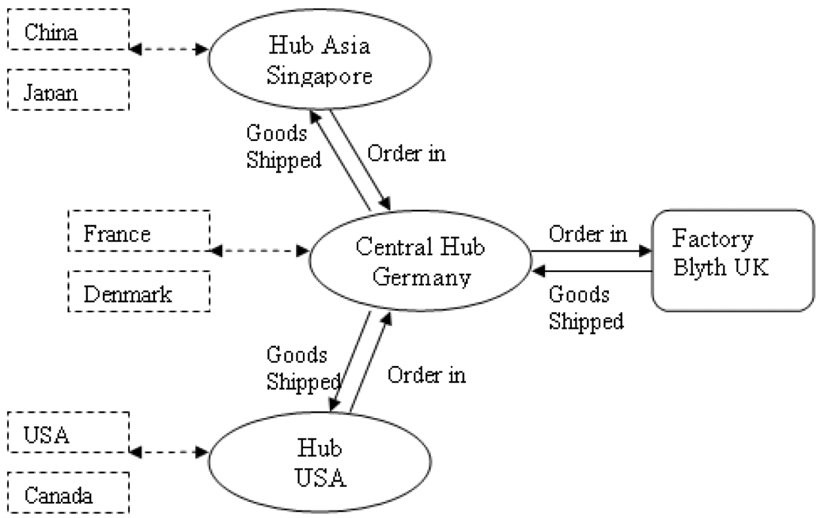
Systems Dynamics is a powerful framework for thinking and explaining how a system's structure generates behaviour. Ortega and Lin (2004), after reviewing the critical literature on System Dynamics conclude that this approach is suitable for modelling complex systems but when it comes to analysis, it contains insufficient analytical support. Therefore, if we would like to carry out in-depth mathematical analysis of behaviour we need to introduce appropriate mathematical tools from control theory (Ackermans and Dellaert, 2005). System Dynamics was founded in control theory and thus, is compatible with its tools and techniques. Ortega and Lin (2005) after studying the use of control theory in supply-chain analyses suggest that control theory analytical tools are quite suitable. However, in the supply chain there is an asymmetric consequences, for example, negative and positive inventories are asymmetric and thus introduce non-linearity in the system. Recent research suggests that non-linearity in the supply chains may lead to chaotic behaviour (Thomsen et al, 1992; Mosekilde, 2002; Sice, French et al, 2000). The control theory is generally linear in nature, and in order to consider effective application in supply chain analysis, it needs to be complemented by non-linear dynamics analyses (Ortega and Lin, 2005; Sice, French et al, 2000).

The research presented here uses a combination of System Dynamics, control theory and non-linear analyses for modelling and exploring the behaviour of the centralised supply chain at Draeger Safety, Blyth, UK. The company is equipped with a sophisticated MRP environment for sharing information and enhancing communication between production and marketing. However, the performance of the supply chain is still perceived as problematic as it is not unusual that high inventories mount up and backlogs develop causing disruption as production is dealing with a crisis to overcome them. A centralised supply chain system was recently implemented with the purpose of diminishing costs and avoiding backlogs. This made Draeger's planning managers even more worried as it was difficult to predict what the consequences of centralised inventories would be for the manufacturing plant in Blyth. A team consisting of the planning department at Draeger Safety, UK and researchers from Northumbria University was formed to study the impact of different decision strategies on the behaviour of the supply chain. The purpose of the study was to model the material and information flows including the decision processes, provide explanation and insight into the link between decision strategies and inventory and backlog oscillations, and to develop a simple microworld that managers can use to conduct what-if scenarios and learn about the behaviour of the supply chain.

THE CENTRALISED SUPPLY CHAIN AT DRAEGER SAFETY, UK

Draeger Safety, UK is an international corporation, manufacturing breathing protection and gas detection equipment. It has a presence in

Figure 1. Schematic representation of the centralised supply chain proposed by Draeger Safety, UK



approximately 200 countries on all continents. Like many other industries Draeger Safety, UK makes use of a cascaded distribution system, with inventory holders at several different levels. In its simplest form (Figure 1), the central Hub, based in Germany, receives stock from the UK Factory and ships this to the main EU markets and to the Pacific and US Hubs. Each of the Hubs acts as a business unit and maintains a warehouse.

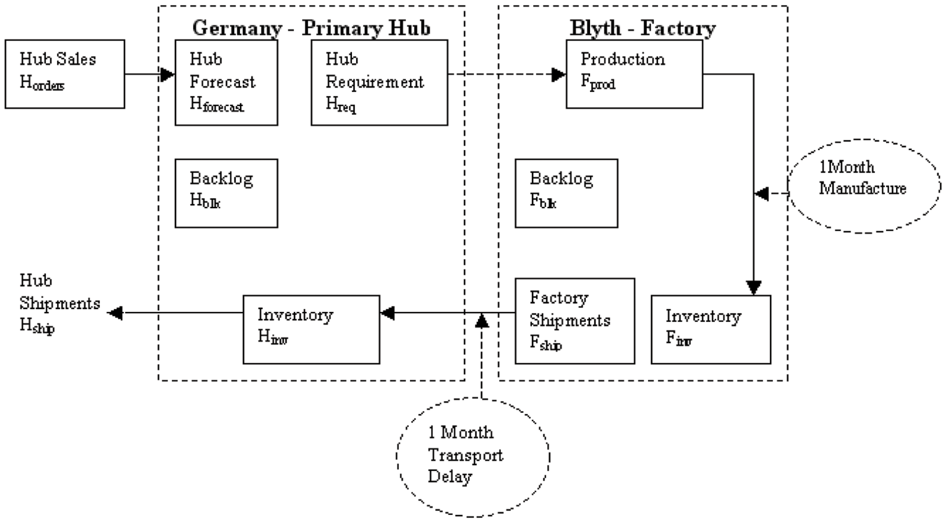
The Hubs receive orders from the Draeger Safety, UK sales agencies linked to them. The sales agencies do not keep inventory or receive shipments from the Hub. The role of the agencies is to receive orders from the customer and to make sales forecasts for their area. They then forward the orders and the forecasts to their respective Hub. The Hubs ship the goods directly to the customer and communicate with production units to help establish production requirements. The process is based on a 2 month forecast. That is, based on the current trends in orders and stock levels, the Hub forecasts its requirements for 2 months ahead. The factory then produces this in the current month so that it can be shipped to the Hub next month; in time to meet the expected demand.

The relationships that exist between the Central Hub and the Secondary Hubs are similar to those that exist between the Factory and the Central Hub. The research was conducted at the Draeger factory in Blyth. Thus, to better understand the operation of the supply chain, a simplified system dynamics model was constructed representing the relationships between the Factory and the Central Hub. The boundaries of the model were chosen based on discussions with Draeger Safety, UK staff. These determined that the model should include the customer, the production plant, the Hub in Germany and the relevant decision making processes. The structure of this portion of the supply chain is illustrated in Figure 2.

THE MODEL

The equations that are used to describe the inventories, backlogs and shipments are discrete (using a 1 month sample interval) and are based loosely on previous analysis of the Beer Game (Sterman 1989; Thomsen et al 1992). These equations are given in Appendix I.

Figure 2. Schematic diagram showing relationships between Factory and Central Hub. The figure represents a 'way it's meant to work' model of the supply chain at Draeger Safety, UK.



The management policies that are used to generate Hub orders and Factory production are based on an anchoring and adjustment heuristic (Sterman 1989). The HUB forecast forms the main driver for the ordering policy. Decision makers operate a form of adaptive forecast, which is formed from incoming orders based on a simple first-order exponential prediction. The mechanism underlying this forecast is characterised by an expression, which takes the form:

$$H_{forcast}(t+2) = (1 - \theta)\, H_{orders}(t) + \theta\, H_{forcast}(t+1) \quad (1)$$

Here, θ represents the rate at which the forecast is adapted. θ = 1, corresponds to a constant forecast, and θ = 0 describes a situation where the immediately previous value of HUB orders is used as an estimate of future demand.

In addition, decision makers were found to adjust orders above or below the expected demand in order to keep their inventory and supply line at the desired level. Thus, the overall ordering policy (HUB request & Factory production) may be characterised by the expressions:

$$H_{req}(t+2) = \max(0, \alpha\, (Q - H_{inv}(t) + H_{blk}(t)) - \alpha\, \beta\, (F_{blk}(t) + F_{ship}(t)) + H_{forecast}(t+2)); \quad (2)$$

$$F_{prod}(t) = \max(0, \alpha\, (Q - F_{inv}(t) + F_{blk}(t)) + H_{req}(t+2)); \quad (3)$$

where, α, (which lies in the range 0-1) defined the fraction of the discrepancy between the desired inventory Q and the effective inventory (Inventory – Backlog), that need to be ordered each month. β (which again lies in the range between 0 – 1) is the fraction of the supply line (requests or production already ordered but not yet received) that is taken into account. If β = 1, decision makers fully recognise shipments already in the pipeline and do not double order. If β = 0, requests (orders) are immediately forgotten and new requests to cover the same lack of inventory are placed in the next month.

Appendix II gives a Simulink block diagram representing the system equations.

MODEL ANALYSIS

An inspection of the model equations (Equations 14 to 19 and Appendix I) indicates that the primary nonlinearities present in the model are of a saturation form. Because of this, initial model analysis is based on a technique commonly used in control theory and employs a locally linear state space representation, in which all backlogs are assumed to be zero. Such an analysis will allow the soundness (or otherwise) of the basic management (feedback) structure to be assessed and will also provide an insight into the various transitions towards instability, without this information being lost in the added complications introduced by nonlinear behaviour.

Thus, if we define the general discrete state space representation as:

$$X(k) = A\,X(k\text{-}1) + B\,U(k) \tag{4}$$

$$Y(k) = C\,X(k)$$

The state vector X(k) as:

$$X(k) = \begin{bmatrix} H_{ship}(t) \\ H_{inv}(t) \\ H_{req}(t+2) \\ H_{forcast}(t+2) \\ F_{ship}(t) \\ F_{inv}(t) \\ F_{prod}(t) \end{bmatrix} \tag{5}$$

And, the input U(k) as:

$$U(k) = \begin{bmatrix} H_{orders}(t) \\ Q(t) \end{bmatrix} \tag{6}$$

Then, it is easily shown that the system matrices can be written as:

$$A = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & -\alpha_H & -\alpha_H\beta_H & , & -\alpha_H & 0 & 0 \\ 0 & 0 & 0 & , & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 1 & 1 \\ 0 & -\alpha_H & \alpha_F - \alpha_H\beta_H & , & -\alpha_H & -\alpha_F & -\alpha_F \end{bmatrix} \tag{7}$$

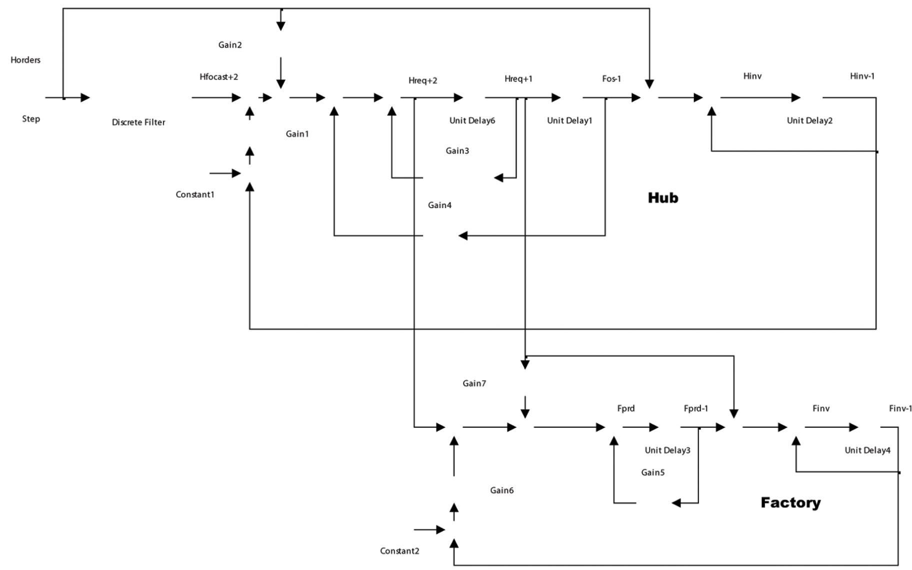
$$B = \begin{bmatrix} 1 & 0 & 0 \\ -1 & 0 & 0 \\ 1 + \alpha_H - , & \alpha_H & 0 \\ 1 - , & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 + \alpha_H - , & \alpha_H & \alpha_F \end{bmatrix};$$

$$C = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \tag{8}$$

and the system block diagram has the form shown in Figure 3.

In linear system analysis the relationship between behavioural modes and the location of the eigenvalues of A is well established. Consequently, it is clear that a plot of the trajectories of the eigenvalues in response to the variation of a specific parameter is a good indication of the influence that the parameter has on system behaviour. Inspection of Equation 7, indicates that the A matrix contains three variable parameters: α, β and θ. In studies of the Beer Game (Thomsen et al, 1992) it is generally accepted that for the majority of managers the value of θ tends to remain constant at 0.75. This is confirmed by finding at Draeger Safety, UK, where conversations with managers suggest that forecast is amended with a smoothing time of approximately 4 months (θ = 0.75). In addition, inspection of the Simulink block diagram (Figure 3 &Appendix II) indicates

Figure 3. Small signal block diagram representation of the unmodified model of the supply chain at Draeger Safety, UK



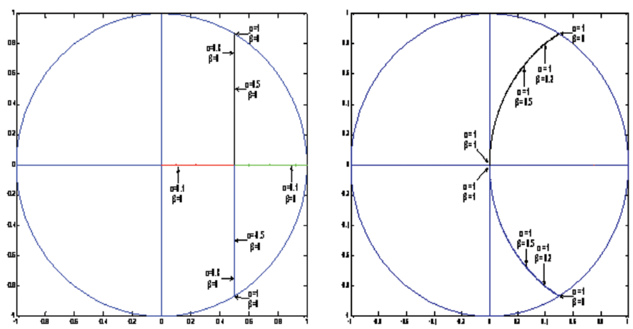
that θ is present only in the disturbance section of the model. Thus, θ only affects the dynamics of the feedforward (or disturbance) signal and can be considered to be outside of the feedback structure. α and β, on the other hand clearly lie inside the feedback loops and consequently will significantly influence the dynamic behaviour generated by the system itself. For these reasons, in the study presented here, θ will remain fixed at 0.75 and the analysis will concentrate only on variations in α and β.

THE INFLUENCE OF α AND β

Figure 4 shows a plot of the eigenvalue locus of the A matrix, calculated as the solution to det(zI - A) = 0 (where I is an identity matrix of dimension A): a) when β = 0 and α is varied from 0 to 1; and: b) when α = 1 and β is varied from 0 to 1. A quick inspection of the figure suggests that there is (at least) one pair of complex eigenvalues and that these intersect with the unit circle at a position 0.5 ± j0.866, for the condition α = 1, β = 0. Clearly, α has a destabilising influence, since the complex eigenvalue pair (Figure 4a) move toward the edge of the unit disc as α increase. β, on the other hand, is clearly stabilising, since the eigenvalues (Figure 4b) move toward the centre of the unit disc as β increases.

As can be seen in Figure 4(a) the condition α = 1, β = 0 generates a pair of complex eigenvalues that lie on the unit circle at a position 0.5 ± j0.866. These are responsible for the 'linear looking' (input dependant amplitude, 6 month period) oscillatory behaviour seen in Figure 5a. This behaviour represents one extreme of the management policy spectrum and is a typical consequence of a regime in which we seek to completely replenish any stock discrepancy at each time step. As α is decreased the oscillations become smaller. For example when α = 0.8, β = 0, the complex eigenvalue pair are located at 0.5 ± j0.745 and the damping ratio is approximately 0.2. The time response for this condition is shown in Figure 5b. As can be seen, the oscillations now decay to zero, but only after a considerable period; about 50 months. There is also a reduction in the maximum

Figure 4. Locus of eigenvalues of A plotted on the z-plane for θ = 0.75. a) β = 0 and α varied from 0 to 1. b) α = 1 and β varied from 0 to 1. Clearly, the complex pair migrates toward the edge of the unit circle as α increase, while they move toward the centre of the unit circle with increasing β.



(a) (b)

amplitude. Clearly (since β = 0), decision making is still based purely on current stock levels, therefore, the improvement in performance must come as a result of the relaxation in the requirement that stock must be maintained at a constant value. When α = 0.5, β = 0, the damping ratio increases to approximately 0.4. The corresponding time response is now relatively fast, with only approximately 25% overshoot and a 15 month settling time, as shown in Figure 5c. Finally, when α = 0.1, β = 0 all of the roots lie only on the real axis. Here the time response is purely exponential (Figure 5d), but once again the settling time has increased to around 50 months.

Figure 4 (b) shows a plot of the eigenvalue locus when α = 1 and β is varied from 0 to 1. Figure 6 shows the corresponding time response at β = 0.2 and 0.5. It is clear from the figures that β is basically stabilising, since the eigenvalues move toward the centre of the unit disc and the oscillations reduce as β is increased. It is clear from Figure 6 that as β increases not only do the oscillations die away more quickly, but also, the steady state level of Hub inventory decreases as a function of both β and the order level. Thus, as β increases, the gap between the desired (Q = 800) and actual Hub inventories increases. For example, in Figure 6b when β = 0.5, the Hub inventory settles at a value of 600 for the initial order level of 400/month, the inventory then reduces to a steady value of 400 when the order level is increased to 800/month. This effect is easily predicted from Equation 2 where the term $\beta x H_{forecast}$ clearly acts as disturbance on the stock correction term $Q - H_{inv}$ (inspection of Equations 2 & 3 shows that this will not be the case for the Factory in which the inventory will settle at Q).

To better understand the observed behaviour, we need to re-examine the structure of the system block diagram (Figure 3). Inspection of the figure reveals that the Factory and the Hub have 'isolated' feedback structures. Therefore, by considering their individual characteristic equations, these can be analysed independently.

Thus, for the condition β = 0 (depicted in Figure 4a), the Factory characteristic equation is:

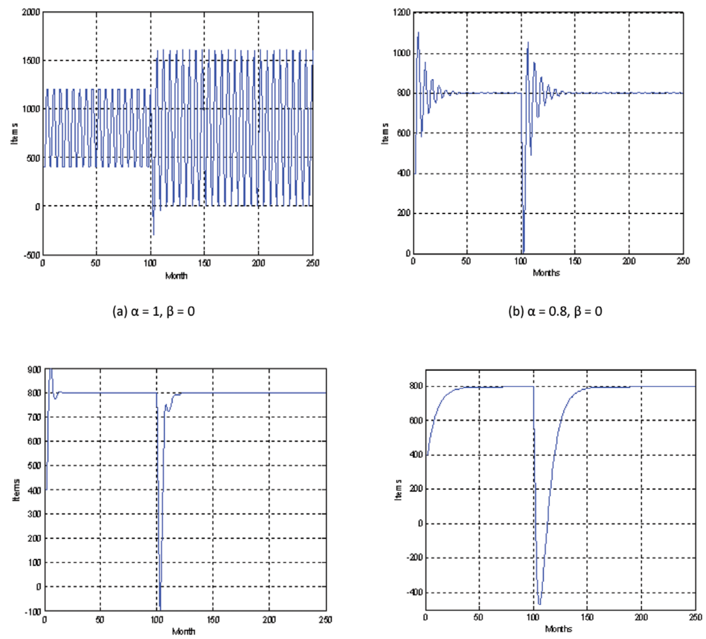
$$(z + \alpha)(z - 1) + \alpha = 0 \qquad (9)$$

This has two eigenvalues, one at z = 0 and a second, which is always real and which lies in the range z = 1 → 0 as α = 0 → 1.

The Hub characteristic equation is:

$$(z^2 + \alpha)(z - 1) + \alpha = 0 \qquad (10)$$

Figure 5. Hub effective inventory for θ = 0.75, α = 1, 0.8, 0.5, 0.1, β = 0 and Q = 800. The figure shows the response of the Hub effective inventory over a 250 month period. The initial Hub inventory is 400 and the Hub orders are held constant at 400/month for the first 100 months these are then increased to 800/month for the remainder of the simulation.



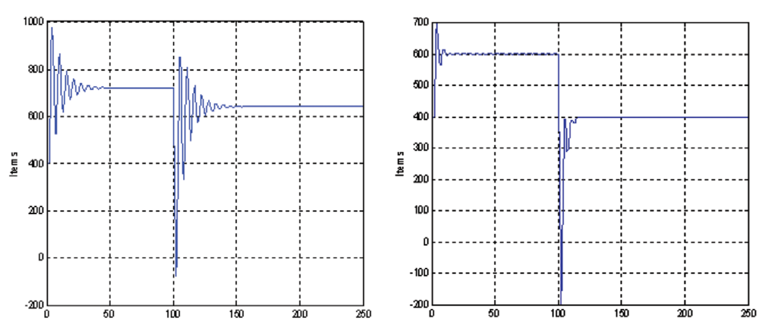
(a) α = 1, β = 0

(b) α = 0.8, β = 0

(c) α = 0.5, β = 0

(d) α = 0.1, β = 0

Figure 6. Hub effective inventory for θ = 0.75, α = 1, β = 0.2, 0.5 and Q = 800. The figure shows the response of the Hub effective inventory over a 250 month period. The initial Hub inventory is 400 and the Hub orders are held constant at400/month for the first 100 months these are then increased to 800/ month for the remainder of the simulation.



(a) α = 1, β = 0.2

(b) α = 1, β = 0.5

This has three eigenvalues. Again one of these is at $z = 0$, the other two form a second order pair that become complex when $\alpha > 0.25$. It is this pair that is clearly identified in Figure 4a. Moreover, it is the Hub's dynamics and not the Factory's that are the potential source of unstable behaviour. The Hub, potentially, becoming unstable for any value of $\alpha > 1$, whilst the Factory would be stable for any value of $\alpha < 2$.

THE EFFECT OF PRODUCTION LEAD-TIME

To better understand Factory/Hub interactions it is intended to investigate the effect of adding an additional two months lead-time into the factory manufacturing process; Figure 7. This additional delay brings the model into line with the classical Beer Game representation. However, unlike in the Beer Game, where the delay occurs naturally due to the nature of the brewing process, here, such an additional delay would tend to be the result of some unforeseen external influence: Perhaps a lack of material supply (due to industrial action by a supplier) or a prolonged upturn in business that outstrips the ability to produce. This form of analysis will allow the resilience of the management structure to be assessed and should provide some insight into the system's ability to recover from unexpected events, since in effect we are forcing the supply chain to operate in a regime where orders arrive 2 months behind expected need.

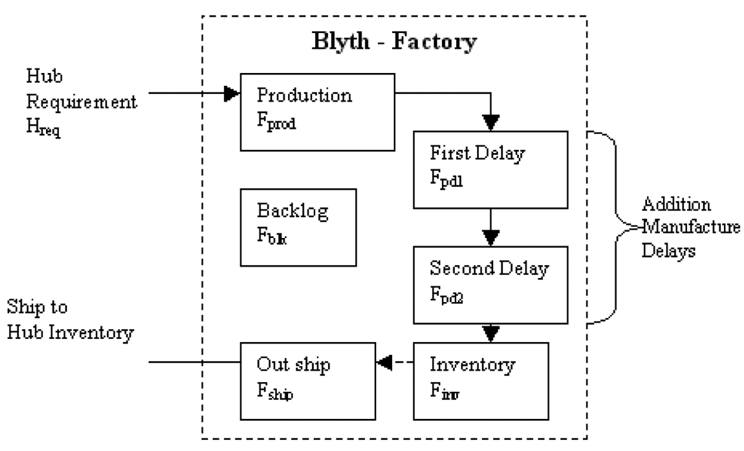
Since the model operates on a one month sample time, 2 additional factory states, F_{pd1} and F_{pd2}, are included to represent the additional manufacturing lead-time. The modified factory equations are given in Appendix III, and again it is relatively easy to show that the A matrix for this modified Factory/Hub arrangement is given by Equation 11.

The system block diagram has the form:

Figures 9 show eigenvalue plots for the modified A matrix for a similar range of values of α and β to those used to generate Figures 4.

The most obvious difference between Figures 9 and Figure 4 is the appearance of a second pair of potentially unstable, complex eigenvalues. On closer inspection, we can deduce that the original set of complex eigenvalues (seen in Figure 4 as the always stable complex pair) must be attributable only to the Hub, since their behaviour and locations are totally unaffected by the introduction of the two additional Factory states. Moreover, it must be the Factory, with its two additional delays, that is the source of the potentially unstable be-

Figure 7. Schematic diagram showing relationships between Factory and Central Hub. The figure represents a 'Production delay' model of the supply chain at Draeger Safety, UK.



Equation 11.

$$A = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & -\alpha_H & -\alpha_H\beta_H & \theta & -\alpha_H & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \theta & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & -\alpha_H & \alpha_F - \alpha_H\beta_H & \theta & -\alpha_H & -\alpha_F & -\alpha_F\beta_F & -\alpha_F\beta_F & -\alpha_F \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}$$

haviour. Figure 10 shows the time response of the modified model when θ = 0.75, α = 0.8, β = 0.1 and Q = 800. An inspection of Figure 9 shows that for these values there are a pair of complex eigenvalues (those attributable to the Factory) that lie outside the unit circle (the Hub complex eigenvalues of course still lying inside the unit circle); and it is these that are responsible for the observed oscillatory response.

Once again, to understand the source of this observed behaviour we need to re-examine the structure of the system block diagram; in this case, Figure 8. From the figure, it is clear that the Factory and the Hub still retain their 'isolated' feedback structures. Moreover, closer inspection reveals that the additional production delays only have an effect on the Factory 'loop'. Consequently, the Hub characteristic equation (Equation

Figure 8. Small signal block diagram representation of the model of the supply chain at Draeger Safety UK, including additional production delays

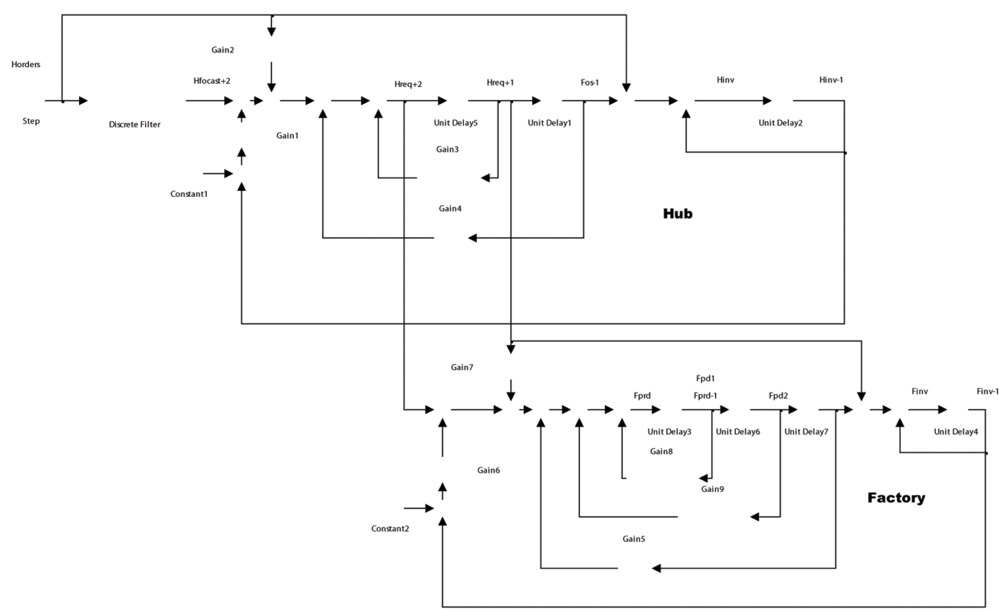


Figure 9. Locus of eigenvalues of A plotted on the z-plane for θ = 0.75. a) β = 0 and α varied from 0 to 1. b) α = 1 and β varied from 0 to 1

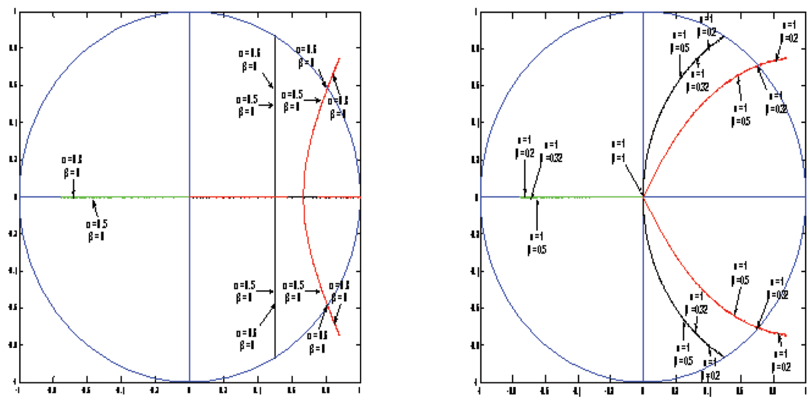


(a) (b)

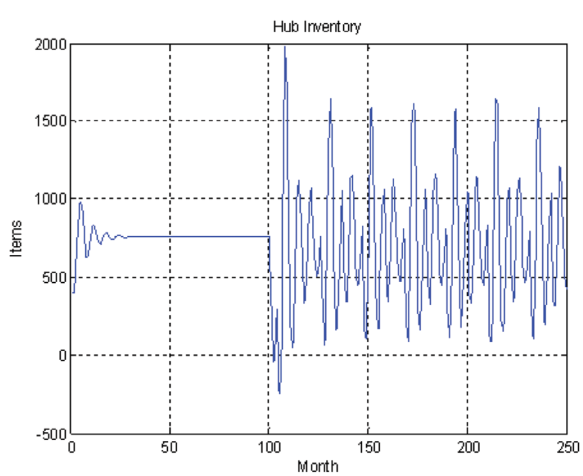
10) is unaffected by the additional production delays. Thus, the complex pair of eigenvalues previously identified as been associated with the Hub remains unaffected and are still clearly visible in Figure 9.

Turning our attention to the factory, the characteristic equation for the system with additional production delays, for the condition $\beta = 0$, is:

$$(z^3 + \alpha)(z - 1) + \alpha = 0 \qquad (12)$$

Clearly, Equation 12 has four eigenvalues. One of these is at $z = 0$, one exists on the negative real axis and lies in the range $z = 1 \rightarrow -0.755$ as $\alpha = 0 \rightarrow 1$ and the other two form the second complex pair seen in Figure 9. These become complex when $\alpha > 0.148$ and intersect with the unit circle

Figure 10. Hub effective inventory for θ = 0.75, α = 0.8, β = 0.1 and Q = 800. The figure shows the response of the Hub effective inventory over a 250 month period. The initial Hub inventory is 400 and the Hub orders are held constant at400/month for the first 100 months these are then increased to 800/ month for the remainder of the simulation.



at a position 0.809 ± j0.5878, for the condition α = 0.618. It is obvious, therefore, that it is now the Factory that has become the primary route to instability.

INFLUENCES OF 'SATURATION' EFFECTS

Since Figure 9 predicts an unstable eigenvalue for the condition, θ = 0.75, α = 0.8, β = 0.1 & Q = 800, the 'stable' initial transient seen for the first 100 months of the response in Figure 10 is somewhat puzzling. However, since we have suggested that the unstable eigenvalue pair can be related to the Factory section of the model (and not the Hub whose response is seen in Figure 10), then it is in the Factory's responses that we need to look for an answer.

Figure 11 shows the Factory effective inventory that corresponds to the Hub response shown in Figure 10. As can be seen the response is oscillatory over the whole timeframe. This form of response is of course the result of the large signal (saturation type) nonlinearities defined in Equations 17 to 20 limiting the growth of the small signal instability defined by the eigenvalues. What is interesting, however, is that prior to the increase in customer orders (from 400 to 800 at month 100) the Factory effective inventory is always positive and, therefore, the Hub demand can be met. After the increase in Hub orders the factory is no longer able to meet the required demand when the desired saftey stock (Q) is 800. Hence, the oscillations seen in the factory response, cascade down to the Hub. Figures 12 and 13, show the equivalent responses when Q is doubled to 1600.

As can be seen with Q = 1600 the Factory effective inventory remains positive over the whole response. Hence, when viewed from the 'isolation' of the Hub, the system appears perfectly stable and the Hub stock is able to settle to a steady value.

Figure 11. The Factory effective inventory response that corresponds to the Hub response seen in Figure 10. That is for θ = 0.75, α = 0.8, β = 0.1 & Q = 800. All initial values are set to 400 and customer orders are increased to 800 after 100 months.

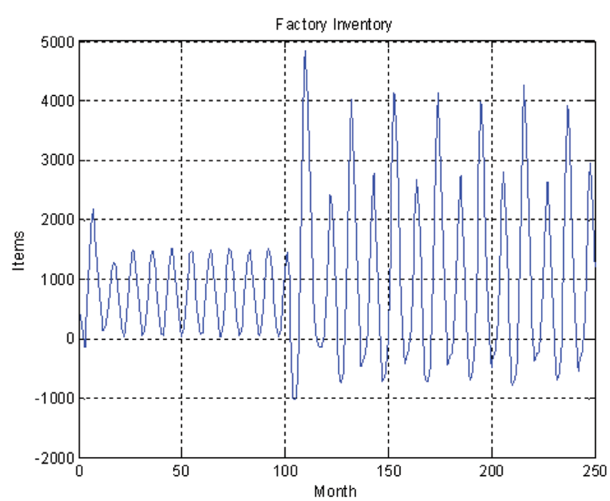


Figure 12. Factory effective inventory for θ = 0.75, α = 0.8, β = 0.1 & Q = 1600

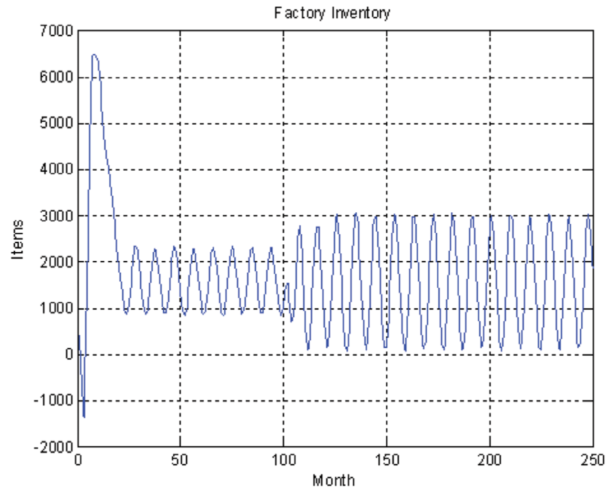
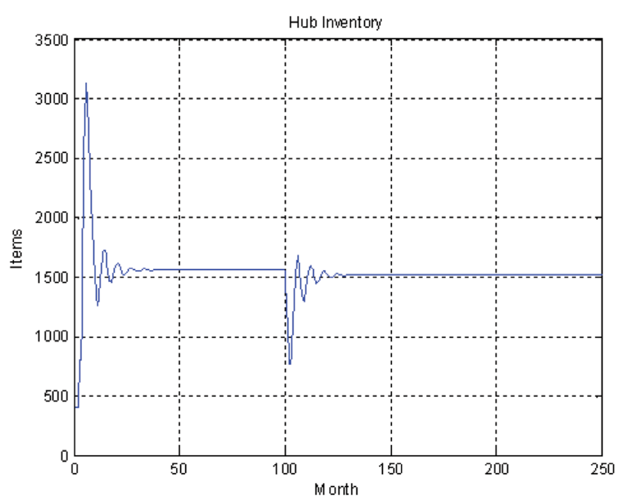


DISCUSSION

In the model, management decisions are represented by the 3 corrective (negative) feedback loops. An initial estimate of Factory production is made based on the forecast for Hub sales in 2 months time. This estimate is then corrected (feedback 1) based on the discrepancy between the current Hub inventory and its desired level multiplied by a 'correction factor', α. This modified estimate is then re-corrected (feedback 2) to take into account any previously placed Hub orders (based on previous attempts to correct the Hub inventory discrepancy) that have not yet arrived and are thus 'still in the pipeline; in this case the multiplying factor is β. The final correction to Factory production (feedback 3), is made based on the discrepancy between current Factory inventory and its desired level, once again this is multiplied by α. In this form, the 'management

Figure 13. Hub effective inventory for θ = 0.75, α = 0.8, β = 0.1 & Q = 1600



policy' appears to be, primarily; one of stock control in the presence of external disturbances (actual product sales). Moreover, when operating close to their desired stock levels (and therefore without backlog) the feedback structures of Factory and Hub can be considered to be 'isolated' from one another. The feedback structure that is in place bares a strong similarity to the classical 'cascade control' structure, familiar to many engineers.

Within the context of this specified 'management policy' the two correction factors α and β, can be thought of as representing the psyche of the decision maker: $\alpha = 1$ and $\beta = 0$, represents one extreme; an aggressive manager thinking only within the confines of his area of control and not recognising the impact of previous decisions (no account of history). In the simulations this resulted in persistent oscillations (Figure 5a), generated purely by the decision making strategy and not as the result of structure of the supply-chain or some external influence (as is often claimed by managers with such tendencies). Such oscillations, while not impacting on customers (as inventories are in general maintained at positive levels) would require larger than necessary warehouse space. Decreasing α, and thus being less rigorous in terms of stock maintenance produces a stabilising effect; Figures 5b & 5c. If, however, α is too small (representing a very cautious manager) the response becomes very slow. This can lead to significant backlogs and the potential for customer dissatisfaction; Figure 5d. Clearly, there will be an optimum choice for α so that the response settles fairly quickly and remains backlog free.

$\beta > 0$, represents a manager that thinks outside of immediate area of control and takes some or full account of history. Taking into account the impact of previous decisions, has a stabilising effect; Figures 6a & 6b. As β increases the response becomes less oscillatory and tends to settle more quickly. $\alpha = 1$, $\beta = 1$ would seem to represent the ideal case (just in time, or deadbeat, management – with the eigenvalues lying at the origin of the z-plane). It is well known, however, that such control policies often prove unreliable, as they tend to be intolerant of unexpected events (such as unforeseen production hold-ups). Moreover, for the conditions simulated backlogs are significant and safety stock must be increased if customer satisfaction is to remain unaffected.

What is more interesting, however, in terms of the analysis presented in this paper is that it is possible to establish a relationship between the two major feedback loops (the Factory loop representing Factory management policies and the Hub loop representing Hub management policies) and potential system behaviours. For example, in the 'as is' arrangement (represented by Equations 9 & 10) the route toward instability is via the complex eigenvalue pair which are generated via the Hub management policy. More importantly, however, because the systems are 'isolated' poor management decisions in the Hub cannot be corrected by good decisions in the Factory. On the other hand, a good manager in the Hub may be able to mitigate poor management decisions in the Factory.

Figures 9 illustrate the influence of α and β, after the introduction of an additional 2 month manufacturing lead-time to simulate the effect of possible production hold-ups. Clearly, by comparing Figures 9 with Figures 4, we can see that α and β have much the same overall effect in this modified system. However, with the introduction of the extra states (additional lead-time), it is the Factory which now provides the primary route toward instability (via the second complex eigenvalue pair; Equation 12). In this situation the previous roles are now reversed and it is the Hub that can do little about poor management decisions in the Factory. Thus, good management and management policies are critical if significant problems are to be avoided (whereas in the case without the additional lead-time, not even the worst manager, if operating a consistent policy, could induce unstable behaviour). For example, Figures 11 and 12 show swings in factory inventory that are more that ten times greater that the disturbance that created them. These, if uncheck, would lead to a breakdown in customer confidence and the factory warehouse facilities grinding to a halt.

MANAGEMENT MICROWORLD

It is clear that the dynamics of the supply chain are intimately dependent on the decision making strategies of the managers. Faced with the prospect of a potentially unstable supply chain, Dreager commissioned the development of a virtual microworld (Senge, 1996) to allow managers to conduct what-if scenarios and to improve their understanding of how different decision strategies influence the performance of the supply chain. The first version of this Microworld was developed in Visual Basic and its interface is shown in Appendix IV. Managers are able to amend decision strategies by adjusting four decision parameters related to inventory, supply line, forecasting and level of desired stock. A graphical representation of the inventory and backlog oscillations allows a quick grasp of the link between decision strategy and the system's behaviour to be established. In addition, the relative cost of operating the supply chain is calculated as a sum of the factory and hub inventories over time and twice the hub's backlog:

$$\text{Costs} = F_{inv}(t) + H_{inv}(t) + 2\times H_{blk}(t) \qquad (13)$$

This is to take into account that backlogs are more expensive as they may lead to customers turning to other suppliers. A prototype of the Microworld is currently being used by the planning department. The planning team had already been involved in validating the model of the supply chain, and thus, had developed an understanding of how behaviour is linked with different decision strategies. Their feedback is valuable in further amending the interface to make it more user-friendly. The Microworld is to be used as a discussion tool for managers in the planning department and across departments to experiment and develop understanding what decision issues are important and what strategies work best.

CONCLUSION

The analysis presented here represents only the initial stages of an investigation into Draeger's supply chain. Moreover, in the results presented decision policies have been applied and maintained over an extended (and in real world term unrealistic) period of time. Never-the-less this analysis has found favour within Dreager Safety, UK and has proven itself to be a powerful decision support tool. It has become obvious that in our investigations so far we have only just scratched the surface of the rich variety of possible behaviours that can emerge. It is the intention, therefore, to continue this research and to further investigate:

- The influence of errors in the forecast.
- The effect of using independent decision strategies (having different values of α and β at the Factory and the Hub) at different levels in the supply chain.
- The impact of the secondary Hubs.
- Modifying the decision strategies (perhaps to a full state variable feedback form or production control in response to forecast) to take into account better information.

ACKNOWLEDGMENT

We would like to thank Mel Hedley, Head of Planning Department and Vince Smith, Operations Director, Draeger Safety, UK for their cooperation, good will and valuable contribution.

APPENDIX A

Inventories in both the Hub and the Factory are updated by adding incoming shipments and subtracting outgoing shipments.

$$H_{inv}(t) = \max(0, H_{inv}(t-1) + F_{ship}(t-1) - H_{ship}(t)) \quad (14)$$

$$F_{inv}(t) = \max(0, F_{inv}(t-1) + F_{prod}(t-1) - F_{ship}(t)) \quad (15)$$

To the extent that inventory plus incoming shipments are sufficient, outgoing shipments are existing backlog plus incoming orders. Otherwise, outgoing shipments are incoming shipments plus inventory, and the new inventory is empty.

$$H_{ship}(t) = \min(H_{orders}(t) + H_{blk}(t-1), H_{inv}(t-1) + F_{ship}(t-1)); \quad (16)$$

$$F_{ship}(t) = \min(H_{req}(t+1) + F_{blk}(t-1), F_{inv}(t-1) + F_{prod}(t-1)); \quad (17)$$

In a similar way, backlogs are updated by adding incoming orders and subtracting outgoing shipments. If incoming orders plus backlogs are completely covered by incoming shipments plus existing inventory the new backlog is empty.

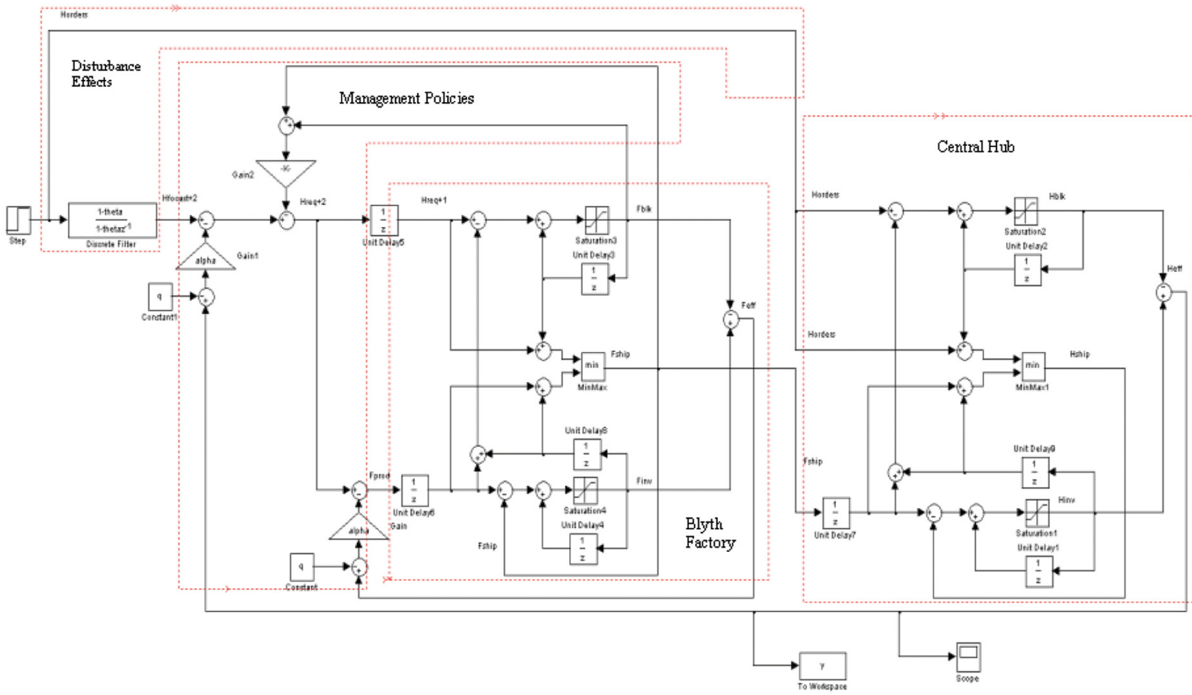
$$H_{blk}(t) = \max(0, H_{blk}(t-1) + H_{orders}(t) - (H_{inv}(t-1) + F_{ship}(t-1)); \quad (18)$$

$$F_{blk}(t) = \max(0, F_{blk}(t-1) + H_{req}(t+1) - (F_{inv}(t-1) + F_{prod}(t-1)); \quad (19)$$

APPENDIX B

Simulink diagram of the Factory - Hub model based on equations. Figure 14 shows a Simulink representation of the model. Inspection of the figure shows the series nature of the Factory-Hub arrangement and the similarity of the modelling relationships used to represent both the Factory and the Hub. It is also easy to identify the classic ‘cascaded control’ feedback structure, which represents the decision making process governing Factory production.

Figure 14.



APPENDIX C

Factory equations including the additional lead-time states:

$$F_{inv}(t) = \max(0, F_{inv}(t\text{-}1) + F_{pd2}(t\text{-}1) - F_{ship}(t)) \tag{20}$$

$$F_{ship}(t) = \min(H_{req}(t{+}1) + F_{blk}(t\text{-}1), F_{inv}(t\text{-}1) + F_{pd2}(t\text{-}1)) \tag{21}$$

$$F_{blk}(t) = \max(0, F_{blk}(t\text{-}1) + H_{req}(t{+}1) - (F_{inv}(t\text{-}1) + F_{pd2}(t\text{-}1)) \tag{22}$$

$$F_{prod}(t) = \max(0, \alpha\ (Q - F_{inv}(t) + F_{blk}(t))$$

$$+ H_{req}(t{+}2) - \alpha\ \beta\ (F_{pd1}(t) + F_{pd2}(t))) \tag{23}$$

$$F_{pd1}(t) = F_{prod}(t\text{-}1) \tag{24}$$

$$F_{pd2}(t) = F_{pd1}(t\text{-}1) \tag{25}$$

Chapter 88
The Drivers for a Sustainable Chemical Manufacturing Industry

George M. Hall
University of Central Lancashire, UK

Joe Howe
University of Central Lancashire, UK

ABSTRACT

This chapter describes the current situation of the chemical manufacturing industry and looks to the future demands on the sector such as: for sustainability, the advent of new bio-based feedstocks for improved energy management and the implications of these demands on the sector. These implications include definitions of sustainability criteria for the chemical manufacturing industry and the need for transparent reporting following the Triple Bottom Line approach. The important role of chemical (or more generally, process) engineers in delivering bio-based sustainable solutions is emphasised, but this also suggests that a new way of thinking about the discipline is required. Indeed, there are arguments that the demand for a sustainable chemical manufacturing sector could bring about the next paradigm shift in the discipline with concomitant education implications.

INTRODUCTION

The Chemical Manufacturing Industry (CMI) can be multinational in operation and varied in scale whilst producing the products which underpin other sectors such as: health provision; clothing; housing and shelter; food and nutrition; entertainment and leisure; transport and tourism—the very fabric of human life. The variety of activity in the sector can be said to demand that, "Process Engineering," is a more correct term to encompass industries as widely different as food processing, minerals processing, pharmaceutical manufacture and petroleum refining. However, there is commonality in their activity where heat and mass transfer, transport phenomena, reaction kinetics, modelling and fluid mechanics are all applied in unit operations albeit to widely varying materials

DOI: 10.4018/978-1-4666-1945-6.ch088

and situations. For this reason in this chapter we have used the term CMI to cover this spectrum of activity and the general approaches which we describe can be applied equally well to all in our opinion.

The products of the chemical industry are derived from inorganic, synthetic organic and biological sources which have been manipulated by a range of process operations which include classical physico-chemical processes such as synthesis, distillation, precipitation, filtration, solvent extraction and crystallisation techniques which have been supplemented by fermentation processes, the application of industrial enzymes and the genetic manipulation of microorganisms in modern biotechnology. These technologies have made a vast number of products available to promote social development and economic growth and prosperity. At the same time the chemical industry has been accused of overexploitation of natural resources, air, water and land pollution (such as by oil production in the Niger River delta, opencast mining on fragile Pacific islands and the catastrophic Deepwater Horizon oil spill in the Gulf of Mexico) and creating social problems associated with rapid industrialisation and the invasion of vulnerable societies and environments for commercial gain (witness the toxic release from the Union Carbide plant in Bhopal, India, in 1984). When Industrial Revolutions have taken place starting from Europe, North America and then into Latin America, Asia and Africa the ills of industrialisation were ignored initially, as the price to pay for progress although eventually the development of organised labour and government structures have improved the situation in many cases. Whilst accepting this historical context (Coley & Wilmot, 2000) the future development of the CMI must nowadays be viewed in the light of the concept of sustainability (Garcia-Serna, Perez-Barrigon, & Cocero, 2007) which means tackling the issues of the change from fossil fuel to bio-based raw materials and energy conservation and management (Hall & Howe, 2010).

This chapter will describe the criteria by which the CMI is judged and how sustainability is reported by the industry. It will then describe the new technologies impacting on process engineers in a sustainable CMI and finally go on to discuss whether the sustainable approach will demand a new type of process engineer and the educational implications of this demand.

BACKGROUND

Defining Sustainability

Sustainability, or Sustainable Development (SD), is a discipline that has long been of interest to scientists, technologists, politicians, and business alike. Thomas Malthus in his, *Essay on the Principle of Population*, of 1798, proposed that the power of population increasing in a geometric ratio would outstrip the power of the earth to sustain mankind increasing in an arithmetic ratio and thus a link was made between population and sustainability. However, the advent of the concept of sustainability can be traced back in modern times to the 1970's but the UN Commission on Environment and Development (the so-called Brundtland Report) in the 1980's was a major point in defining the topic (World Commission on Environment and Development, 1987). The Commission was originally instructed to investigate the issues of global inequality, resource distribution and global population impacts and recommend solutions to these issues. Their oft-quoted report definition of sustainable development is, "Development which meets the needs of the present without compromising the ability of future generations to meet their needs."

The report linked economic development with social and environmental concerns for the first time and a balance of economics, social justice and environmental protection was proposed if sustainable development was to happen - this became known as the Triple Bottom Line. The

Brundtland Commission was the starting point for the many UN-sponsored events and initiatives such as the Rio Summit in 1992 on environment and development and the Kyoto Protocol (1997) on greenhouse gas emissions and onwards through a series of negotiations leading up to the inconclusive COP 15 meeting in Copenhagen in 2009 which is still being debated today.

Early implementation of these ideas in industry linked long-term sustainability with competitiveness where obvious links existed between, say, energy efficiency and savings which would benefit the traditional (financial) bottom line and the TBL (Florida, 1996; Judge & Douglas, 1998). Other studies have linked sustainability with organisational capability leading to increased competitiveness (Aragon-Correa & Sharma, 2003) and the promotion of sustainability into corporate strategy (McGee, 1998). More recently there has been the introduction of sustainability considerations at the operational level which would assess the viability of new projects, the introduction of new technology and even overall company structure against the background of sustainability (Labuschagne, Brent, & Van Ercka, 2005).

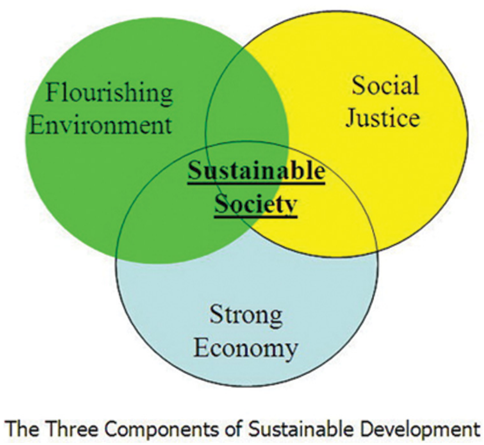
However, as mentioned above, the CMI is a very varied sector covering a range of raw materials and processing operations; different scales and global impact of operation and differing environmental impacts as a consequence of its activities. As a result we should ask ourselves: is there a coherent approach to sustainability in the sector and are the current chemical engineers being educated in sustainability appropriate to the needs of a sustainable industry? Batterham (2006) argued that process engineers would play a significant role in achieving sustainability goals through their understanding of the molecular and micro levels and their integration into macro systems together with their abilities in systems analysis, modelling and process balances. Furthermore, addressing these different levels would also make process engineering practice assess the sustainability agenda as a whole - chemical engineers must change the way they practice and embrace sustainability concepts and implement them.

The Triple Bottom Line and Corporate Social Responsibility

The Triple Bottom Line (TBL) (Figure 1) has emerged as a popular conceptualization and reporting vehicle for articulating corporate social, environmental, and economic performance and is arguably the most accepted impact review model within 'green' or 'socially responsible' businesses since the 1990s (Brown, Dillard, & Scott Marshall, 2006). It has been embraced by business and commerce to legitimise their activities in the eyes of the general public, government and environmental watchdogs. The concept of Corporate Social Responsibility (CSR) has been developed to allow businesses to measure and promote their impact on the three pillars of the TBL and several definitions of CSR exist (Carroll, 1999) often reflecting the viewpoint of the definers. However, they usually contain concepts of the integration of social and environmental concerns alongside economics and the interaction of the business with its employees, the local community and society at large. The term CSR is often associated with activities of conventional business rather than those social enterprises or non-profit-making enterprises where social and environmental concerns are paramount in their philosophy. There is of course some scepticism over the sincerity, practicality and even the legitimacy of this approach given the wide spectrum of business scale, operating styles, cultural attitudes and the strength of national governments to monitor and enforce a TBL model. Some examples of CSR activity include:

- corporate philanthropy and sponsorship although this can be seen as pure public relations
- local community investment and support for worthy causes although again there are

Figure 1. The triple bottom line



concerns over the influence of business in the public arena and which worthy causes are chosen

- stakeholder engagement brings dialogue between the business and all those affected by its activities as long as the definition of a stakeholder is sufficiently wide
- social and environmental reporting being given equal weight to financial reporting. Such reporting can be used to hold a business to account especially if done in conjunction with corporate codes of conduct which lay out the company, "values," and standards of behaviour. This aspect of CSR will be discussed later as it is seen as an essential tool to judge progress towards sustainable business operation.

SUSTAINABILITY ASSESSMENT

The sustainability of any enterprise or activity can be described by two Carbon-management concepts, Carbon Footprinting and Carbon Labelling, which are popular indicators to the general public that their purchasing is ethical while a third concept, Life Cycle Assessment (LCA) also can be used to investigate the sustainability impact of the CMI. Increasingly, these concepts are being applied across the, "Supply Chain," which brings into focus the activities of the companies which supply the central operation under assessment (the CMI here) and also those companies they sell to or who distribute and dispose of their products. The development of these tools to describe the impact of industry activity on the environment is essential if the issues involved are to be argued in reasoned rather than emotive terms. They also give credence to claims by governments, industry and interest groups which can be trusted by the general public.

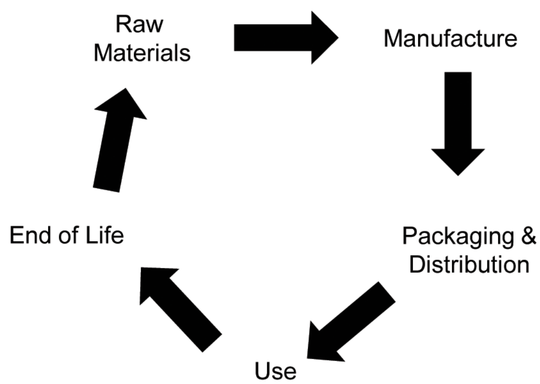
Life Cycle Assessment

Life Cycle Assessment is the investigation and evaluation of all the environmental impacts of a given product, process or service. Concepts such as Carbon Footprinting and Ecolabelling (see below) rely on LCA as it provides a methodology which has some international standing and uniformity. An early definition of LCA was, "the process of evaluating the effects that a product has on the environment over the entire period of its life cycle…extraction and processing; manufacture; transport and distribution; use, reuse, and maintenance; recycling and final disposal" (United Nations Environment Programme, 1996).

There are variants on the basic LCA definition, a full LCA is sometimes called, "cradle-to-grave," including all activity from raw material sourcing to disposal of all components after use (Figure 2).

Where a product generates no waste because all materials are recycled or converted to biologically-safe materials the term, "cradle-to-cradle," is used. The LCA can be used for specific elements of a product stream such as energy, water, packaging and raw materials. The core elements of LCA are available in several software packages which lead the user through the phases, provide generic categories and conversion factors and impact assessment models. Variants for specific applications and sectors abound and international cooperation

Figure 2. Life cycle assessment: cradle-to-grave



has lead to greater uniformity and consolidation of methodologies. Case studies for a range of manufacturing processes and products are given in Table 1 which also indicates the issues which were raised by each case study.

The LCA is a powerful tool in the analysis of commercial activity, including the CMI, so will be described in some detail here in order that interested parties can see the relevance to their own situation. The description of an LCA process here is based on that of the International Standards Organisation 14040 Series which is a generally recognised (International Standards Organisation, 2006).

As shown in Figure 3 an LCA will normally be divided into four activities:

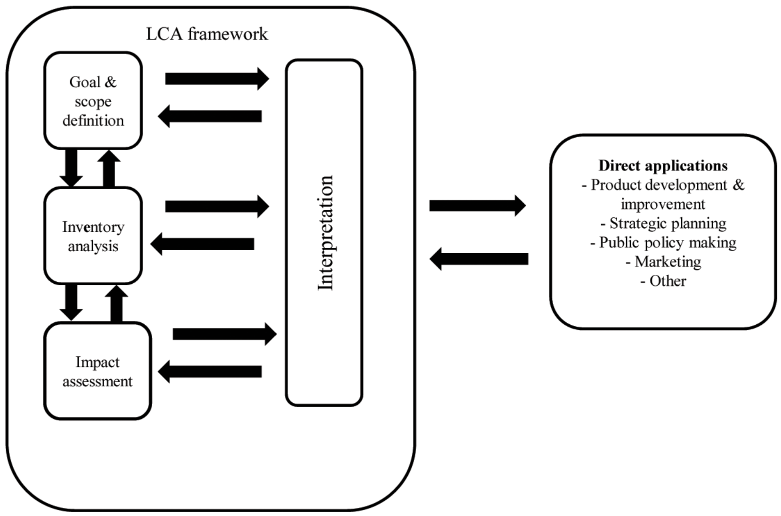
***Phase 1: Goal and Scope*:** the goal decides whether all or specific aspects (e.g. energy) of the operation are included. The system boundaries are set by the scope definition and can be divided into four areas: (1) pre-manufacture, (2) manufacture, (3) packaging and distribution, and (4) use and end of life. Consideration of all areas would be, "cradle-to-grave," as mentioned above, but can be more limited such as, "cradle-to-factory gate," which would only include the first two areas. This phase also decides the purpose of the LCA and for whom it is being done as this will affect the data collected and its conversion to meaningful units. If a processing plant produces more than one product (co-products) then there must be an allocation of impact between them. The simplest approach, system allocation, is made on the basis of the mass or the economic value of the product but does discern differences in process operations which lead to the co-products – not all process operations have equal impact. An alternative approach (preferred by the ISO 14040 series) is system expansion (Weidema, 2003).

***Phase 2: Inventory analysis*:** is a data collection phase and includes all inputs (e.g. energy and raw material), outputs (products) and emissions (to air, water, soil, and solids) or those selected

Table 1. Life cycle assessment case studies in the manufacturing industries

Products/Process	Scope	Issues	Reference
Cocoa	Cradle-to-grave	Missing/unreliable data	Ntiamoah and Afrane (2008)
Tomato ketchup	Cradle-to-grave	Capital equipment inputs Wholesale & retail stages omitted	Andersson, Ohlsson and Olsson (1998)
Paper pulp	Cradle-to-factory gate	Enzymatic processing to reduce environmental impacts	Skals, Krabek, Nielsen & Wenzel (2008)
Wood-based products	Cradle-to-grave	Waste recycling or energy by combustion	Jungmeier, Werner, Jarnehammar, Hohenthal and Richter (2002)
Personal computer	Cradle-to-grave (cradle?)	Recycling rates Energy consumption in use	Choi, Shin, Lee & Hur (2006)
Fine chemicals (pharmaceuticals)	Cradle-to-factory gate	Environmental impact and molecule complexity Energy consumption	Wernet, Conradt, Isenring, Jimenez-Gonzalez & Hungerbuhler (2010)

Figure 3. Stages in an LCA



for inclusion. Accurate, relevant information is essential and must be available or derived from secondary data such as utility bills for water, gas and electricity. This activity is the most time consuming and challenging if a company has not attempted any such exercise before. A production system can be broken down into unit processes, batch or annual production, whichever best defines the system in meaningful numbers, called the functional unit.

***Phase 3: Life Cycle Impact Analysis*:** in this activity the inventory analysis information is processed and first of all assigned to an environmental impact category with appropriate units which may conform to systems such as ISO 14000 Series or be process-specific. Six common environmental impact categories are:

- ***global warming*** where the main contributor is combustion of fossil fuels expressed as carbon dioxide equivalents
- ***acidification*** which affects waters, forests and caused mainly by combustion for electricity, heating and transport and expressed as sulphur dioxide equivalents
- e***utrophication*** which leads to algal blooms, oxygen depletion and fish deaths is caused mainly by fertiliser nitrogen run off expressed as nitrate equivalents
- ***ozone depletion*** caused by man-made halocarbons
- ***land use*** in the production of products and expressed as by unit area per year
- ***photochemical*** smog from volatile organic compounds produced from unburnt petrol and diesel and organic solvents causes respiratory problems and reduces agriculture yields—expressed as ethane equivalents.

These categories are not exclusive and for certain applications the energy, water and effluent categories can be simplified from those above or made process-specific (Azapagic, Clift, & Predan, 2004). Once categorised any emissions should be converted to the reference units for that category using equivalence factors. A sensitivity check and normalisation process will determine the accuracy and relevance of the data collected. Finally, the inventory data can be weighted in terms of the most important environmental impact. The weighting criteria are, again, areas of debate and can be based on: the judgement of a panel of experts; financial considerations and targets set by the company or government edict.

***Phase 4: Life Cycle Interpretation*:** the results of the impact analysis are compared with the original goal and scope of the project and judged, somewhat subjectively, against them. This analysis need not be left until the end but can take place continuously to ensure that the LCA is really achieving the goals and the scope is correct. This iterative approach to the interpretation of data will allow incremental improvements and/or changes to the goals and scope as necessary. The final interpretations should indicate the completeness of the data, the appropriateness of the analysis and reach conclusions and lead to recommendations for process improvement.

The LCA as described above has been applied successfully to a wide range of activities and processes and so should be applicable to the wide ranging CMI. It has evolved to cover environmental, cost and social aspects and as these different versions all have an importance for the CMI and a brief description of each is appropriate here. The early development of LCA can be traced back to the late 1960s – early 1970s (Boustead, 1996) and was a general environmental impact assessment tool (E-LCA now) which evolved by introducing separate categories to reflect new uses. An understanding these impact factors led to Life Cycle Costing (LCC) to assess the financial, time and resource costs of the above impact factors, calculating, for example, the amount of pollution caused distribution methods.

An E-LCA rarely included elements of human or social assessment directly but they can have some element of human welfare included within them. Azapagic *et al.* (2004) noted that the impacts of persistent chemicals on air, land and water lead to human, animal and eco-system damage. However, including societal elements into LCAs is difficult as they are not necessarily measurable physical attributes and therefore difficult to quantify. So, finally, it should be noted that the concept of the Social Life Cycle Assessment (S-LCA) has been developed recently to complement the traditional E-LCA and in doing so give a fuller assessment of the sustainability of goods and services (Benoit, et al., 2010). Guidelines for the S-LCA of processes and products have been drawn up (Benoit & Mazijn, 2009) putting the process into the context of E-LCA. An important goal for the S-LCA has been proclaimed as the improvement of the social conditions of stakeholders in the process/product covered by the S-LCA (Jorgensen, Finkbeiner, Jorgensen, & Hauschild, 2010). Stakeholders have been defined (Benoit & Mazijn, 2009) as: workers, consumers, the local community and society at large, consumers (all stages) and value chain actors and, within these, there are many subjective impact categories such as child labour, fair salary, equal opportunity, migration, secure living conditions and technology development. Thus S-LCA claims to assess the social and socio-economic impacts of all life cycle stages and is a systematic process using best available science to collect best available data on, and report about, social impacts (positive and negative) in product life cycles from extraction to final disposal (Benoit, et al., 2010). The feasibility of integrating social aspects into LCAs seems challenging but it could prove to be a rewarding exercise. Griesshammer *et al.* (2006) concluded that there are many hurdles to overcome for S-LCA to be comprehensive and needed:

- to improve the data situation (qualitative, semi-quantitative and/or fully quantitative)
- carry out more case studies
- establish an accepted social indicator list (including impact categories)
- a connection with CSR needs to be realised and implemented.

Objective indicators measure impacts (i.e. wages, working hours) whereas subjective indicators focus on the experiences or feelings of the relevant stakeholder (i.e. assessing the wealth of society as a broad notion) (Jorgensen, et al., 2010). It is difficult to assess how the concept will achieve these tasks and truly measure the needs of creatures as complex as humans and their complex social environments. The two most pressing research needs are for case studies and for the development of methodological sheets for inventory analysis. It is obvious that the S-LCA could become a useful tool to promote the activities of the CMI or a stick to beat it. Nevertheless, it will become incumbent on the CMI to get to grips with these new assessments of its activities.

Carbon Footprinting and Labelling

Carbon Footprinting (CF) is a measure of the Greenhouse Gases (GHG) associated with the manufacture of products taking into account: raw material sourcing, processing, packaging and distribution and waste treatment. Emissions are described as, "direct," when associated with the main process or activity and, "indirect," when associated with upstream and downstream activities. The term GHG can be defined as carbon dioxide only, or include other gases, particularly methane (with a GHG effect over 20 times that of carbon dioxide), as carbon dioxide equivalents. In some cases it is difficult to convert an activity or process into GHG units and conversion factors are not uniform. Hence several definitions of CF have been proposed some more rigorous than others, as described by Wiedmann and Minx (2007), who proposed the following definition of the term, "The carbon footprint is a measure of the exclusive total carbon dioxide emissions that is directly and indirectly caused by an activity or is accumulated over the life stages of a product."

As mentioned above, the size of the CF can vary depending on how many core and peripheral activities relating to product are included e.g. the activities of suppliers to the principal manufacturer and even the GHG associated with the consumer travelling to buy the goods. Again, this is a contentious issue as the calculation of the CF is complex and there is ample scope for misleading an uneducated public.

Carbon Labelling (CL) is a system that could enable the consumer to judge the green credentials of a product from the packaging in a similar manner to that for nutritional information for foods. The form of the CL and the method for determining it are again open to interpretation and not as yet subject to international coding or scrutiny although ecolabels are given to products considered to have less environmental impact than their competitors. Such labels take several forms: self-certification by producers, certification by producer trade organisations or by third party (independent) schemes. In all cases the extent of compliance, trade restrictions if products are not certified and the scientific basis for the claims are all contentious issues. The developed economies have driven Ecolabelling as an issue, as one would expect, and companies use it as a marketing tool for their products. One very high profile ecolabelling example is shown in the fish processing industry for canned tuna, although the issues raised have general applicability to the CMI. Thus, Iles (2007) argued that seafood producers are invisible to the consumer who only recognised the well known retailers of their products so consumer pressure on producers was less telling than that of the production chain community (see The Supply Chain below). However, the demand by developed country consumers for ethically sourced fish products has now been extended to include the processing methods used. These should be equally ethical with due respect to the environment and societal impacts employed by the industry. Thrane, Ziegler, and Sonesson (2009) discussed the use of ecolabelling for wild-caught seafood products where LCA studies showed that significant environmental impacts were attributable to post-landing processing and criteria reflecting this should be included in an LCA and energy consumption, materials and waste handling and waste water were highlighted. Although specifically describing a sector of the food processing industry these comments (on producer invisibility and on ethical processing) apply widely in the

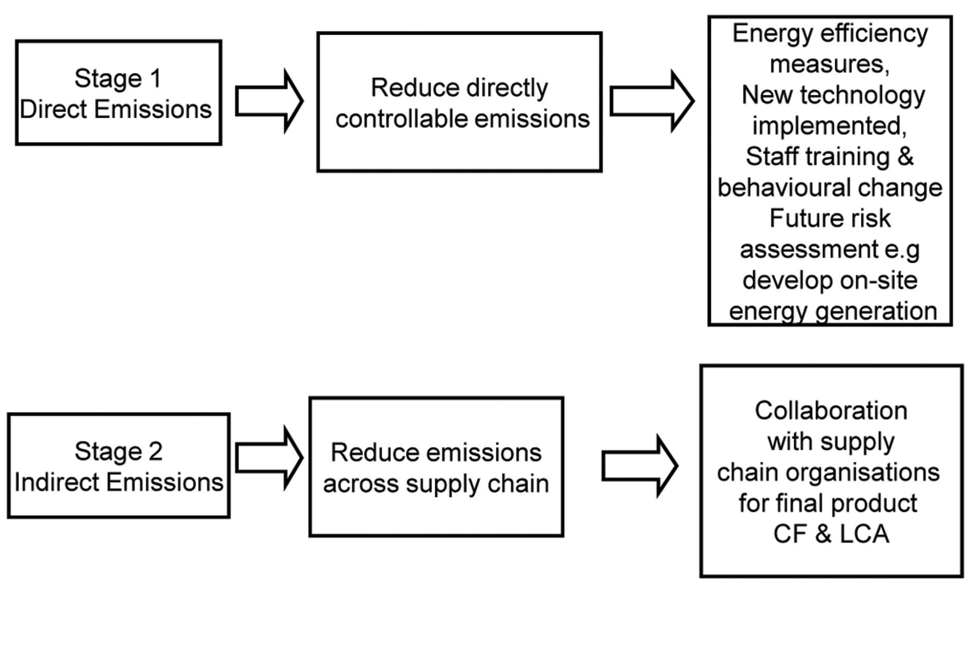
CMI and it would be to the sector's benefit to be less invisible and to promote its ethical processing credentials.

Supply Chain Contribution

Large companies with many business interactions have used interventions in the supply chain to streamline operations and gain commercial benefits through: increased efficiency and productivity; product development and reduced waste. A reasonable question to ask is, can the same approach reduce GHG emissions and promote sustainability? The answer is undoubtedly, "Yes," but when GHG emissions, an LCA or a CF are taken into account current operations along the supply chain might require change to have a positive environmental impact. Actions to reduce the CF, such as energy use reductions, will also give overt economic benefits (or might not be considered for implementation at all) but can also contribute to good public relations (contributing to CSR and the TBL). The supply chain approach must be applied in an all-embracing manner, rather than each company in the chain (including the central operation) looking only at the contribution of their own activities with a cumulative effect—which would be the traditional way to proceed. Such a co-ordinated approach demands collaboration (and trust) up and down the supply chain, around the central operation, with savings being identified for the product as a whole. The Carbon Trust in the UK is one organisation which has developed supply chain models and supported case studies (Carbon Trust, 2006). Figure 4 illustrates the components of the supply chain carbon savings methodology.

Once again the food industry which processes primary products for the consumer is a good example of the supply chain approach. The emissions associated with supplying food to the plate can be divided into direct emissions from energy consumed in the home (23%), indirect emissions from the supply chain (69%), and travel emissions in getting the food to the home (8%) (Carbon Trust, 2006). Thus, the large supply chain component, if mobilised appropriately, could have a massive sustainability impact and the central

Figure 4. Supply chain carbon reduction methodology (a possible stage 3 carbon offsetting has not been included)



company by influencing its suppliers could have global impact and deliver genuine TBL benefits. Iles (2007) argued that seafood producers could be made more accountable through a production chain view and associated pressures making them more transparent in the process and ways to achieve this, were:

- identify and track companies to remove their invisibility
- develop product chain campaigns so that companies influenced each other
- develop mechanisms to compare companies to improve industry practices
- develop methods to track consumption, production and management changes
- develop interactive consumer tools so that consumers get feedback on their purchasing habits which can also be fed back to the producers.

These considerations can be applied across the CMI with equal force.

Reporting Sustainability Activity and CSR

In order to establish the sustainability of the CMI it is necessary to determine the criteria by which it is judged. These criteria might be the same as for any other sector in most cases but should include those peculiar to the CMI. Furthermore it is necessary to apply methodologies which allow measurement of the industry impacts on the environment and the effectiveness of sustainability policies when applied, such as LCA, CF and Supply Chain analysis. In an E-LCA the conventional Impact Analysis categories described previously: global warming; acidification; eutrophication; ozone depletion, land use, and photochemical smog work very well for the CMI as they reflect the importance of emissions and their impact on the environment. However, we have already indicated the need to extend the range of EIA categories to reflect better the impact of the industry through human and eco-toxicology for example. Other categories could reflect the social impact of the CMI, either, directly on workers in the industry, on the surrounding community and even (inter) nationally – the S-LCA. Such categories might be more difficult to define but will allow the LCA approach to reflect all aspects of the TBL rather than just the environmental. One attempt to achieve such reporting is the Global Reporting Initiative (GRI) which has developed sustainability reporting guidelines to encompass the three areas of the TBL—the current guidelines are the third generation (G3) and still subject to scrutiny and change. Starting from a number of common principles the reporting framework (based on the G3 guidelines) includes specific sector supplements to reflect unique sectoral issues and community impacts. It is also developing supply chain sustainability issues through a Global Action Network (GAN) project (Global Reporting, 2011).

A fundamental question raised earlier is whether there can be a coherent approach to sustainability in the CMI sector and, if not, is this important? The development of a standardised set of sustainability criteria would have benefits such as:

- making realistic comparisons between companies and different sub-sectors
- ensuring robust methodologies of assessment through application in a variety of settings
- making knowledge transfer from industry-to-industry or academia-to-industry easier
- establishing a common language of sustainability to be used in negotiations and enforcement of (inter)nationally agreed treaties and protocols
- giving legitimacy to CSR and make communication with the lay public more transparent

- reducing the cost of producing LCA through economies of scale and standardisation of inputs with IT-based support.

At the same time the different scale of operation and range of processes and products within the CMI sector militates against a rigid approach and some sub-sectors face specific sustainability issues which must be addressed in a unique manner, as mentioned above in relation to the GRI sector supplements. For example, while everyone would agree that all products must comply with health and safety criteria in their use the demands on the pharmaceutical industry are greater than on the consumer goods industry which would be greater than on speciality and base chemicals which are more divorced from the consumer. The industry response to these demands must affect the sustainability of that sub-sector and hence the LCA criteria applied to it should reflect this.

Food Processing is one of the specific sectors covered and the main sector topics for reporting developed in a two year process are:

- Sourcing
- Labour/management relations
- Healthy and affordable food
- Public policy
- Costumer health and safety
- Product and service labelling
- Marketing communications
- Breeding and genetics
- Animal husbandry
- Transportation, handling, and slaughter.

The topics listed above reflect the particularly sensitive business of food production and the consumer's perception of the industry where expectations are becoming more and more stringent – but not exclusively so. Sector supplements exist for the energy utilities and Mining and Metals and other CMI sectors with reports in preparation are: construction, oil and gas, the automotive industry and telecommunications.

Green Engineering

Garcia-Serna *et al.* (2007) give a broad review of the philosophies, disciplines and technologies which have been brought together to apply sustainability to chemical (process) engineering and which have been labelled, "Green Engineering." They also recognised that the education of chemical engineers in green engineering was crucial in making the shift to a sustainable future. If green engineering is to be considered at all levels (molecular, micro- and macro-) it should be included from the early stages of the educational programme. Graedel and Allenby (2009) suggested that green engineering is a move towards a more responsible technology but did not ask how the social and environmental aspects of sustainability can be incorporated into the engineering profession.

The American Chemistry Society (ACS) delivered a public policy statement on sustainability and the, "chemical enterprise," which consists of all the industry, trade associations and educational and professional organisations underpinning the sector suggesting that they had a role to play in sustainable development (American Chemistry Society, 2008). The document identified eight areas of importance for a sustainable chemical enterprise:

- green sustainable chemistry
- LCA
- toxicology
- renewable feedstocks
- renewable fuels
- energy intensification of processing
- separation, sequestration and use of carbon dioxide
- sustainability education.

In addition, the non-technical barriers to a sustainable CMI were recognised (Satterfield, et al., 2009):

- develop working definitions and practical metrics to measure progress towards sustainability
- quantify the true cost of products to promote sustainable options
- promote cross-functional and multi-disciplinary communication
- support continuous improvement through forward thinking, collaborative, goal-orientated, non-technology specific regulations and/or incentives which could be adapted as sustainable technology evolves
- incorporate sustainability principles at all levels of education.

The report then went on to recommend various support tools to achieve these aims. Later work by the Harvard-Yale-ACS-GCI Green chemistry project (Matus, et al., 2007) delved deeply into the challenges facing green chemistry and recognised the following barriers to implementation: economic and financial, regulatory, technical, organisational, cultural and definitions and metrics.

Each of these barriers covered a range of objections; for example, included under the regulatory barrier was the possible cost of recertification of processes by the US FDA (Food and Drug Administration) when changes were made to already accepted processes in the name of sustainability. Under cultural barriers were a lack of awareness in both the chemistry community and the general public and common misconceptions that green chemistry products were more expensive, less effective and not based on rigorous science. Some possible solutions to these barriers were mooted, such as: creating incentives for development/implementation of innovation; facilitating linkages and networks to spread the word on green chemistry; increase research activity in green chemistry and to raise the profile of positive environmental/health impacts rather than taking a defensive approach. Finally, there needed to be a national framework for green chemistry policy which should reach out beyond the USA, particularly to the emerging chemical enterprise in China and India and it falls to the process engineering fraternity to do likewise and deliver a CMI that reflects these changes.

Public Perception and Ethical Considerations

The public perception of the CMI as described in the Introduction to this chapter is usually one of a disaster waiting to happen. Pollution, spillages and explosions when they occur are headline news yet the safe operation of processing plant, governed by strict Health and Safety procedures, goes unmentioned and unappreciated. This might seen to be the accepted view of the news industry, after all, "Man bites dog" will always outweigh, "Dog bites man." As mentioned previously proactive reporting of sustainable achievements and CSR are the way forward for the sector rather than the current invisibility—the public needs to acknowledge the debt it owes to the CMI for making life more than tolerable for many people. While it will always be a difficult sell—few processing plants are easy on the eye, nose or ear—an open, honest approach to immediate neighbours and the wider community is essential. It must also be recognised that the current fossil fuel-based CMI did not spring up fully formed but has evolved over the last 150 years and with each step change in processing plant complexity and process innovation mistakes, sometimes catastrophic, have been made. Modern computer-aided design and modelling have taken some risk out of plant and process development but the keen eye of the experienced process engineer is still needed to spot potential design faults.

The future of the CMI will throw up new challenges of both public perception and ethics when the sector becomes reliant on renewable biomass as a raw material and on synthetic biology as a means of its conversion to useful products. The control of renewable resources may benefit some countries through their ownership of vast biomass reserves (e.g. Brazil) but some smaller countries will find it hard to protect their natural resources (e.g. policing activity at sea even within a 200 mile Exclusive Economic Zone). The prospect of synthetic biologists, "playing God," by creating new life forms and the possible dangers of accidental or criminal release of such life forms is already exercising the minds of legislators and the scientific community alike. Given the past experience of the CMI as a fossil fuel-based enterprise it seems incumbent upon it to tackle the new challenges openly and to equip the process engineer of tomorrow to understand the issues. Some comments on these issues will be made in the sections below on the new technologies for the CMI.

New Technology Affecting the CMI

The development of a sustainable CMI demands the application of new technologies and fortunately process engineering has responded in the past to such demands (Favre, Falk, Roizard, & Schaer, 2008) and it is suggested that they have an ethical and moral duty to do so again to deliver a sustainable society (Byrne & Fitzpatrick, 2009). What are the challenges for a sustainable CMI? Firstly, the need to recognise that the CMI cannot rely on the traditional fossil sources of basic chemicals for manipulation and transformation into useful products and that the process operations based on these raw materials are not sustainable. Instead the CMI will rely on renewable raw materials based on biomass for platform chemicals, transforming them into products (currently focussed on polymers and fuels) which are described as, "bio-based," materials. This will have fundamental implications for sustainable engineering based on renewable carbon accounting and on claims to be a carbon-neutral industry. Additionally, it will be necessary to take the present state of knowledge in biotechnology to another level where engineering and biology are combined to design and synthesise novel functions and systems ranging from enzyme combinations to whole organism analogues—synthetic biology. The ability to design and synthesise DNA sequences and synthetic biological systems based on them will bring a completely new view of process engineering with governance, intellectual property, safety/security, and ethical issues demanding a new type of process engineer to deal with them including the ability to grasp the wider social dimensions of developing processes/products as proposed under the S-LCA banner. It has been suggested that these pressures could lead to the next paradigm shift for process engineering (Hall & Howe, 2010). The implications of a bio-based CMI leaning heavily on synthetic biology to replace fossil fuel technology are profound and worthy of more detail here.

Development of a Bio-Based CMI

The biggest current use of biomass is for conversion to biofuels although this is not the most efficient use for it and does not reflect the large number of fossil fuel-based products which must be substituted for in the future. So, biomass could be the source of plastics, paints and dyes, adhesives and fertilisers to name a few examples. The biomass available for conversion is made up of cellulose, hemicellulose and lignin which are usually found in conjunction in plant material. Cellulose is the easiest molecule to manipulate, being a polymer of glucose, whilst hemicellulose and lignin are more intractable materials and make cellulose harder to extract. Sources of biomass include natural forests, grasslands and marine ecosystems and agro-systems such as field crops and plantations. The commercial exploitation of these sources; their geographical location and ownership and their relationship to human food production are all fiercely debated issues where the ethics and CSR for the CMI are under heavy pressure. The term biomass also gives the idea that all is grist to the mill and the biodiversity of the parent sources is overlooked although they could be the source of valuable natural products, livelihoods and cultural significance for the local population (Erosion, Technology and Concentration, 2010).

Synthetic Biology

Relationships between engineering and biology have developed over a long time: from the early food fermentations through to modern industrial biotechnology using whole organisms or enzyme extracts to produce products such as antibiotics and functional food components. These activities have also brought about a good understanding of the physiology, growth characteristics and genetics of the organisms involved, such as *Penicillium* spp, *Aspergillus* spp, *Saccharomyces cerevisiae,* and *Escherichia coli* which could be manipulated for greater expression of natural or implanted products. The genetic manipulation of these organisms in current biotechnology is considered to be *ad hoc* or serendipitous at best whereas synthetic biology offers specific design for purpose.

Although it has grown from the engineering/biology axis other fundamental advances in a third sphere have enabled synthetic biology to become nearer to reality. These developments in mathematics, computer modelling and information storage, retrieval and communication and have enabled the complex biological systems to be mapped, quantified and masses of data transmitted as necessary. As a result of the potential control which can be achieved there are great claims for synthetic biology in fulfilling the promises which conventional biotechnology cannot deliver. Table 2 gives a list of the broad areas of activity with specific applications within these areas. The list is pretty all-encompassing with no area of current process engineering omitted. Immediate goals are the next generation of biofuels which are capable of driving the high-fuel usage sectors of heavy haulage, railways and aviation. Another area of immediate impact will be in the production of drugs and pharmaceuticals such as the production of the antimalarial drug (artemisinin) precursor, artemisinic acid in engineered yeast (Ro, et al., 2006) as an alternative route to extraction from the medicinal plant, where limited availability is reflected in price, and a shift from plant to microbial production would give a reliable and affordable supply (Zeng, Qiu, & Yuan, 2008). This project was supported by the Bill and Melinda Gates Foundation, addresses a massive health issue and being near to fruition thus attracts the headlines for synthetic biology.

Synthetic biology is also of great public interest because it deals in the fundamentals of life with concomitant ethical, security and safety issues. The successful sequencing of the human genome (International Human Genome Sequencing Consortium, 2001; Venter, et al., 2001) gave synthetic biology another media boost but also raised the spectre of, “Frankenstein,” organisms with malign uses or, at the very least, the threat of accidental release. Thus, this eye-catching and newsworthy disciple has been the subject of debate far removed from academia (Specter, 2009) which has brought about calls for regulation by bodies other than the active synthetic biology commu-

Table 2. Applications for synthetic biology

Energy	Bio-medical	Environment	Agriculture	Other
Biofuels	Smart drugs & delivery systems	New (biodegradable) packaging	Biomass utilization	Smart materials
Cellulosic biomass conversion	Therapy vectors	Spillage detection	Food production	Green chemistry & engineering (sustainability)
	Tissue repair	Bioremediation		Synthesis of non-natural molecules (e.g. proteins)

nity itself. Alongside the scientific discovery goes great commercial potential and fears for a profit-driven monopoly of multinational companies who can afford to fund the initial research (Erosion, Technology and Concentration, 2010). The replacement of natural sources of bio-active compounds (such as artemisinin) could also deprive developing countries of revenue (Balmer & Martin, 2008). With synthetic biology being based on the manipulation of genetic material there is the added issue of the Intellectual Property Rights (IPR) for the new life forms created. The models for the development of the synthetic biology-based industry may learn lessons from the fast-changing computing and software industry (Henkel & Maurer, 2007).

The pace of progress in synthetic biology is also frightening with the first synthetic organism, from the poliovirus genome (7,741 base pairs) taking two years of work (Cello, Paul, & Wimmer, 2002) whilst the genome of the bacteriophage ΦX-174 (5,386 base pairs) took just two weeks in the J Craig Venter Institute (Smith, Hutchinson, Pfannkoch, & Venter, 2003). The first bacterium to be synthesised (also by the Venter Institute) was *Mycobacterium genitalium* with 589,000 base pairs (Gibson, et al., 2008). This opened up the concept of a viable minimal cell, produced by removing genes which are not essential for life, but with the minimum number of components to support biological synthesis from inserted DNA material. *M genitalium* carries 485 genes and has the smallest genome in laboratory organisms and about one quarter (115 or more) could be removed with no affect on genome functionality. More conventional microbial carriers (or "chassis") for synthetic biology include E coli, yeasts, *Bacillus subtilis,* and *Pseudomonas putida* reflecting the wide knowledge about these organisms built up over the years. Future developments could include cell-free applications where the non-specific elements of the living cell chassis are removed from the application.

Synthetic biology owes a debt to the engineering design cycle approach for its development. Process engineers are well versed in taking concepts from the chemistry and biochemistry fields and converting them into industrial scale processes through a process of design-build-commission. Plant design involves putting together a multitude of standard parts and unit operations into the most efficient system through an iterative process—recognising that a number of designs and process routes might be feasible practically but not from a commercial point of view. Learning the art of process design is at the very core of chemical engineering education being the culmination of the separate disciplines which make up the subject. Thus, process design is based on fundamental concepts such as heat and mass transfer, transport phenomena, reaction kinetics and modelling and fluid mechanics. The basic principles for the process in question are then broken down into the unit operations which comprise the complete process and described in block flow diagrams, process flow diagrams and piping and instrumentation diagrams. Other considerations include product throughput and quality; financial constraints and process criteria such as safety, flexibility and operational characteristics. All this knowledge can be applied to synthetic biology in the consideration of what route to take to production. The analogy between (process) engineering design and synthetic biology has been writ large in that the idea of taking discrete and standardised genetic units and putting them together to make an engineered organism is as direct or simple as in the physical world. One approach to the provision of these standard parts is the Biobricks Foundation which is a public-benefit organisation originating from workers at MIT, Harvard and University of California, San Francisco. The declared aim of the foundation is to make freely available the fundamental components, or bioparts, needed to conduct synthetic biology and in doing so to introduce the mindset which underpins, for example, chemical engineering design (Biobricks Foundation, 2011).

However, just as physical chemical plant must be coaxed into an operational equilibrium so the genomic components of a synthesised organism must be brought together carefully to function correctly and there has been an evolution in the complexity and scale at which this can be done (Andrianantoandro, Basu, Karig, & Weiss, 2006; Canton, Labno, & Endy, 2008; Purnick & Weiss, 2009).

The other, more practical, input from the chemical engineering fraternity to synthetic biology could be in defining the processability of engineered organisms and their products. Currently synthetic biology seems to be directed towards the genetic control of the organism for specific product expression but a substantial element in the cost of bio-products is their separation and purification—Downstream Processing (DSP). Here the chemical engineer could ask the question about processability and define the DSP characteristics required in the final design. This issue is being addressed in some instances, for example the use of *e coli* to produce biofuels which are expressed externally and being immiscible with the aqueous fermentation broth can separated from it easily. Where products are expressed and water soluble it may be possible to select for ease of DSP, for example, by developing organisms which require a minimal/simple fermentation medium which can be easily removed in the early/high volume stages of DSP. The minimal cell would be a good model for this approach. Where products are expressed as internal inclusion bodies they must be separated from the cell contents. Ways to achieve this separation would be helped by simple cell biochemistry and susceptibility to cell disruption paving the way for separation of the cell contents and the inclusion body.

Education for Sustainable Process Engineering

There is a need to ensure that the new generation of chemical engineers recognises the importance of sustainability in general and how to apply such principles in all aspects of process design. Garcia-Serna *et al.* (2007) proposed that sustainability should be introduced early on and so permeate all the other major teaching elements which make up a chemical engineering course - but how should sustainability be incorporated into a very full curriculum and at what level (see Table 3)?

Other aspects of a university degree have always been prominent in chemical engineering education such as problem solving and the modern chemical engineer with good mathematical ability and literacy, combined with the ability to communicate with those from a range of disciplines, can find employment in areas far removed from the CMI. The issue of how to fit sustainability into this crowded timetable offers a range of options (Favre, et al., 2008):

Table 3. Chemical engineering degree curriculum

Curriculum area	Subject
Basic Science	Mathematics
	Physics
	Chemistry
	Computing
Core engineering	Thermodynamics
	Physical chemistry
	Fluid mechanics
	Transport phenomena
	Unit operations
	Reaction engineering
	Plant design
	Process dynamics & control
	Health, safety & environment
	Plant, equipment & materials
Electives	Biotechnology, bioprocessing & fermentation
	Particle science
	Polymer technology

- no change in the curriculum as it fits the bill already and has proved to do so despite significant changes in the industry
- overhaul the curriculum to become a, "curriculum for the future" (Armstrong, 2006)
- adapt the current curriculum to meet the new challenges of sustainability and the needs of green chemistry (McDonough, Braungart, Anastas, & Zimmerman, 2003).

A recent exercise to establish how sustainability, in the broadest sense, is being incorporated in to chemical engineering education was conducted in the USA (Allen, Murphy, Allenby, & Davidson, 2009a) covering 366 engineering colleges and all the engineering disciplines including civil, environmental, mechanical and systems engineering and also chemical, bio and materials engineering. Four strategies were discerned:

- dedicated sustainable engineering courses in any of the major disciplines
- integrate sustainable engineering concepts into existing courses to raise awareness of students
- focus on technologies which will be important in sustainable engineering
- mixed teaching strategy and some interdisciplinary courses with non-engineering departments

Allenby, Murphy, Allen, and Davidson (2009b) reflected on the conceptual challenge of sustainable engineering and the educational conflict between teaching the topic as a speciality or as a component of other engineering disciplines. They commented on the social dimensions of sustainability which are less quantifiable and more normative and subjective than the typical material taught in engineering courses and which staff found less easy to teach.

Dedicated undergraduate sustainable engineering courses might only attract those students for whom the very idea of sustainability is vitally important whilst deterring the general engineer. A standard engineering degree in any subject area, including sustainability elements, followed by specialisation at post-graduate level might be a better way to attract engineers into the area of sustainability. Another argument says that all engineers should be aware of sustainability, hence the need for integrated courses but a limited number need to be specialists – hence the need for post-graduate courses in sustainability (with proper focus). As mentioned above the current chemical engineering degree course is full of intellectually-demanding material which is taught through a problem solving/design format combined with practical classes and students finding their way through this challenge become well-rounded individuals capable of tackling the wide sustainability agenda at this time. In this case the mixed teaching strategy would come to the fore but this leads the education debate into the realms of the disciplinarity of sustainable develop.

Chemical Engineering in the Future: Disciplinarity

The by-word for sustainability has been cross- or multidisciplinarity as demonstrated by the TBL or concentric models (Satterfield, et al., 2009). However, within academia the, "silo," mentality still prevails with fierce protection of expertise or specialist knowledge and a resultant lack of understanding between the social, cultural, scientific and economic disciplines and most importantly what can be learned by one discipline from the others. There is also a fear factor in entering into another domain where the academic is not the master and their assumptions and knowledge can be questioned. But technical solutions to sustainability can only work if they have social and cultural acceptance and their economic significance is recognised—the TBL and S-LCA writ large. Academics who move from their own domain into that of others can be deeply mistrusted and treated as dilettantes at best and loose cannons at worst. Yet it is such free thinkers who can draw together the various strands of the sustainability web and recognise the interconnectivity of the subject. Another issue working against the cross- or multidisciplinary approach to sustainability is early specialisation which often separates the arts and sciences in the secondary schooling system and leads the science student into ever more esoteric areas as they progress through the university system. This experience does not develop the wide-ranging broad-brush mental flexibility capable of dealing with sustainability (and with synthetic biology) and as a result regards it as a "fuzzy" or "elusive" concept, in particular its qualitative aspects. The gulf between the "two cultures" of the social and physical sciences described by C. P. Snow (1959) still holds today.

CONCLUSION

In the future, the concepts of sustainability must be embraced and their application in the CMI must be articulated to a sceptical public—the sector must be seen to be doing its bit. The advent of a new raw material base, and the means to manipulate it, must be welcomed but will mean an equally new paradigm to process engineering practice. The meeting of biology, engineering and information sciences (in synthetic biology) will demand a flexible approach, one which the process engineering curriculum and design teaching already supports. The commercial, ethical, and social impact of a sustainable CMI brought about by this new world will be under increasing scrutiny and an open, honest relationship with the public should be encouraged, indeed celebrated.

Chapter 89
Cellular or Functional Layout?

Abdessalem Jerbi
University of Sfax, Tunisia

Hédi Chtourou
University of Sfax, Tunisia

ABSTRACT

The cellular layout has been compared to the traditional functional layout using multiple comparison methodologies that either lack objectivity or are highly time-consuming. The main purpose of this chapter is to propose a novel and objective methodology. Hence, a critical analysis of ten comparison studies is followed by the presentation of the layouts simulation models. Subsequently, the proposed comparison methodology is described. Following this methodology, simulations are conducted according to a plan of experiments developed from Taguchi standard orthogonal arrays. Consequently, results, expressed in Signal to Noise ratios, are analyzed using ANOVA. Next, a mathematical model is derived by interpolation between the factors and interactions effects. This model must be validated by the confirmation test, otherwise the comparison methodology should be reiterated while considering new interactions. This cycle should be reiterated as much as necessary to obtain a valid mathematical model. The proposed comparison methodology has been applied with success on an academic manufacturing system.

INTRODUCTION

The increased competition within industry has resulted in manufacturing companies spending considerable effort to improve flexibility and responsiveness to meet customer needs. Cellular manufacturing, a facet of group technology, has emerged as one of the major techniques being used for the improvement of manufacturing competitiveness. A large number of empirical, analytical and simulation studies have been devoted to compare the cellular layout (CL) to the classical functional layout (FL). Simulation-based comparative studies constitute the mainstream of this research field. Varied results were reported by these comparative simulation studies. Indeed, different researches found the FL always superior to the CL with regard to all used performance measures (Jensen, Malhotra, & Philipoom, 1996; Morris & Tersine, 1990, 1994). Further researches reported that the CL is superior to the FL in all operating conditions (Pitchuka, Adil, & Anantha-

DOI: 10.4018/978-1-4666-1945-6.ch089

kumar, 2006; Shafer & Charnes, 1992). Finally, other simulation studies showed that every layout could outperform the other in different particular experimental conditions (Faizul huq, Douglas, & Zubair, 2001; Farrington & Nazametz, 1998; Li, 2003; Shafer & Charnes, 1995; Suresh & Meredith, 1994). The divergence in the studies conclusions is referred to as the “cellular manufacturing paradox” (Shambu, Suresh, & Pegels, 1996). In fact, Agarwal and Sarkis (1998) and Shambu et al. (1996) reviewed a number of FL-CL comparative studies. However they did not identify any objectivity flaws responsible for the conflicting conclusions. Indeed, they simply reported the major findings of some published studies without any critical objectivity assessment.

Actually, methodologies used by comparison studies vary widely but can be classified into three groups. In the first group, authors used the one-factor-at-a-time method. So the two layouts are first compared for one manufacturing context considered as the “base model”. Then, other experiments are carried out in order to test the robustness of the layout choice obtained in the base model. Every experiment corresponds to the modification of a single operating factor (Morris & Tersine, 1990, 1994). In the second group authors considered only some specific combinations of the studied factors settings without any justification (Faizul huq et al., 2001; Li, 2003; Suresh & Meredith, 1994). In the third group authors used the full factorial design technique in order to study the effect of all factors (Farrington & Nazemetz, 1998; Jensen et al., 1996; Pitchuka et al., 2006; Shafer & Charnes 1992, 1995). Methodologies belonging to the two first groups undoubtedly lack objectivity in the choice of the experimentation conditions. Therefore, they do not permit to attach any statistical confidence level to their conclusions. In addition, they do not provide any information about factor interaction. The third group methodology is highly time-consuming. In addition, it is impractical when the number of factors to study is large.

This chapter essentially focuses on the development of an objective FL-CL comparison. It first highlights the lacks of objectivity of the main published FL-CL simulation-based comparison studies in order to explain the origin of their conflicting conclusions. Then it deals with the development of comprehensive FL and CL simulation models using the widely used commercial simulation software Arena 7.0. Finally, it presents the framework of a methodology, based on the coupling of the Taguchi method of experiment design (TM) and simulation. This methodology can be easily applied to any manufacturing context and provides trustworthy results with a minimum experimentation effort.

The remainder of this chapter is organized as follows. The next section presents a taxonomy of the key factors used in the main published FL-CL comparison simulation studies. The foremost used performance measures are also presented in this section. Finally it presents and analyses the findings of a number of relevant studies. The third section presents some general simulation features, needed for modeling both layouts. Then, it respectively gives details of the developed FL and the CL simulation models. Section four gives a general presentation of the objective comparison methodology and then presents a comprehensive academic case study depicting its application. The final section includes some general conclusions and discusses future work prospects.

COMPARATIVE STUDIES FRAMEWORK

Main Experimental Factors

General Manufacturing System (MS) Characteristics

Every MS is characterized by a number of machines arranged either into departments in the functional layout, or else, into manufacturing cells in the cellular layout. Following the FL structure, the shop is composed of *d* departments *Di* (*i*=1, …, *d*). Each of them includes *Mn* functionally equivalent machines. In contrast, the CL is composed of *c* independent manufacturing cells *Cj* (*j*=1, …, *c*). Each cell is a cluster of *Mf* different machines dedicated to a number of similar part types. Furthermore, every MS is designed for a demand pattern comprising different products. Products are identified by two indicators, which are the type (*t*) and the family (*f*). Products are grouped into families according to the similarity of their manufacturing process. Each product type requires a number of manufacturing operations (*mopt*).

Degree of Decomposability of the Part Machine Matrix (DD)

This degree translates the feasibility of the decomposition of the MS into independent cells. In fact, the more the product/machine matrix is diagonal, the more the decomposability is feasible. This degree is negatively correlated to the density of off-diagonal elements.

Batch Size (BS)

Products are generally manufactured and transferred in batches in order to reduce machine setup and transport between machines. Numerous authors included *BS* in there comparison studies as a variable factor and demonstrated that the combination of small batch sizes with an efficient scheduling rule results in the improvement of the cellular layout performances. Most authors used the same batch size for both cellular and functional layouts.

Demand Rate (DEMAND)

The demand rate is mainly expressed by the batch inter-arrival times (*IAT*) in the MS. A large part of authors generated this time by common probabilistic distributions. Others used constant *IAT*. Besides, some authors focus only on the stability of this factor without changing its average value.

Transfer Time (TT)

This parameter corresponds to the interdepartmental travel times in the FL. They are often modeled using appropriate probabilistic laws. In the CL these times correspond to the durations of intra-cell moves. Generally, they are very small compared to those in the FL.

Transfer Mode (TM)

Because of the considerable interdepartmental distances in the FL products are generally transferred by batches in order to reduce transfer costs. Some studies also used this transfer mode between same-cell machines whereas others make use of operations overlapping. This mode exploits the proximity of same- cell machines to allow simultaneous execution of different operations on parts of the same batch.

Flow Direction (FLOW)

A number of authors included the flow direction within a cell as an experimental factor. This factor has two possible levels: “unidirectional” or “backtracking allowed”.

Scheduling Rules (RULE)

Part batches arriving at a department or a cell are put in a waiting queue until the required machine becomes idle. These batches are then sequenced in order to establish the order in which they will be processed. This order is specified by the use of standard scheduling rule such as “First Come First Served” (FCFS), “Shortest Process Time” (SPT), “Earliest Due Date” (EDD) or else, “Repetitive Lots” (RL). The limited versions of the first three rules, FCFS-L, SPT-L and EDD-L are used in order to avoid the duplication of machines setups for the same product type. Finally, the RL rule selects batches of the same type that the one just processed in order to minimize setups.

Processing Time (PT) and Set up Time (ST)

As for the *IAT*, most studies generally modeled both times by independent probabilistic laws. On the other hand, other studies formulated *ST* as a fraction of *PT*.

Set up Time Reduction Factor (δ)

This factor materializes one of the most key advantages of the CL. Indeed, part types of a same family need generally similar setups. Hence, if a machine is set up for a part type and then should be set for a same-family part type, the nominal setup time for the second part is reduced by the δ factor.

Performance Measures

Work in Process (WIP)

WIP is one of the most popular performance measures used in the FL-CL comparative studies (Farrington & Nazametz, 1998; Jensen et al., 1996; Li, 2003; Morris & Tersine, 1990, 1994; Shafer & Charnes, 1992, 1995; Suresh & Meredith, 1994). It essentially characterizes the fluidity of the material flow in the system.

Mean Flow Time (MFT)

MFT constitutes the other most popular measure used in FL-CL comparative studies (Faizul huq et al., 2001; Farrington & Nazametz, 1998; Jensen et al., 1996; Li, 2003; Morris & Tersine, 1990; Shafer & Charnes, 1992, 1995; Suresh & Meredith, 1994). It also characterizes the fluidity of the material flow in the system. The *MFT* is the average time that every batch remains in the system in order to be manufactured.

Due Date Related Measures

Researchers used essentially Mean Tardiness (*MT*) and Mean Earliness (*ME*) as due date related performance measures (Farrington & Nazametz, 1998; Jensen et al., 1996). *MT* is the average over all tardy jobs of the difference between delivery date and the promised due date. *ME* is similarly obtained for all early jobs. Other researchers used the percentage of tardy jobs (*TARDY*) and the percentage of early jobs (*EARLY*).

Other Measures

FL-CL comparative studies consider several other performance measures. The system *Throughput*, considered as productivity measure, is the average number of parts exiting the system by time unit (Faizul huq et al., 2001; Morris & Tersine, 1994). It is also used for detecting the attainment of steady state indicator in a simulation run. Besides, some studies used the operator utilization rate (*OPUR*) (Morris & Tersine, 1994), the average machine utilization rate (*MUR*) (Farrington & Nazametz, 1998; Morris & Tersine, 1994; Shafer, & Charnes, 1995), the mean "queue" waiting time (Pitchuka et al., 2006) or the average *ST/PT* ratio (Li, 2003) as performance indicators. The first two measures must be maximized to ensure a high degree of resource exploitation but the third and fourth measures should be minimized to improve the efficiency of the MS.

Comparative Studies Findings

By means of four simulation experiments, Morris and Tersine (1990) examined the influence of the ratio *ST/PT, TT*, *DEMAND* stability and parts *FLOW* within cells on the performance of CLs compared to FLs. In this comparative study, the performances were measured using *MFT* and *WIP*.

Results demonstrate that in the quasi totality of the tested contexts, the FL always outperforms the CL and generates smaller *MFT* and *WIP*. Besides, comparison results reveal that the ideal context for CL must be characterized by a high *ST*/*PT* ratio, a stable *DEMAND*, a unidirectional *FLOW* and a substantial *TT* between process departments.

To find out the operating conditions under which the CL outperform the FL, Shafer and Charnes (1992) investigated 24 combinations of *DD*, *mopt*, *PT* and *BS*. As for the previous study, authors used the same performance measures. They found the CL superior to the FL in all operating conditions according to both performance measures.

Morris and Tersine (1994) extended the results of their first comparison study (Morris & Tersine, 1990) by investigating the impact of a dual resource constrained shop on the performances of CL and FL using three operator scheduling rules in the CL. Simulation observations were collected for four performance measures including the mean *Throughput*, the *WIP*, the *MUR* and the *OPUR*. Results reveal that the FL outperformed the CL on all of the used performance measures regardless of the operator scheduling rule.

Authors investigate the sensitivity of their results relatively to changes in shop congestion level and changed respectively the *IAT* and *OPUR* in two other experiments. It appeared that the FL still outperforms the CL.

Besides, Suresh and Meredith (1994) aimed to overcome the loss of pooling synergy in the CL. Hence, they used simulation in order to compare the CL to an efficiently operated FL (EFL) using average *MUR*, *WIP* and *MFT* to assess the two layout's performance measures. The EFL is characterized by an optimal *BS*, a reduced *TT* and part-family-oriented scheduling rules. The main experimental factors involved in this study were *PT*, *ST*, *BS*, δ and *IAT*. First, every experimental factor was tested separately. Then all the experimental factors were tested together. The FL was found to be superior to the CL for large batch sizes (*BS*>32). However, for relatively small *BS*, the CL could outperform the FL if δ is smaller than 0.2. Comparison results do not change when the variability of *PT*, *ST* or *IAT* were separately reduced. On the other hand, if all factor effects were combined, the CL outperformed the FL even for small *BS*.

Shafer and Charnes (1995) used simulation to study a manufacturing context inspired from Morris and Tersine (1990). In fact, they used the same levels of the following factors: *t*, *f*, *c*, *d*, *Mn*, *Mf* and *mopt*. Authors aimed to compare alternative loading procedures for CL and FL in a variety of operating environments defined by combinations of 4 factors: *FLOW*, *TT,* labor constraints and MS congestion level. The third factor was modeled using two levels of the operator number while the last factor was modeled through the variation of the *PT*. Besides, each layout was investigated using two loading policies. For the FL the first policy permitted machine dedication while the second did not. On the other hand, for CL the first policy restricted the processing to only one batch at a time in a cell and the second allowed the processing of different batches at the same time. Both policies authorized CL operations overlapping. The authors used *MFT* and *WIP* in a two stage comparison methodology. In the first stage, labor constraints were not considered. In the second stage, a constraint was imposed on labor allowing only 8 operators to the whole shop in both configurations. It is worth noting here that the presence of one operator is required during setups and processing operations. The first stage simulation results demonstrate that the two layouts were equivalent regarding *WIP* while the CL generated lower *MFT* than the FL. In contrast, in the second comparison stage the FL showed lower *MFT* than the CL. The authors justified this result by the labor constraint effect on the CL. Indeed, according to the authors the labor constraints handicaps more seriously the CL since it reduces the operations overlapping possibilities while its effect on the

FL is not significant since the departments have only 3 machines in average.

Another study by Jensen et al. (1996) assessed the FL and CL performances through *MFT*, *WIP MT*, *ME* and *TARDY*. They based their study on a full- factorial experimental plan involving layout type, *RULE*, *DEMAND* variability and δ as experimental factors. To determine the influence of each factor on the studied performance measures, the authors analyzed their simulation results by ANOVA. Aside from the layout type, the most influent factor was found to be *DEMAND* variability followed by δ and *RULE*. Then, the authors performed a pairwise comparison of *RULE*. Results demonstrate that SPT-L and EDD were the best performing rules regarding *MFT* and *MT* respectively. Finally, they compared layouts using the best found *RULE*. The results of this final step revealed that the FL was always superior to the CL with regard to all performance measures.

As for Farrington and Nazemetz (1998), their comparative study is based on a three-factor-full-factorial experimental plan. The three experimental factors were the layout type, the *PT* variability and the *IAT* variability. It's worth noting here that the high variability level was associated to a small *BS* and vice versa. They assessed the two layouts using different performance measures, namely *MFT*, *WIP*, *TARDY*, *MUR* and a number of others less common measures. Comparison results prove that the FL is superior to the CL in a context defined by a high variability of *PT* and a low variability of *IAT*. But, when both factors show high variability, the performances of the two layouts are close. Besides, The CL outperforms the FL in all remaining conditions.

Faizul huq et al. (2001) presented in their comparison study a straightforward two-factor-full-factorial simulation plan using the *MFT* and the *Throughput*. The two studied factors were *BS* andδ. For the sake of objectivity, the authors used the EFL concept. ANOVA investigation showed that the two layout *Throughput* performances were not significantly different. In deed, the two layouts presented significant differences in some of the studied combinations only in terms of *MFT*. In fact, The CL outperformed the FL only for small *BS* and very largeδ. In all other conditions, the FL was clearly superior.

Regarding Li (2003), the author used *MFT* and *WIP* to explore the superiority domains of both layouts in a diversity of contexts. These contexts are defined by the *FLOW*, the *TM*, the variability of *PT*, the variability of *ST* and finallyδ. The performance measures results analysis showed that the major factor in establishing the superiority of one of the two layouts isδ. Hence, the CL outperformed the FL at high level of δ and the FL was the best layout in the low δ region. Both layouts showed equivalent performance measures for intermediate value ofδ.

The last reviewed study, done by Pitchuka et al. (2006), compared FL to CL using a four-factor-full-factorial experimental plan featuring *PT*, *ST*, *BS* and *IAT*. The authors considered only the "queue" waiting time as performance measure. It was shown that the CL can outperform the FL in the majority of the studied contexts. Indeed, in the CL numerous work centers generated inferior "queue" times to those of the corresponding work centers in the FL.

Objectivity Assessment

Conditions Favoring FL

Jensen et al. (1996), Pitchuka et al. (2006) and Shafer and Charnes (1992) considered very low *TT* which implicitly advantage the FL, since one of the main advantages of the CL is time saving by locating machines required to manufacture a part close to each other. On the other hand, Jensen et al. (1996), Morris and Tersine, (1990, 1994) and Pitchuka et al. (2006) used a CL with no operations overlapping allowed in part processing. This does not permit to take advantage of CL benefits. Moreover, Farrington and Nazametz (1998) stated that they chose not to reduce the *ST* in the CL context. Their motivation was to avoid any biases in favor of the CL. But, by doing so, they favored the FL since they eliminated one of the main advantages of the CL.

Conditions Favoring CL

The study of Shafer and Charnes (1992) is obviously biased in favor of the CL. In deed, the authors consider single-machine departments. So, they eliminate the main and probably the only benefit of this type of layout: the pooling synergy effect between same department machines. Consequently, the results were clearly in favor of the CL even with the assumption of null transfer times advantaging the FL. Regarding Li (2003), the study featured unidirectional cell *FLOW* by duplicating the necessary machines to avoid backtracking. This indirectly led to the reduction of the cell number. The machine duplication within cells biased the comparison results in favor of the CL. In fact, this attaches to the CL the main advantages of the FL which is the synergy between functionally equivalent machines. As for Suresh and Meredith (1994), they used FL *TT* relatively very high compared to the *PT*. This probably advantage the CL and make clear why its performance are superior to the performance of the FL in almost all the testing contexts even though no operations overlapping has been used in the CL.

Other Conditions

This category essentially includes the lack of vital information about the used experimental factor settings as well as key elements defining the manufacturing contexts. Indeed, even if Morris and Tersine, (1990, 1994) provided in their studies the material handling equipment speed, they did not mention any distances between departments or machines. These distances are required in order to evaluate the *TT* in the two layouts. On the other hand, Farrington and Nazametz (1998) and Shafer and Charnes (1992) did not mention the *RULE* they used. In addition, Farrington and Nazametz (1998) failed to report numerous key experimental factors such as *mopt*, *IAT* and *PT*. Despite its established importance, Jensen et al. (1996) did not use the *BS* as an experimental factor neither did they mention its constant value used throughout the investigation.

Other lacks of important data are included in this category, particularly technical simulation-related information such as the replication length (Farrington & Nazametz, 1998; Li, 2003) and the warm-up period length (Farrington & Nazametz, 1998). On the other hand, numerous incongruities appear in different comparative studies. For example, the difference between the two shop configurations of the CL studied by Li (2003) is not clear. Indeed, in the figures illustrated by the authors, the arrows indicating the products *FLOW* show that there is no backtracking flow even in the CL with backtracking flow allowed. These incongruities are more serious in Faizul huq et al. (2001) study. Indeed, despite stating that no inter-cell moves were allowed, the authors defined the inter-cell travel time by a uniform law.

The use of inappropriate MS data appears especially in the study of Faizul huq and al. (2001). Indeed, the major flaw of this study is the definition of the manufacturing context. In fact, they used the same routings for the same product types. This generated three identical manufacturing cells. More gravely, the use of single-product families annuls any setup operation in the cell except for the initial setups. Hence, the factor δ becomes irrelevant and any results showing the importance of this factor are seriously questionable.

SIMULATION MODELS

Basic Simulation Features

FL and CL layouts simulation models are developed using the commercial simulation software

Arena 7.0 (Kelton, Sadowski, & Sadowski, 2002). This simulation tool integrates all the needed simulation functions including animation, analysis of input and output data. Every MS model consists of the four main components: manufacturing orders launching and attribute assignation, part transfer, part manufacturing and statistics collection.

Manufacturing Orders Launching and Attribute Assignation

Manufacturing orders (MOs), being batches of parts of the same type, are launched by "Create" modules. Every "Create" module defines batches *IAT* following the used probabilistic rule in addition to their *BS*. A specific "Create" module is dedicated for each part type. As soon as parts are lunched, they pass through an "Assign" module where characteristics are attributed to them. These characteristics are either time-related such as *PT* and *ST*, or also identification indicators such as part's type as well as part's family and factors necessary to the MS piloting like part's routing or "Sequence".

Part Transfer

Parts are transferred, either individually or in batches, between physical locations modeled by the "Station" modules, in which they should undergo the required manufacturing steps. These locations are either machines in CL or departments in FL. Transfer are carried out by "Route" modules permitting to prescribe destinations as well as transfer times. These modules use "Sequence" attribute of the transferred parts in order to prescribe the next destination. The "Sequence" corresponds to the part routing expressed as stations list.

Two manufacturing strategies could be followed for the parts transfer in the shops: "with operations overlapping" or "without operations overlapping". In the first strategy, parts of the same batch could be processed simultaneously on different machines of a department or a cell. In the second strategy, all parts of the same batch are processed on the same machine of the cell or department before being transferred collectively to the next machine or department. In all cases, batches must be split by "Separate" modules before accessing any machine. Batch reconstitution for transfer is performed using "Batch" modules.

Part Manufacturing

Every machine is modeled by a "Process" module, associated to a "Station" module and a "Resource" module. The "station" module determines the physical location of the machine and the "Resource" module represents the capacity and the availability of the machine itself. In fact, the "Process" module seizes the associated resource for the required period of time and then releases it. So, the machine becomes idle and available again for manufacturing another part. The machine resource is seized during a period of time that corresponds to the *PT* of the part being processed and eventually the required *ST* if the machine was set for a different part type. The *ST*, when relevant, is weighed by the setup reduction factor δ whenever the part type belongs to the family of the last processed one.

Statistics Collection

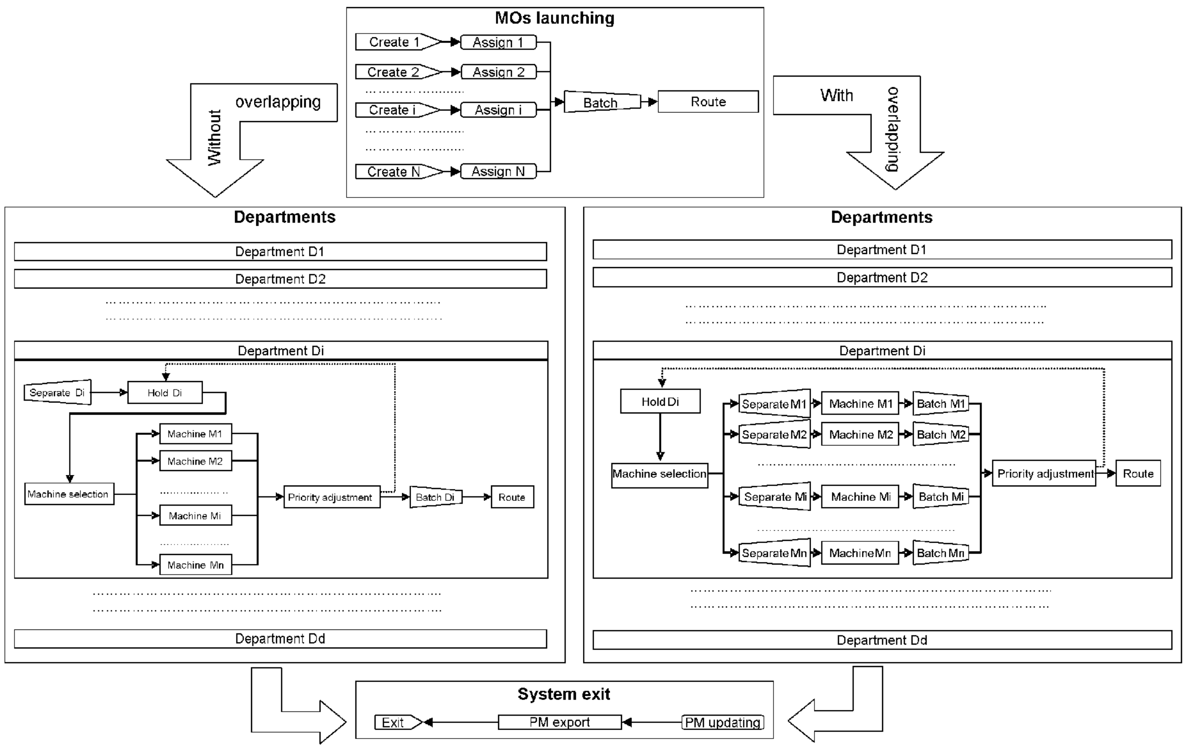
Before leaving the MS, every batch must go through an "Assign" module in which the parameters defined as performance measures are computed and updated. The acquired data is then stored in an Excel file using a "Readwrite" module for eventual treatment and analysis.

Functional Layout Model

The functional layout model is composed of three sections: "MOs launching", "Departments" and "System exit" (see Figure 1).

MOs are launched by "Create" modules dedicated each part type. Each "Create" module

Figure 1. FL model



is coupled to an "Assign" module. The generated parts are then grouped into batches and routed to their first manufacturing step's department. A batch arriving at a department is made waiting in a queue modeled by a "Hold" module. This module is governed by a priority rule that could be FCFS, SPT or any other priority rule. When at least one of the department machines becomes available, the "Hold" module releases the prioritized batch from the waiting queue. The released batch is then transferred to the "Machine selection" sub-model that selects one among the available machines. The logic of this sub-model is coherent with the waiting queue priority rule.

When operations overlapping are not allowed, every batch is split once it reaches the assigned machine. Hence, each batch can be treated only by a single machine. On the other hand, if operations overlapping are permitted, parts batches are split before accessing the department queue. So, parts become independent and could be dispatched to several machines of the same department to be processed simultaneously. In both cases, batches are gathered by a "Batch" module right after processing and before the transfer to next manufacturing step. The combination of the operations overlapping strategy, the machine selection process and the waiting queue priority rule define the shop scheduling policy.

Cellular Layout Model

The CL model is composed of "*c*" sub-models corresponding to the "*c*" MS cells. Each sub-model is composed of three sections: "MOs launching", "Machine cells" and "Cell exit".

As for the FL, MOs are launched by "Create" and "Assign" modules dedicated to each part type. The generated parts are then grouped in batches before being routed to the general cell queue. Such a queue holds part batches until their first routing step machine becomes available. In addition, each machine has its own waiting queue. Both queues are governed by the same priority rule.

If operations overlapping are allowed, batches are split just before leaving the cell general queue. Hence, every part can follow its routing without waiting for the other batch parts. Batches are finally regrouped just before the cell exit. In contrast, if operations overlapping are not implemented, every batch is split when it reaches the machine next machine on its routing. Batches are regrouped once their processing is accomplished. Then, they are transferred towards the following machine or to the system exit.

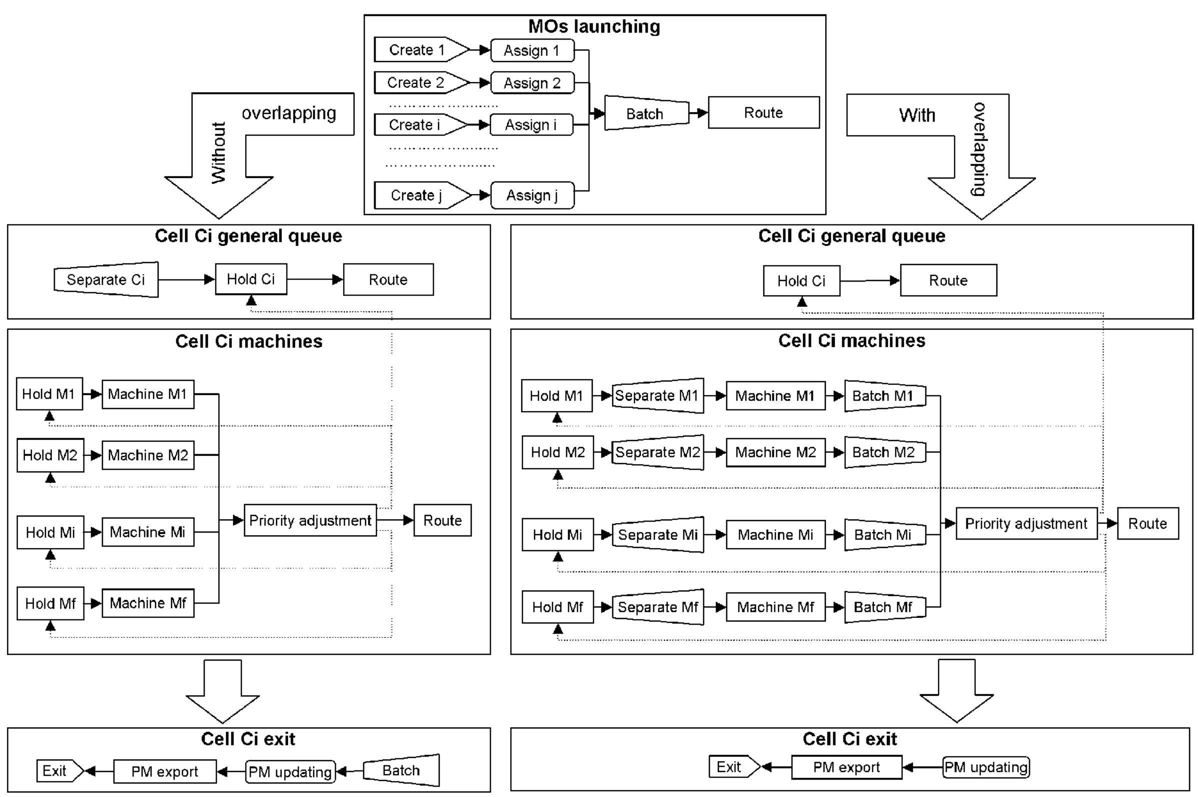
THE OBJECTIVE COMPARISON METHODOLOGY

Overview

The objective comparison methodology (OCM) aims essentially at the development of a mathematical model permitting to predict the superiority of one layout or the other. It is the product of the application of Taguchi method of experiment design. Hence, the OCM is mainly composed of 3 main phases:

- Phase 1: Choosing MS parameters and setting their levels
- Phase 2: Construction of the experiments plan, results analysis and development of the mathematical model

Figure 2. CL model



- Phase 3: Refinement of the simulation plan and improvement of the mathematical model

Each of these phases is composed of one or several stages. Some stages should be reiterated several times.

Phase 1: Choosing Levels of the Manufacturing System Parameters

In the first phase of the OCM the manager must choose the MS parameters as well as their levels. Generally, every MS can be characterized by three types of parameters: signal factors, control factors and noise factors.

Signal Factors (SF)

Signal factors are factors that are expected to affect the average response. In addition, these factors identify the manufacturing context and are kept constant in every application of the OCM. This category includes the department's number *d*, the cell's number *c*, the number of equivalent machines in every department *Mn* and the number of different machines in every cell *Mf*. The four other signal factors are the number of part families *f*, the number of part types by family *t*, the number of manufacturing operations *mopt* and the existence or no of inter-cell moves.

Control Factors (CF)

As for the signal factors, control factors can affect the average response but, more importantly, can affect the extent of the variability about the average response. These factors are to be varied throughout the simulation plan. This category includes the *ST,* the *PT*, the *TT,* the I*AT* and theδ. The three other Control factors are the *BS*, the *RULE* and the *TM*. For more objectivity of comparison results, *ST*, *TT* and *PT* are put into the following ratio forms *ST/PT* and *TT/PT*. Indeed, *ST* and *TT* being nonproductive activities, these ratios are used to compare them to *PT* which is a productive activity. In addition to the studied CFs, several factor interactions (CFI) could also be investigated in every application of the OCM. CFI between CF_x and CF_y is here noted $CF_x xCF_y$.

Noise Factors (NF)

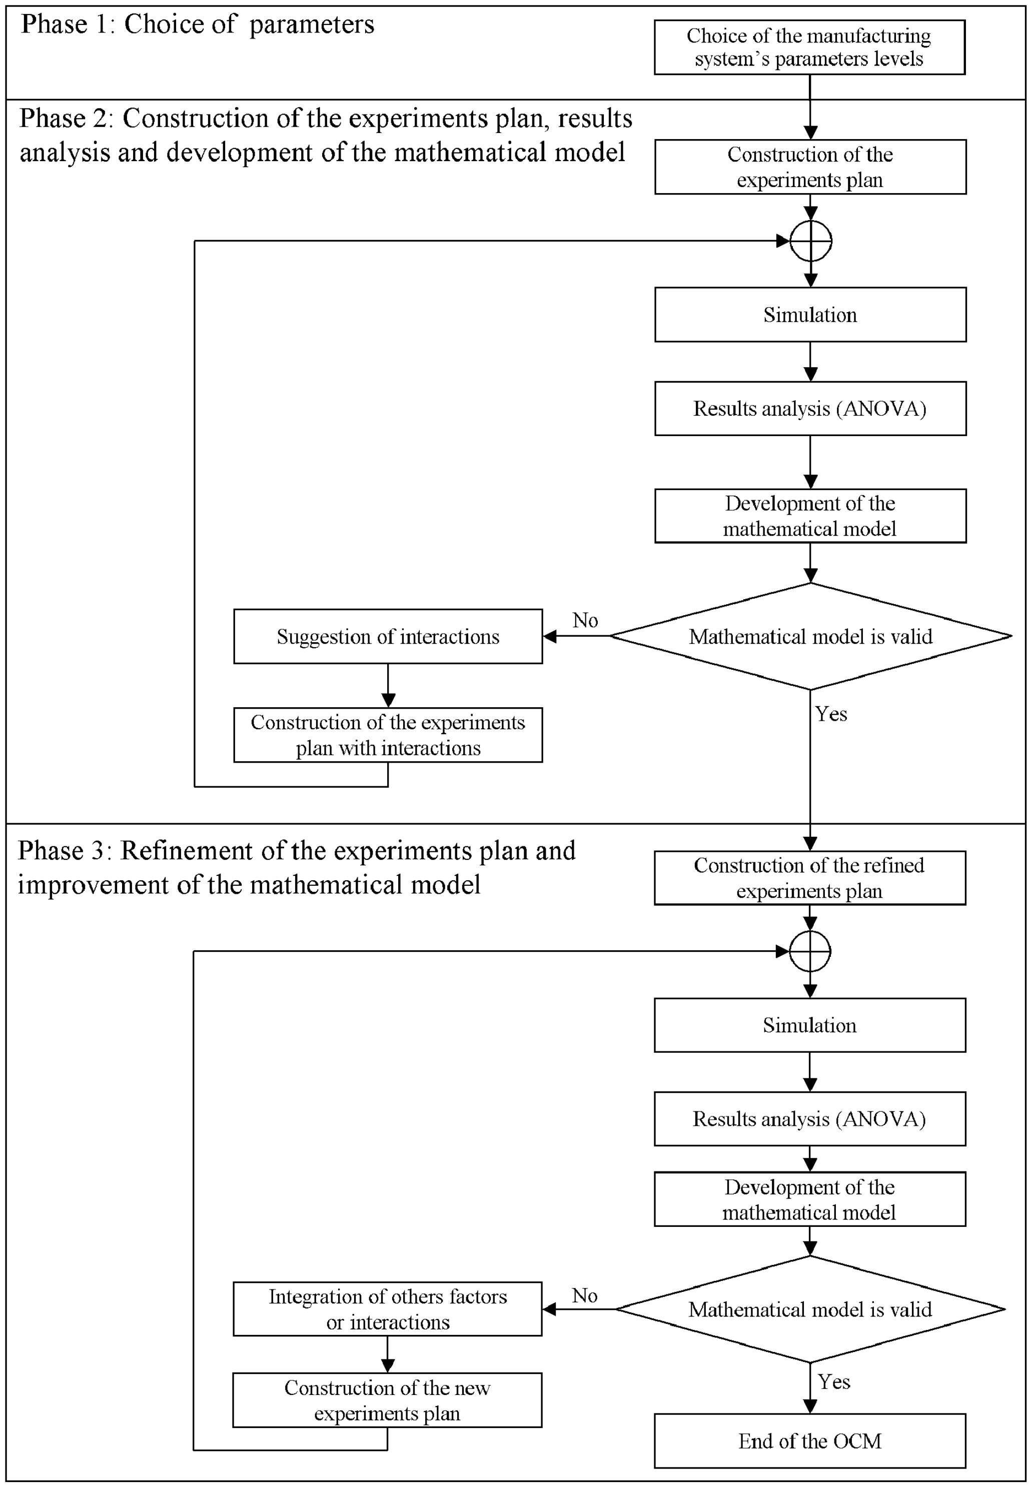
Noise factors are difficult or even impossible to control. Some of these factors could have a direct influence on the MS performances. Hence, instead of controlling them, the methodology aims at determining a solution in terms of CF that is robust relatively to unpredictable variations of *NF*.

Phase 2: Construction of the Experiments Plan, Results Analysis and Development of the Mathematical Model

The main purpose of the second phase of the OCM is to develop the mathematical model. This model gives an interpretation of the SM parameters effect's on the performances of the two layouts. It is developed through the following stages:

- **Stage 1:** An initial plan of experiments is constructed using standard OAs developed by Taguchi (Taguchi, Elsayed, & Hsiang, 1989). This plan is a set of experiments (simulations) where several CFs levels are varied from an experiment to another. It permits to considerably minimize the experimental effort.
- **Stage 2:** Simulations are conducted and performance measures of the two layouts are collected. The performance measures are expressed using the signal to noise ratio (*S/N*). This ratio is an essential indicator of the ability of the system to perform robustly in the presence of some noise effect (Park, 1998). There are three type of *S/N* ratios: lower-the-better (LB), nominal-the-

Figure 3. Overview of the OCM



best (NB), and higher-the-better (HB). In the OCM, the HB type *S/N* is used.

- L is better than FL, it is proposed to maximize the HB type S/N characterizing the MFT ratio MFTFL/MFTCL
- **Stage 3:** Simulations results are then analyzed by the analysis of variance method (ANOVA). The ANOVA establishes the relative significance of CFs in terms of their percentage contribution to the response (Phadke, 1989; Ross, 1996). The relative significance of CFs is translated by the Fischer factor "*F*" (Montgomery, 2001). The ANOVA also estimates the variance of error.
- **Stage 4:** The mathematical model is developed by interpolating the CFs effects. The validity of the developed mathematical model is then verified through the confirmation experiment. This experiment consists of adopting in an extra simulation experiment the best levels of CFs. If the average of the results of the confirmation experiment is within the limits of the confidence interval (CI) of the predicted result, then the mathematical model is considered confirmed (Kiefer, 1977). Hence the OCM can move to the following phase. Otherwise, interactions between CFs are taken in account in a new model. The second phase of the OCM is then reiterated from the third stage. This cycle should be reiterated as much as necessary to get a valid mathematical model. In each iteration, the insignificant interactions must be eliminated and replaced by other interactions.

Phase 3: Refinement of the Simulation Plan and Improvement of the Mathematical Model

The purpose of this phase is to refine the simulation plan and to improve the mathematical model developed in the second phase. So, in this plan, only the most significant CFs and CFIs are considered. Besides, for each CF, additional levels are investigated to study the non-linearity effect of the process factors. This phase is very similar to the second phase. Indeed, it essentially includes the same main stages. Only the choice of factors and interactions to integrate in the mathematical model is different. Once the improved mathematical model developed, its validity is tested.

Academic Case Study

The studied MS is inspired from the comparison study of Morris and Tersine (1990). This MS is composed by 30 machines grouped in 8 departments in the FL and 5 cells in the CL. It is also characterized by 30 part types grouped in 5 families. Every part family is composed of 6 part types. Each part type requires from 2 to 6 production operations. In addition, no inter-cell moves are required.

The FL and CL simulation models were developed using the ARENA commercial software. Observations were then collected for two performance measures: *MFT* and *Throughput*. The second measure is used solely for warm up period detection. The results show that a warm up period of 200000 minutes is needed. The models can then be run for 800000 minutes.

Choice of MS Parameters

The CFs are here studied using two levels each as depicted in Table I. It is worth noting that the original level corresponds to the level initially used in the MS.

Initial plan of Experiments

Each of the two level CFs has 1 degree of freedom (DOF). Hence, the total degree of freedom (TDOF) required for the studied seven CFs is 8 [=7×1+1]. As per Taguchi's method the total experiments number of the selected OA must

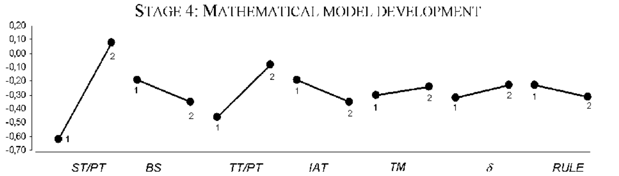
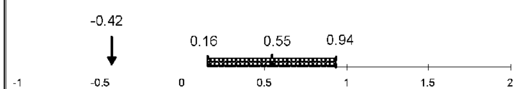
STAGE 4: MATHEMATICAL MODEL DEVELOPMENT



STAGE 5: MATHEMATICAL MODEL CONFIRMATION RESULTS



be greater than or equal to the TDOF, an $L_8(2^7)$ OA was selected for the initial experiments plan (Taguchi et al., 1989). This OA has seven columns and eight experiment-runs (rows). The seven CFs are assigned to the OA columns as depicted in Figure 4 (stages1&2). Every suggested experiment by the OA is then run for 2 replications in order to compute the *S/N* ratios. Results are shown in Figure 4 (stages 1&2). The results of ANOVA indicate that only the CFs *ST/PT*, *TT/PT*, *BS* and *IAT* are statistically significant (Figure 4-stage 3). Figure 4 (stage4), that depicts the main effects of the CFs, confirms these remarks. In this figure, the importance of the CF is expressed by its slope.

Based on the computed *S/N* ratios, the mathematical model is developed by linear interpolation. In this model, every CF can take one of two values: 1 or 2, depending on the chosen parameter level:

$$S / N = -1.53 + 0.70 \times (ST / PT) - 0.16 \times BS + 0.38 \times (TT / PT) - 0.16 \times IAT + 0.07 \times TM + 0.09 \times \delta - 0.08 \times RULE \quad (1)$$

Then, the confirmation experiment considers the maximum value of *S/N* ratio to choose optimum levels of the CFs. Hence the chosen levels are ST/PT_2, TT/PT_2, IAT_1, BS_1, δ_2, TM_2 and $RULE_1$ where X_i is the ith level of the control factor *X*. In this case, the expected result in terms of *S/N* ratio is 0.55 Db. The computed 95% confidence interval is equal to CI=±0.39 Db. Therefore, the expected result should lie between 0.16 Db and 0.94 Db. As depicted in Figure 4 (stage5) the best expected response of -0.42 Db obtained by the confirmation experiment is outside the limits of the CI. The mathematical model is hence considered invalid. Additional analysis and experimentation are needed.

Simulation Plan with Interactions

Two additional iterations were needed to obtain a valid mathematical model. Only the results of the second iteration are depicted here. Based on the first iteration simulation plan ANOVA results, the simulation plan in the second iteration considers *TT/PT×RULE*, *ST/PT×RULE*, *ST/PT×BS*, *BS×RULE, TT/PT×BS, IAT×RULE* and *IAT×BS* as CFIs. Each of these CFIs has 1 DOF. The required TDOF is then equal to14 [=7×1+6×1+1]. Hence, the $L_{16}(2^{15})$ is the OA to use. This OA has fifteen columns and sixteen experiment-runs. The factors were assigned to the $L_{16}(2^{15})$ OA us-

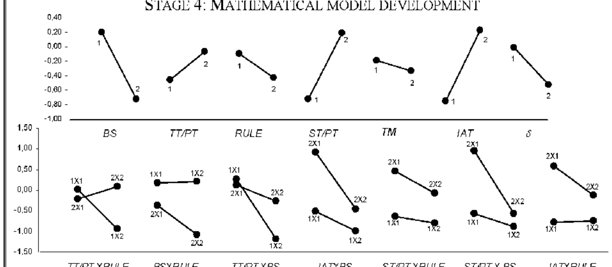
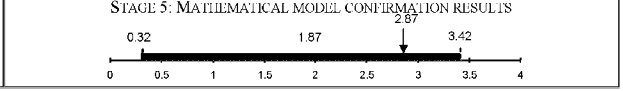
STAGE 4: MATHEMATICAL MODEL DEVELOPMENT



STAGE 5: MATHEMATICAL MODEL CONFIRMATION RESULTS



ing the linear graphs displayed in the Figure 5 (stages1&2). This figure also shows the associated simulation results.

ANOVA results indicate that only the CFs *BS*, *ST/PT*, *IAT* and δ are statistically significant (Figure 5- stage 3). It also demonstrates that only the CFIs $TT/PT \times RULE$, $TT/PT \times BS$ and $ST/PT \times BS$ are statistically significant. Figure 5 (stage4) illustrates the main effects of the CFs and CFIs. In this figure the importance of a CFI is expressed by the slope difference between the interaction two curves. The mathematical model is then developed:

$$\begin{aligned} S / N = & -4.44 + 1.70 \times BS - 3.12 \times (TT / PT) \\ & + 0.54 \times RULE + 3.26 \times (ST / PT) - 0.14 \\ & \times TM + 3.45 \times IAT - 0.51 \times \delta + 1.26 \\ & \times (TT / PT) \times RULE - 0.73 \times BS \times RULE \\ & + 1.08 \times (TT / PT) \times BS - 0.89 \times IAT \\ & \times BS - 0.36 \times (ST / PT) \times RULE - 1.20 \\ & \times (ST / PT) \times BS - 0.75 \times IAT \times RULE \end{aligned} \quad (2)$$

The levels of the CFs in the confirmation experiment are as follows: BS_1, TT/PT_2, $RULE_1$, ST/PT_2, TM_1, IAT_2, δ_1. Two confirmation trials were conducted and results show that the developed mathematical model is valid (Figure 5-stage5).

Refinement of the Simulation Plan and Improvement of the Mathematical Model

The refined simulation plan considers the control factors *BS*, *ST/PT*, *IAT* and δ in addition to the CFI $ST/PT \times BS$. In addition to the two studied levels, each of the three CFs was analyzed by way of a third level. This additional level corresponds to the original level as depicted in Table 1. Hence, the required TDOF is 13 [=4×2+1×4+1]. So, the $L_{27}(3^{13})$ OA was selected for the refined simulation plan and the CFs were assigned to this array using the linear graphs displayed in the Figure 6 (stages1&2). This figure depicts also the OA and

Table 1. Control factors

CF	Original Level	Level 1	Level 2
ST/PT	3	1	5
IAT	Exp (525) mn	Exp (420) mn	Exp (630) mn
δ	0.35	0.2	0.5
BS	38	25	50
RULE	*RL*	*RL*	*FCFS*
TM	With operations overlapping	With operations overlapping	Without operations overlapping
TT/PT	0.8 for FL ; 0.3 for CL	0.4 for FL ; 0.15 for CL	1.2 for FL ; 0.45 for CL

the simulation results. It's worth noting that the original levels of the unused CFs in the refined plan (*RULE*, *TM* and *TT/PT)* are chosen (Table 1).

The analysis of simulation results shows that only *ST/PT* and *BS* are significant (Figure 6-stage3). This observation is confirmed by the Figure 6 (stage4) that illustrates the main effects of the CFs and CFIs. The developed mathematical model is written as follows:

$$S / N = -3.83 - 0.59 \times (ST / PT)^2 - 0.15 \times BS^2 - 0.12 \times IAT^2 - 0.01 \times \delta^2 - 0.11 \times (ST / PT)^2 \times BS^2 + 0.47 \times (ST / PT)^2 \times BS + 0.43 \times (ST / PT) \times BS^2 - 2.17 \times (ST / PT) \times BS + 3.94 \times (ST / PT) + 0.65 \times BS + 0.68 \times IAT - 0.06 \times \delta \quad (3)$$

The confirmation experiment shows that the developed mathematical model is valid (Figure 6-stage5).

The MS manager can use this mathematical model to determine the best layout of its MS machines. He can also investigate the effect of the change of one or several CFs levels on performances of the two layouts. In fact, if the computed *S/N* ratio value is negative then the FL is the outperforming layout. In contrary, if the predicted *S/N* ratio value is positive then the CL outperforms the FL. Finally, the two layouts performances are considered equivalents if the *S/N* ratio value predicted by the mathematical model is close to zero. Table 2 depicts the CL and FL superiority contexts expressed as combinations of the CFs.

This table can be used by the manager to determine the more effective layout for every one of the 81 possible level combinations of the four considered CFs. In deed, the intersection between the line that represents the combination of the *ST/PT* and *BS* levels and the column corresponding to the *IAT* and δ levels gives the best performing layout. For example, the CL is the best layout for the following CFs levels combination: ST/PT_2, BS_1, IAT_2 and δ_2.

The mathematical model can also be used to predict the best layout for "intermediate levels" of the CFs *ST/PT*, *BS*, *IAT* andδ. Indeed unlike the *TM* and *RULE* CFs which are discrete and can be investigated only for specified levels, *ST/PT*, *BS*, *IAT* andδ are continuous factors. For example for the following setting combination: $ST/PT_{1.5}$, $BS_{2.2}$, $IAT_{1.4}$ and $\delta_{2.4}$ the FL outperforms the CL. In this case, le level X_i of the CF X is obtained by linear interpolation between the different levels of this CF.

CONCLUSION

This chapter presents an objective methodology for comparing functional and cellular layouts. This methodology aims to help MS managers choosing the appropriate layout for their manufacturing system. The developed methodology is based on the Taguchi method for the design of experiments and results analysis combined to discrete event simulation. This method permits, through a minimal experimental effort, to reliably evaluate the effect of each MS parameters on the system performances. It also reveals the possible interactions between MS parameters. The goal of this methodology is the development of a mathematical model predicting the superiority of one of the two layouts. In fact, once developed and validated, the mathematical model can be used by

Table 2. Level combinations giving layout superiority

		IAT_1			IAT_2			IAT_3		
		δ_1	δ_2	δ_3	δ_1	δ_2	δ_3	δ_1	δ_2	δ_3
ST/PT_1	BS_1	FL	FL	FL	FL	FL	FL	FL	FL	FL
	BS_2	FL	FL	FL	FL	FL	FL	FL	FL	FL
	BS_3	FL	FL	FL	FL	FL	FL	FL	FL	FL
ST/PT_2	BS_1	CL	CL	CL	CL	CL	CL	CL	CL	CL
	BS_2	FL	FL	FL	CL	FL&CL	FL	CL	CL	FL&CL
	BS_3	FL	FL	FL	FL	FL	FL	FL	FL	FL
ST/PT_3	BS_1	CL	CL	CL	CL	CL	CL	CL	CL	CL
	BS_2	CL	CL	CL	CL	CL	CL	CL	CL	CL
	BS_3	FL	FL	FL	CL	CL	CL	CL	CL	CL

the MS manager to predict the *S/N* ratios for any combination of the MS parameters. The sign of the predicted *S/N* ratio indicates the best layout. The model can also be exploited to interpolate the results between the studied levels of continuous parameters such as batch inter arrival time or batch size. An academic case study showed the capacity of this methodology for choosing the best layout for a MS.

The developed methodology can find direct applications in the industry. However, many aspects of the comparison methodology should undergo further developments. The first task is the enlargement of the application scope to other control factors such as various levels of the number of operators or different degrees of the operator's qualification. In addition, in order to minimize the effort provided by the MS manager, the automation of coupling between the simulator and the analyze software is also projected. This should increase the chance of the proposed methodology to be successfully applied and validated on real cases.

ABSTRACT

It is generally expected that future and emerging nanoscale computing devices will be built in a bottom-up way from vast numbers of simple, densely arranged components that exhibit high failure rates, are relatively slow, and connected in an unstructured way. Other than that, there is little to no consensus on what type of technology and computing architecture holds most promises to go far beyond today's top-down engineered silicon devices. Highly structured crossbar-like and cellular automata architectures have been proposed as possible alternatives to the von Neumann computing architecture, which is not generally well suited for emerging, massively parallel and fine-grained nanoscale electronics. While the top-down engineered semi-conducting technology favors regular and locally interconnected structures, emerging bottom-up self-assembled devices tend to have to be unstructured and heterogeneous because of the current lack of precise control over these processes. In this paper, we survey and assess two types of random dynamical networks, namely Random Boolean Networks (RBNs) and Random Threshold Networks (RTNs), as candidates for alternative computing architectures and models for future nanoscale information processing devices. In a high-level approach that is based on previous work, we illustrate that they have the potential to offer superior properties over highly structured crossbar- or mesh-like cellular automata architectures, such as an inherent and scale-invariant robustness, more efficient communication capabilities, manufacturing benefits for bottom-up self-assembled devices, and the ability to learn and solve tasks successfully. We also show that RBNs can learn and generalize. Our investigation is driven by the need for alternative computing and manufacturing paradigms to mitigate some of the challenges traditional approaches face.

DOI: 10.4018/978-1-4666-1945-6.ch090

INTRODUCTION AND MOTIVATION

The advent of multicore architectures and the slowdown of the processor's operating frequency increase are signs that CMOS miniaturization is increasingly hitting fundamental physical limits. A key question the industry faces is how computing architectures will evolve as we reach these fundamental limits. What type of device and architecture will guarantee a sustainable and continuous progress in the information and communication technology for the next 10-20 years? A likely possibility within the realm of CMOS technology is that the integration density will cease to increase at some point, instead, only the number of components, i.e, the number of transistors, will continue to increase, which will lead to chips with a higher area. This trend can be observed with current multi-core architectures, and is expected to continue. Besides the unsolved challenge of programming large multi-core systems, the trend has implications on the interconnect architecture, the power consumption and heat dissipation, and the reliability. Another possibility lies in the smooth and incremental transition to hybrid systems, which combine traditional silicon technology with new nano- and molecular-scale components, such as carbon nanotubes and nanowires. Yet another possibility is to go beyond silicon-based technology and to radically change the computing and manufacturing paradigms, by using for example bottom-up self-assembled devices. Self-assembling nanowires (Ferry, 2008) or carbon nanotube electronics (Avouris, Chen, & Perebeinos, 2007) are promising candidates, although none of them has resulted in electronics that is able to compete with traditional CMOS so far. What seems clear is that the current way with build computers and the way we algorithmically solve problems with them may need to be fundamentally revisited. The goal of this paper is to explore such a radical new approach and to evaluate its potential.

While the top-down engineered CMOS technology favors regular and locally interconnected structures, future bottom-up self-assembled devices tend to have irregular structures because of the current lack of precise control over these processes. We therefore hypothesize that, compared to current CMOS technology, which allowed engineers to implement a logic-based computing architecture with extreme precision and reliability, future and emerging computing architectures will be increasingly driven by manufacturing constraints and particularities. Independent of the emerging device and fabrication technologies, we assume in this paper that future nanoscale devices will be built from (1) vast numbers of densely arranged devices that (2) are arranged and interconnected in some unstructured way and that (3) exhibit high failure rates. We take this working hypothesis for granted in this paper and address it from a perspective that focuses on the interconnect topology. This is justified by the fact that the importance of interconnects on electronic chips has outrun the importance of transistors as a dominant factor of performance (Meindl, 2003; Ho, Mai, & Horowitz, 2001; Davis et al., 2001). The reasons for that are twofold: (1) the transistor switching speed for traditional silicon is much faster than the average wire delays and (2) the required chip area for interconnects has increased.

In (Zhirnov, Cavin, Leeming, & Galatsis, 2008), Zhirnov et al. explored integrated digital *Cellular Automata* (CA) architectures—which are highly regular structures with local interconnects (see Section)—as an alternative paradigm to the von Neumann computer architecture for future and emerging information processing devices. They argue that CAs are well suited for semiconductor technology, which "[…] favors the realization of regular, locally connected structures […]." Here, we are interested to explore and assess a more general class of discrete dynamical systems, namely *Random Boolean Networks* (RBNs) and *Random Threshold Networks* (RTNs), for emerging technologies. We will focus on RBNs, but RTNs are included in this paper because they offer an alternative paradigm to Boolean logic, which offers significant potential for new and efficient devices.

We are interested to provide answers to the following questions:

- Do RBNs and RTNs offer benefits over CA-architectures? If yes, what are they?
- How does the interconnect complexity compare between RBNs/RTNs and CAs?
- Does any of these architectures allow to solve certain problems more efficiently?
- Is any of these architectures inherently more robust to simple errors?
- Can CMOS and beyond-CMOS devices provide a benefit for the fabrication of any of these architectures?

We will argue and illustrate that—at least from a theoretical perspective—random dynamical networks offer superior properties over classical regular CA-based architectures, such as inherent robustness as the system scales up, more efficient information communication capabilities, and manufacturing benefits for bottom-up fabricated devices, which motivates this investigation. We will present recent results on the dynamic behavior and robustness of such random dynamical networks while also including manufacturing issues in this mini-assessment.

To answer the above questions, we will present and extend recent results on the complex dynamical behavior of discrete random dynamical networks (Rohlf, Gulbahce, & Teuscher, 2007), their ability to solve problems (Mesot & Teuscher, 2005; Teuscher, Gulbahce, & Rohlf, 2007), novel interconnect paradigms (Teuscher, 2007; Teuscher & Hansson, 2008), damage spreading in spatial and small-world networks (Lu & Teuscher, 2009), and self-assembled interconnect models (Teuscher et al., 2009).

RANDOM DYNAMICAL NETWORKS

Random Boolean Networks

A *Random Boolean Network* (RBN) (Kauffman, 1968; Kauffman, 1984; Kauffman, 1993) is a discrete dynamical system composed of N nodes, also called *automata*, *elements* or *cells*. Each automaton is a Boolean variable with two possible states: $\{0,1\}$, and the dynamics is such that

$$F : \{0,1\}^N \mapsto \{0,1\}^N , \tag{1}$$

where, $F = (f_1, \ldots f_i, \ldots f_N)$, and each f_i is represented by a look-up table of inputs randomly chosen from the set of N nodes. Initially, K_i neighbors and a look-table are assigned to each node at random. Note K_i (i.e., the fan-in) can refer to the *exact* or to the *average* number of incoming connections per node.

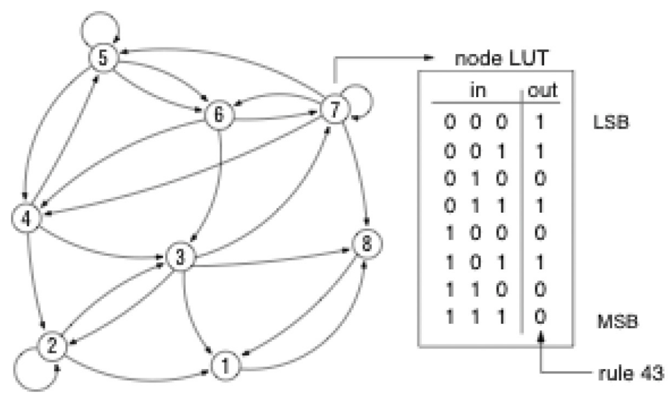
A node state $\sigma_i^t \in \{0,1\}$ is updated using its corresponding Boolean function:

$$\sigma_i^{t+1} = f_i(x_{x_{i_1}}^t, x_{x_{i_2}}^t, \ldots, x_{x_{K_i}}^t) \tag{2}$$

These Boolean functions are commonly represented by *lookup-tables* (LUTs), which associate a 1-bit output (the node's future state) to each possible K-bit input configuration. The table's out-column is called the *rule* of the node. Note that even though the LUTs of a RBN map well on an FPGA or other memory-based architectures, the random interconnect in general does not.

We randomly initialize the states of the nodes (initial condition of the RBN). The nodes are updated synchronously using their corresponding Boolean functions. Other updating schemes exist, see for example (Gershenson, 2003) for an overview. Synchronous random Boolean networks as introduced by Kauffman are commonly called *NK* networks or models. Figure 1 shows a pos-

Figure 1. Illustration of a random Boolean network with N=8 nodes and K=3 inputs per node (self-connections are allowed). The node rules are commonly represented by lookup-tables (LUTs), which associate a 1-bit output (the node's future state) to each possible K-bit input configuration. The table's out-column is commonly called the rule of the node



sible *NK* random Boolean network representation (N=8, K=3).

Random Threshold Networks

Random Threshold Networks (RTNs) are another type of discrete dynamical systems. An RTN consists of N randomly interconnected binary sites (spins) with states $\sigma_i = \pm 1$. For each site i, its state at time t+1 is a function of the inputs it receives from other spins at time t:

$$\sigma(t+1) = \text{sgn}(f_i(t)) \tag{3}$$

with

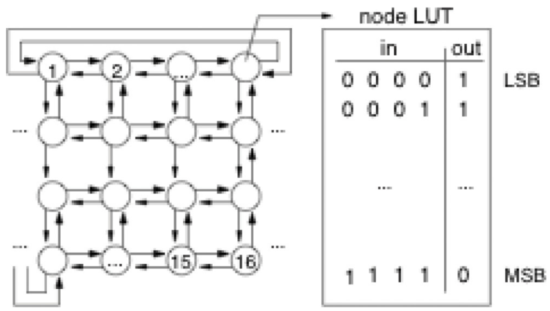
$$f_i(t) = \sum_{j=1}^{N} c_{ij}\sigma_j(t) + h \tag{4}$$

The N network sites are updated synchronously. In the following, the threshold parameter h is set to zero. The interaction weights c_{ij} take discrete values c_{ij}=+1 or ↕1 with equal probability. If i does not receive signals from j, one has c_{ij}=0.

CELLULAR AUTOMATA ARCHITECTURES

Cellular automata (CA) (Wolfram, 1984) were originally conceived by Ulam and von Neumann (Neumann, 1966) in the 1940s to provide a formal framework for investigating the behavior of complex, extended systems. CAs are a special case of the more general class of random dynamical networks, in which space and time are discrete. A CA usually consists of a D-dimensional regular lattice of N lattice sites, commonly called *nodes*, *cells*, *elements*, or *automata*. Each cell i can be in one of a finite number of S possible states and further consists of a transition function (also called *rule*), which maps the neighboring states to the set of cell states. CAs are called *uniform* if all cells contain the same rule, otherwise they are *non-uniform*. Each cell takes as input the states of the cells within some finite local neighborhood. Here, we only consider non-uniform, two-dimensional (D=2), folded, and binary CAs (S=2) with a radius-1 von Neumann neighborhood, where each cell is connected to each of its four immediate neighbors only. Figure 2 illustrates such an CA. The Boolean functions in each node must therefore define 2^4=16 possible input combinations. To

Figure 2. Illustration of a binary, 2D, folded cellular automaton with N=16 cells. Each node is connected to its four immediate neighbors (von Neumann neighborhood)



be able to compare CAs with RBNs, we do not consider self-connections.

DAMAGE SPREADING AND CRITICALITY

Random Boolean and Threshold Networks

As we have seen above, RBNs and their complex dynamic behavior are essentially characterized by the average number of incoming links (fan-in) per node (e.g., Figure 1 shows a *K*=3 network with 3 incoming links per node). It turns out that in the thermodynamic limit, i.e., $N \to \infty$, RBNs exhibit a dynamical order-disorder transition at a sparse critical connectivity (Derrida & Pomeau, 1986) (i.e., where each node receives on average two incoming connections from two randomly chosen other nodes), which partitions their operating space into 3 different regimes: (1), sub-critical, where $\left\langle K \right\rangle < K_c$, (2) complex, where $\left\langle K \right\rangle = K_c$, and (3) supercritical, where $\left\langle K \right\rangle > K_c$. In the sub-critical regime, the network dynamics are too "rigid" and the information processing capabilities are thus hindered, whereas in the supercritical regime, their behavior becomes chaotic. The complex regime is also commonly called the "edge of chaos," because it represents the network connectivity where information processing is "optimal" and where a small number of stable attractors exist.

Similar observations were made for sparsely connected random threshold (neural) networks (RTN) (Rohlf & Bornholdt, 2002) for $K_c = 1.849$. For a finite system size *N*, the dynamics of both systems converge to periodic attractors after a finite number of updates. At K_c, the phase space structure in terms of attractor periods (Albert & Barabási, 2000), the number of different attractors (Samuelsson & Troein, 2003) and the distribution of basins of attraction (Bastolla & Parisi, 1998) is complex, showing many properties reminiscent of biological networks (Kauffman, 1993).

RESULTS

In (Rohlf et al., 2007) we have systematically studied and compared damage spreading (i.e., how a perturbed node-state influences the rest of the network nodes over time) at the sparse percolation (SP) limit for random Boolean and threshold networks with perturbations. In the SP limit, the damage induced in a network (i.e., by changing the state of a node) does not scale with system size. Obviously, this limit is relevant to information and damage propagation in many technological and natural networks, such as the Internet, disease spreading in populations, failure propagation in power grids, and networks-on-chips. We measure the damage spreading by the following methodology: the state of one randomly chosen node is changed. The damage is then measured as the Hamming distance between a damaged and undamaged network instance after a large number of *T* system updates. For an electronic system, for example, we can compare such a damage event with a single event upset caused by electromagnetic radiation.

We have shown that there is a characteristic average connectivity $K_s^{RBN} = 1.875$ for RBNs and $K_s^{RTN} = 1.729$ for RTNs, where the damage spreading of a single one-bit perturbation of a network node remains constant as the system size *N* scales up. Figure 3 illustrates this newly discovered point for RBNs and RTNs. For more details, see (Rohlf et al., 2007).

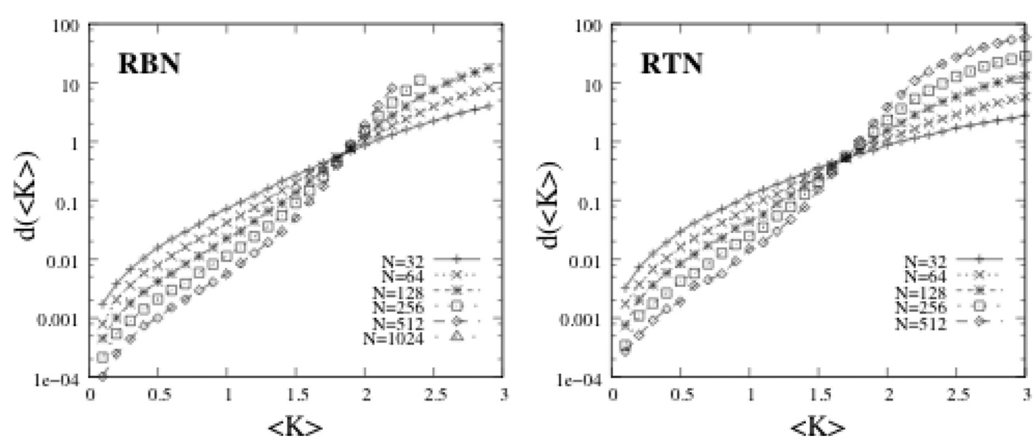
DISCUSSION

Both and are highly relevant for nano-scale electronics for the following reason: assuming we can build massive numbers of *N* simple logic gates that implement a random Boolean function, the above findings tell us that on average, every gate should be connected somewhere close to both and in order to (1) guarantee optimal robustness against failures for any system size and (2) optimal information processing at the "edge of chaos." We are also hypothesizing that natural systems, such as the brain or genetic regulatory networks, may have evolved towards these characteristic connectivities. This remains, however, to be proved and is part of ongoing research.

Cellular Automata

We have used the same approach as described above to measure the damage spreading in cellular automata. In order to vary the average number $\langle K \rangle$ of incoming links per cell in a cellular automata (e.g., as pictured in Figure 2), we have adopted the following methodology: (1) for a desired average number of links per cell $\langle K \rangle$ for a given CA size of *N* cells, the total number of links in the automaton is given by $L=N\langle K \rangle$; (2) we then randomly choose *L* possible connec-

Figure 3. Average Hamming distance (damage) $\langle d \rangle$ after 200 system updates, averaged over 10,000 randomly generated networks for each value of $\langle K \rangle$, with 100 different random initial conditions and one-bit perturbed neighbor configurations for each network. For both RBN and RTN, all curves for different N approximately intersect in a characteristic point K_s



tions on the regular CA-grid with uniform probability and establish the links. Damage is induced in the same way as for RBNs and RTNs: the state of one (or several) randomly chosen node(s) is changed. The damage is measured as the Hamming distance between a damaged and undamaged CA instance after a large number of T system updates, in our case T=200.

RESULTS

Figures 4, 5, and 6 show the average damage of both RBNs and CAs for different system sizes and for a damage size of 1 and 10 respectively. We have left out RTNs for this analysis. As one can see, both the RBN and the CA average damage for different N approximately intersect in the characteristic point $K_s^{RBN} = 1.875$. This point is less pronounced for the larger damage sizes (Figures 5 and 6). The reasons for this are finite size effects because the damage becomes too big compared to the system size. This can be seen in Figure 6 for the RBN *N=100* curve, which represents an outlier, i.e., does not intersect well with the other curves. The RBN curves confirm what was already shown above in Figure 3, and are merely plotted here for comparison with the CA architectures and their system sizes imposed by square lattices.

Interestingly, the CAs show different damage propagation behavior for different system sizes and connectivities. First, we observe that the average damage for one-bit damage events (Figure 4) is independent of the system size N for up to approximately $\langle K \rangle$=2.5 average incoming connections per cell. This behavior disappears completely for large damage sizes (Figure 6). Second, Figure 4 shows that all curves intersect at $K_s^{RBN} = K_s^{CA} = 1.875$. Third, Figure 6 suggest that for larger damage sizes, K_s^{CA} disappears for CAs. Fourth, the average damage for larger damage events, i.e., 10 and 20 in our examples, converges to the same final values for both RBNs and CAs as $\langle K \rangle$ approaches 4.

Figure 4. Average Hamming distance (damage) $\langle d \rangle$ after 200 system updates, averaged over 100 randomly generated networks for each value of $\langle K \rangle$, with 100 different random initial conditions and a damage size of 1 node for each network. See text for discussion

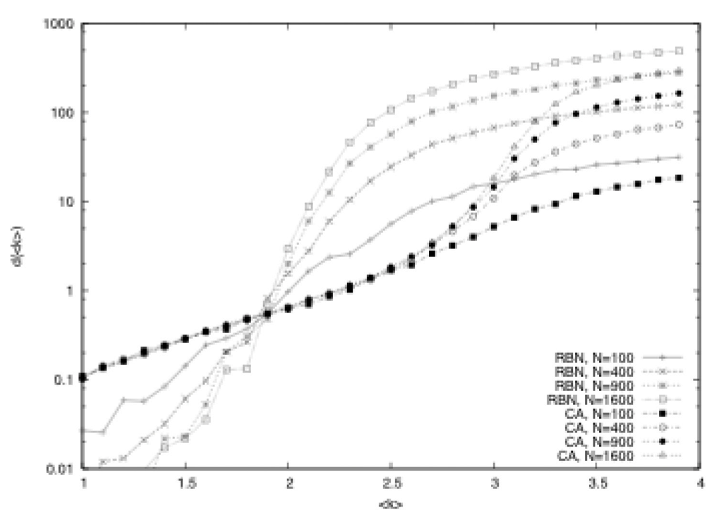


Figure 5. Average Hamming distance (damage) $\langle d \rangle$ *after 200 system updates, averaged over 100 randomly generated networks for each value of* $\langle K \rangle$*, with 100 different random initial conditions and a damage size of 10 nodes for each network. See text for discussion*

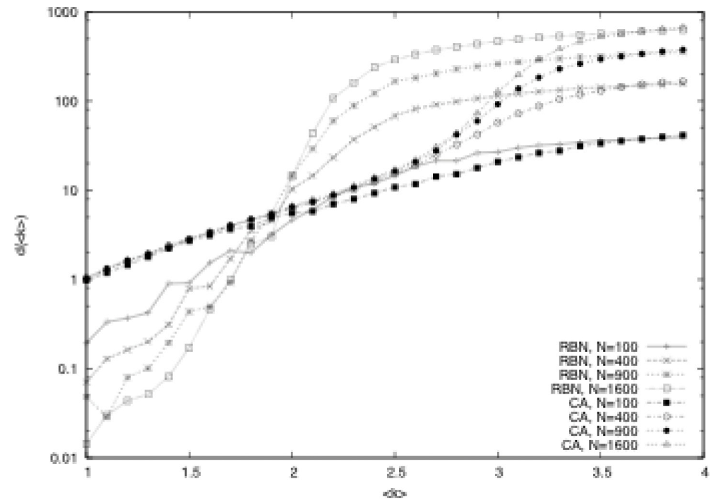
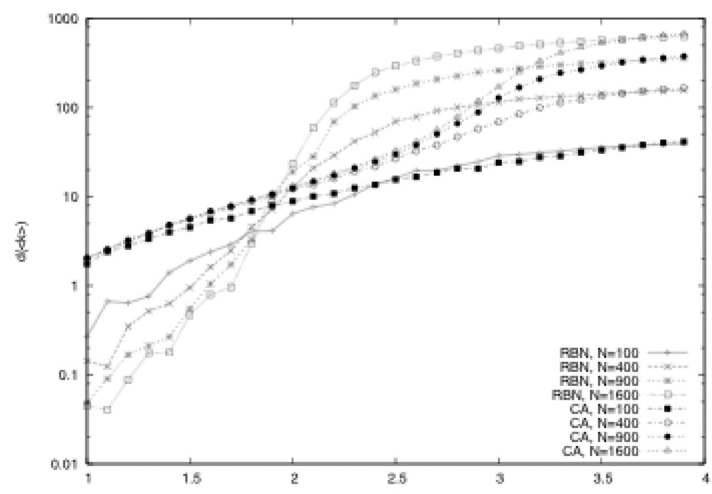


DISCUSSION

We hypothesize that the particular behavior can be explained by the percolation limit of the cellular automata. Da Silva et al. (Silva, Hanson, & Roux, 1989) found that the link probability at the percolation limit is approximately $p \sim 0.6$, which means that the average connectivity at the perco-

Figure 6. Average Hamming distance (damage) $\langle d \rangle$ *after 200 system updates, averaged over 100 randomly generated networks for each value of* $\langle K \rangle$*, with 100 different random initial conditions and a damage size of 20 nodes for each network. See text for discussion*



lation limit in our CA topology with a maximum of 4 neighbors is given by $\langle k \rangle$=4*p*=2.4. This value corresponds to the experimentally observed value where the damage spreading suddenly becomes dependent of the system size. Because of the local CA connectivity, there are lots of disconnected components below the percolation limit. Below this limit, the damage spreading is thus very slow and limited by the disconnected components, reason why it is essentially independent of system size. Above the percolation limit, the CA suddenly becomes connected and damage spreading becomes therefore dependent on the system size. For larger damage events, such as 10 or 20, damage becomes more dependent on system size even below the percolation limit because there is a higher probability that damage is induced in several disconnected components at the same time.

More recently, Lu & Teuscher (Lu & Teuscher, 2009) have also investigated the damage spreading in spatial random networks with extreme local connections and with small-world topologies. They found that spatially local connections change the scaling of the relevant component at very low connectivities ($K \ll 1$), that there is no critical connectivity of stability K_s for locally connected networks, and that the critical connectivity K_s changes to lower values compared to random networks for small-world networks.

In summary: for single-node damage events, CAs offer system-size independent damage spreading for up to about $\langle K \rangle = 2.4$ (which corresponds to the percolation limit), however, this particular behavior disappears for larger damage events. We conclude that in the general case, CAs do not possess a characteristic connectivity K_s, where damage spreading is independent of the system size N. Such a connectivity, however, exists for both RBNs and RTNs, which makes them particularly suitable as a computing model in an environment with high error probabilities or systems with low system component reliabilities. Examples are logical gates based on bio-molecular components (Benenson et al., 2001), where high failure rates can be expected.

COMPLEX NETWORKS AND WIRING COSTS

Most real networks, such as brain networks (Sporns, Chialvo, Kaiser, & Hilgtag, 2004; Eguéluz, Chialvo, Cecchi, Baliki, & Apkarian, 2005), electronic circuits (Cancho, Janssen, & Sole, 2001), the Internet, and social networks share the so-called *small-world* (SW) property (Watts & Strogatz, 1998). Compared to purely locally and regularly interconnected networks (such as for example the CA interconnect of Figure 2), small-world networks have a very short average distance (measured as the number of edges to traverse) between any pair of nodes, which makes them particularly interesting for efficient communication.

The classical Watts-Strogatz small-world network (Watts & Strogatz, 1998) is built from a regular lattice with only nearest neighbor connections. Every link is then rewired with a *rewiring probability p* to a randomly chosen node. Thus, by varying *p*, one can obtain a fully regular (*p*=0) and a fully random (*p*=1) network topology. The rewiring procedure establishes "shortcuts" in the network, which significantly lower the average distance (i.e., the number of edges to traverse) between any pair of nodes. In the original model, the length distribution of the shortcuts is uniform since a node is chosen randomly. If the rewiring of the connections is done proportional to a power law, $l^{-\alpha}$, where l is the wire length, then we obtain a *small-world power-law network*. The exponent α affects the network's communication characteristics (Kozma, Hastings, & Korniss, 2005) and navigability (Kleinberg, 2000a), which is better than in the uniformly generated small-world network. One can think of other distance-proportional distributions for the rewiring, such as for example a Gaussian distribution, which has been found between certain layers of the rat's neocortical pyramidal neurons (Hellwig, 2000).

In a real network, it is fair to assume that local connections have a lower cost (in terms of the associated wire-delay and the area required) than long-distance connections. Physically realizing small-world networks with uniformly distributed long-distance connections is thus not realistic and distance, i.e., the wiring cost, needs to be taken into account, a perspective that recently gained increasing attention in complex networks community (Petermann & Rios, 2006). On the other hand, a network's topology also directly affects how efficient problems can be solved.

Teuscher (Teuscher, 2007; Teuscher et al., 2009) has pragmatically and experimentally investigated important design trade-offs and properties of an irregular, abstract, yet physically plausible 3D small-world interconnect fabric that is inspired by modern network-on-chip paradigms. The results confirm that (1) computation in irregular assemblies is a promising and disruptive computing paradigm for self-assembled nano-scale electronics and (2) that 3D small-world interconnect fabrics with a power-law decaying distribution of shortcut lengths are physically plausible and have major advantages over local 2D and 3D regular topologies, such as CA interconnects. More recently, Teuscher et al. (Teuscher et al., 2009) proposed two simple growth models for non-classical nanowire interconnects with the goal to both the cost and the communication of such networks. They have also used an evolutionary algorithm to evolve optimal network topologies under given cost and communication constraints.

DISCUSSION

There is a trade-off between (1) the physical realizability and (2) the communication characteristics for a network topology. A locally and regularly interconnected topology, such as that of a CA, is in general easy to build (especially for top-down engineered CMOS technology) and only involves minimal wire and area cost (as for example shown by Zhirnov et al. (V. Zhirnov et al., 2008)), but it offers poor global communication characteristics and scales-up poorly with system size. On the other hand, a random topology, such as that of RBNs or RTNs, scales-up well and has a very short-average path length, but it is not physically plausible because it involves costly long-distance connections established independently of the Euclidean distance between the nodes. The RBN and RTN topologies we consider here as thus extremes, such as CA topologies. The ideal topology lies in between: small-world topologies with a distance-dependent distribution of the connectivity. Such topologies are located in a unique spot in the design space and also offer two other highly relevant properties (Kleinberg, 2000b; Teuscher, 2007): (1) efficient navigability and thus potentially efficient routing, and (2) robustness against random link removals. For these reasons, we can conclude that small-world graphs are the most promising interconnects for future massive scale devices. This outcome is further supported by the quantitative analysis presented in (Teuscher at al., 2009): unstructured network-on-chip topologies obtained by the growth models show specific wire-length distributions that are beneficial for the communication and minimize the wiring cost.

These outcomes seem contradictory with Bilardi & Preparata (Bilardi & Preparata, 1995) argument that future architectures will naturally be driven toward regular and locally interconnected architectures. However, our findings have a different starting point, namely a set of computing nodes randomly distributed in space, which is motivated by the way we imagine such a system would be fabricated. Given that physical arrangement, we then ask the question of what the optimal interconnect is.

SOLVING TASKS WITH RANDOM BOOLEAN NETWORKS

In their pioneering work, Carnevali & Patarnello (Carnevali & Patarnello, 1989) used two global stochastic optimization techniques, *Simulated Annealing (SA)* and *Genetic Algorithms (GA)*, to train feedforward random Boolean networks to solve computational tasks. Paternello and Carnevali showed that global stochastic optimization is able to train networks for simple memorization and generalization tasks. Teuscher et al. (Teuscher et al., 2007) used the same techniques to train random Boolean networks and showed that they can successfully solve simple computational tasks as well. Their preliminary results also hinted at the effect of the critical connectivity on the training and generalization performance. In this section we first replicate the above-mentioned results and then analyze the dynamics of learning and generalization in RBNs. In particular, we investigate how the network connectivity influences these dynamics.

EXPERIMENTAL SETUP

For our purpose, we use genetic algorithms to train the networks for solving the bitwise AND, the even-odd, and the mapping task. The bitwise AND task consists of calculating the bitwise logical AND of two l-bit binary numbers. The networks thus have a $2 \times l$-bit inputs and an l-bit output. For the even-odd task, we have an l-bit binary input and a one-bit output. The output is one if the number of 1s in the input is an odd number, and 0 otherwise. The mapping task consists of an l-bit input and an l-bit output. The task consists of producing the same number of 1s in the output as there are in the input, but without considering the order of the bits. In order to perform these tasks with RBNs, we add additional input and output nodes to the regular network nodes. These nodes are connected randomly to other nodes in the network. While the input nodes only provide the input signals to the network, the output nodes may also compute a Boolean function.

In order to use GAs, we encode the network into a bit-stream that consists of both the network's adjacency matrix and the Boolean transfer functions for each node. The genetic operators consist of the standard mutation and one-point crossover operators that are applied to the genotypes in the network population. We further define a fitness function f and a generalization function g. For an input space N of size n and an input sample M of size m we write:

$$E_M = \frac{1}{m}\sum_{j\in M} d(j),\ f = 1 - E_M$$

where $d(j)$ is the Hamming distance between the network output for the j-th input in the random sample from the input space and the expected network output for that input. Similarly, we write:

$$E_N = \frac{1}{n}\sum_{i\in n} d(i),\ g = 1 - E_N$$

where $d(i)$ is the Hamming distance between the network output for the i-th input from the entire input space and the expected network output for that input.

The simple genetic algorithm we use to train the network is as following:

1. Create a random initial population of S networks.
2. Evaluate the performance of the networks on a random sample of the input space.
3. Apply the genetic operators to obtain a new population.
4. Continue with steps 2 and 3 until at least one of the networks achieves a perfect fitness or after G_{max} generations are reached.

While optimizing feedforward networks, we have to make sure that the mutation and crossover operators do not violate the feedforward topology of the network. Also, there is a subtle difference between feedforward RBNs and general (recurrent) RBNs: since recurrent RBNs can have feedback loops and thus have memory, we have to take into account the dynamical properties of the network and run them long enough to ensure they fall into an attractor. The network size N and the connectivity K determine the length of the transients, however, due to ambiguous outputs on cyclic attractors, we further calculate the majority activation of the output nodes over a number of time steps equal to the size of the network.

Carnevali & Patarnello (Carnevali & Patarnello, 1989) introduced the notion of *learning probability* as a way of describing the learning and generalization capability of their feedforward random networks. They defined the learning probability as the probability of the training process yielding a network with perfect generalization, given that the training achieves perfect fitness on a sample of the input space. To calculate this measure, we run the training process r times and store both the f and g values.

RESULTS

Figure 7 and 8 show the learning probability of feedforward RBNs on the even-odd and the bitwise AND task for $K = 2$ networks. As one can see, as the size of the input space increases, the training process requires a smaller number of training examples to achieve a perfect learning probability. We tune the GA parameters, such as the variation rate and the maximum number of generations

Figure 7. The learning probability of feedforward networks on the bitwise AND task on different problem sizes. As the number of input bits increases, the learning process requires a smaller fraction of the input space during the training to achieve a perfect learning score. $N = 50$, $K = 2.0$, $G_{max} = 3000$, initial population size = 50, crossover rate = 0.6, mutation rate = 0.3. The GA was repeated for 700 times

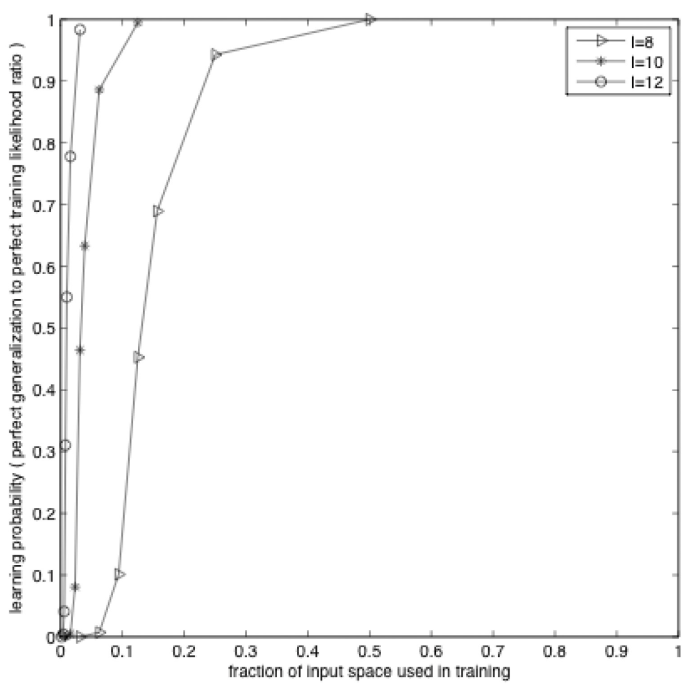


Figure 8. The learning probability of feedforward networks on the even-odd task for various input sizes. As the number of input bits increases, the learning process requires a smaller fraction of the input space during the training to achieve a perfect learning score. For I = 3, some of the networks can solve a significant number of patters without training because the task is too easy. N = 50, K = 2.0, G_{max} = 3000, initial population size = 50, crossover rate = 0.6, mutation rate = 0.3. The GA was repeated for 700 times

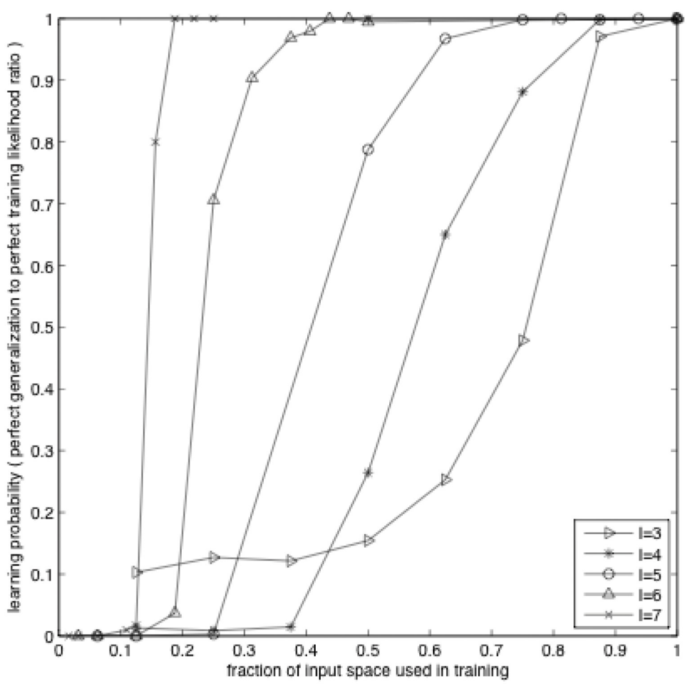
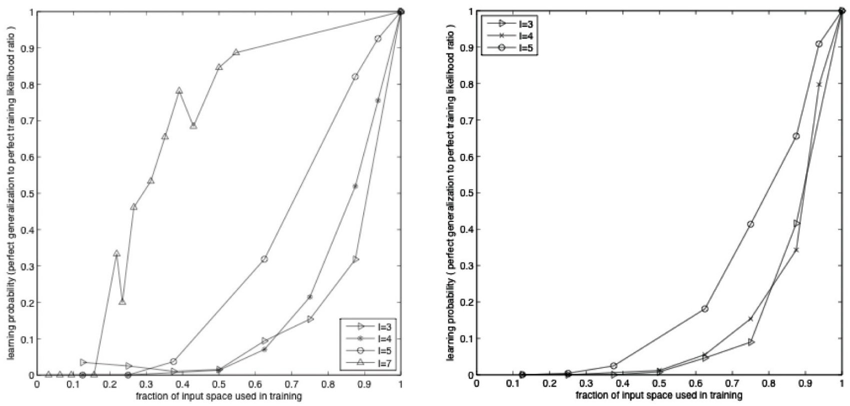


experimentally, depending on how quickly we achieve perfect fitness on average. These result directly confirm Carnevali & Patarnello (Carnevali & Patarnello, 1989) experiments.

Next, we create the same learning probability curves for RBNs to show that they too can solve these simple tasks. Figure 9 illustrates the results for the even-odd task. Similar to feedforward networks, we observe that as the problem size increases, a lower proportion of training samples is required to achieve high learning probabilities. On the other hand, we observe that it is more difficult to get the network to learn the tasks. The network reaches a learning probability of 1 only when we use the entire input space during the training phase. The average node inputs $\langle K \rangle$ in this experiment was 2.0, so all networks were in the critical regime. To see how the three connectivity regimes (i.e., subcritical, critical, supercritical) affect the learning probability, we generated network populations of various $\langle K \rangle$ to solve the even-odd task with five input bits.

Figure 10 (left) shows the learning probability of RBNs with different average *K*s for the even-odd task for five inputs (i.e., the input space has 32 patterns). As one can see, networks with supercritical connectivity ($\langle K \rangle = 3.0$) achieve a lower learning probability than the networks at the "edge of chaos" ($\langle K \rangle = 2.0$ and $\langle K \rangle = 2.5$) and at subcritical connectivities ($\langle K \rangle = 1.0, 1.5, 1.875, 1.95$). However, networks with subcritical connectivity show a interesting jump from zero to perfect learning probability when the training sample size reaches 0.6. For $\langle K \rangle = 2.0, 2.5$, and 3.0, the network

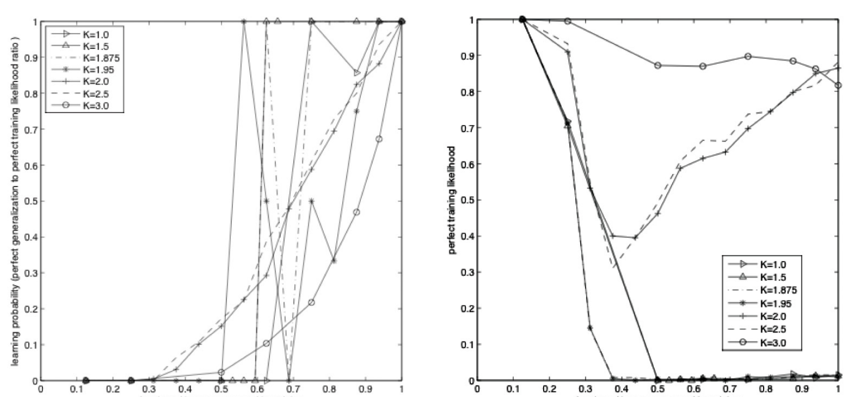
Figure 9. (left) The learning probability of RBNs for the even-odd task for various input sizes. N = 20, <K> = 2, G_{max} = 500. To calculate the likelihood we repeated the GA 500 times. (right) The learning probability of RBNs for the mapping task for various input sizes. N = 40, <K> = 2, G_{max} = 1000. We calculated the likelihoods over 260 runs. For both the mapping and even-odd tasks we used an initial population size of 50, a crossover rate of 0, and mutation rate of 0.7 for the GA



achieves some level of learning probability with smaller sample sizes (Figure 10 (left)).

Figure 10 (right) shows the training probability for the even-odd task. We see that subcritical K networks make the training very difficult. As the input sample size increases, the amount of information in the samples also does and subcritical networks do not have the flexibility to learn the task easily. On the other hand, networks in the complex and chaotic regime can easily learn the task. Moreover, although the critical $\langle K \rangle$ = *2* networks have more difficulty in learning the samples, they can generalize better, and thus have a higher learning probability than the networks with supercritical connectivity, which simply memorize the patterns they have learned.

Figure 10. (left) Learning probability of RBNs with different average K for even-odd task with five inputs. (right) Training probability of RBNs with different K for even-odd task with five inputs. N = 20, G_{max} = 500, initial population size = 50, crossover rate = 0, mutation rate = 0.7. We calculated the likelihood over 400 runs



DISCUSSION

We have shown that both feedforward and general (recurrent) RBNs can solve simple tasks and are able to generalize. While critical networks generalize better then subcritical and supercritical networks, the solution is harder to find. Our results show that there is great potential in training such networks more complex tasks and that the control of statistical properties of the network topology during the learning phase is an important parameter of generalization success.

MANUFACTURING ISSUES

As Chen et al. (Chen et al., 2003) state, "[i]n order to realize functional nano-electronic circuits, researchers need to solve three problems: invent a nanoscale device that switches an electric current on and off; build a nanoscale circuit that controllably links very large numbers of these devices with each other and with external systems in order to perform memory and/or logic functions; and design an architecture that allows the circuits to communicate with other systems and operate independently on their lower-level details."

While we can currently build switching devices in various technologies besides CMOS (see (V. V. Zhirnov, Hutchby, Bourianoff, & Brewer, 2006; Bourianoff, Brewer, Cavin, Hutchby, & Zhirnov, 2008; Hutchby, Cavin, Zhirnov, Brewer, & Bourianoff, 2008) for an overview), one of the remaining challenges is to assemble and interconnect these switching devices (or logic functions) to larger systems, and ultimately to design a computing architecture that allows to perform reliable computations. As mentioned before, there is little consensus in the research community on what type of technology and computing architecture holds most promises for the future.

The motivation for investigating randomly assembled interconnects and computing architectures can be summarized by the following observations:

- long-range and global connections are costly (in terms of wire delay and of the chip area used) and limit system performance (Ho et al., 2001);
- it is unclear whether a precisely regular and homogeneous arrangement of components is needed and possible on a multi-billion-component or even Avogadro-scale assembly of nano-scale components (Tour et al., 2002)
- "[s]elf-assembly makes it relatively easy to form a random array of wires with randomly attached switches" (V. V. Zhirnov & Herr, 2001); and
- building a perfect system is very hard and expensive

We have hypothesized in (Teuscher & Hansson, 2008) and (Teuscher, 2007) that bottom-up self-assembled electronics based on conductive nanowires or nanotubes can lead to the random interconnect topologies we are interested in, however, several questions remain open and are part of a 3-year interdisciplinary research project at Los Alamos National Laboratory (LANL). Our approach consists in using a hybrid assembly (as others explore as well, e.g., (Ferry, 2008)), where the functional building blocks will still be traditional silicon in a first step, while the interconnect is made up from self-assembled nanowires. Nanowires can be grown in various ways using diverse materials, such as metals and semiconductors. We have chosen a novel way to grow conductive nanowires, which Wang et al. (Wang, Li, Akhadov, & Jia, 2007) at LANL have pioneered and demonstrated: Ag nanowires can be fabricated on top of conducting polyaniline polymer membranes via a spontaneous electrodeless deposition (self-assembly) method. We hypothesize that this will allow to densely interconnect silicon components in a simple and cheap way with specific distance-dependent wire-length distributions. We believe that this approach will ultimately allow us to easily and cheaply fabricate RBN-like computing architectures.

Random threshold networks, on the other hand, could be rather straightforwardly and efficiently implemented with resonant tunneling diode (RTD) logic circuits (see e.g., (Pettenghi, Avedillo, & Quintana, 2008)), and represent a very interesting alternative to conventional Boolean logic gates. The reported results in this paper on random threshold networks can thus directly be applied to the implementation of such devices. There has been a significant body of research in the area of threshold logic in the past (see e.g., (Muroga, 1971)), but to the best of our knowledge, random threshold networks have not been considered as computing models for future and emerging computing machines.

CONCLUSION

The central claim of this paper is that locally interconnected computing architectures, such as cellular automata (CA), are in general not appropriate models for large-scale and general-purpose computations. We have supported this claim with recent theoretical results on the complex dynamical behavior of discrete random dynamical networks, their robustness to damage events as the system scales up, their ability to efficiently solve tasks, and their improved transport characteristics due to the short average path length. In a nutshell, the arguments why we believe that CAs are *not* promising architectures for future information-processing devices, are as following:

- their local interconnect topology is not small-world and has thus worse global transport characteristics (than small-world or random graphs), which directly affects the effectiveness of how general-purpose algorithmic tasks can be solved.
- in terms of a complex dynamical system, they operate in the supercritical regime () with the widely used von Neumann neighborhood, which makes them sensitive to initial conditions;
- they do not generally have a characteristic connectivity K_s, where damage spreading is independent of system size, which makes a system inherently robust; and
- it is unclear whether a precisely regular and homogeneous arrangement of components is possible at the scale of future information processing devices.

We have assessed RBNs and RTNs as alternative models, however, as we have seen above, they come at a serious cost: the uniform probability to establish connections with any node in the system independent of the Euclidean distance between them is not physically plausible and too expensive in terms of wiring cost. The ultimate interconnect topology is small-world and has a distance-dependent distribution of the wires (Teuscher, 2007; Teuscher & Hansson, 2008; Petermann & Rios, 2006). It was also been confirmed recently (Lu & Teuscher, 2009) that a critical connectivity K_s exists for such small-world networks as well.

OPEN QUESTIONS AND UNADDRESSED ISSUES

Naturally, there are a number of open questions and issues that we have not addressed because they are beyond the scope of this paper. In particular, an irregular topology with random logical functions makes the mapping of a given digital circuit much harder, if not impossible in certain cases. On the other hand, a regular interconnect topology clearly makes the mapping task easier. We believe, however, that automated design tools can address this challenge. After all, computation in random assemblies is not completely new and has been more or less successfully tried by others, e.g., (Patwardhan, Dwyer, Lebeck, & Sorin, 2006; Lawson & Wolpert, 2006, Tour et al., 2002), however in different contexts and with a different perspective in mind than we have presented here.

We have deliberately *not* focused on any particular application in this paper because our results are independent of the application. However, it is noteworthy that locally interconnected CAs have been proven to outperform other general purpose architecture on very specific applications. A good example are cellular neural networks (CNNs) (Chua & Roska, 2002), which, e.g., allow to perform certain image processing tasks orders of magnitude faster than any other machine.

Further, it is unknown at this point how exactly our findings fit into the interconnect predictions made by Rent's rule, however, the rule may not be applicable to our non-traditional circuits since it is based on empirical results. Further research on this is planned.

Last but not least, we would like to mention that, although we have only considered 2D arrangements and interconnects here for simplicity, the future is clearly 3D (e.g., see (Pavlidis & Friedman, 2007)). The main reason is that the average wire length in 3D is shorter than in 2D interconnects.

OUTLOOK

We believe that computation in random self-assemblies of simple components and interconnections is a highly appealing paradigm, both from the perspective of fabrication as well as performance and robustness. Future work will focus on (1) the manufacturing issues, (2) appropriate design methodologies, (3) addressing the mapping issues, and (4) more realistic models, which will allow to better assess the performance and cost, and (5) specific applications.

ENDNOTE

1 This paper is a significant extension of work first presented at the Nanoarch 2008 workshop, Anaheim, CA, USA, Jun 12-13, 2008, and subsequently published in (Teuscher et al., 2009b). This present chapter contains a new section on "Solving Tasks with Random Boolean Networks."

This work was previously published in Theoretical and Technological Advancements in Nanotechnology and Molecular Computation: Interdisciplinary Gains, edited by Bruce MacLennan, pp. 295-314, copyright 2011 by Information Science Reference (an imprint of IGI Global).

Chapter 91
Creative Regions in Europe:
Exploring Creative Industry Agglomeration and the Wealth of European Regions

ABSTRACT

This chapter examines the existence of regional agglomerations of manufacturing, service and creative industries, and the relationship between these industries and the wealth of regions. Through an analysis of 250 European regions, three important conclusions can be inferred from the results obtained in this chapter. The first is that creative industries play an important role in the wealth of the regions. The second is that the most creative regions are characterized by having more high-tech manufacturing industries than the rest of the regions, although the number of low-tech manufacturing firms is similar. Lastly, in the richest regions, a greater share of high-tech manufacturing industries coexists with a greater share of creative industries. The importance of this chapter resides in the fact that up until now no analysis has demonstrated that creative industries are the most important industries in regional wealth.

1. INTRODUCTION

The localization of creative industries, as highlighted by the work of Stam et al. (2008), Cooke (2008), Lazzeretti et al. (2008), Capone (2008) and Power and Nielsen (2010), is an area of increasing importance in the literature on geographic agglomerations. These industries are in fact groupings of specific sectors of low-technology manufacturing and knowledge-intensive services, which is why their importance is related to the ever-increasing dependence of manufacturing sectors on service industries (Peneder et al., 2003; Pilat and Wölfl,

DOI: 10.4018/978-1-4666-1945-6.ch091

2005; Drejer and Vinding, 2005; Wood, 2006; Aslesen and Isaksen, 2007b), and on what we could call the *Knowledge and Service Economy* (Windrum and Tomlinson, 1999; Bishop, 2008; Aslesen and Isaksen, 2007a; Aslesen and Isaksen 2007b; Strambach 2008).

Existing studies show which activities can be included in creative industries (UNCTAD, 2010), and why these industries form agglomerations (Lazzeretti et al., 2009; Lorenzen and Frederiksen, 2008). However, although the existence of relationships between manufacturing and services agglomerations in their different definitions of high and low (Leydesdorff et al., 2006; Leydesdorff and Fritsch, 2006; Vence-Deza and González-López, 2008; Heidenreich, 2009) have been the aim of some analyses, the above mentioned analyses have not been carried out to examine the possible relationship between manufacturing agglomerations – including both high and low-tech industries – and creative industries. This paper attempts to fill this gap. In addition, the core importance of the paper is based on the fact that it points out empirically how important creative industries are in developing economies and bringing prosperity to European regions. The results obtained have implications for academia as well as for policymakers.

The empirical study is based on a sample of 250 regions in 24 European countries. The data was taken from Eurostat's *Structural Business Statistics* and *Regional Economic Accounts* databases. The data was used to evaluate manufacturing, service and creative industry agglomerations based on the *Location Quotient* (LQ) of firms by regions. Following this, the relationship between these agglomerations and GDP was verified.

Three important conclusions are pointed out. The first is that creative industries play an important role in the wealth of a region. The second is that the most creative regions are characterized by having more high-tech manufacturing sectors than others, although they have a similar share of low-tech manufacturing firms. The third is that in the richest regions a greater share of high-tech manufacturing industries coexists with a greater share of creative industries, thus showing the importance of creativity.

The outline that we have used in this paper is as follows: in Sections 2 we briefly summarize the recent basic theory on the study of maps of manufacturing, service and creative industry agglomerations to determine the localization patterns and the relationships they have on the aforementioned studies. In Section 3, we include the empirical study where we set out the variables used, the sources the data was extracted from and the methodology used for their study as well as the results obtained. Conclusions can be found in Section 4.

2. MAPS OF AGGLOMERATIONS IN MANUFACTURING, SERVICES AND CREATIVE INDUSTRIES

The maps of agglomerations in manufacturing, services and creative industries are representations of sectors which are located in a geographic zone, whether it is a city, region or country. Examples of these maps can be found in studies on the different terminologies used to name these agglomerations according to their characteristics: industrial districts, clusters, milieux and Local Production Systems. Therefore, we have maps of sectoral concentrations for most of the European countries (Becattini and Coltorti, 2006; Crouch and Farrel, 2001; Pitelis and Pseiridis, 2006; Boix and Trullén, 2011).

Recently, the study of maps of clusters and districts has acquired a new dimension, in which instead of limiting the localization of the different industries and services at separate levels, the maps are more aggregated. Examples of the former can be found in the studies carried out by Becattini and Coltorti (2006), who point out the different industrial districts in Italy – the shoe industry located in Brenta, Fermano Maceratese and Verona, the tile industry in Sassuolo and the textile industry in Prato and Biella, among others. In Spain, these types of studies have also been carried out by Boix and Trullén (2011), among others and the same has occurred in the majority of European countries and on other continents. At first, the agglomerations studied corresponded to industry while the service sector (O'Donoghue and Gleave, 2004) was incorporated later as its influence on the economies increased. Pilat and Wölfl (2005) have pointed out that this increase is the result of the relationship between manufacturing and service industries and because the former tends to subcontract some activities to firms with specialized services located in the same country or in a foreign country. Studies such as the one by Heidenreich (2009) found that regions specialize either in manufacturing or in services, while Wood (2006) pointed out the dependence that manufacturing has on services, and especially knowledge-intensive services (KIS).

In Table 1 we have included the sectors that come under manufacturing and services industries from the NACE Rev.2 classification and have separated them according to their technology and knowledge levels.

A specific case study of agglomerations which includes manufacturing and services of different types is that of *creative industries* (Stam et al. 2008; Lazzeretti et al., 2008; Capone, 2008; De Propis et al., 2009; Power and Nielsén, 2010). According to Pratt (2008), it was toward the end of the 1990s when this terminology began to be used in Europe, to be more precise, when the British Department for Culture, Media and Sport (DCMS) drew up its map of creative industries in 1998.

The question about which activities are creative was influenced by the inclusion of activities that involve copyright or other intellectual property (Towse, 2010). The most widely extended definition of creative industries is that of the DCMS (2009) which defined creative industries, as "those industries that are based on individual creativity, skill and talent. And which have the potential to create wealth and jobs through developing intellectual property." Howkins (2005) believes that it "is more consistent to restrict the term to an industry where intellectual labour is predominant and the result is intellectual property." UNCTAD (2010) considers creative industries as "any economic activity producing symbolic products with a heavy reliance on intellectual property and for as wide a market as possible." The difference is in the DCMS's use of the term "individual," which has been argued by some authors (Healy, 2002; Garnham, 2005; Pratt, 2005; O'Connor, 2007).

The most comprehensive taxonomy of creative industries, which is particularly appropriate to cross-country comparisons has been proposed by UNCTAD (2010). Table 2 contains the transformation to NACE Rev 2 of these activities, separating them by manufacturing or service industries. It has been verified that creative industries are made up of sectors pertaining to low-tech manufacturing and knowledge-intensive services, although the majority of the sectors included are service industries and especially KIS.

When comparing the definition of creative industries as per the British Department for Culture (Pratt 2008, DCMS 2009) with the characteristics attributed to KIS sectors (Nählinder, 2005; Doloreux et al., 2008; Strambach, 2008; Muller and Doloreux, 2009; Shearmur and Doloreux, 2009), both make reference to the talent and abilities of persons and firms to create knowledge (Larsen, 2001; Aslesen and Isaksen, 2007b).

Secondly, the most aggregated analysis studies high, medium and low-technology manufacturing sectors globally, sometimes separately (Cooke et al, 2007, chap. 8), and other times jointly (Robertson and Patel, 2007). The differences in technology levels are based on R&D intensity (Hatzichronoglou, 1997), which the OECD uses to establish its four types of manufacturing industries: a) high-technology, b) medium-high-technology, c) medium-low-technology and d) low-technology. What is taken into account in services is knowl-

edge, since the relationship existing between the manufacturing and service sectors allows the latter to transfer knowledge to the former, as well as to create it (Miles, 2008). This is why the analysis of knowledge-intensive services (Bishop, 2008) predominates in the services industry, since they are associated with the *knowledge-based economy* (Windrum and Tomlinson, 1999; Aslesen and Isaksen, 2007a; Bishop, 2008; Strambach, 2008).

Lastly, we find the analysis of the relationship between manufacturing and service agglomerations (Leydesdorff et al. 2006; Leydesdorff and Fritsch, 2006), to which the relationship between agglomerations and wealth – measured by GDP per inhabitant – is sometimes added (Heidenreich, 2009; Vence-Deza and González-López, 2008). However, the relationship with creative industries has not been sufficiently explored.

In the studies currently being carried out on maps at aggregate level, some patterns have been detected with respect to the importance of high-tech sectors in manufacturing and services in relation to the generation of knowledge and to regional wealth (measured by GDP per inhabitant).

There is not a common opinion (Leydesdorff and Fritsch, 2006; Leydesdorff et al., 2006; Robertson and Patel, 2007; Bishop, 2008; Vence-Deza and González-López, 2008; Heidenreich, 2009; The Center for Strategy and Competitiveness, 2009) about whether high-tech manufacturing sectors are the only relevant ones since their importance is usually associated with that of medium-high tech sectors, even though the presence of medium-tech industries is considered important for regional wealth. In the case of service sectors, however, the importance of knowledge-intensive services (KIS) and high-tech knowledge-intensive services (HTKIS, which are included in KIS) can indeed be observed.

Vence-Deza and González-López (2008) pointed out that the principal trend in European regions is towards geographic concentration of high-tech sectors in manufacturing and services and that this concentration takes place in the regions with the greatest GDP per inhabitant. However, Leydesdorff and Fritsch (2006) and Leydesdorff et al. (2006), in two studies for Germany and Holland, verified that medium-tech sectors are much more important than high-tech sectors in the knowledge base of a region or country. It has also been observed that high-tech knowledge-intensive services (HTKIS) are the most important for the service sector while other knowledge-intensive services (OKIS) have a lesser effect on the territorial knowledge base.

In Heidenreich's opinion (2009), the richest regions – those with a high GDP – are those which have a high percentage of jobs both in high-tech sectors as well as in medium high-tech manufacturing sectors and in knowledge-intensive services (KIS), but have a low percentage of jobs in low and medium-tech manufacturing sectors. The Center for Strategy and Competitiveness (2009) in its study on KIBS (knowledge-intensive business services) sectors in Europe found that regions with strong KIBS sectors had the highest prosperity levels in Europe. Contrary to this finding, Bishop (2008) argues that for the United Kingdom development depends on diversification rather than depending solely on KIS sectors or on any other single sector. It is not strange to reach this conclusion for the United Kingdom, which is one of the countries that places greatest importance on the role of creative industries. Therefore, the evidence is not really clear about what type of industries determine the wealth of regions.

Our next question refers to the relationship between industries and whether the studies existing at present show a regional trend towards specialization in high or low sectors.

Heidenreich (2009) found a pattern in European regions where low and medium low-tech (LMT) sectors coexist with high and medium-high sectors, but did not find a similar situation in manufacturing and services, i.e., in regions which specialize in manufacturing and services.

Accordingly, Robertson and Patel (2007) evidenced the compatibility between high-tech manufacturing and low-tech manufacturing industries. Therefore, in European countries, the presence of high-tech manufacturing industries is compatible with the presence of low-tech manufacturing industries.

Regarding to creative industries, Power (2002, 2003), Cooke (2008), Stam et al. (2008), Lazzeretti et al. (2008), Capone (2008), De Propris et al (2009), Baum et al. (2009), and Power and Nielsén (2010) have studied their location from an aggregated viewpoint. These studies conclude that creative industries tend to be located in the major urban areas of each country.-

In terms of the relationship between location and wealth, the DCMS creative industries concept expresses "their potential for wealth and job creation." Power and Nielsén (2010) found that creative and cultural industries are located in the wealthiest European regions, while Stam et al. (2008) showed that the presence of the creative class has a higher impact on employment growth than creative industries. Baum et al. (2009) also pointed out that locations need human capital if they intend to prosper in creative industries.

In our empirical study we have broadened these conclusions to include the study of creative regions which has not been carried out previously.

3. METHODOLOGY

a) Sample and Variables

The sample comprises 250 European regions. The data for this study was compiled from Eurostat's *Structural Business Statistics* (SBS) and *Regional Economic Accounts (REA)* databases and corresponds to 2008. The countries whose data was not available, such as Greece, Luxembourg and Malta, were not included.

The variables extracted were used to calculate the *Location Quotient* (LQ) for manufacturing (high, medium-high, medium-low and low tech), services (HTKIS, OKIS and LKIS) and creative industries for each region with relation to EU-27. The Location Quotient (LQ) is an indicator of the existence of industrial agglomerations in a region. The formula used in our study is presented in Exhibit 1.

Additionally, the data on GDP per inhabitant for each region was taken in order to examine its relationship with creative industries and to compare it with the results in reference to manufacturing and services.

The following statistical calculations were carried out based on the aforementioned limitations. First, the correlations between industries were calculated to find out in which cases there were positive or negative correlations as well as their correlation with respect to GDP per inhabitant. Second, a cluster analysis was carried out to see whether groups of regions by GDP per inhabitant and the number of creative agglomerations could be established. An analysis of whether there were norms with respect to high-tech and low-tech manufacturing agglomerations was carried out on groups of clusters of more or less creative regions.

b) Results

b.1) Results of the Correlations

The results of the correlations are shown in Table 3. To analyze them, we focused first on the cor-

Exhibit 1. LQ formula

$$LQd = \frac{\text{Firms in NACE}_i \text{ in region A / Total firms in NACE}_i \text{ in EU}}{\text{Manuf. or service firms in region A / Total manuf. or service firms in EU}}$$

(1) Excluding wearing apparel, leather, and printing, included in "creative industries."

(2) Includes only telecommunications and information service activities as the rest (motion picture, video and television, sound recording and music, broadcasting, computer programming, and scientific research and development) are included in "creative industries."

(3) Excluding publishing, architectural and engineering activities, advertising, and arts, entertainment and recreation, included in "creative industries."

(4) Excluding retail sale of other goods in specialized stores, included in "creative industries."

Source: Eurostat. *Structural Business Statistics* (SBS) Database relations between sectors without taking GDP into account. Afterwards we looked at the correlations between GDP and industry (manufacturing and services).

From the results in Table 3, the following can be deduced:

- The results of the relationship between manufacturing sectors show that there is a positive correlation between high-tech manufacturing, medium-high manufacturing and medium-low manufacturing sectors. However, the correlation is negative between high-tech and low-tech non-creative sectors, and between medium-high and low-tech non-creative sectors. Consequently, the results do coincide with those of Heidenreich (2009), who concluded that high and medium-high coexist with medium-low manufacturing. Robertson and Patel (2007) also found this coexistence.
- High-tech, medium-high and medium-low manufacturing and the three groups of non-creative services are correlated. Therefore, contrary to what Heidenreich (2009) states, regions do not specialize in manufacturing or in services. Moreover, it is important to notice that low-tech non-creative manufacturing has a negative correlation with knowledge-intensive non-creative services.
- In the case of creative industries, there is a positive correlation with services as well as with manufacturing, except for low-tech non-creative manufacturing.

Based on these initial results, if there is a positive correlation with high-tech industries and knowledge intensive services, then it can be concluded that there are more high-tech industries in creative regions than other types of industries.

If we include the results obtained when relating sectors with GDP per inhabitant, the results obtained show:

- There is a positive correlation between GDP per inhabitant and the localization of high-tech manufacturing industries, medium-high tech manufacturing, OKIS non-creative (other knowledge-intensive non-creative services), and less-knowledge intensive services and creative industries.
- The correlation is negative with low-tech non creative industries.

These results do not coincide with Heidenreich (2009) or Vence-Deza and González-López (2008), who find that the wealth of a region does depend exclusively on high-tech industries and knowledge-intensive services.

Another result shows that there is a positive correlation between GDP per inhabitant and creative industries, which include low-tech manufacturing, HTKIS and OKIS. However, they do not include high-tech manufacturing industries. Therefore, creative regions do not depend exclusively on high-tech industries and knowledge-intensive services, contrary to the findings of Heidenreich (2009), Vence-Deza and González-López (2008).

b.2) Cluster Results

The cluster technique was conducted in order to obtain group structures. Thus, the process was divided into two stages, as recommended by various authors (Punj and Stewart, 1982; Hair et al., 1996:515). In the first phase, a hierarchic method was used to obtain a suitable number of groups, followed by a non-hierarchic method (k-means) to establish the group distribution and definitive composition, based on the number of groups obtained during the first stage. A dendogram was obtained for application in three to five groups. However, in our opinion, it seemed more suitable to choose five groups to show all the diversity

Table 4. Mean of agglomerations in the 5 clusters (Industry agglomerations and GDP PPS per inhabitant)

Agglomerations/ Clusters	1 High-manufacturing regions	2 LKIS regions	3 Intermediate regions	4 Low-tech non-creative regions	5 Super-creative regions
High-tech (LQs)	**2**	0	1	0	**2**
MedHigh-tech (LQs)	**4**	1	1	1	**4**
MedLow-tech (LQs)	3	2	2	2	3
Low-tech non creative (LQs)	2	3	2	4	2
KIHTS non creative (LQs)	1	1	1	1	1
OKIS non creative (LQs)	5	2	2	1	4
LKIS (LQs)	7	6	3	3	6
Creative (LQs)	**4**	1	4	2	**8**
Mean GDP PPS per inhabitant	26,180 (2nd)	22,900 (4th)	23,612 (3rd)	16,780 (5th)	**33,850 (1st)**
Number of regions	69	62	42	44	32

within the European regions. The coincidence between the two methods in the assignment of regions to the groups was 90%. Description of the groups is shown in Table 4.

In addition, the ANOVA analysis applied to each independent variable (LQs) used to obtain the groups revealed that all variables discriminate the classification into the five groups with all of them being significant at $p<0.01$. Additional statistical procedures were based on the ANOVA test to identify the differences between the group of belonging of regions and their GDP pps. The test was significant at $p<0.01$. This exercise shows that the group of belonging or cluster of regions, presents GDP pps differences across regions in general (Table 4). The results we obtained (Table 4) are:

- Five cases can be verified in the clusters depending on whether or not regions are creative, and the importance of all groups of industries. The first are the regions we call *high-manufacturing regions*; the second are the LKIS regions (*less-knowledge intensive services*); the third are the *intermediate regions*; the fourth are the *low-tech non-creative regions*; and the fifth are the *super-creative regions*, which have a higher mean of creative agglomerations than the rest.
- When calculating the mean GDP per inhabitant for these regions we can see that it is highest in the super-creative regions.
- High-manufacturing regions have a mean of agglomerations in all groups of industries which is similar than the super-creative, except for the creative industry group. Both regions have a higher number of OKIS non-creative agglomerations than the others.
- Creative agglomerations in intermediate regions are higher than those in LKIS regions and low-tech non-creative regions.

In super-creative regions there is a greater number of high-tech manufacturing industries and creative industries. However, the mean of low-tech industry agglomerations is very similar in the five clusters. Therefore, we can conclude that in the most creative regions, where the mean GDP per inhabitant is higher, high-tech manufacturing industries go hand in hand with low-tech manufacturing industries, which is comparable to the results obtained by Robertson and Patel (2007).

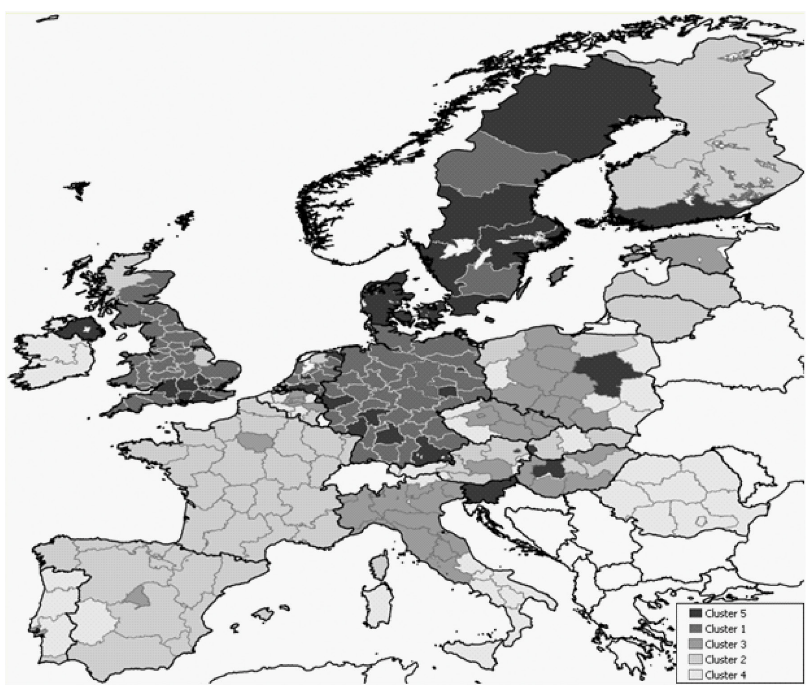
Examples of *super-creative regions* (Figure 1) include Berlin, Hamburg, Utrecht, Northern Holland, Vienna, Stockholm, Inner London, Outer London, Berkshire, Buckinghamshire and Oxfordshire. *High-manufacturing* regions include Düsseldorf, Greater Manchester, East Anglia and Essex. *Intermediate regions* include Madrid, Île de France, Veneto, Lazio and Emilia-Romagna. *LKIS regions* include Catalonia, Valencian Region, Salzburg and Brittany. *Low-tech non-creative regions* include Puglia, Campania and Extremadura.

5. CONCLUSION

This paper strives to answer the question of how much influence the existence of manufacturing, service and creative industrial agglomerations has on a region's wealth. To respond to this question, the industrial agglomerations of manufacturing, services and creative industries of 250 regions in 24 European countries were calculated. Afterwards, the relationships between agglomerations and between agglomerations and GDP were verified.

The studies carried out up until now on the maps of manufacturing and service agglomerations (Leydesdorff and Fritsch 2006, Leydesdorff et al 2006, Vence-Deza and González-López 2008, Heidenreich 2009) have shown the importance of the relationships between both. However, when analyzing whether the most important sectors in the development of a region are high-tech and services, as measured by GDP, the results obtained do not always coincide (Vence-Deza and González-López 2008, Leydesdorff and Fritsch 2006, Leydesdorff et al 2006). Additionally, the studies usually show an incompatibility between the agglomerations of high-tech and low-tech manufacturing sectors within the same region (Heidenreich 2009). Nevertheless, the empirical analysis carried out in this paper demonstrates that this incompatibility should be qualified. In

Figure 1. Regions in the five clusters



fact, in the most creative regions the agglomerations of high-tech manufacturing industries are greater than in the rest of the regions, while they are similar in low-tech manufacturing industries. The compatibility of high-tech and low-tech manufacturing industries was also shown by Robertson and Patel (2007).

In addition, this paper verifies that the wealth of a region is not only related to the agglomerations of high-tech manufacturing industries found in the region, but also to the creative industries found there. Another relationship which has been verified in this paper is the relationship of creative industries and knowledge-intensive services (KIS), which emphasizes their importance in the creation of knowledge and regional development (Windrum and Tomlinson, 1999; Bishop, 2008; Aslesen and Isaksen, 2007a; Strambach, 2008).

Three important conclusions can be inferred from the results obtained in this paper. The first is that creative industries play an important role in the wealth of a region. The second is that the most creative regions are characterized by having more high-tech manufacturing industries than the rest of the regions although the number of low-tech manufacturing industries is similar. Lastly, in the richest regions a greater number of high-tech manufacturing industries coexist with a greater number of creative industries.

The contributions and results found in this work are important for both academia as well as for policymakers. It opens new lines of research for the former in the relationships between industries, as our study goes beyond those carried out on manufacturing and services. Policymakers will find the study of use because the results show the role creative industries play on regional wealth, in addition to demonstrating that the most creative regions have a need for the coexistence of diversified sectors that simultaneously include a high share of both high-tech manufacturing and creative industries.

ACKNOWLEDGEMENT

The authors would like to thank Ministry of Science and Innovation and Universitat Politècnica de València (Spain) for financially supporting this research (ECO2010-17318 MICINN Project and Research Project n. 2677-UPV).

Chapter 92
Design of Manufacturing Cells Based on Graph Theory

José Francisco Ferreira Ribeiro
University of São Paulo, Brazil

ABSTRACT

In this chapter a comparative study is presented between (I) sequential heuristics, (II) simulated annealing, (III) tabu search, and (IV) threshold algorithm for graph coloring and its application for solving the problem of the design of manufacturing cells in a job shop system production. The job shop production system has a very large proportion of all manufacturing activity. The principal concepts of manufacturing cells, graph theory, and heuristics are presented. The results obtained with these algorithms on several examples found in the literature are consistently equivalent with the best solution hitherto known in terms of numbers of inter-cell moves and dimensions of cells.

INTRODUCTION

Over 75% of all parts manufactured in the industry are produced in batches of 50 parts or less. Consequently, the production in batch and the production on demand constitute a considerable proportion of all manufacturing activity (Groover, 1987). Job shop is a production environment that produces parts in small batches. It's a production environment common in small and medium enterprises. The parts require different manufacturing operations and must be performed through various production departments and in different sequences (Oliveira, Ribeiro and Seok, 2009). Orders differ in the number of parts, design, processing times, setup times or urgency. The high demand for machinery and the different production sequences can cause long queues in the shop floor. The consequence is delivery times unreliable, whereas nowadays delivery times should be short and reliable (Ribeiro and Pradin, 1993). Clustering is the task of classifying a collection of objects, such as documents, parts, or machines, into natural categories. Clustering techniques are widely

DOI: 10.4018/978-1-4666-1945-6.ch092

used in many areas such as machine learning, data mining, pattern recognition, image analysis and bioinformatics. The design of manufacturing cells or clustering consists in partitioning the set of parts to be manufactured in an industry into families and the available machines into groups or cells, so that each family is associated with one machine group, and vice-versa. Each family-group pair constitutes a manufacturing cell. This concept lies on grouping similar parts in families, proposing to produce them in cells that have specially selected machines to accomplish this. This procedure leads to greater automation, set up time reduction, standardization of the tools used and a reduction of manufacturing cycles (Ribeiro and Meguelati, 2002). A greater efficiency in management and manufacturing is expected, due to the decomposition of the production global system in sub-systems of reduced dimension. Workshops operating on this principle, called Group Technology (Burbidge, 1975), offer a reduction in unproductive manufacturing time, resulting in greater flexibility, just in time and productivity (Hyer and Wemmerlöw, 1989).

However, the design of manufacturing cells requires the solution of a complex mathematical problem: the block-diagonalization of an incidence matrix [parts × machines] corresponding to the global production system. This block-diagonalization uses as its optimization criterion the minimization of the number of elements in the matrix outside the diagonal blocks. These elements represent inter-cell moves and, in practice, imply undesirable movement of parts to machines in other cells that are not present in the cell to which the part is assigned. That is the reason why, regarding the manufacturing cells, there is an attempt to minimize the number of inter cell moves, at the same time that a balance of workloads between the different cells projected is sought. This is treated as a combinatorial problem for which there is no polynomial time algorithm (Garey and Johnson, 1979), and the most common approach in the literature is to propose heuristic algorithms.

BACKGROUND

A large number of techniques have been used in recent years (Sing, 1993) to hit the block-diagonalization of the matrix, designing manufacturing cells and implementing Group Technology in the industries. For example:

a. Mathematical programming: Won (2000), Albadawi, Bashir, and Chen (2005), Panchalavarapu and Chankong (2005), Slomp, Chowdary, and Suresh (2005), Rajagopalan and Fonseca (2005), Adil and Ghosh (2005), Yin, Yasuda, and Hu (2005), Foulds, French, and Wilson (2006)
b. Branch and bound: Ramabhatta e Nagi (1998), Boulif and Atif (2006)
c. Fuzzy logic: Xu e Wang (1989), Chu and Hayya (1991)
d. Genetic algorithms: Suer, Vásquez, and Peña (1999), Zhao and Wu (2000), Dimopoulos and Mort (2001), Suer, Peña, and Vázquez (2003), Gonçalves and Resende (2004), Hicks (2004), Solimanpur, Vrat, and Shankar (2004), Rajagopalan and Fonseca (2005), Vin, De Lit, and Delchambre (2005), Gonçalves and Tiberti (2006), Jeon and Leep (2006)
e. Neural networks: Lozano, Canca, Guerrero, and Garcia (2001), Guerrero, Lozano, Smith, Canca, and Kwok (2002), Solimanpur, Vrat, and Shankar (2004), Pashkevich and Kazheunikau (2005)
f. Meta-heuristics — tabu search and simulated annealing: Caux, Bruniaux, and Pierreval (2000), Baykasoglu (2003), Spiliopoulos and Sofianopoulou (2003), Xambre and Vilarinho (2003), Cao and Chen (2005)
g. Data analysis: Ribeiro and Pradin (1993), Diallo, Pierreval, and Quilliot (2001), Rios, Campbell, and Irani (2002), Ribeiro and Meguelati (2002), Ribeiro (2003), Oliveira, Ribeiro and Seok (2009)

h. Graph theory: Rajagopalan and Batra (1975), Askin and Chiu (1990), Rath, Das and Sahu (1995), Selim (2002), Ribeiro (2009)

The main different methods from the literature are approximate methods (not optimal), because the problem is NP-complete. The computational time is very high when we use exact methods to solve large-size examples.

GRAPH COLORING

A coloring of a graph G(V, A), with), with V a set of N nodes and A a set of M edges (Matula, Marble, and Isaacson, 1972, Christofides, 1975, Korman, 1979) is an assignment of any color belonging to set of colors C = {ci} for each node of V, where two nodes connected by an edge of A cannot have the same color.

I.e., a coloring of G is a function f: V → C | if (i, j) ∈ A ⇒ f(i) ≠ f(j). A k-coloring of G(V, A) is a coloring with k colors, i.e., a partition of V in k independent sets of nodes.

In this case, G is a k-coloring graph. The chromatic number λ(G) of G is the smaller number of colors for which a k-coloring of G exists. The graph coloring problem is NP-complete (Garey and Johnson, 1979).

It is a high combinatorial problem: for example, a complete and exhaustive enumeration of all colorings consists in an $O(M.k^N)$ algorithm (Aho, Hopcroft and Ullman, 1983). But, some immediate results can be obtained of the definition, such as:

a. A graph G is bi-chromatic if and only if is bipartite
b. A complete sub-graph of G with t vertices Kt is t-chromatic
c. A graph G with two or more edges is at least 2-chromatic

The concepts of graph coloring, clique (a complete sub-graph of G) and independent set of nodes are close:

a. k colors are necessary to coloring k nodes of a clique with cardinality k, thus λ(G) is greater than or equal to the cardinality of the greatest clique of G
b. Let us consider $S_1 \dots S_k$ disjunctive subsets of S generated by the k-coloring; then = $\cup S_i$ = S, i = 1 … k, and each S_i is an independent set and each Si is an independent set in which any couple of edges is not connected.

GRAPH COLORING AND MANUFACTURING CELLS DESIGN

In a graph G(V, A) associated to a production system, V = {set of parts to be manufactured}. The dissimilarity indexes between parts are calculated, for example, based on the existing differences between their production sequences.

In this case, an edge connecting two nodes i and j exists if the dissimilarity dij is greater than or equal to a critical dissimilarity established a priori.

This critical dissimilarity can be modified in any instant with the objective of higher or lower number of edges of the graph and then, the number designed of cells.

Two nodes connected cannot have the same color, resulting in a coloring where the parts with different colors have dissimilarity indexes greater than or equal the fixed value for critical dissimilarity.

Parts with the same color will be assigned to the same family and manufactured in the same cell of machines.

The distribution of machines is carried out considering the number of operations carried out in each family: a machine is assigned to the family in which it will be most used.

Table 1. Matrix MPM-LOAD [parts × machines]

	Machine 1	Machine 2	Machine 3	Machine 4
Part 1	0	15	0	40
Part 2	25	0	60	0
Part 3	0	35	0	50
Part 4	90	0	70	0
Part 5	30	0	0	0

Example

From the initial data a matrix MPM-LOAD[parts × machines] is obtained (see Table 1), which provides the total time spent by each part transiting in the program of each machine. This matrix is called work load matrix and its coefficients are calculated as follows:

load[i,j] = unit[i] × ∑ duration[i, k]
k | program[i, j] = j

where:

unit[i] = unit number of parts[i] to manufacture.
duration[i, k] = duration of operation k on a part[i].
program[i, k] = type of machine used to perform operation k on a part[i].

Let the matrix MPM [parts × machines] (see Table 2), that informs the use ($MPM_{ij} = 1$) or not ($MPM_{ij} = 0$) of part i by the machine j. The matrix D [parts × parts] (see Table 3) gives the dissimilarity index between parts ("distances between parts") to be manufactured. Two manufacturing cells will be designed for this workshop. If the critical dissimilarity is equal to 1, G(V, A) is the graph shown in Figure 1, i.e., three-coloring, and not acceptable because the workshop must be partitioned in two cells. Then, the critical dissimilarity value is incremented to two and the two-coloring graph shown in Figure 2 is obtained. After defining the families of parts, machines are assigned to the most demanding families. The distribution of machines is carried out considering the number of operations carried out in each family: a machine is assigned to the family in which it will be most used. The matrix CELLS [parts × machines] in Table 4 presents the workshop partitioning in 2 manufacturing cells and this solution is very good: there are no inter-cell moves and the dimensions of cells are equal to [2 × 2] for cell 1 and [3 × 2] for cell 2.

DISSIMILARITY INDEXES BETWEEN PARTS

Similarity measures for parts or machines have a long history of use for manufacturing cells design

Table 2. Matrix MPM [parts × machines]

	Machine 1	Machine 2	Machine 3	Machine 4
Part 1	0	1	0	1
Part 2	1	0	1	0
Part 3	0	1	0	1
Part 4	1	0	1	0
Part 5	1	0	0	0

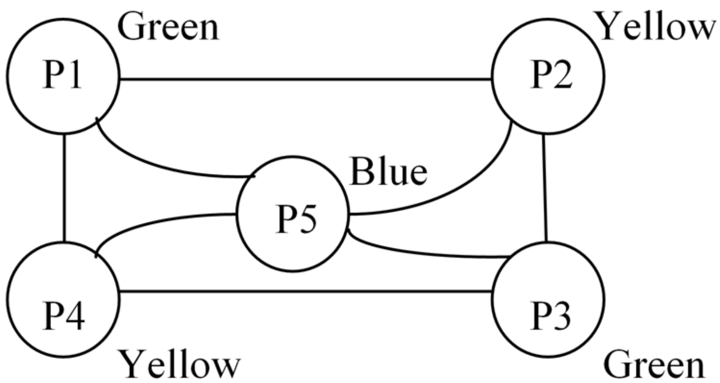

Figure 2. Two-coloring graph

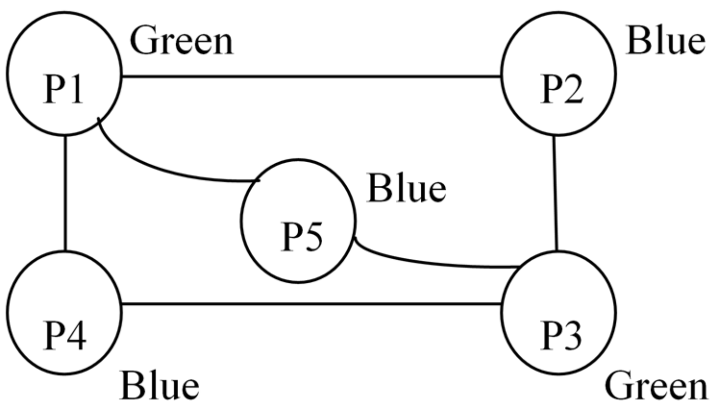

problems. The first use of similarity measure for the manufacturing cells design problem was by McAuley (1972). Let:

x_{ij} = number of parts processed by machines mi and m_j (number of matches)
x_i = number of parts processed by machine m_i only
y_{ij} = number of parts that are not processed by either m_i or m_j (number of misses).

McAuley (1972) adopted a Jaccardian similarity measure in evaluating similarities of pairs of machines. This measure considers x_{ij} as a main factor for similarity and divides it by the number of parts which either machine m_i or m_j processes. After the use of the first similarity measure, many other different types of similarity measures have been introduced, for example: Bipartite, Kusiak, McAuley-Jaccard, BUB, Russel and Rao, Sorenson, Simple Matching, Ochiai (Oliveira, Ribeiro and Seok, 2008). Jaccardian similarity measures (Bipartite, McAuley-Jaccard, Sorenson and Ochiai) are adopted for many cell formation problems (Wei and Kern, 1989). Sorenson's measure is a simple modification of McAuley's measure, where xij has more weight (Romesburg, 1984). However, it is reported that these Jaccardian similarity measures are limited because they do not use the number of misses, yij (Moiser, 1989, Islam and Sarker, 2000). Selim and Abdel (2003) distinguished those Jaccardian similarity measures from non-Jaccardian measures which use yij (Kusiak, BUB, Russel and

Rao, Simple Matching). Among them, Kusiak's measure is one of the simplest (Kusiak, 1987). As said before, they use not only xij but also yij in the similarities. Simple matching was first introduced in the field of medicine. This measure simply adds yij to both the top and bottom of McAuley's Jaccardian measure. The most successful non-Jarccardian measure is the BUB similarity measure. This measure has been successfully adopted by many clustering algorithms because their distribution of values are more normal and continuous (Baroni-Urban and Buser, 1976). Other notable non-Jarccardian measures are Russel and Rao's and Ochiai's in Romesburg (1984). Note that there are two big differences between the bipartite similarity matrices and other similarity coefficients usually used for manufacturing cells design problems. First, while we construct both similarity matrices for machines and parts, most array-based clustering algorithms use only a machine-machine similarity matrix to construct cells of closely related machines and then part families are constructed according to these machine cells. Second, diagonal entries of similarity coefficient matrices do not play any role, so all diagonal entries are considered 0. However, it is reasonable when the similarity of each machine or part with itself has bigger similarity than with others.

More details on the similarity measures can be found in Sarker (1996) and Sarker and Islam (1999) that are dedicated to analyzing most of the existing similarity measures in the literature based on a set of important properties developed by Baroni-Urban and Buser (1976).

In this chapter the dissimilarity indexes between parts i and j are calculated by quantifying the differences between their production sequences. The proposed method compares the production sequences of parts i and j utilizing the binary matrix MAT [parts × machines], where:

$$\mathrm{MAT}_{ij} = \begin{cases} 1 & \text{if machine j is utilized to manufacture part i} \\ 0 & \text{if machine j is not utilized to manufacture part i} \end{cases}$$

Then, the dissimilarity index between parts i and k is computed as follows:

$$D[i,k] = \sum_{j=1}^{\text{number of machines}} \boldsymbol{\mu}[\mathrm{MAT}_{ij}, \mathrm{MAT}_{kj}]$$

where:

$$\mu[a_{ij}; a_{kj}] = \begin{cases} 1 & \text{if } \mathrm{MAT}_{ij} \neq \mathrm{MAT}_{ij} \\ 0 & \text{otherwise} \end{cases}$$

This procedure is based on the similarity computation used, for example, by Kusiak (1987), Wei and Kern (1989), Ribeiro and Meguelati (2002), Oliveira, Ribeiro and Seok (2008) and Ribeiro (2009).

ALGORITHMS

Sequential Heuristics

Let us consider a Table that defines an order for the N nodes of G. A sequential method S consists in coloring successively $V_1 \dots V_N$, assigning to these nodes the color of the minimum index not utilized by their neighbors. The choice of the node is imposed in each iteration and the choice of the color is trivial, corresponding to an algorithm sample and compact in $O(N^2)$.

But, this heuristic can be very detrimental, despite the existence of an optimal order. In fact, if $\lambda(G) = k$, then a partition of nodes exists in k independent set of nodes $S_1 \dots S_k$. Inserting in V the nodes in crescent order of the number of the independent set of nodes, this heuristic finds the optimal solution searching N! orders. An order by the nodes can be established, for example, by three manners as follows:

a. The simpler manner to implement S consists in utilizing the natural order of the numbers of nodes, i.e., $V_i = i$ for all node i. This heuristic is called FFS (First Fit Sequential).

b. By utilizing the crescent order of the degree of the nodes, Wesh and Powell (1967) propose the algorithm called LFS (Largest First Sequential).

c. An order is defined as follows: I) V_N is the node with minimum degree; II) For i = N-1 … 1, the node V_i is the node of minimum degree in the sub-graph generated by $V - \{V_N \ldots V_{i+1}\}$. This order is the basis of the algorithm proposed by Matula, Marble, and Isaacson (1972) and it is known by SLS (Smallest Last Sequential).

These three heuristics obtain good and bad results at random. Then, the implementation of meta-heuristics simulated annealing and tabu search utilizes them for obtaining an initial solution.

Simulated Annealing

Kirkpatrick, Gelatt and Vecchi (1983) have created the simulated annealing meta-heuristic. This technique is based on the annealing of metals in metallurgy: a metal cooled very fast presents a lot of microscopic defeats, corresponding to a local minimum in optimization problems. If the cooling is slow, the atoms arrange its structure, the defeats missing and the metal has, then, an ordered structure, equivalent to the global minimum in optimization. Simulated annealing in combinatorial optimization has some similarity with thermodynamics. The energy of the system is represented by an arbitrary real number T, i.e., the temperature.

Simulated annealing begins by local search or heuristic procedure (FFS, LFS or SLS), because the method always begins from a feasible initial solution s, and the six steps bellow are activated:

a. Take at random a transformation s' instead to find the best or the first improved solution in the neighborhood

b. Build the resulting solution s' and calculate the variation of cost $\Delta f = f(s') - f(s)$

c. If $\Delta f \leq 0$ the cost is better. Make s = s'

d. If $\Delta f > 0$, the cost is worse. The penalty is higher when the temperature is low and Δf is big. An exponential function has the appropriate properties. A probability of acceptation $a = e^{-\Delta f/T}$ is calculated and, then a parameter p is taken at random in [0, 1]. If $p \leq a$, the transformation is accepted, even with degradation of the cost and the solution is modified: s = s'. Otherwise, the transformation is rejected and s is conserved for the next iteration

e. The convergence is assured by lowering T slowly at each iteration, for example, T= kT, k < 1, but close

f. The algorithm stops when T attempts a limit equal to a ε fixed close to 0. In the implementation, the neighborhood of the solutions is defined by lists, but not on the graph.

Tabu Search

Tabu search was created by Glover (1989, 1990) and has no stochastic character. For the same computational time, tabu search generally presents better results than simulated annealing. Three fundamental points constitute the technique:

a. In each iteration, the neighborhood V(s) of the actual solution s is completely examined and the best solution s' is chosen, even if the cost is higher

b. Tabu list T forgives the return to a solution recently obtained. This list stocks in a compact manner, the steps traversed by the algorithm. Then, the method seeks s' in V(s) – T

c. The best solution found is stocked, because unlike the simulated annealing, it is rarely the last one

The method stops after a maximum number of iterations or after a maximum number of iterations without improving the best solution or when V(s) – T = ∅. The problematic point is the capacity C of the tabu list T. Glover's research knows that C = 7 to 20 is sufficient to prevent cycles, for any dimension of the problem. T is utilized as a short term memory. In each iteration, the C^{th} transformation of T (the oldest) is substituted by the last transformation realized. In the implementation, T is simply generated as a data structure of type queue. Werra (1990) and Hertz (1991) propose tabu search to solve the sub-problem of the existence of the k-coloring, for k fixed a priori. The technique begins to assign k arbitrary colors to the N nodes. If the k-coloring is attempted, the coloring procedure is repeated for k-1 colors. Frequently, the assignment presents conflict, i.e., nodes connected with the same color. Then, the objective consists in minimizing the total number of conflicts, converting the problem of existence in an optimization problem on the number of conflicts. The neighborhood is formed by all assignments obtained by exchanging the color i of a node α to another color j (α must have at least one neighbor with color i). Tabu search forgives α to take its previous color during NT iterations, NT = capacity of tabu list. In the iteration, the search seeks the best neighbor of the actual assignment, i.e., the neighbor that minimizes the number of conflicts. The search stops if the number of conflicts is equal to 0 (it means a k-coloring) or if the maximal number of searches in the neighborhood is over. The method is considered good for finding a coloring close to the optimal. It begins with a value of k corresponding to a superior limit, obtained, for example, by a heuristic procedure. If the tabu search solves the problem with k colors, the procedure is repeated for k-1.

The results described in the literature are very impressive, even for big graphs (10,000 nodes = 10,000 parts). The initial number of iterations of the search is lower (0 to 10 iterations), but increase quite a bit for the last values of k. This fact shows the hardiness of the existence problem when the procedure is close to the optimal solution.

Threshold Algorithm

Provided that the problem of partitioning an X collection of n objects with a dissimilarity of classes, in a fixed k number, so that the diameter d(P) among the classes is minimum. This corresponds to constructing a threshold G_s graph, a partial sub-graph of G(V<A), that should be k-colorable. To color the graphs of the vertices, a technique based on the algorithm by Guénoche (1993) was used. This algorithm enumerates all of the partitions in a fixed number of minimum diameter classes. It is based on a threshold graph in p colors, with each color defining a class. Many heuristics to approximate the diameter and the partitions of minimum diameter are enumerated only at the last stage. Let d(P) the diameter of the partition of V into p classes. A superior limit, s, for d(P) is heuristically determined. Then, the k-colorations for G_s are enumerated. As long as there is at least one possible k-coloration, the value s is decreased and a new iteration is processed. When the algorithm stops, the highest value obtained is equal to the remaining partition diameters. To enumerate all of the possible partitions of X, in minimum diameter K classes, this algorithm is applied, which is comprised of 3 stages and has an $O(k^{N-k})$ complexity. In the first stage a heuristic method is used to determine the maximum s, highest approximation to d(P), such that Gs will be k-colorable. The maximum s is determined by a method of dichotomic subdivisions of the variation interval of the dissimilarities in a sequential coloring method, in this case the saturation algorithm (called "Dsatur"). In this algorithm, at each iteration, the rate of saturation $DS_i(\alpha)$ is defined

as the number of colors already employed by the neighbors of α. The procedure consists of:

a. coloring the most sizable vertex with the color 1
b. in the following stages, take the vertex free of maximum DS and color it with the least possible index color

In the second stage, once the maximum s has been set, all of the Gs colorings are enumerated in k colors. With the aid of "Dsatur", maximum if possible, a clique of G_s is obtained, where each node represents a class. Then, according the order of saturation, the other vertices are colored in all possible manners. If a vertex is near the colored vertices, these will not be able to be used to color them. Thus, all of the partitions in k classes of less than s diameter are obtained. In the third stage, a decreasing order of the edges of the dissimilarity values, starting from s, are considered. An edge can be inserted in the graph as long as there is a compatible partition, that is, if the edge connects different types of nodes.

Thus, each inserted edge eliminates some previously obtained partitions. The first edge that cannot be inserted, since there would be no more compatible partitions left, has equal value to the highest interclass dissimilarity value. The remaining partitions for a fixed number of classes are of minimum diameter.

RESULTS

Table 5 summarizes some tests carried out with the programs corresponding to the sequential heuristics, simulated annealing, tabu search and threshold techniques. These programs are written in MatLab and run on a microcomputer. Using examples found in the literature, a comparison is presented between the best solution known (BS) and the solutions obtained by sequential heuristics (SH), simulated annealing (SA), tabu search (TS) and threshold method (TM).

The result presented to the sequential heuristics is the best solution obtained by the three options described above. Parameters, such as temperature, ε, NT, etc., for running the programs corresponding to simulated annealing and tabu search algorithms were chosen differently for each example, by attempt, always with the objective to find the best solution. In the 1st column of Table 5, the example given is given; in the 2nd, the methods utilized for solving the example: BS (the method responsible by the best solution known), SH: sequential heuristics, SA: simulated annealing, TS: tabu search, TM: threshold method; in the 3rd, the number of cells; in the 4th, the number of parts and machines; in the 5th, the number of inter-cell moves; in the 6th, the dimensions of the cells obtained; in the 7th, the computational time (in seconds — Pentium 2.20 GHz, 1.99 GB RAM).

CONCLUSION AND FUTURE RESEARCH DIRECTIONS

In this chapter, a comparison between sequential heuristics (SH), meta-heuristics simulated annealing (SA) and tabu search (TS) and threshold method (TM) developed for graph coloring with the objective of solving the cellular manufacturing design problem has been presented. The results obtained are either the best one known or already of a high standard for the simulated annealing, tabu search and threshold method. Threshold method and simulate annealing were better than tabu search and sequential heuristics in terms of the inter-cell movements or the dimensions of the solutions for several examples from the literature treated. Tables 6 and 7 present, respectively, the solutions obtained by sequential heuristics (SH) or tabu search (TM), and simulated annealing (SA) or threshold method (TM) for the workshop proposed

Part 6							1	1	1		1	1
Part 9							1	1	1		1	1

The four algorithms take very little computational time. Thus, it is sure of obtaining a solution, which is either optimal or feasible within a very reasonable computational time. Nevertheless, for large examples generated at random, the metaheuristic tabu search presented best results than simulated annealing for the same computational time.

When the computational time is free, the results obtained generally are the same or threshold method is better.

The procedure of dissimilarity indexes computation is a very important step of the method. This parameter has a hard role in the partitioning of parts, because it measures the "distances" between parts. With this in mind, research on the computation of differences between parts was recently conducted in DMB implement factory for sugar cane located in Brazil, where 3,500 parts are manufactured by 101 machines. The objective of this study is to explore the specific characteristics of the industrial real case instances in order to obtain a high standard solution.

Chapter 93
Ethos as Enablers of Organisational Knowledge Creation

Yoshito Matsudaira
Japan Advanced Institute of Science and Technology, Japan

ABSTRACT

This chapter considers knowledge creation in relation to improvements on the production line in the manufacturing department of Nissan Motor Company and aims to clarify the substance that enables such knowledge creation. For that purpose, firstly, embodied knowledge observed in the actions of organisational members who enable knowledge creation will be clarified. By adopting an approach that adds a first, second, and third-person's viewpoint to the theory of knowledge creation, this research will attempt to define enablers of knowledge creation. Embodied knowledge, observed in the actions of organisational members who enable knowledge creation, is the continued practice of ethos (in Greek) founded in ethics and reasoning. Ethos is knowledge (intangible) assets for knowledge creating companies. Substantiated analysis classifies ethos into three categories: the individual, team and organisation. This indicates the precise actions of the organisational members in each category during the knowledge creation process and it is easier to commit further to knowledge creation activities.

INTRODUCTION

My chapter examines production improvement activities in the automobile manufacturing industry as a process of knowledge creation, and aims to clarify the factors that enable knowledge creation in a process of knowledge creation (the SECI process by Nonaka & Takeuchi).

DOI: 10.4018/978-1-4666-1945-6.ch093

For the sake of analysis, it adopts a knowledge creation theory (Nonaka & Takeuchi, 1995) to which have been added first, second and third-person viewpoints (Matsudaira & Fujinami, 2008). In this study, the statements of the interviews are analysed and interpreted through the framework of categories of socialisation, externalisation, combination, internalisation, which constitute the knowledge-creating process of the theory of knowledge creation, to which first, second, and third-person's viewpoints were added. I apply the proposed framework to the case of Oppama plant of Nissan Motor Company. By newly introducing first, second, and third-person's viewpoints, it will be possible to achieve a much better way of utilising the theory of knowledge creation within the actual situations than was ever possible. The inclusion of these viewpoints make possible a grasp, not possible using a past theory of knowledge creation, of action and the subjective aspects of organisational members who create knowledge. And from that it will be possible to elucidate the factors, which enable knowledge creation.

This chapter consists of ten sections. It begins with a review of literature on knowledge-based management, centring on the conventional treatment of the enablers of knowledge creation. Sections 3 and 4 provide theoretical reviews of knowledge-creating process. Section 5 describes the standpoints, from which interviews of the people engaged in the knowledge-creating process were conducted in order to clarify the enablers of knowledge creation. Section 6 elucidates the background of the object of the study and explanations, and Section 7 describes the research methodology. Section 8 is the main part of this chapter, aiming to show ethos as the enabler of knowledge creation through analysis and interpretation of the interviews. The discussion of possibilities for future research in Section 9 leads to the conclusion, which is last section.

LITERATURE REVIEW

In this chapter, I will try to clarify the enablers of knowledge creation, which are involved in the process of production line improvement. The problem of enablers of knowledge creation has been discussed in knowledge-based management. I would like to start by surveying the research on the topic and by showing how the enablers of knowledge creation have been treated in research. Through this I will demonstrate that this research views enablers of knowledge creation from a quite different viewpoint.

The theory of knowledge creation lists 'organisation's intention', 'autonomy', 'fluctuation and creative chaos', 'redundancy' and 'requisite variety' as enablers of knowledge creation. These are necessary when a manager is supervising the knowledge-creating process on the level of organisation.

Von Krogh et al. (2000) defines knowledge enabling as the whole set of organisational activities, which positively affect knowledge creation, stating that 'knowledge enabling includes facilitating relationships and conversations as well as sharing local knowledge across an organisation or beyond geographic and cultural borders '(p4). As the examples of knowledge enablers, they names the following: 'instilling a knowledge vision', 'managing conversations', 'mobilising knowledge activists', 'creating the right context' and 'globalising local knowledge'. These are also suggested from a viewpoint of a manager, who aids knowledge creation on organisational level.

Nonaka & Toyama (2005) present a dynamic model of a knowledge creating company and state the factors, which enable knowledge creation. Here they list 'knowledge vision', 'driving objectives', 'dialogue', 'practice', 'ba (shared context) ', 'knowledge assets' and 'environment' as enablers. These enablers also animate knowledge creation on the organisational level

The enablers of knowledge creation mentioned above are suggested from the viewpoint of a manager who aids knowledge creation of organisational members on the organisational level. Moreover, these enablers are connected with how an organisation as a whole should motivate the organisational members, who create knowledge, as well as what kind of relationships members should build between themselves and with the outside environment.

This research does not try to view the enablers of knowledge creation on a macro organisational level as did von Krogh et al., as slogans, as points to pay attention to, as actions, which managers should have in mind in order to motivate organisational members who create knowledge, or as ways to create relationships between organisational members or between members and the outside environment. Here I will define enablers on a micro level as things and ways organisational members used in order to create knowledge. I will also take into consideration subjective aspects such as sense of values of organisational members.

In order to grasp such subjective aspects as concrete actions of organisational members, which were needed for creating such knowledge, and also the sense of values, which serves as a basis for these actions, this research will use a framework, which introduces first, second, and third-person's viewpoint (Matsudaira & Fujinami, 2008) into the theory of knowledge creation described above.

Most of the enablers examined by preceding research are externally operating factors, separated from the actual subject of knowledge creation. However, the enablers in our research are intrinsic to the active subject of knowledge creation, are inseparable from it.

PEOPLE'S ABILITIES, NECESSARY FOR KNOWLEDGE CREATING PROCESS

Although I will treat these production improvement activities as a knowledge-creating process, first I would like to look into the SECI model of knowledge creation (Nonaka & Takeuchi, 1995; Nonaka, 1991, 1994). SECI model supposes that knowledge is created through a conversion process of explicit knowledge and tacit knowledge of four phases: socialisation, externalisation, combination, and internalisation (Nonaka et al., 2000, pp.9-10).

1. **Socialisation:** Socialisation is the process of converting new tacit knowledge through shared experiences. Tacit knowledge can be acquired only through shared experience, such as spending time together or living in the same environment. Socialisation typically occurs in a traditional apprenticeship, where apprentices learn the tacit knowledge needed in their craft through hands-on experience, rather than written textbooks or manuals.
2. **Externalisation:** Externalisation is the process of articulating tacit knowledge into explicit knowledge. When tacit knowledge is made explicit, knowledge is crystallised, thus allowing it to be shared by others, and it becomes the basis of new knowledge. Concept creation in new product development is an example of this conversion process.
3. **Combination:** Combination is the process of converting explicit knowledge into more complex and systematic sets of explicit knowledge. Explicit knowledge is collected from inside or outside the organisation and then combined, edited or processed to form new knowledge. The new explicit knowledge is then disseminated among the members of the organisation. The combination mode of knowledge conversion can also include the 'breakdown' of concepts. Breaking down a concept such as a corporate vision into operationalised business or product concepts also creates systematic, explicit knowledge.
4. **Internalisation:** Internalisation is the process of embodying explicit knowledge into tacit knowledge. Through internalisation, explicit knowledge created is shared throughout an organisation and converted into tacit knowledge by individuals. Internalisation is closely related to 'learning by doing'. Explicit knowledge, such as product concepts or manufacturing procedures, has to be actualised through action and practice.

Socialisation and externalisation emphasises feeling, that is, direct experience conveyed via the body, and intuition. That which is derived from feeling is reality-related raw information. The importance of real, on-the-spot experience is often emphasised because it yields information that cannot be obtained simply by reading data collected by others. Information derived from reality contains many items that cannot be converted into data. Some measurement techniques are necessary in order to generate data; however, no measurement techniques exist for many phenomena. When we consider phenomena that we cannot measure, our only recourse is to gather information with our own body.

In combination, logical thinking plays an important role. However, it is difficult to promote combination by thinking alone. For example, it is not easy to maintain motivation at the stage of planning of improvements of the production line. Emotional energy should provide a drive for thinking.

In internalisation, tacit knowledge gains results in assessments that go beyond reason, that is to say, in empirical judgments (sense of values). Excellent empirical judgments are cultivated by the repetition of high-quality experiences. A sense of values may be defined as the abstract expression of empirical knowledge related to likes and dislikes. An individual forms his or her own sense of values via experience. A sense of values provides criteria to assess what is important, and this may differ depending on the person.

TRI-DIRECTIONAL APPROACH TO ORGANISATIONAL KNOWLEDGE CREATION

In "socialisation", "externalisation", "combination" and "internalisation" – the expressions used in SECI model – the analytic viewpoint is located outside the organisation. It is a viewpoint of a transcendent being looking down at the organisation. It is as if we are looking at a surgery through a glass. My aim in this paper is to look at knowledge creation not from a viewpoint outside the organisation, but to look at it from within, from the viewpoint of an agency belonging to an organisation, i.e. the iFA members, and direct my gaze to the concrete actions and the subjective side of the actors who perform knowledge creation.

In socialisation and internalisation, when the subject of research is intuitive understanding and empirical judgments (sense of values), the question is how they should be handled. Intuition and emotion are subjective phenomena. They are difficult to handle because it is difficult to understand other individuals. The only way to proceed is to listen to the reports of the parties concerned regarding the workings of the intuition and emotion of individuals. Therefore, it is indispensable to interview the parties concerned.

This technique may be the best we have at our disposal, even though it is not easy to gain admittance to the hearts of the parties concerned. We do have the skill of sympathy. By making comparisons with our own experience, we can assess the accuracy of the intuition of others and share their enjoyment and grief. We cannot objectively describe the intuition and emotion of others from the standpoint of the observer. However, sympathy allows us to talk about the heart of others.

Moreover, circumstantial evidence is not entirely meaningless; it can provide supporting facts. The presence of subjective reports and of objective facts with consistency enhances the accuracy of subjective reports. Objective facts consist of products and services as results as well as sketches or memos that were produced at the various stages of development of the products and services. What we seek are descriptions of the internal world backed by objective facts. Explanations based on cause and effect are impossible in the case of objective facts because they cannot act as the causes of subjective reality. However, objective facts can become the results of subjective reality. Therefore, subjective reality can be envisioned by backtracking to cause and effect.

There is the subjective reality of the parties concerned, understanding via the sympathy of neighbouring persons, and supporting evidence provided by objective facts. These are thought to be subjective phenomena. As such, they are three different ways of approaching intuition and emotion. It is thought that approaching from three directions at the same time may enable research of intuitive understanding and empirical judgment (sense of values). The three methods of approach may be named as follows:

[the first-person's viewpoint] the subjective reality of the parties concerned
[the second-person's viewpoint] understanding via the sympathy of neighbouring persons
[the third-person's viewpoint] supporting evidence provided by objective facts

It is necessary to observe and analyse phenomena in an integrated manner from three different viewpoints in order to understand human beings and organisations. Varela and Shear (1999) pointed out the importance not only of a third-person viewpoint, but of a first- and second-person viewpoints, too. Essentially, subjective phenomena must be handled raw, and thus are not considered science but are treated in combination with the second-person's viewpoint and the third-person's viewpoint.

WAYS OF REPRESENTING VIEWPOINTS

Socialisation and Internalisation

We believe that we can basically organise the actuality of the creative activities that we have approached from three different directions by following the SECI model.

In the SECI model, knowledge creation is regarded as consisting of the following four phases: socialisation, externalisation, combination, and internalisation. In socialisation, we want to ascertain what the problem is by means of our five senses. In the case of quest, the quest is assigned a direction under a sense of values, that is, under the influence of having determined what is important. When this phase is examined from the three viewpoints, it is necessary to carefully observe the following points:

(1) **Socialisation**

When this phase is examined from the three viewpoints, it is necessary to carefully observe the following points:

[the first-person's viewpoint] The points that should be carefully observed are those places which explained the discovery of the issues that needed to be addressed.
[the second-person's viewpoint] If the leading role is assigned to the parties concerned, focus on the points that show how and when those people in supporting roles accepted the motivation and goals of the parties concerned.
[the third-person's viewpoint] Carefully observe the wide range of attempts and trials that were undertaken in the process of problem-finding, for example, whether attempts were made by the group to visit those places where customers live.

(2) **Internalisation**

In the case of internalisation, we organise whether and how a sense of values was obtained or verified. Clarify the differences in the sense of values before the launch of the project and after it ended. It is necessary to carefully observe the following points:

[the first-person's viewpoint] Things considered to be important (for example, customer satisfaction). Is there satisfaction with the results of the work?
[the second-person's viewpoint] Opinions about the optimal company culture and organi-

sation (human relations), the goals of the organisation, and its course of action.

[the third-person's viewpoint] The described contents of the project shareable within the organisation.

Externalisation and Combination

The interest, which comes from a position that values explicit knowledge, is externalisation and combination.

(1) **Externalisation**

In "externalisation", as well as in "socialisation", the ability that aids knowledge creation is considered to be feeling and intuition, so the hypothesis is generated by these two. The formation of a hypothesis is two-sided, containing both a selective eye and the ability for sympathy. It is necessary to form a hypothesis so that it becomes an answer to the ultimate goal of how things should be.

Imaginative power is important in concept creation and the abilities such as using keywords or visualising ideas function effectively. However, it is important not only to conceive, but also to have a selective eye that picks out only those buds which can eventually bear fruit. When this phase is examined from the three viewpoints, it is necessary to carefully observe the following points:

[the first-person's viewpoint] How to conceive the proper state of affairs.

[the second-person's viewpoint] How do the members interpret the idea, what is their reaction and the impact of the idea on them (sympathy).

[the third-person's viewpoint] The mechanisms and the technology which were actually built.

(2) **Combination**

"Combination" is a stage, in which the practical use of information, made through the combination of explicit knowledge, and the systematisation of knowledge and explicit knowledge of two or more groups on organisational level are combined. The ability to support knowledge creation in "combination" is, as in the case of "internalisation", thinking and emotion. In "combination", the actor performs theory formation. The ability to coordinate everyone when needed so, that a feeling of unity can be obtained, becomes important. It is also an important task to motivate individuals and maintain the incentive. When this phase is examined from the three viewpoints, it is necessary to observe carefully the following points:

[the first-person's viewpoint] The choice of what can be used.

[the second-person's viewpoint] Methods of advancing discussion based on that selection.

[the third-person's viewpoint] Design of the whole based on selection.

BACKGROUND

In Nissan Motor Company (Nissan), the manufacturing ability of production plants in Mexico or China has improved, and their gap with the manufacturing ability of the factories in Japan is getting smaller. There was a sense of impending crisis in Oppama plant (Kanagawa prefecture, Japan), which is one of the manufacturing factories of Nissan in Japan: if they do not raise the manufacturing ability, others will catch up. Oppama plant produces the so-called compact cars such as March and Cube, the popularly-priced cars selling for 1,400,000 to 1,700,000 yen. On the other hand, Tochigi plant (Tochigi prefecture, Japan), produces such cars as President (about 10 million yen), which is classified into "sports & speciality" class, and Skyline (sedan type, about 3,800,000 yen). Oppama plant requires its production line to be less costly than the one used for the types of cars produced in Tochigi plant.

For example, when we compare wages per hour, if we set Renault as 100%, in Japan they would constitute 120-130%, and in Mexico only 10%. If we take this concrete cost difference into account, it is better to produce Cube of the next term in Mexico, rather than in Japan. If Oppama plant does not reach a cost level, which would surpass Mexico, the next term type Cube will be produced in Mexico, it will not be possible to produce it in Oppama plant, and this would at the same time mean a serious downsising of employees. Thus, the Oppama Challenge Declaration of "Reaching a Cost Level Surpassing Mexico" was issued, and the full-scale operation began in July, 2006.

What is Oppama Challenge?

Oppama challenge is a "survival strategy for re-capturing quantity-of-production." The idea is to swiftly perform "a reform in manufacturing ability" through bench marking with low displacement cars and LCC (Low Cost Competitive) countries, as well as through intensification of collaboration between the construction site and technology, and ultimately aim for the world best factory in terms of QCT (Quality Cost Time). This reform completely eradicates doubts about factory cost competitiveness of Japan and greatly contributes to improvement in manufacturing ability of the whole of Nissan Corporation. It aims at attracting cars from all over the world by the newly attained world best manufacturing ability and freeing itself from the status of a factory for domestic use.

What is iFA?

Oppama challenge consists of six teams and one of them is iFA. iFA stands for "integrated Factory Automation". It is a combined team consisting of 18 persons assembled from various divisions of Nissan, such as the Body Division of the Manufacture-Department, the Assembly Section, the Production Division of Engineering Department and the Engineering Division. iFA means rectification (streamlining) of the flow of things and cheap automation. The effort is aimed at paying attention to the flow of things within iFA and constructing a situation, where nothing is wasted and the flow has no backwater. In order to achieve this goal, there is a need for an ingenious and cheap automation "Karakuri[1)]". If an enormous amount of money is spent on automation, there would be no cost reduction. The aim is to perform a rectification (streamlining) of the flow and achieve a situation where nothing is wasted.

The basis for iFA members' way of thinking about production is the so-called NPW (Nissan Production Way) (Nissan Motor Company, 2005), which Nissan set forth beginning from 1994. Let us briefly explain the main points of NPW.

Nissan Production Way considers a mechanism of manufacturing that transforms input to output to be the "Production System." It can be said that the profitability and competitiveness in production activity are the results of the quality of this system management performance measures and QCT.

Aim of NPW is to improve the company's "Profitability and Competitiveness" and accomplish the above, we must construct the total optimisation of "Production System", which thoroughly synchronises with the needs of our customers.

There is the concept of "Two Never Ending" in NPW.

1. Never ending synchronisation (Douki) our manufacturing with the customers
2. Never ending quests to identify problems and in place solutions

"Never ending synchronise (Douki) our manufacturing with the customers" is to purchase the following three Douki in depth in order to develop trust in the customer, bring the presence closer to the customer, and develop long-term Nissan fans in the customer by offering high-quality products and services.

- **Synchronisation of Quality:** To build in quality that our customers demand in processes
    - Never receive any defects
    - Never produce any defects
    - Never pass any defects
- **Synchronisation of Cost:** Through Elimination of Wastes that our customers would not wish to pay for
- **Synchronisation of Time:** Delivery of our products and services our customers on timeReduction of lead-time for production and development to synchronise our production with our customers as closely as possible

"Never ending quests to identify problems and in place solutions" takes the negative "problems", which tend to be concealed until nowadays, and proactively reveals them; therefore, it enables us to see these problems in a positive light, by recognising the gap between the "Want-to be condition of manufacturing" and the "Current condition", as opportunities (chances) for improvement and innovation.

RESEARCH METHOD

As a research method I used informal interviews, where items of inquiry and order are not standardised. The reason for this choice is that an interview can be performed flexibly, that adjusting to subject's interests or the flow of conversation is easy, and that a researcher, when needed, can ask the subject in detail about points he is doubtful about or matters related to a reply.

THE ANALYSIS AND THE INTERPRETATION OF INTERVIEWS

This research treats the activities of production line improvement at Nissan Oppama plant as a knowledge-creating process. The purpose of analysis and interpretation is to clarify the actions of organisational members, which enable knowledge creation. For that reason, the statements of the interviews are analysed and interpreted through the framework of categories of socialisation, externalisation, combination, internalisation, which constitute the knowledge-creating process, to which first, second, and third-person's viewpoints were added.

Table 1. Outline of interview

Date	Length of time	Place	Interviewee
16th October 2007	About 3 hours	Nissan Oppama plant (Kanagawa prefecture)	iFA sub-leader four iFA members
4th December 2007	About 3 hours	Nissan Oppama plant	iFA leader iFA sub-leader four iFA members
4th April 2008	About 3 hours	Nissan Oppama plant	iFA member
25th May 2008	About 2 hours	Tokyo	iFA member
22nd September 2008	About 2 hours	Nissan Technical Centre (Kanagawa prefecture)	iFA leader
26th December 2008	About 2 hours	Nissan Oppama plant	iFA member
1st July 2009	About 2 hours	Nissan Technical Centre	iFA member

Enablers of Knowledge Creation

I will look into the interviews and examine the enablers of knowledge creation for each of the processes: socialisation, externalisation, combination and internalisation. The classification and the interpretation of the interviews are summarised in Table 2. (Each of the items at the beginning of the interpretation is a selected quote of part of a remark, made during the interviews).

Ethos as an Enabler of Knowledge Creation

From the classification and the interpretation of Table 2, from the knowledge-creating processes

Table 2. Enablers of knowledge creation (The number of each item corresponds with the classification of Table 3)

	Socialisation
First-person's viewpoint **Viewpoint:** **How was the problem, which should be tackled, discovered?**	**(1) "Taking the losses from the lower process to the upper process"** Having steadfast plans and ideals leads to problem discovery. When you are going around, looking at the production site, observing the activities of the workers, being conscious of the ideal of bringing the losses from the lower process to the upper, having in mind the question: "What could the next improvement be?", you always find some actions that are out of place. **(2) "Looking at other shops"** Directing interest not to the shops (divisions) you initially started in, but to other shops, leads to problem discovery. From such remarks as "I have been in Oppama plant for a long time, but have never seen other shops" there is a shift of subject of interest to "Let's all of us members go and see all the other shops in the factory". After going around and seeing other shops anew, there is much astonishment and many discoveries of usable points: points, which then become the raw material for problem discovery.
Second-person's view point **Viewpoint:** **How did the surrounding members accept the feelings and aims voiced by the parties concerned?**	**(3) "It all started from trying to find out, what iFA is there for"** The members of iFA did not start with actual plans or ideas to make things cheaper, or with examining concretely the points for improvement, such as the reduction of how many workers can be expected in the production process. First and foremost they thoroughly questioned the reason for being there, what they had gathered there for, and started with coming to a common denominator in terms of the way of thinking about production.
Third-person's viewpoint **Viewpoint:** **The attempts made in the process of problem-finding.**	**(4) "Sharing opinions about Douki production and bringing together ways of thinking."** The members were brought together as iFA and given two to three weeks time to conduct discussions in order to share their philosophies, create views and ways of thinking about production as a single body, iFA. Exactly because they were given this time and opportunity, because they could share their philosophies, they could progress in the same direction even when they were performing improvement related activities of quite harsh nature, "as if we were trying to squeeze water out of already dry rag" (words of one of the members). Because an attempt was made to provide them with this time and opportunity, they could share their ways of thinking about NPW, which is the ideal they were aiming at, and perform the actual activities.
	Externalisation
First-person's viewpoint **Viewpoint:** **How to conceive the optimal state of affairs?**	**(5) "Rectification of the flow of things", "ingenious automation called 'Karakuri'"** Slogans of reaching "a situation where there is no waste" and "cheap automation" are definitely pointing at the optimal state of the production line, at the way it should be. But these phrases are only expressing the goal. Judging these as not really touching on the essence of the iFA, the leader made the ideals more sophisticated, changing the "situation where there is no waste" to "rectification (streamlining) of the flow of things" and from "cheap automation" to "ingenious automation called 'Karakuri'". This change not only indicates the goal to the members, but forms an image of what they concretely need to do. **(6) " The model is the Nissan Production Way"** When asked about the ideas they have about the production line, about the basis for the direction of their efforts, all members answered: NPW. There is an ethical goodness called NPW and by having it as a basis, externalisation in the knowledge creation process, aiming at the improvement of the production line, is promoted.

continued on following page

Table 2. Continued

Second-person's view point **Viewpoint:** **How do the members interpret the ideas, what is their reaction to them and the impact of the ideas on them?**	**(7) " NPW is the foundation for the hypothesis"** A basis is necessary to formulate a hypothesis. The basis for the hypothesis, aimed at improvement of the production line, is NPW. A hypothesis is built through checking it against NPW. NPW is a sort of a resource, judged to be good in the Production Division. The image of rectification (streamlining) of the production line is drawn according to it. In externalisation the members conceive the way of thinking of NPW as an ethical goodness or resource. When they waver in their decisions, when they have to decide their priorities, it is NPW they turn to. This ethical goodness leads people of production division of Nissan to actions, as if saying: "This is what you should do". **(8) "Everyone understood when they heard the words 'moving the waste to the upper process' "** At first, faced with the problem of improving productivity, members wrestled with the choice between moving the waste either to the upper or to the lower process, each relying on their own keywords such as "getting rid of stocks" or "Douki", and faced the problems of improvement without a clear understanding of the reasons for their actions. However, thanks to the leader's concept, which used a metaphor of river (upper process in Japanese is called 'upper stream') and grasped the essence of the problem, namely "driving waste upstream", members though: "This is it. Now I get it. We just need to drive the waste up". Due to it, they noticed that the essence of the improvement related actions they were performing unconsciously was, in fact, driving the waste to the upper process.
Third-person's viewpoint **Viewpoint:** **Mechanisms which were actually built.**	**(9)Shishi Odoshi** 'Shishi Odoshi' is a type of transfer equipment using an AGV (Automatic Guided Vehicle: an unmanned cart, which carries parts to the required places in a factory) which carries boxes filled with picked parts and pours them onto a lane. Members ingenuously made a mechanism, which is cheap to produce and which easily moves the box filled with parts brought by AGV onto the rail. By analogy with up-down movement of a bamboo pipe, which inclines under the weight of water and is often set up in Japanese gardens, they called it Shishi Odoshi.
	Combination
First-person's viewpoint **Viewpoint:** **How did the members conceive the choice of what can be used?**	**(10) "Thinking whether it can be done in a simpler way"** When you are trying to improve the whole production line, you tend to think of large-scale, complicated mechanisms. Members tried to think of how they could simplify it instead. Furthermore, they put out their antennas to receive information from the outside world in the hope of gaining cues for simplifying there.
Second-person's view point **Viewpoint:** **How did the members discuss that selection?**	**(11) "Break the walls and do it together"** All iFA members came from different divisions. If they followed the way of thinking of their old divisions, there could be no teamwork. On the path to improvement iFA sets no restrictions on exchange of necessary things and able personnel. This breaks the walls members' old divisions set up in terms of ways of thinking and behavioural patterns and leads them to work on the improvements and tackle problems together as a single unit: iFA. Combination is promoted by the fact that people of various divisions participate and that explicit knowledge is being added.
Third-person's viewpoint **Viewpoint:** **Design of the whole based on the selection**	**(12) "Came to see the production line as a whole, and not in parts"** In case of improvement of a production process like that of iFA, it is vital to have a vision that covers the whole, from the beginning to the end, and not just parts. This way you cease to view problems separately. And when you see it as a whole, you can choose the sections, which should be given priority. While you are going from the sections to the whole and back in amoeboid-like movement, tacit knowledge and connection between people expands, helping to expand also the scope of the improvement.
	Internalisation
First-person's viewpoint **Viewpoint:** **Things members learned to consider as important through the activities and evaluation of work done**	**(13) "Looking at improvements in terms of the whole picture"** One of the points members think to be important is to grasp the whole picture. Being able to see the whole picture of the improvement means that the members managed to understand the improvement as a whole through the processes of socialisation, externalisation and combination and truly feel the importance of grasping the whole picture. **(14) "There is no such thing as 100% perfection"** An improvement is a continuous effort and there is no such thing as a final shape to it. The second you consider any state as final you lose any opportunities to make the production line better. Many of the members said in almost the same words: "We are still continuing", "We are not finished with improvements yet". As long as the production activities continue, the improvement goes on. These are the values of iFA.

continued on following page

Table 2. Continued

Second-person's view point **Viewpoint:** **Opinions related to corporate culture and the optimal state of the organisation, goals of the organisation, and its course of action**	**(15) "Every one of us has his own vision of what he wants to do with the plant"** All the members have their own vision of what they want to do with the production plant. This means that each of the members has a different sense of values. And this serves as the source of knowledge creation. Through the struggle between each member's respective values, organisational members cross their boundaries, dialectically producing new values. Values are internalised by the individual, driving the problem discovery in socialisation further. **(16) "We want to create the best manufacturing site in the world"** Through their belonging to iFA the members began to feel themselves as a part of the movement to "create the best manufacturing site in the world", which is the goal of the organisation. The direction of this movement is the idea that a manufacturing site has to be cheap, not wasteful and have all the necessities at hand. They came to believe in these values through their activities in iFA.
Third-person's viewpoint **Viewpoint:** **The described contents of the project shareable within the organisation**	**(17) "We'd like to find ways to tell others about our activities"** When the reality of a project like iFA is not institutionalised within the organisation and is not established as corporate culture, it is difficult to explain and describe such a reality objectively. Therefore, one of the iFA members wrote a novel, describing the activities of iFA. Moreover, with cooperation of people who participated in the project and those who did not, the activities were summarised in a story-like narrative called "Nissan Inside Story", thus providing the information not only for the people who are connected with improvements of this particular Nissan's factory, but so that it is possible to share it with all those working in Nissan.

of socialisation, externalisation, combination, and internalisation it is possible to detect the actions repeatedly performed by organisational members as factors, which enable knowledge creation. For example, in the knowledge-creating process of socialisation we can see an action repeatedly done for problem discovery, which consists of getting interested in other divisions, which members had never been a part of, and going around them for inspection. The actions repeatedly done by organisational members in each of the four phases of knowledge-creating process – socialisation, externalisation, combination and internalisation – are the intangible knowledge assets, which enable knowledge-creating process. These knowledge assets enable organisational knowledge creation through habits of organisational members.

What does this point to? It points to a certain ethos, embodied in organisational members. Ethos gradually becomes embodied through the interaction between the organisational members during the activities related to knowledge-creating process.

The word "ethics" comes from Latin word "ethica", which goes back to Greek word "ethika". Ethos originally meant a place one is accustomed to live in, and at a level of community means customs and traditions. An explanation of ethics going back to the Greek origin of the word can be found in Aristotle's Nicomachean Ethics (Ross, 1928; Ross et al., 1998; Broadie & Rowe, 2002). What needs a careful consideration is that things, which are called "ethical (ethikos)"are not the customs one acquires naturally, but those that become a routine through careful and intentional moulding (Sekine, 2001). Ethos is the habits intentionally embodied by the organisational members themselves during knowledge creation in order to implement the ethical goodness of NPW.

Classification of Ethos

If ethos, which is clarified knowledge assets, is put together, confusion arises in its accumulation and utilisation. The reason for it is that ethos is embodied or embedded within different layers: individuals, the team and the factory (organisation). In order to clarify this distinction, we introduced first, second, and third-person's viewpoints and analysed knowledge-creating process. In Table 3 we have classified ethos discussed above from three points of view: that of the individuals, the team and the factory.

Table 3. Classification of ethos by first, second, and third-person's viewpoint (The number of each item corresponds with the classification of Table 2)

	First-person's viewpoint
Ethos embodied in individuals	(1) Keeping in mind ideals and aims when looking at the site (2) Having the interest in other divisions, posts and production stages (5) Reflecting on the self in actions (6) Having ethical goodness as the norm for thoughts and actions (10) Not complicate matters (13) Sharing the philosophies (points of view, ways of thinking), and grasping the whole picture (14) Generate a sense of values through practice
	Second-person's viewpoint
Ethos embedded in the team	(3) Groping for identity, questioning raison d'etre and sharing the way of thinking about production (7) Having a basis for hypothesis creation (8) Clarifying concepts by using metaphors and analogies, clarifying unconscious acts (11) Not heeding the borders between divisions in work, thus combining different explicit knowledge (15) Building a new sense of values through synthesis of different values (16) Departing from practice when defining the course of action
	Third-person's viewpoint
Ethos embedded in the plant (organisation)	(4) Providing time and opportunity to share philosophies between members (9) Concretising, using analogies as hints (12) Conceiving plans by going from the parts to the whole and back, expanding explicit knowledge in amoeba-like movement (17) After finishing the project, leaving behind the concrete contents of activities as explicit knowledge in a story-like form

FUTURE RESEARCH

Firstly, the object of this research was a production division of an automotive manufacturer, and if we extend our scope to research and development divisions, it is possible to enrich the knowledge of this research even further, possibly discovering other types of ethos which enables knowledge creation.

Secondly, ethos, which is a high-quality tacit knowledge, as a source of knowing, created through specific time, space and human relations, is inseparably connected to a certain context, which in case of this research are the activities aimed at improving the production line by iFA in Oppama challenge. It is necessary to conduct a comparison of ethos described in this chapter with the ethos of the production line when not involved in the project we described, to see what is same and what is different.

CONCLUSION

The understanding based on the ethos, which enables knowledge creation, illuminates the individual and concrete human reality, such as what organisational members do, what sense of values they have, how they grapple with problems as an organisation etc. As a counter position to the two major strategy theories, which constitute the mainstream of present research – the positioning school (Porter, 1980) and the resource-based view of the firm (Wernerfelt, 1984; Barney, 1986, 1991, 2001) – which represent the logical analysis strategy, here I laid stress on the rehabilitation of people's wisdom, practice and action. Ethos is not just a habit, it is a habit with has ethics embodied or embedded within it. In the context of the material of this research ethos is a habit that makes possible to implement NPW – the goodness, which has been accepted and shared within the production division of Nissan. Knowledge creation is made possible through repeated spinning of SECI processes. And what has been thus revealed is an ever-repeating habit, in other words – ethos. Ethos is an ethical goodness, NPW, which has been embodied and embedded.

Next, I would like to give some suggestions to those actually working with ethos.

In this research, I have tried to elucidate a part of ethos, which lurks in the depths of human ability to create anew, ordaining knowledge creation from behind the scenes. I have shown that ethos enabled knowledge creation in terms of improvement of the production line, which made it possible to lower the cost of production to the level of Mexico, which was the goal of Oppama challenge, and also managed to secure the production of the new model of Cube for Japan and the North America. Ethos, while efficiently employing the knowledge producing tradition, stemming from accumulation of experience and inherited from generation to generation in a business organisation, is a concept that provides key to sustainable growth. The reason for this is that the continuous innovation through knowledge creation is indispensable for sustainable growth, and that ethos, while being the output produced by the knowledge-creating process, at the same time becomes the input that leads to the next knowledge-creating process.

Ethos is the intangible knowledge assets, which maintain knowledge creation. Since we introduced first, second, and third-person's viewpoints in this research, we have elucidated and categorised ethos, which enables knowledge creation, from three points of view - that of the individuals, the team and the factory (organisation). For the knowledge workers, who practice knowledge creation in a business organisation, this classification becomes an accumulation and utilisation of knowledge assets, an input for next knowledge creation and proves helpful for maintaining knowledge-creating process.

Ethos, which enables knowledge-creating process, can be shown in a figure as follows.

Let us explain the figure. The activities of improvement of the production line, which aim at implementation of streamlining of the flow - the ideal or proper condition - these activities through their process produce ethos. It is not that knowledge-creating activities, which aim at implementation of streamlining of the flow of things, become a cause, resulting in inventions and reforms, which allowed the streamlining to take place. The process between inventions and reforms and the reality gave birth to ethos of various kinds. And NPW functions as the reference of frame that gave birth to that ethos, providing the basis for it. Through actual practice of ethos, as a result of it, the various inventions and reforms, which implemented streamlining of the flow of things, could be made.

Ethos produces as its output the knowledge of the inventions and reforms, related to the production line, knowledge, which members wanted to implement. Moreover, since ethos also serves as the input of knowledge creation, it also plays its role in spinning SECI processes at high speed, increasing the quality and the quantity of knowledge, making a spiral repetition possible. Ethos,

Figure 1.

which enables knowledge creation, is embodied by organisational members and is embedded by the team and the organisation.

Finally I would like to describe the managerial implication of this research.

In corporate management, knowledge assets are the intangible assets, which, unlike physical assets, are implicit and are in a state of dynamic transformation. For a firm they are an essential resource indispensable for value production.

The knowledge assets contain not only the knowledge made explicit for example by patents, but also the implicit knowledge needed to produce it. In other words, the former is the explicit knowledge, which can be indicated formally, such as concrete improvements and designs of a production line, whereas the latter is the knowledge of ethos, which produces such improvements and designs in the first place. Since the former can be easily indexed with firm's values, it tends to be considered as knowledge assets, constituting the source of firm's competitive advantage. However, ethos, which is continuously keeping the knowledge-creating process alive, is what is truly attractive for corporate management or an organisation, although, being one of the types of implicit knowledge, it is difficult to index. What was indexed, was indexed as a result of the justified past, and in order to assess its value for the future one has to look into what is hiding behind it. And what is behind it is nothing other than ethos. It is ethos that is always functioning as the driving force for the next knowledge-creating process. In this sense, this research revealed numerous ethoses constituting intangible knowledge assets in the production department of Nissan Motor Company. They play the role of continuing and promoting the creation of knowledge, which serves as the source of sustainable competitive advantage for a firm.

Ethos, which is a knowledge asset, is by no means unchangeable. It dynamically changes, as do all intangible assets. Since the next knowledge-creating process is always set in a new context with a new locality of the problem, maybe not all the contents of ethos, but some are changed or created anew to meet the new requirements. We should not forget that in management, ethos has to be adjusted according to the context. People related to knowledge-based management should fully understand that every recreation of ethos is a new knowledge-creation. And that this point of view is vital for a continuous promotion of knowledge-creating process.

I believe that this research was successful in its role of showing the indispensability of ethos - the new concept of knowledge assets, which enables knowledge creation - for future knowledge-based management.

ENDNOTE

"Karakuri" is a type of Japanese traditional craftsmanship, which was invented in the 1770s. Its famous example is a doll, which carried tea. The distinguishing characteristic of Karakuri is that mechanisms do not rely on any dynamic force like electricity or batteries. Bearing the mechanism of Karakuri in mind, the members are working to implement cheap automation at the production site.

Chapter 94
Engineering Design as Research

Timothy L.J. Ferris
Defence and Systems Institute, University of South Australia, Australia

ABSTRACT

Research is defined as an activity that creates new knowledge. This is often misunderstood in the engineering community as necessarily requiring a scientific contribution that advances the theory of some matter related to engineering materials or processes. Consequently, typical engineering research projects investigate physical phenomena thought likely to be interesting in potential applications or to describe the characteristics of processes used in engineering work. The results of such projects provide a fragmented, abstracted view of the phenomena investigated, which is difficult to use in engineering decision making related to contextualised situations. This chapter shows how the actual design of engineered artefacts is research because it provides knowledge of the impact of the integration of various elements of existing knowledge, which demonstrates the properties of the designs achieved through the design work and leads to discovery of solutions to the various challenges of integration discovered through the project which attempts to achieve the integration.

INTRODUCTION

Research is defined as an activity which develops new knowledge (Department of Education Training and Youth Affairs, 2001). A major challenge we have in understanding the nature of research is our preconceptions concerning the nature of knowledge, since the creation of knowledge is the objective of all research activities. In this chapter we introduce the particularly important issue of engineering activity and the act of design itself as research, that is, as methods of creating new knowledge. This is distinct from performing investigations about the engineering and design processes as an observer of those processes with the purpose of better understanding the processes. The idea of engineering activity and design being a research methodology requires explanation because it is quite different to the usual interpretation of research in engineering.

DOI: 10.4018/978-1-4666-1945-6.ch094

It is usually expected that the knowledge that is developed in processes to which we assign the name 'research' is objective and generalizable to a wide range of problems. This understanding is derived from the idea of research as implemented in the natural sciences and fields inspired by their methods, in which the goal is to find out knowledge about the phenomenon or situation which is the subject of the work, and the work is regarded as completed when a sufficiently good theory or explanation of the situation is determined.

The idea of research concerning the discovery of generalizable knowledge about the subject matter of the investigation is prevalent in engineering related research conducted in universities, by both faculty and graduate students, and in the regulations for research degrees in engineering and in the engineering research journals published in recent decades. The engineering research journals of the 1950's, particularly prior to the changes in the US education and research system that followed Sputnik, reflected a different vision of the nature of engineering research and its relation to the achievement of engineering design. The latter will be discussed later in this chapter.

The idea of generalizability of knowledge relates to the manner in which it can be applied to situations other than the narrow set of situations in which the observations were made (Lee & Baskerville, 2003). Generalizability can be established in several ways and can have different meanings dependant on the manner in which it is achieved. The natural sciences use statistical analysis of observations to determine the confidence that can be established that the null hypothesis is not wrongly rejected, and so seek to establish results as being universally applicable across all analogous cases. Fields which accept interpretivist views of knowledge may be satisfied with developing knowledge that is true within the bounds of the situation of observation, without demanding that the knowledge obtained be demonstrated for a broader range of situations (Lee & Baskerville, 2003). In general, the notion of generalizability demands the assumption that the matter of observation is uniform across the range of the generalization so that the observed sample represents a wider space (Lee & Baskerville, 2003).

When we look for objective, generalisable knowledge about subject matter we narrow our view of the nature of knowledge through the Positivist lens to concerning knowledge about external things. This is not the only view of knowledge which exists, and unnecessarily constrains research since it excludes the development of knowledge of other kinds.

KNOWLEDGE

We present now a discussion of the nature of knowledge which is necessary to develop a top-down approach to the evaluation of methods of research. We review some recent distinctions in the description of knowledge.

"Know that" is a formulation used to describe declarative knowledge, following Gilbert Ryle's distinction between "knowing that" and "knowing how" (Ryle, 1948). This distinction has been noted as significant in engineering, where both kinds of knowledge are required (Bucciarelli, 2003). Declarative knowledge is a kind that can be articulated in words or mathematics that represent ideas concerning the nature and relations of things. As such, declarative knowledge is a form of knowledge which it is fairly easy to teach and learn because it is possible to reduce the teaching or learning to recitation of the representation of the knowledge. The recitative character of declarative knowledge is discussed by Biggs (Biggs, 1999). Declarative knowledge is any knowledge which can be formulated in statements which convey the knowledge itself, whether that knowledge is generalizable across a wide range of cases or of limited applicability.

"Know how" is Ryle's formulation to describe the capacity to perform a function. This capacity is quite distinct from the capacity to describe the area of knowledge related to the function or the relevant theory. Biggs (1999) describes this kind of knowledge as "functional". Functional knowledge emphasizes the person's capacity to perform a function, not to articulate description of what is known. Functional knowledge does not preclude the ability to articulate what is known, but emphasizes ability to perform an act. The distinctive feature of functional knowledge is the knower's orientation to doing a function rather than describing something. Should someone articulate functional knowledge into a description it would be possible for another person to learn the description as declarative knowledge, which that person could recite, but not be able to perform appropriately.

A third kind of knowledge is named "knowing" in Nissen (2006), and by Biggs (1999) as "procedural knowledge", or "skill". The emphasis in this kind is on ability to choose and perform some action in an appropriate and effective manner. Nissen says that knowing how to ride a bicycle is demonstrated by mounting and actually riding a bicycle. The only test of "knowing" is a practical test in which the candidate must perform the action. Ability to articulate anything about the matter of action or a theory about the action is irrelevant to "knowing". "Knowing" contrasts with "know how", where the emphasis is on ability to perform a function, because "knowing" is usually associated with skills such as ability to discern when a particular action is apposite. The difference between "know how" to ride a bicycle and "knowing" how to ride a bicycle is that in the "know how" formulation the knower is able to perform the set-piece tasks associated with riding a bicycle, but may not yet be ready to integrate all the tasks into safe riding of a bicycle on a roadway with traffic. The "knowing" formulation refers to the more advanced achievement of being able to integrate all the set-piece tasks into effective and safe cycling in a normal situation.

The three kinds of knowledge span from the ability to abstract, describe and theorize about subject matter, through applied knowledge which enables performance of functions, to practical ability to perform whole and complex activities. These kinds of knowledge form identifiable points in the characterization of knowledge. Any particular knowledge held by a particular person will have its own combination of abstract theorizing and ability to act, and so could be described as belonging at a particular point along a continuum. Identification of the three kinds of knowledge is useful for theorizing about the nature of knowledge, and research.

Research is an activity which creates new knowledge, which could be of any kind. The new knowledge may be in an abstracted, declarative, form, or may be embedded in the capacity of a person to act appropriately as either functional or procedural knowledge. In describing research as means to produce new knowledge, it is important that the new knowledge be new to everyone. However, the knowledge advance may be of any size, including very small, and may be situationally constrained.

RESEARCH METHODS

At least some academic research degree regulations in engineering demand that the research work not apply "the normal engineering method"[1]. These regulations presume that there is clear agreement as to what constitutes a normal engineering method. There are two grounds for scepticism that there is a clearly agreed engineering method. These grounds are that:

1. There is very little teaching of method in engineering programs beyond quite rudimentary descriptions of things such as the project life-cycle. That is, descriptions of the engineering method omit detailed explanation of how the creative work of engineering

which synthesises solutions to problems is actually done. This knowledge is the purview of Design Studies, which itself reflects diversity of views about what constitutes the design process (Dorst, 2008; Gregor & Jones, 2007; March & Smith, 1995; Walls, Widmeyer, & El-Sawy, 1992).

2. Engineers, in general, discuss methodology very little. The engineering culture emphasises investigation of the technologies and principles which are applied in the technologies but says little about either how the principles are discovered or applied to achieve engineering outcomes. The measure of a good engineer is one who can successfully achieve challenging objectives (Hopkins, 1954).

Engineers tend to be a pragmatic lot who get on and do the work without extended discussions of the methods and principles upon which the work is based. Individual engineers develop a good pragmatic understanding of methods applicable to the kind of work that they do, largely through experience, including observation of the effectiveness of methods which they have attempted to use. This is an approach to knowledge consistent with the approach discussed above under the name "knowing".

The words from the research degree regulations "not apply the normal engineering method" are often interpreted to mean that design cannot be research because design is considered to be a normal engineering activity and therefore excluded. Design is a significant part of engineering work and the design of almost any product, from the simplest to the most complex, is the result of an engineering design activity.

We need to explore this issue. Design concerns development of situated knowledge. The outcome of design is knowledge which is specific to the particular need addressed by the project. The situated knowledge developed by design is specific to the particular solution which is offered. The knowledge that we developed through the design process is specific to the choice of technology and the system architecture selected and provides "proof by construction" that the design idea is valid and effective (Hevner, March, Park, & Ram, 2004). The action of design always, but specifically including the case of design of novel or innovative products, demands rigor in the use of the underlying principles to posit an appropriate design and in the evaluation of the results achieved (Hevner, et al., 2004).

To posit design as a research methodology challenges the tacit idea, held particularly strongly in the natural sciences because of their Positivist conceptualisation of knowledge and therefore significantly influencing many engineers, that knowledge created through research should be generalizable to all cases (Lee & Baskerville, 2003). The knowledge developed in a particular design project is specific to the particular design implemented through the project and the context in which, and for which, it is tested. That is, a design project produces distinctly situated knowledge of what is apposite in constrained circumstances.

Various authors have written about research methodologies which are suitable for use, or which are commonly used, in particular disciplines. These works are often designed as texts for research methods courses. Such courses are usually designed to provide students with instruction in how to conduct activities in the discipline in which they are studying a research degree. Research methods courses which teach one, or a very few research methods, leave students with the impression that proper research must be done using one of the methods described in the course.

Engineering should not be approached as a field which permits only a few particular research methods. This is because the core concern of engineering is the development of suitable solutions to address needs. Therefore methods of research in engineering need to include methods which can explore the scientific phenomena which may be applied in a solution, but also need to be inclusive of research methods which can explore the nature of the need to be addressed and the effectiveness of any proposed solution to be a solution to the need which has been presented, and could explore the methods for doing engineering work (Ferris, 2009). The evidence provided by the content of mainstream engineering research journals shows that much of the engineering research publication since the 1960s has been constrained to discovery about scientific principles which may be useful in future engineering projects. This is evidenced by the focus of journals being mainly centred on technology areas, with only a few, less well-known, journals addressing niche areas. In the next section we discuss a different interpretation of engineering research evidenced in engineering journals during the 1950s.

ENGINEERING JOURNALS IN THE 1950s

We turn attention now to the content of engineering journals published in the 1950s because a significant number of papers emphasizing the whole of product system level of development were published during that decade. This section of the chapter is supported by a detailed analysis by the author (Ferris, 2007a, 2007b, 2008). In the context of the present work the point to be drawn from the history of the 1950s publications was the recognition of the achievement of a significant engineering design providing a product or system as being, itself, a research product and worthy of publication in an engineering research venue. This recognition and emphasis receded with the changes in education and engineering research following Sputnik.

Two important trends influencing the understanding of research in engineering occurred during the 1950s. Before the 1950s engineering was taught in institutions with names such as "Institute of Technology", and was only just entering into institutions known as universities. During the 1950s the professional standing of engineering was growing based on the obvious benefits of the rigorous application of complex scientific methods to the achievement of engineering objectives. This shifted the standing of engineering from being concerned with the instantiation of things in workshops and factories, with all the associated connotations of dirty hands, to a field in which there was obvious benefit to be obtained through the application of advanced scientific theory, with the connotations of dealing with generalizable knowledge. This difference was important in the transition of engineering to become recognised as having a proper place in the university. The new view of engineering more closely aligned with concepts associated with the Platonic ideal associated with most of the other professions based on university education. The transition was supported by the obvious advances in engineering which had occurred during World War II as a result of fundamental scientific research into matters enabling the development of technologies which had made a significant difference in the war effort.

Universities were seen as the highest place of learning in most fields. So, during the 1950s when the physical sciences had already been accepted as legitimate fields of university activity, fields such as engineering were trying to be recognised as acceptable. The claim for engineering to enter the university was based on the demonstrable importance of application oriented scientific research in the advancement of engineering achievement of significant new technologies. Application oriented scientific research is research focused on the development of knowledge of the scientific principles associated with particular phenomena which are expected to be useful in applications in the foreseeable future. The pathway to be accepted into the university as a suitable field relied on a field demonstrating credentials as suitably "scientific". The claim to be scientific was supported by following something that appeared to be "the scientific method" in research and teaching in the manner used in the natural sciences. The focus of the natural sciences is to explain how and why things are as they are (March & Smith, 1995) which contrasts with the fundamental concern of engineering with the properties of artificial things (Simon, 1996). The matter of the scientific method will be discussed in a later section of this chapter.

Engineering journals report research related to engineering. Since the 1960s the majority of articles in the majority of engineering journals have reported investigations of particular situations or phenomena which appear to be potentially interesting in the possible engineering of solutions to needs. In this sense the work belongs in engineering journals, which properly contain research which is of interest to those who intend to make artificial things to have a planned effect.

However, the approach to investigation, as reported in most engineering journal articles, is largely abstraction from the context of a solution to a complete need to provide characterisations of particular phenomena, materials or components which may be useful in future engineering work. The post 1960s engineering research paper style is to present the research issue in an abstracted manner, as an issue separated from the practical context which motivated, or any practical application of, the work. In some fields the motivation of projects is to refine the theory which is already in the literature but without the refinement being called for by those who practice in the field.

The research methods which are used include empirical methods in which tests of real instances of the subject matter are performed to build conclusions and simulation and modelling studies in which the properties of a model of a scenario are investigated. Modelling and simulation research can be very valuable because it enables the exploration of the characteristics of a wide range of cases cheaply and conveniently. The value depends on whether the subject matter is amenable to physical investigation or can only be investigated through simulation. In either case the knowledge developed is of a "know that" kind that concerns the properties of the abstraction investigated rather than the behaviour of the subject matter in the context of a real instance.

Another notable change in engineering research papers commencing in the 1960s has been a shift in the balance of authorship of research papers to the university sector from the engineering practitioner sector. This change is associated with the change of subject matter because practising engineer's concerns are with finding means to address needs rather than describing abstractions of things which might be useful in some future engineering project.

In the 1950s the engineering journal literature was rather more diverse. There was greater diversity of authorship, including a significant proportion authored by practicing engineers, and diversity in the classes of subject matter. There were a reasonable number of papers discussing advances in engineering science but there were a large proportion of papers which discussed the development of solutions to particular needs. Some of these papers described solutions to needs addressed by engineers in their engineering work, that is the papers presented theoretical frameworks for particular kinds of analysis that addressed particular practical design needs. For example, the early volumes of *IRE Transactions on Reliability* outlined the theory of reliability as required by engineers who needed to do reliability analysis as part of their design activity. There were also many papers which described the implementation of product or system designs. These papers were written in a manner that would help other engineers confronting related problems to recognise the important issues and approaches to solutions which had been demonstrated successful by somebody else.

Of the two classes paper identified in the 1950s the former class, the theoretical and empirical contributions related to understanding of engineering relevant phenomena are fairly closely aligned to the papers published more recently. However, even here there is a significant difference. The papers published in the 1950s generally provided a clear, brief, explanation of what need in the physical domain had prompted the work which was reported in the papers. The work was not reported in an abstract manner, largely separated from its contribution as part of the solution of a broader engineering problem.

The papers describing the design of complete products and systems are a genre which has become rare in the engineering research literature. The papers describing the design of complete products and systems describe the results of projects in which the act of design created new knowledge that was perceived as worthy of publication as a description of new knowledge. The concept of engineering design as research, creating new knowledge of significant value to the engineering community, in the act of successfully designing a novel solution to a need was accepted in the 1950s, and has since faded from the engineering community.

The difficulty with accepting design as research arose during the 1950s as the engineering community sought to gain university status and consequently shifted its concept of research to that which would produce knowledge of the "know that" kind. The change in the kind of knowledge sought in engineering research resulted from the Platonic ideal, resulting in knowledge of the abstraction of something, rather than the concrete instantiated form of the subject matter, was seen as necessary to gaining a place within universities. The result has been an emphasis on discovery of generalisable knowledge of the "know that" kind in engineering research. The effect has been to separate the academic and practice communities so that, whilst an engineering degree is a prerequisite for entry into either the academic or engineering practice communities the two communities and career paths then diverge.

1950's EXAMPLES OF DESIGN AS RESEARCH

We now discuss three examples of papers demonstrating design as research dating from the 1950s. These are only samples from amongst many available from the decade. The first of our studies concerns the development of a photographic data logger which included both time and magnitude grids (Riblet, 1956). This paper commences by reviewing existing data logging and plotting instruments, noting that there are two classes of recorders. The two classes are those that directly write on a paper chart, useful for low-frequency signals, and those producing a photographic record through reflecting a light beam from a mirror, capable of responding high-frequency signals. The latter class do not include calibrated taxis and grids for the timescale and magnitude resulting in a very slow process of reducing data to a usable form.

The authors introduced their project objectives. They set out to develop equipment which could simultaneously plot a function on the time grid and make the chart produced in the data plotter the final data form. Their product simultaneously plotted the function being measured; the time grid; and a magnitude grid. They recognised that achieving these objectives would require design of three significant elements. After describing the goal the paper describes the design solutions for each of these major elements. The description was a verbal description of the elements as built and the rationale applied in the design. The paper concludes with an evaluation of the instrument developed in terms of the quality of the plots produced and an evaluation of the labour saved.

The second study concerns the development of a plasmatron tube (Johnson & Webster, 1952). Existing vacuum and gas tubes provided either high impedance, continuously controllable, low current or low impedance, uncontrolled, high current operation. The absence of a tube type capable of providing low impedance, high and controllable current operation presented a difficulty for designers in certain applications.

The tube designed was described using words to explain the principal by which worked, photographs to show its physical construction and test results. In addition the authors presented formulae which would assist in design of the components to achieve desired performance and a theoretical description of how the tube performed. The paper provided the information necessary for another engineer to design a similar product and the principal performance characteristics graphs to enable readers to understand its performance characteristics. This paper showed the design of a novel component type with the information necessary for users to use it or for others to design similar components.

The third case concerns the design of a very high power pulsed magnetron tube (Okress, Gleason, White, & Hayter, 1957). These authors provide detail of the electrical characteristics of the tube which they were required to build, noting that the specified parameters were very ambitious. The authors identified a number of major technical challenges. The technical challenges included achieving the required performance and achieving reliability that would make the component useful. The work commenced in 1946 and design was completed in 1953 with the paper being published in 1957, including an account of the reliability achieved.

The methods of addressing the technical problems resulted in development of appropriate materials. The paper describes the scientific experiments performed to demonstrate the suitability for purpose of the materials found. A further problem identified and solved was the difficulty of manufacture of such a large tube.

It is clear that the product was very challenging. The purpose was not explained but much else about the design was described. The performance and test results for the completed tube were provided showing successful completion of the project. What is significant is that this paper shows how the authors successfully satisfied their objective and solved a number of significantly challenging problems.

Each of the three papers discussed in this section demonstrated the successful design of a product which was inherently very challenging showing how such a design project can satisfy a novel need in a suitable way and how design activity may demand discovery of various kinds of solution to many distinct needs. The solution of the various needs that together comprise the project may involve a variety of research methods and lead to discoveries of various kinds.

DESIGN AS RESEARCH METHOD

The idea of the scientific method of how scientists proceed with research is a myth concerning how observations are transformed into knowledge. The common descriptions of the scientific method start with the proposal of an hypothesis which will be tested through the collection of appropriate empirical data. By nature of the case the empirical observations can only refute the hypothesis but can never prove it. This situation leads to several problems:

1. Often the research question is distorted so that the researcher can create an hypothesis which can be tested given the resources available.
2. Often the researcher's belief about the situation is reconstructed as a null hypothesis so that when the null hypothesis is refuted the researcher feels justified in asserting that their belief about the subject matter is supported.
3. The method, as described, does not provide an explanation of how the researcher can develop knowledge in a field which does not already have a body of work which can be used to construct formal hypotheses.

4. The result of such research is conclusions about particular hypotheses which represent abstractions from the context in which the observed phenomena exists or any situation in which the knowledge might be useful. The objective of such research is the development of knowledge for its intrinsic value, not its instrumental value.

The result of research performed using an hypothesis testing approach is the creation of scientific knowledge describing certain aspects of the matters which are being investigated. This knowledge is often obtained in a situation where the researcher's objective is to obtain information about a situation which appears interesting for the intrinsic value of the knowledge sought. The impact of orientation to the intrinsic value of the knowledge is that the questions asked and the termination point of the research project are determined based on the expected achievement of the knowledge which is perceived to have an intrinsic value. The consequence is that the knowledge obtained may not be relevant to any application. The problem of distortion of the research questions in order to have questions which are amenable to answer by the standard method frequently results in good work which is difficult to apply.

The nature of the research process discussed above is that it provides knowledge about questions which are abstracted from their context. Abstraction is often necessary in order to construct the problem in a form which can be addressed using this approach. However, abstraction by its nature removes the matter of investigation from its context resulting in knowledge which is largely context independent. The difficulty of abstracted context independent knowledge is that it is difficult to integrate such knowledge into an arrangement which applies that knowledge to achieve a desired outcome. The difficulty in applying scientifically derived knowledge to achieve a desired outcome is a consequence of the different kinds of knowledge, as discussed above.

Scientifically derived knowledge concerns the development of a generally valid theory which explains the observations. As such it concerns knowledge of the "know that" kind. That is, scientifically derived knowledge is concerned with description of things, transforming our awareness of those things from perception of the state of nature to description of a theory that explains the state of nature. The description of the theory is, inherently, and explicit articulated form. When someone desires to use knowledge and to integrate elements of knowledge to create some meaningful product the knowledge required is not just of the "know that" form describing the elements which must be integrated. The act of integrating the fragments of knowledge to achieve a useful outcome is an act of constructing knowledge in either the "know how" or "knowing" forms. The dynamism of the knowledge created in the act of application to the solution of a need occurs because in the act of integration of the elements of knowledge that described the abstracted phenomenon of the elements are transformed from knowledge about abstraction is to means to achieve an end.

We consider now the fundamental difference between science and engineering. Science seeks knowledge which enables the description of a state of affairs which already exists. Engineering is concerned with action which leads to desired outcomes. Engineering has two foci of action: the design of the product system itself; and the engineering organization and process which achieves the production focus. In relation to the engineering process some perform research of a prescriptive kind, as described by a number of design scientists, whose interest is to determine the processes that would be prescribed in order to achieve a desirable design (March & Smith, 1995; Walls, et al., 1992). In the development of a prescriptive theory, that is a theory which is designed to instruct future action, the researcher must be careful to consider the impact of the context in the situations observed, which are used to develop the theory, so that that context does not produce inappropriate prescription for other contexts (Dorst, 2008).

In relate to the former objective of engineering, the development of suitable solutions to needs, leads to work continuing until the need is satisficed (Simon, 1996). If the need is routine we may be able to rely on precedence to guide a new design. If the need is very ambitious we might need to perform fundamental research to discover methods to solve the problem. In the case of routine design there is little that is particularly new that is discovered in the design process, since the design space is constrained to lead to an incremental variation of existing methods to achieve a suitable solution. In the case of design of novel products and systems there will be many discoveries made as the engineer seeks to integrate existing related knowledge of the various elements into a solution to the need. Another difference between science and engineering is that engineering is concerned with achieving a sufficient solution, which satisfices the need, rather than the completely satisfying theory sought by the scientist.

The engineer's goal is to make something which is useful. Usefulness is the characteristic that determines if an engineered product is successful and, by extension, the success of the engineer (Hopkins, 1954). To be useful a product must suit its purpose and intended situation of deployment, its *sitz im leben*.

To satisfy the opposite for the intended *sitz im leben* evaluation criterion the engineer may need to do significant research to develop understanding of the need. This requires significant care to ensure that the questions asked in the investigation do not lead to a particular set of findings which lead ultimately to the circular reasoning that the investigator finds what they presumed to be present by the nature of the question which they asked (Dobson, 2001) The process of designing a novel product, or a product using a different technology than has previously been used, to address that need will produce significant new knowledge of how that need can be addressed. Therefore, design is a means of creating new knowledge concerning the problem space and means of addressing the problem, and so a methodology for research.

The differences between engineering and science imply different epistemologies and possibly different ontologies. Both believe that there is a real world with which practitioners interact. Neither the engineer nor the scientist is a post-modernist, but rather both are significantly influenced by Positivist reasoning. As such both believe we can observe the world and make real observations and that multiple people could make the same observation. Both are Critical Realists who believe that observations are affected by the circumstances in which they are done but both believe that the object which prompted an observation is real and that differences in what is seen are the result of perturbations caused by the observation situation and differences of view point experienced by different observers. Recognition of this problem has led physical scientists and engineers to develop methods to compensate for variations of observation caused by the point of view. Both the scientist and engineer are positivists because they believe that there is real stuff.

The difference between the positions taken by the scientist and engineer is that a scientist is concerned with creating universally true knowledge and, in contrast, the engineer's concern is the delivery of apposite satisficing solutions to needs, which results in the engineer having a distinctly specific view of knowledge and discovery. To this end it is necessary for the engineer to have case specific knowledge. The engineer needs both general scientific knowledge and case specific knowledge. The engineer will also use phenomenological knowledge, that is knowledge which describes something repeatable may be useful even in the absence of a substantial theory to explain the observations. A lot of successful engineering work has been based on phenomenological knowledge, such as the engineering work based on graphical representations of relationships of variables where the relationship was too complex to express mathematically or numerically at the time the engineering work was done.

KNOWLEDGE DEVELOPED THROUGH DESIGN

Design and construction of a solution to a need demonstrates that it is possible to achieve a solution to address the need. That knowledge, alone, is not very exciting and would not be a satisfactory finding of a research project because it provides no foundation for further action. What is exciting as research is the development of understanding of how the need was addressed so that in future similar, but different, cases we have knowledge that will guide our approach. In this, useful research through the activity of design develops a theory which links design requirements with the solution developed and the method of developing the design (Markus, Majchrzak, & Gasser, 2002). Contrary to Hickey (1960), who asserted that "engineering answers the hypothesis that it is possible to build something", the purpose of engineering design is not to answer the hypothesis that it is possible to build a solution to the particular need, it is about coming up with an apposite satisficing solution to that need.

The engineer's goal is to produce a suitable solution to the need. Design based research determines the characteristics of a suitable solution, and carries through at least one design to a state in which it satisfices the need. Design based research in engineering concerns understanding what constitutes a suitable solution and determining whatever is needed to achieve such a solution. Hickey's view is a force-fit of an engineering activity into a scientific conceptualisation of research, which is inappropriate. It is notable that Hickey's view was published in 1960, when engineers were seeking to present and promote engineering as "scientific".

A point of difference between the design based research methodology and the scientific methodology is that design produces an instance of a solution to the need. That is, design produces a specific instantiation related to a specific problem. It is a reasonable to expect that there might have been other ways to address the need. And, we cannot prove that the solution offered is the best solution but rather, only an effective or satisficing solution. In contrast a scientist seeks to demonstrate that knowledge created is true, and so aims to make absolute assertions. Consequently, scientists are dissatisfied with the need to specify caveats on the quality or generalizability of the knowledge that they obtain.

Whilst the scientist cannot prove that the knowledge created is true their intention is to create universally applicable knowledge. In contrast the engineer's solution is never claimed to be universally desirable nor the best possible solution, but rather the best that the engineer was able to produce in the circumstances. Design yields background knowledge about components, materials and their behaviour which impact the product, but may also be useful in other cases.

CONCLUSION

Research is generally recognised as an activity which creates new knowledge. The discussion in this chapter has concerned the manner in which the action of designing novel engineering solutions to needs is a research process, contrary to much popular opinion. This chapter has examined the underlying conceptualisation of research embodied in the form of research which has become common in engineering since the 1960s, which is a form of research similar to that performed in the various science disciplines, and largely based on Positivist principles.

Underlying the conceptualisation of research is the question of what is seen as constituting knowledge. Research methods associated with the development of objective and generalizable knowledge are designed to produce scientific type understanding of extant things. This contrasts with the fundamental nature of engineering which concerns the development of solutions to needs. Therefore engineering has three levels of specificity. The need is specific and must be appropriately understood. The architectural approach to the design of a solution presents decisions about specific methods of instantiation of a solution to the need. The third layer of specificity in engineering design is the particular design which is used to realise the architectural approach which has been decided for the solution. Each of these three specific matters results in discovery related to specific ways of achieving solutions to the needs. The effectiveness of solutions which are offered may be evaluated but it is not possible to determine if any solution which is offered is the best possible solution or the best solution that could have been offered at a time or the best solution that could have been offered for a certain resource expenditure or according to some other measure of desirability. All that can be determined is that the solution satisfices the need when evaluated across the range of criteria determined as appropriate evaluation criteria. Therefore the kind of knowledge created by design as a research methodology is fundamentally different than the kind of knowledge created by science oriented research methodologies.

The knowledge created by science oriented research methodologies is desired for the intrinsic value it is believed to have. The knowledge is expected to be objective and generalizable and will be of some explicitly expressible form, consistent with the "know that" conceptualisation of knowledge. The knowledge created by the design methodology is desired for its instrumental value; the ability to achieve a solution to a problem that it enables. Knowledge generated through design is specific to the need addressed and the design approach used. The knowledge generated through design is of the "know how" form and may contribute to knowledge of the "knowing" form as experience with a number of design projects enables an engineer to develop better judgement about appropriate design strategies. The knowledge developed through design includes knowledge related to the achievement of the product which is designed and may contribute to knowledge of the design process as means for the performance of future design projects.

KEY TERMS AND DEFINITIONS

Design: A human activity which combines existing knowledge and things to generate an output which is desired.

Engineering: A human activity centred on providing appropriate solutions to needs.

Know How: A form of knowledge which concerns being able to do particular itemised actions.

Know That: A form of knowledge which can be explicitly stated, and so can be learned and taught in the form of those statements.

Knowing: A form of knowledge related to the fluent and appropriate performance of action.

Knowledge: That which one has a suitable foundation for being assured is a true or appropriate description or method of interacting with the world or a part thereof.

Research: A human activity which creates new knowledge.

Science: A human activity centred on seeking to understand observed phenomena, things and situations with the purpose of providing accuratedescriptions and explanatory theories ofthe things observed.

***Sitz Im Leben*:** Situation in life, following usage in Theology which originated with Hermann Günkel.

Chapter 95
Engineer-to-Order:
A Maturity Concurrent Engineering Best Practice in Improving Supply Chains

Richard Addo-Tenkorang
University of Vaasa, Finland

Ephrem Eyob
Virginia State University, USA

ABSTRACT

General Engineer-to-Order (ETO) design of product capacity projects among many others, includes design for large electric machine, huge centrifugal pumps, diesel/natural fuel power plant engines, steam turbine, boiler, ship power, et cetera. ETO is basically a product development process, which starts with a product specification and finishes with an engineering design as its deliverable. It rarely includes manufacturing processes. The main drawback is with issues concerning its long lead-time. Research shows that an excessive lead-time is more often than not caused directly or indirectly by factors related to the design phase. This chapter thus, endeavours to introduce a best practice concurrent approach for reducing the lead-time at an engineer-to-order product design/development stage by seeking to integrate business information technology systems in the design and operational phases. It also introduces a new concurrent best practice approach by way of seeking to integrate other related business systems, e.g., (Enterprise Resource Planning (ERP)) such as (Enterprise Service Architecture (ESA) application processes with Service-Oriented Architecture (SOA)) as a platform for applications and processes for effective communication. Furthermore, the chapter presents and discusses a model of classical concurrent engineering (CE) ETO operational process. ETO key elements, ETO success factors, and series of state of the art ETO classical ERP engineering design tools, as well as the "best practice" product life cycle are all discussed.

DOI: 10.4018/978-1-4666-1945-6.ch095

INTRODUCTION TO ETO FROM A CONCURRENT ENGINEERING PERSPECTIVE

Industrial manufacturing companies producing engineered products on an engineer to order (ETO) in a concurrent engineering approach (i.e. partners from various divisions in the organizations) have traditionally found business opportunities. Through the design and product development expertise and an ability to respond to demands for customisation with improved product performance, customers are increasingly seeking for more affordable prices and a much reduced lead-times, which also require improved manufacturing efficiency. These companies are thus being driven to improve the integration of the design, manufacturing and procurement functions (Cameron, and Braiden, 2004). In order to facilitate this improvement in the integration of the various partners involved, and to improve the overall product time to enhance and better define the product as well as properly document the design process, a concurrent engineering process needs to be adopted in the supply chain management (SCM). Concurrent engineering process which very much operates in the same vain as a collaborative engineering process, is a process in which the appropriate partner organizations are committed to integrating their system processes to work interactively. Thus, to visualize, develop and implement engineered products and programs that correspond with their pre-determined objectives. Concurrent engineering in this sense is moderate collaborative engineering approach that is much more focused on the engineering product design process of concurrent cross-functional partner organizations together in order to create products that are much better, much affordable and with a much reduced lead-time.

Engineer to order products may require a specific set of item numbers, bills of material (BOM), and routings; these are usually complex with long lead times. Customers are also normally heavily involved throughout the entire design process and manufacturing process for an engineer to order a product. It is usually limited to an engineering design process which involves the tasks of engineering analysis, concept design, architectural design, detailed design and manufacturing process design. It does not include the manufacturing phase of materials acquisition, fabrication and assembly. In a traditional ETO operation, product functionality is the major design focus (Chen, 2006).

The product design process phase takes enormous time of the entire process lead-time. Thus, the new and improved ETO – CE process flow model approach proposed in this chapter seeks to reduce the long lead-time by its CE approach of all the partners as well as communicating and exchanging product design information on a common platform. This new improved approach as compared with the classic ETO process flow approach will bring all partners in the design supply chains together both locally and globally by using a system oriented architecture (SOA) – extensible mark-up language (XML) communications on a common platform across the world-wide-web. Thus, providing an opportunity for even different design teams in different organizations, with different SCM information systems (IS) to link-in easily and faster to resolve any design issues. Thereby, reducing any delay in design processes, which is the cause of long lead-times in classical ETO processes. ETO – CE approach in improving product design supply chains enhances an industrial manufacturing organization's ability to gain effective and efficient control of the upstream through to the downstream of their ETO product design processes and assume a dynamic concurrent approach to supply chain rather than a reflexive to lead-time threats. The follow section gives more elaboration of how ETO – CE integration into supply chains could improve the chain.

Supply Chain - ETO - CE Process Integration

ETO's successful integration into manufacturing supply chain is by efficiently and effectively incorporating the various engineer-to-order activities and processes from the upstream in the supply chain (suppliers) through to the downstream (end customers). Considering the current global competitive pressures, manufacturing industries have followed through with series of business strategies and different approaches in their bid to enhance the value for the end customer (Kim, 2005; Chopra and Meindl, 2001). Industrial manufacturers who succeed globally continue to adapt, develop and improve their supply chain network value as the market condition becomes more progressive (Kumar et al., 2006; Reichhart, and Holweg, 2007).

The significance of speed in product development activities and processes, lean manufacturing practices, quality, cost and flexibility in the supply chain should be well supported and managed by advanced infrastructures in supplier sourcing, logistic management, information systems and technologies as well as very good customer relations management (Gunasekaran et al., 2008). Thus, value in ETO products is realised in product development of the supply chain, mostly in a concurrent approach through collaborative partnerships and integrations that recognize contributions from the product development process, procedure, information, finance, management of knowledge, innovation and relationship management (Barber, 2009). Therefore, the approach of successfully integrating ETO methodologies enhances supply chain flexibility and value. This reflects the current state of embedding process improvement into the supply chain operations of product development a as being proactive in managing supply-demand fulfillment concurrently (Lee, 2004; Ketchen et al., 2008; O'Marah and Hofman, 2010; Porter, 1990).

Integration strategy programs, applications and processes involving all stakeholders in product development (i.e. customers, suppliers, marketers, accountants, design engineers, production engineers, manufacturing engineers, etc.) during the capacity management, enhances the ETO supply chain to a shorter delivery lead-time on customer specification and orders (Swafford et al., 2006). Customer relationship effect in ETO methodology integration in the supply chain increases understanding in customer demand, managing complaints and improving customer satisfaction which critical responsive element through the ETO value chain (Li et al., 2006; Holweg, 2005). According to Zhou and Benton (2007) quality information sharing on a common and assessable platform among stakeholders enhances ETO supply chain practices such as just-in-time (JIT) and lean lead-time delivery. Thus, the capability to collect, disseminate various data, information from customers across ETO supply chain nodes concurrently will enable internal manufacturing strategies to respond effectively to the needs of customers. This paper presents a maturity concurrent engineering "best practice" approach in ETO methodology in product development. An improved CE- ETO model proposed in the subsequent sections in a concurrent approach is expected to reduce the lead-time making ETO methodology leaner by also successfully integrating enterprise resource processes and applications in the ETO supply chain.

Thus, new trends reunite technical and non-technical disciplines such as product engineering partners, marketing/brokers and accounting/financial controllers. This collaboration aims at satisfying the customer. Therefore, the product design partners in industrial organizations must also collaborate in defining and analysing the product specification aimed at satisfying the end customer. Hence, the approach to ETO process, concurrently in a collaborative approach, mainly dwells with the product design aspect. ETO product and the engineering process lead-time is well managed and compensated for in the product design stage which turns to take a chunk of the process time. Engineer to order is a manufacturing process whereby finished products are built to unique customer specifications. These engineering product design processes are elaborated in detail in the following sections from engineering analysis to manufacturing process design.

Engineering Analysis

Engineering analysis is the aspect of engineering product design, which involves technical investigative processes and theories to reveal the properties and circumstances of an engineering system, product or concept design/structure. Engineering analysis also involves the tool and methods required in the technical investigative processes or theories. This when successfully investigated could lead to an engineering design or ironically to a simply failed process that could always be re-analysed to find out where the failures lay in the process? Therefore, this analysis must always be carried through before proceeding to produce a concept design of an ETO product to rectify the huge cost which comes with failures in the engineering systems and process design.

Concept Design

Concept design is the very first stage of an engineering design work where all the engineering drawings are mainly centered. These concept designs consist of very basic engineering 2D drawings and sectional views. The 2D engineering draws and sectional views are later developed along the process line to a more detailed 3D engineering draws with their sectional views as well. Concept design in an engineering design process has certain specific stages of conceptual design work stages that are required to transfer information into the needed requirements for the detailed engineering design of a specific engineering product. These stages include a description of the general concept, definition of the requirements or specifications of the concept plan and description of what the concept is aimed at realizing at the end as well as lists of activities for the concept. A good conceptual design comprises of the creation of a proposal or an initiative, the investigation of that proposal, or an initiative into a representation of the proposal. On this note, conceptual design can range from basic blueprint line diagrams to structural 2D engineering drawings. Thus, if the concepts are not clearly drawn, the proposal will not be completely understood, and the result potentially will be compromised.

Architectural Design

Architectural design means often the same as engineering design. It is the application of engineering design standards to engineering product design works and bill of materials (BOM) of the detailed design. Architectural design is the state in engineering product design where the conceptual design is further developed, modified or processed in a more detailed design capable of being sent to the next stage of product design.

Detailed Design

This stage in the engineering product design stage is where the detail engineering design is achieved by the design team. By using both the requirement specification (conceptual design), and the architectural specification (architectural design), provided in the previous stages of the design process. The outcome at this stage of the process will be a detailed design which will be featured in detail, describing the interfaces and functions provided by the engineering design product. This detailed design will then serve as the basis for the manufacturing process stage.

Manufacturing Process Design

This is the stage of the engineering product design where the detail design is processed for manufacturing. Material request and acquisitions are determined at this stage for fabrication and product assembly. Thus, the process and technology analysis, assembly process planning and component process planning in the detail design stages are all implemented at this stage.

The following section introduces some of the benefits for CE approach in ETO to improve the design chain and reduce the lead-times. It discusses existing research on these industrial manufacturing approaches and also their collaboration and integration successes as well as the various stages of a product life cycle (PLC).

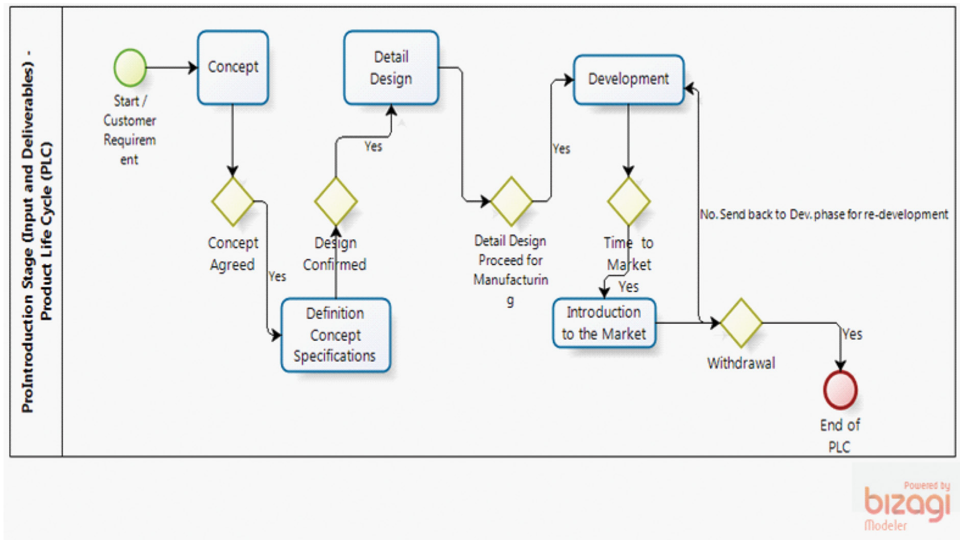
BACKGROUND REVIEW

Over the past decade industries in almost all markets have been facing a boosting level of competitiveness. There are many reasons for this, but most of them can be followed to some of the following principal trends: shortening product life cycles, globalization of the market, rapid technological changes, environmental issues, and higher complexity of products, customers demanding products with more features, higher quality, lower cost, and demand for more and more customized products. Concurrent Engineering (CE) is an integrated product development approach that emphasises the response to customer expectations by producing better, cost effective and much faster product development process. It also supports multidisciplinary team values of co-operation and trust; thus, sharing and exchanging required knowledge and information in a manner that will enhance decision making processes and also emphasis on simultaneous consideration during the design stage and all the other Product Life Cycle (PLC) aspects of the product development. PLC is the progress of a product from its concept through to its development and introduction to the market and then its withdrawal from the market or final disposal. One of the most salient means to reduce development time is through the use of "concurrent engineering." Concurrent engineering is defined by the Institute for Defence Analysis (IDA) as "the systematic approach to the integrated concurrent design of products and related processes, including manufacture and support".

Thus, PLC management confronts the need to balance fast response to changing consumer demands with competitive pressure to seek cost reductions in sourcing, manufacturing and distribution. It needs to be based on a close alignment between customer-facing functions (e.g. marketing, sales, customer service) and supply functions (e.g., purchasing, manufacturing, and logistics) (Combs, 2004; Conner, 2004; O'Marah, 2003). Hence, Product life cycle (PLC) management has become a strategic priority in many company's boardrooms (Teresko, 2004). According to Yassine, and Braha, (2003); Concurrent engineering (CE) is an engineering management philosophy and a set of operating principles that guide a product development process through to an accelerated successful completion. In general, CE values rely on a single, but powerful, principle that encourages the incorporation of the later stages of production concerns into the upstream phases of a development process chain such as during the engineering-to-order (ETO) phase of a product development, etc. This would lead to shorter development times, thus, improving product quality, and lowering development–production costs.

Concurrent engineering is hereby aimed at the timely availability of critical design information to all the design development participants. For most intricate engineering tasks all significant information required by a specific design development team cannot be completely available at the start of that task. Therefore, CE requires the most of such information and the ability to share and communicate useful information on a timely basis with the right design experts. The concept of concurrent engineering (CE) has been known for quite a while now, and it has been widely recognized as a major enabler of fast and efficient product development. This chapter examines the extent to which CE "best practices", as obtained

Figure 1. Introduction stage (input and deliverables) - Product life cycle (PLC) - Input and deliverables (BizAgi process modeller)



from a broad literature review, are being used effectively in companies globally. Some of the positive impact of formal CE programs is proven by previous research (Portioli-Staudacher, *et al.*, 2003). Figure 1 illustrates the stages of a product life cycle (PLC) highlighting the inputs and deliverables in one completed flow process with intermittent decision loop at each milestone stage of the flow process.

As the product development stage is wiry in market size but there is a growth supply chain, it is imperative that substantial research and development costs be incurred in getting the product to this stage. In addition, marketing costs may be too high to just test the market or undergo commencement promotion and set up distribution outlets. Therefore, it is highly unlikely that industries will make profits on products at the development stage when rigorous work has not been duly than to fulfil all the required customer requirements. Products at this stage have to be carefully monitored to ensure that they start to grow and pick in the market. Otherwise, the best option may be to withdraw or end the product. The need for immediate profit is not a pressure as the lack of it is an expectation at this stage. The product is promoted to create awareness of the market as well as satisfying customer requirements. Thus, if the product is not competitive, an initial pricing strategy is employed to build pricing momentum to maximise profits. Limited numbers of product will be available in few outlets of a distribution chain. Therefore, development stage should encompass a number of activities that will include:

- **Concept:** Overview of the customer requirement that an opportunity seeks to address, supported by evidence of market need.
- **Definition:** High-level definition of customer requirements and analysis of a business opportunity.
- **Design:** Analysis of customer requirements creating project plan and detailed product specification.
- **Development:** Data and software (CAD/CAM) development.
- **Development Testing:** Testing of the product against pre-defined test schedules

to ensure satisfactory performance against customer requirements.

- Development of pricing.
- Development of user guide
- Introduction of the product to the market (Time to Market). etc.

Product lifecycle management and the efficiency of information reuse relies on the definition and management of corresponding information and communication between various product design teams in various manufacturing organizations. Collaborating and sharing information concurrently in the ETO supply chains ensures the consistency and traceability of product information throughout the product lifecycle. The sales-delivery process of engineer-to-order (ETO) products presents a great potential for design reuse, i.e. the reuse of previously validated design solutions in the design of new product variants according to customer-specific requirements (Brie`re-Coˆte´, *et al,* 2010). Much as lean manufacturing (LM) in manufacturing organizations is currently enjoying its second prime, manufacturers in several industries are implementing lean practices to keep pace with the competition and achieve better results by reducing product design lead-times significantly Demeter, and Mateusz (2011).

The principles of concurrent engineering (CE) in the same vein as that of lean production has enabled manufacturing organisations to significantly improve their competitiveness. The application of CE principles has enabled many organisations to simultaneously improve productivity, quality and customer service (Riezebos, *et al,* 2009). Similar benefits have been achieved through the integration of information technology (IT) in ETO processes. Thus, integrating IT and ETO – CE principles are seen to be interdependent and complimentary by some; whilst others have seen that as the approaches as being mutually exclusive. This section thus, presents reviews of the use of some ERP systems could collaborate within the ETO processes to concurrently improve the supply chain. The following section elaborates further on the trends and perspective in ETO new product introduction and development (NPI/D). In order to meet the ever increasing customer demand and preferences is well documented. Therefore, customisation has been stimulated as a source of competitive advantage for ETO industrial manufactures. Despite these factors, most of the researched work in operations and supply chain management has side-lined the need for improvement of the ‘engineer- to-order’ (ETO) supply chain sector (Gosling, and Naim, 2009). Hence the following section will highlight a few of the essence of the global trends and perspectives in ETO new product introduction and development supply chains.

CE Global Trends and Perspectives in ETO

According to Tennant, and Roberts, (2000), an effective New Product Introduction and Development (NPI/D) process, which is a concurrent process, can enhance an organisation’s competitiveness. This can be done by compressing product development lead-times, and enabling the upstream and downstream processes in a supply chain to be considered when taking decisions at the product concept design phase. The application of Concurrent Engineering (CE) (or Integrated Product Development [IPD]) is gradually becoming the norm for developing and introducing new products to the market place (Ainscough and Yazdani, 2000). However, the degree to which companies have implemented it and the amount of success varies (Ainscough and Yazdani, 2000; Balbontin *et al.*, 2000). Many of the companies competing today in international markets consider new product introduction and development (NPI/D) as an important factor for achieving sustainable competitive advantages. Both academics and industrial managers alike are constantly searching for methods and practices that will allow them to improve the organization and management of their NPI/D processes and boost their effectiveness. The average success rate of NPI/D projects today is approximately 60% (Cooper, and Edgett, 2003). The aim of this research is to 1. shorten new product development times, 2. achieve more efficient developments, and 3. superior products.

Manufacturing companies have re-systematized their NPI/D processes and have moved from a sequential path, in which there is a negligible interaction among the departments involved and the activities required to develop the product which is carried out sequentially, towards an integrated path, known as concurrent engineering (CE) in which the activities overlap and all the departments collaborate from the beginning. This new organizational design has helped companies to improve their performance by leading to lower costs, higher quality, major knowledge creation and shorter product development times (Barba, 2001; Umemoto, *et al.,* 2004). All of this has raised competitive skills of companies. Hence, the aim is to avoid continuous setbacks and the other problems that arise with the traditional approach, improving NPI/D performance. This new practice tries to speed up the process, increasing flexibility, adopting a more strategic perspective with more sensitivity to change in the environment, solving problems through teamwork, developing diverse skills, and improving internal communication (Barba, 2001). To achieve the above mentioned objectives, CE is based on three basic elements (Koufteros, *et al.*, 2001):

1. Concurrent work-flow
2. Early involvement of all participants and groups contributing to product development
3. Team work. In other words, CE is the early involvement of a cross-functional team to simultaneously plan product, process and manufacturing activities and mentioned earlier in the previous paragraphs.

Many studies demonstrate that CE can successfully solve the typical problems of traditional. NPD, leading to clear improvements in quality and marked reductions in development time and costs (Calantone and Di Benedetto, 2000; Herder and Weijnen, 2000; Barba, 2001; Koufteros, *et al.*, 2001). On the other hand, further recent research also has also revealed that, the use of CE on its own does not always lead to positive results and that success in improving innovation capabilities depends on the context, in which CE is applied. That is, on the prevailing competitive and technological circumstances (Valle, and Va´zquez-Bustelo, 2009). Therefore, a conclusion is reached that the scale of a vagueness and intricacy present in the process of innovation may moderate the effectiveness of concurrent NPI/D characteristics on performance. Hence, the matter to be considered is not, whether CE is a mechanism for improving performance in the introduction of new products but, rather, under what circumstances such as improvement can be accomplished. It seems, however, that, in spite of many research efforts; a consensus is still lacking and that there are many empirical disagreements. This lack of agreement is the reason for this review of the global trends and perspective of CE.

According to Campbell, and Mohun, (2007), industrial manufacturing company endeavour to create an advanced core-system analytical solution that integration processes across their manufacturing industry. Thus, this will enhance the efforts by industrial processes by reducing lead-time variability and minimizing the transition times to achieve performance consistency. Therefore, to achieve this kind of core-system integrated product design and manufacturing collaboration, service-oriented architecture (SOA) turns out to be the most preferred systems' application platform. SOA is the most suitable systems' application platform for the recommended Enterprise Service Architecture to enhance this integration process effectively and efficiently. Further to this analytical leverage of CE system applications and processes; this collaboration has also been accordingly confirmed by Valle, *et at.*, (2009) research on 'Concurrent engineering performance: Incremental versus radical innovation'. They reveal that the use of CE on its own does not always lead to positive results and that success in improving innovation capabilities depends on the context, in which CE is applied. Gao, *et al.,* (2000), argues that the extensive applications of computer aided engineering (CAE) technologies are necessary so that the maximum design efficiency and effectiveness can be accomplished prior to initial sample production. The main characteristic of such an approach is depended on the system integration in accordance with the design process.

ETO KEY SEGMENTS

Most of those difficulties are caused by inefficient information; however, the most significant ETO problem is long lead-time. The ETO product delivery lead-time greatly influences the duration of any project. However, the completion of a product is dependent on the timely availability of ETO, Elfving, (2003). Extensive research has been carried out on solutions for reducing the lead-time and implementing time compression in supply chains Tsinopoulos, and Bell, (2008). Lead-time reduction is considered as fundamental for overall business improvement (Womack and Jones, 2003) and a cornerstone for lean thinking. One or a combination of three main strategies - elimination, combination and reduction can be used to reduce the lead-time. Research has identified two types of lead-time reduction in supply chains, reducing the mean lead-time and reducing lead-time variation (Hendericks, *et al. at.*, 2007). According to a study, long lead-time has more than half of its causes associated directly or indirectly with the design phase (Elfving, 2003).

Some of the typical examples are:

- Tiresome compilation and poor consistency of design input
- Modifications due to early commitment and lack of understanding
- Modifications due to design errors
- Primitive practice of supplementary design and endorsements
- Complications requiring a large number of design experts

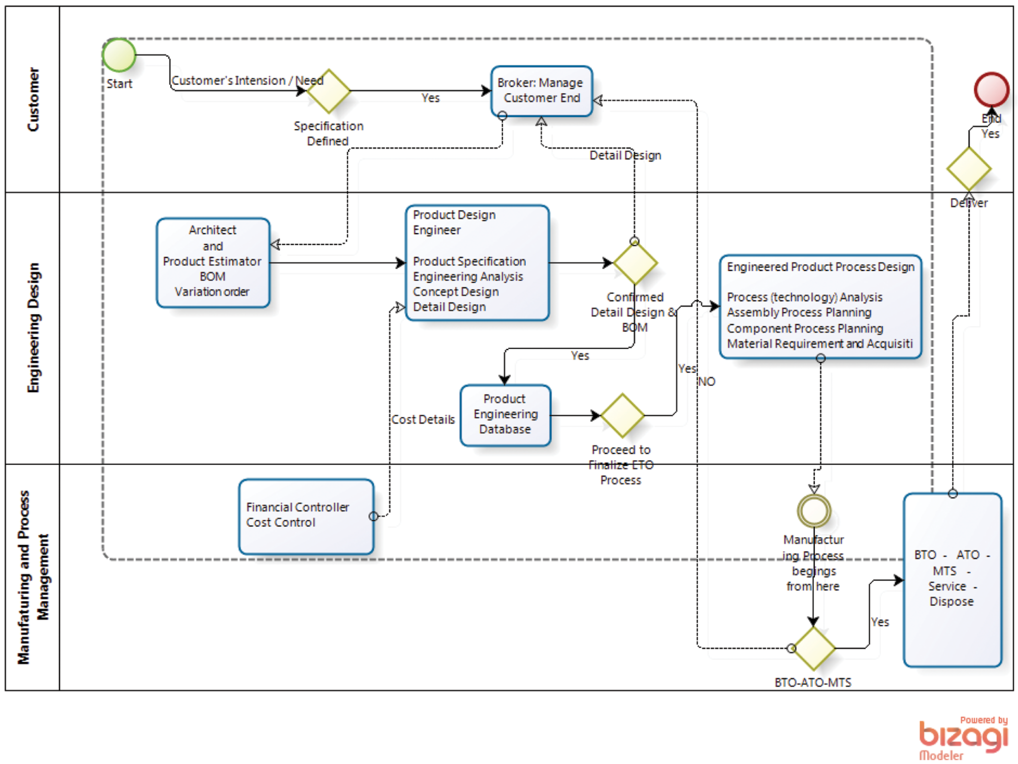
Although there may be many other factors, the causes have their roots partially in poor coordination and poor communication due to the fragmented design environment and the involvement of a large number of various specialists. Therefore, providing a more effective computer-mediated collaborative environment seems to be conducive for resolving the problem.

AN IMPROVED ETO: CE OPERATION PROCESS AND MODEL FOR SCM

ETO is a product development process that starts with a product specification and finishes with an engineering design. In a classical ETO operation, product functionality is the major design focus. Various design testing may be carried out in the design process to verify the product design in progress. The design and standardization of a manufacturing process may be a development focus as well, when intended for serial/volume production.

Figure 2 illustrates a typical Engineer-To-Order (ETO) concurrent engineering approach process model. As already emphasised in the sections above, the whole process always begins with the interest of the customer. The customer's intension or need about a product is passed or received by a broker (Marketer). The confirmed specification in question is then passed on to the product engineering team or partners with the first contact being the architect or the estimator, who then, processes the data to produce a bill of

Figure 2. An improved ETO concurrent engineering (CE) approach - Process model diagram - A typical ETO process model marked in the dotted area: Facilitated by BizAgi process modeller software



materials (BOM). The BOM is then passed on to the product engineer design department. On receiving the product specification which has come to them the design engineer proceeds to perform their engineering analysis as per the product specification to develop the concept design of the product. With the concept design and cost details from the accounts and financial controller's department, a detailed design is then arrived at.

The detailed product design is then sent to a central product engineering database where the engineered process design department accesses it for engineering process analysis (technologies required for production), assembly process planning, and component process planning and finally tested for material requirement and acquisition, then passed on for manufacturing. This is the stage where the Engineer-To-Order process actually finishes and then prepares to enter the manufacturing stages - (Build-To-Order [BTO], Assemble-To-Order [ATO], and Make-To-Stock [MTS]) upon the customer's satisfaction of the ETO product via the broker or marketer. ATO – this is a manufacturing or production approach where all the basic components of the product are already available but not yet assembled, but this is done and sent quickly to the customer once the order for production is received. BTO – this is sometimes also referred to as "Make-To-Order" (MTO). It's a manufacturing or production approach where products are built or made once a confirmed order is received from a customer. This is the current approached employed for highly customized or low quantity production, and it is also the oldest method of order fulfilment in existence. MTO - this is sometimes also referred to as build to stock (BTS). This is an already manufactured and assembled production approach, which depends or is based upon the history or anticipation of supply and demand of the product in question. Thus, large quantity of the product is manufactured, assembled and stocked in warehouses and are supplied when the demand order is received.

These processes flow through from the final delivery of engineered-to-order product that is, if there are no arising faults over time during the ETO process. Finally, disposing off entire if the product exhausts through its life cycle. Thus, ETO is the operation mode that engages in product and process designs. It may include manufacture of the product design if it is one of a kind, but the two (design and manufacture) processes typically occur in sequence. An ETO concurrent engineering approach is an operation in which both design and manufacture processes occur in parallel, in order to optimally minimize the product development time that spans a product specification and delivery of the final product. ETO starts usually working closely with the customers at the stage of specifying a customer need or defining a product specification because when an ETO product is not well defined and confirmed a huge lose will be incurred when the product design progresses. The following section introduces and elaborates on ETO "best practice" as a focal point for this chapter.

ETO BEST PRACTICE

Engineer-to-Order (ETO) is an important production approach in concurrent engineered design and manufacturing; this plays an important role in economies by way of the industrial organizations optimal outputs. Typical ETO products include large electric machine, huge centrifugal pumps, diesel/natural fuel power plant engines, steam turbine, boiler, ship, etc., (Li, 2002). The collaborative design for ETO products has some special engineering design requirements relative to other products, see Box 1:

SUPPLY CHAIN MANAGEMENT TO CRITICAL SUCCESS FACTORS

ETO, a state of the art system tool with collaborative engineering Enterprise Resource Planning (ERP) systems, such as Enterprise Service Architecture (ESA) application processes. Service-Oriented Architecture (SOA) as a platform for this system application and processes provides effective communication for this collaborative engineering system approach, which proves that it is possible to have it all. Thus, clear cost notability and much competence and control among the various partners with a state of the art engineer-to-order ERP software system tools which suits or easily links the design methods of each partner in the design team. The engineer-

Box 1. ETO product design

Multiple objectives: Besides the product structure and its production operation procedures (e.g., routings and routes), ETO product design should also evaluate the feasibility of production planning, services, quality, procurement, etc. That is to say, ETO product design must face to a whole supply chain instead of the independent design activities.
Multiple functions: This is to support the realization of multiple objectives. It is necessary for the department of sales and the ETO enterprise together with its key suppliers and customers; to participate in a collaborative design process instead of only the research and development (R&D) department.
Integrated design: Product design system should not be considered as isolated software but must be closely integrated with other related business systems, e.g., Enterprise Resource Planning (ERP) such as Enterprise Service Architecture (ESA) application processes with Service-Oriented Architecture (SOA) as a platform for applications and processes effective communication, to realize data, functions and process integration (Valle, and Va´zquez-Bustelo, 2009; Campbell, and Mohun, 2007).

ing design software industry is saturated with series of efficient engineering design units that have had to make unnecessary major changes to their software operation processes just to accommodate the reporting requirements of these ERP design software systems. Thus, if the finance and accounting management partners and team's reporting do not adequately reflect the real status of the engineer-to-order design product and their engineering operation process, their final value must be in some doubt.

In an engineer-to-order design environment, estimating the bill of materials (BOM), design process engineering, scheduling and cost are particularly difficult due to time constrains. Hence, identifying the right partners with the requisite capabilities at the right time is very essential for a successful engineer-to-order design process. Since a longer lead-time always incurs extra cost and penalties, engineering product design partner in an engineer-to-order process team need the capabilities to monitor the actual progress against the plan scheduled for the engineer-to-order process basis. These capabilities of the individual engineering product design partners coupled with the collaboration of their various state of the art Enterprise Resource Planning (ERP) engineering design software systems will always achieve a successful engineer-to-order design product for the collaborating partners.

A case example of ETO – CE approach in improving supply chains is the case of an Australian furnishing industry which was subjected to severe competition from global suppliers in the last decade. Supported by the government's Action Agenda, the Furnishing Industry Association of Australia developed the ''Production Efficiency Program'' to improve efficiency of the industry. This "Production Efficiency Program" as attributes and approach similar to that of the ETO – CE approach. Thus, the core of the program was three showcase projects demonstrating how return on investment can be achieved with the application of advanced manufacturing technologies to significantly reduce the design lead-time. Instead of committing large capital expenditure in IT based manufacturing systems, the showcases started by applying concurrent engineering principles by bringing all the design team and organizational partners together on a common platform. Hence, transformed the business practices to adopting latest IT systems for the designing, planning and control of manufacturing supply chain processes. The outcome as reported in the case study of the small furniture company achieved 30% increase in productivity by implementing a new scheduling system that assisted implementation of lean manufacturing and other manufacturing principles and best practices (Mo, 2009).

ETO CLASSIC TOOLS

Classical engineer-to-order state of the art tools for a collaborative engineering design product includes the following listed below in Table 1.

CONCLUSION AND RESEARCH GAPS

ETO in its classical perspective is covered in the previous paragraphs above in a predominantly concurrent or collaborative design engineering process. Due to the need for effective control and reduction of lead-time in the entire ETO supply chain process, it is quite obvious that the design stage is responsible for a chunk of the frequent

Table 1. New and classic ETO tools

New ETO Design Software Tools	Classic ETO Design Software Tools

Siemens NX	Iron CAD
PTC Pro. Engineer	Mechanical CAD
Catia V6	AutoCAD

extended lead-time. Therefore, efficiency in reducing this as well as improving the integration and communication applications and processes in an ETO supply chain is very much an imperative. Thus, for future research, engineering enterprise system tool for engineering Enterprise Resource Planning (ERP) systems such as Enterprise Service Architecture (ESA) application processes with Service-Oriented Architecture (SOA) as a platform for applications and processes will enhance the efficiency required when effectively and efficiently integrated within the ETO supply chain. This approach will also go a long way to reduce the design lead-time and also improving effective communication in the design engineering chain for industrial competitive advantage. As a concluding remark, ETO supply chain managers in manufacturing industries should start to link their operational processes to create responsiveness by advancing product development processes. Employing manufacturing flexibility in a concurrent fashion within ETO supply chain management information systems and information technology systems as well as customer relationship integration earlier in a product development process chain will enhance a competitive advantage for the user.

KEY TERMS AND DEFINITIONS

Concurrent Engineering: Concurrent engineering in this sense is moderate collaborative engineering approach that is much more focused on the engineering product design process of concurrent cross-functional partner organizations together in order to create products that are much better, much affordable and with a much reduced lead-time.

Customer Oriented Supply Chains Management: This is where the entire supply chain management is geared or focused towards cordinating events for the full satisfaction of the end customer.

Engineer-to-Order: ETO is a product development process, which starts with a product specification and finishes with an engineering design as its deliverable.

ETO-CE Best Practice Approach: The ETO-CE operational process is termed as the "best practice" approach in this chapter.

ETO-CE Operational Process Model: An ETO process flow model which utilizes the concurrent engineering operational principle in improving ETO supply chains.

ETO-CE SCM integration process: This is where some ERP / IT systems are integrated in the ETO-CE supply chains to enhance effective and efficient improvement in the entire ETO supply chain management.

Supply chain: a system of technology, activities, information, people as well as organizations and resources involved in moving a product or service from supplier to customer at the right place and at the right time.

Supply Chain Management: Supply Chain Management is the management of the entire interconnected chain of an organization including the activities, technology, information, the people as well as the all the other resources involved.

Section 8
Emerging Trends

*This section highlights research potential within the field of Industrial Engineering while exploring uncharted areas of study for the advancement of the discipline. Introducing this section are chapters that set the stage for future research directions and topical suggestions for continued debate, centering on the new venues and forums for discussion. A pair of chapters on supply chain management and green computing makes up the middle of the section of the final 14 chapters, and the book concludes with a look ahead into the future of the Industrial Engineering field, with "*Zero-Downtime Reconfiguration of Distributed Control Logic in Industrial Automation and Control.*" In all, this text will serve as a vital resource to practitioners and academics interested in the best practices and applications of the burgeoning field of Industrial Engineering.*

Chapter 96
Advanced Technologies for Transient Faults Detection and Compensation

Matteo Sonza Reorda

ABSTRACT

Transient faults became an increasing issue in the past few years as smaller geometries of newer, highly miniaturized, silicon manufacturing technologies brought to the mass-market failure mechanisms traditionally bound to niche markets as electronic equipments for avionic, space or nuclear applications. This chapter presents the origin of transient faults, it discusses the propagation mechanism, it outlines models devised to represent them and finally it discusses the state-of-the-art design techniques that can be used to detect and correct transient faults. The concepts of hardware, data and time redundancy are presented, and their implementations to cope with transient faults affecting storage elements, combinational logic and IP-cores (e.g., processor cores) typically found in a System-on-Chip are discussed.

1. INTRODUCTION

Advanced semiconductor technologies developed in the past few years are allowing giant leaps forward to the electronic industry. Nowadays, portable devices are available that provide several orders of magnitude more computing power than top-of-the-line workstations of few years ago.

DOI: 10.4018/978-1-4666-1945-6.ch096

Advanced semiconductor technologies are able to achieve such improvements by shrinking the feature size that is now at 22 nm and below, allowing integrating millions of devices on a single chip. As a result, it is now possible to manufacture an entire system (encompassing processors, companion chips, memories and input/output modules) on a single chip. Smaller transistors are also able to switch faster, thus allowing operational frequencies in the GHz range. Finally, low operational voltages are possible, significantly reducing the energy needs of complex chips.

All these benefits have however a downside in the higher sensitivity of newer devices to soft errors. The reduced amount of charge needed to store memory bits, the increased operational frequencies, as well as the reduced noise margins coming from lower operational voltages are making the occurrence of soft errors, i.e., unexpected random failures of the system, more probable during system lifetime.

Among the different sources of soft errors, radiation induced events are becoming more and more important, and interest is growing on this topic from both the academic and the industrial communities.

As described in (Dodd et al., 2004), when ionizing radiations (heavy ions or, protons in space, neutrons, and alpha particles in the earth atmosphere) hit the sensitive volume of a semiconductor device (its reserve biased depletion region) the injected charge is accelerated by an electric field, resulting in a parasitic current than can produce a number of effects, generally referred to as Single Event Effects (SEEs). Single Event Latchup (SEL) is the destructive event that takes place when the parasitic current triggers non-functional structures hidden in the semiconductor device (like parasitic transistors that shorten ground lines to power lines, which should never conduct when the device is operating correctly). Single Event Upset (SEU) is the not-destructive event that takes place when the parasitic current is able to trigger the modification of a storage cell, whose content flips from 0 to 1, or vice-versa. In case the injected charge reaches the sensitive volume of more than one memory device, multiple SEUs may happen simultaneously, causing the phenomenon known as Multiple Bit Upset (MBU). Finally, Single Event Transient (SET) is the not-destructive event that takes place when the parasitic current produces glitches on the values of nets in the circuit compatible with the noise margins of the technology, thus result in the temporary modification of the value of the nets from 0 to 1, or vice-versa.

Among SEEs, SEL is the most worrisome, as it corresponds to the destruction of the device, and hence it is normally solved by means of SEL-aware layout of silicon cells, or by current sensing and limiting circuits. SEUs, MBUs, and SETs can be tackled in different ways, depending on the market the application aims at. When vertical, high-budget, applications are considered, like for example electronic devices for telecom satellites, SEE-immune manufacturing technologies can be adopted, which are by-construction immune to SEUs, MBUs, and SETs, but whose costs are prohibitive for any other market. When budget-constrained applications are considered, from electronic devices for space exploration missions to automotive and commodity applications, SEUs, MBUs and SETs should be tackled by adopting fault detection and compensation techniques that allow developing dependable systems (i.e., where SEE effects produce negligible impacts on the application end user) on top of intrinsically not dependable technologies (i.e., which can be subject to SEUs, MBUs, and SETs), whose manufacturing costs are affordable.

Different types of fault detection and compensation techniques have been developed in the past years, which are based on the well-known concepts of resource, information or time redundancy (Pradhan, 1996).

In this chapter we first look at the source of soft errors, by presenting some background on radioactive environments, and then discussing how soft errors can be seen at the device level. When then present the most interesting mitigation techniques organized as a function of the component they aims at: processor, memory module, and random logic. Finally, we draw some conclusions.

2. BACKGROUND

The purpose of this section is to present an overview of the radioactive environments, to introduce the reader to the physical roots of soft errors. Afterwards, SEEs resulting from the interaction of ionizing radiation with the sensitive volume of semiconductor devices are discussed at the device level, defining some fault models useful to present fault detection and compensation techniques.

2.1. Radioactive Environments

The sources of radiations can be classified in different ways, depending on where the system is deployed. We can consider three so-called radiation environments: space, atmospheric and ground radiation environments (Barth et al., 2003).

The space radiation environment is composed of particles trapped by planetary magnetospheres (protons, electrons, and heavier ions), galactic cosmic ray particles (heavy ions and protons) and particles from solar events, such as coronal mass ejection and flares, which produce energetic protons, alpha particles, heavy ions, and electrons (Barth et al., 2003). The maximum energy the particles have ranges from 10 MeV for trapped electrons up to 1 TeV for galactic cosmic rays (1 eV being equivalent to $16x10^{-21}$ Joules). Due to the very high energies involved, shielding may not be effective in protecting circuits, and therefore the impact of ionizing radiation on electronic devices should be investigated deeply, to devise effective fault compensation techniques.

Atmospheric and ground radiation environments are quite different with respect to the space environment. Indeed, when cosmic ray and solar particles enter the Earth's atmosphere, they interact with atoms of nitrogen and oxygen, and are they are attenuated. The product of the attenuation process is a shower of protons, electrons, neutrons, heavy ions, muons, and pions. Among these particles, the most important ones are neutrons, which start to appear from 330 Km of altitude. Neutron density increases up to the peak density found at about 20 Km of altitude, and then it decreases until the ground level, where the neutron density is about 1/500 of the peak one (Taber et al., 1995). The maximum energy observed for the particles in the atmospheric radiation environment is about some hundreds of MeV.

At the ground level, beside neutrons resulting from the interaction of galactic cosmic ray and sun particles with the atmosphere, second most important radiation source is the man-produce radiation (nuclear facilities).

No matter the radiation environment where the system is deployed, we have that when radiations interact with semiconductor devices two types of interactions can be observed: atomic displacement or ionization. Atomic displacement corresponds to modifications to the structure of silicon device, which may show for example displaced atoms, and it is out of the scope of this chapter. Conversely, the latter corresponds to the deposition of energy in the semiconductor, and it is focused in this chapter.

Radiations may inject charge (i.e., ionize) a semiconductor device in two different ways: direct ionization by the particle that strikes the silicon, or ionization by secondary particles created by nuclear reactions between the incident particle and the silicon. Both methods are critical, since both of them may produce malfunctions (Dodd et al., 2003).

When an energetic particle passes through a semiconductor material it frees electron-hole pairs along its path, and it loses energy. When all its energy is lost, the particle rests in the semiconductor, after having travelled a path length called particle range. The energy loss per unit path length of a particle travelling in a material is known as linear energy transfer (LET), measured in $MeVcm^2/mg$: the energy loss per unit path length (MeV/cm) divided by the material density (mg/cm^3). As an example, a particle having an LET of 97 $MeVcm^2/mg$ deposits a charge of 1 pC/mm in Silicon.

Heavy ions inject charges in a semiconductor device by means of the mechanism called direct ionization (Dodd et al., 2003). Protons and neutrons do not produce enough charge by direct ionization to cause single-event effects, although recent studies showed that single-event effects due to direct ionization by means of protons are possible (Barak et al., 1996) in highly scaled devices. Indirect ionization is the mechanism through which protons and neutrons produce single-event effects. Proton, or neutron, entering a semiconductor device produces atomic reactions with silicon atoms, originating by-products like alpha or gamma particles. These by-products can deposit energy along their paths by direct ionization, causing single-event effects (Dodd et al., 2003).

2.2. A Device-Level View of Radiation Effects

The parasitic current induced by (direct or indirect) ionization can result in a number of different device-level effects, depending on when and where the charge injection takes place. We can broadly classify the device-level effects as destructive and not destructive. As far as digital electronic devices are considered, the most important destructive SEE is the SEL, while the most relevant not destructive SEEs are SEUs/MBUs and SETs. The following sub-sections describe these phenomena.

2.2.1. Single Event Latchup

Semiconductor devices like pMOS or nMOS transistor contains parasitic structures, composed of two bipolar transistors forming a silicon-controlled rectifier, as depicted in Figure 1.

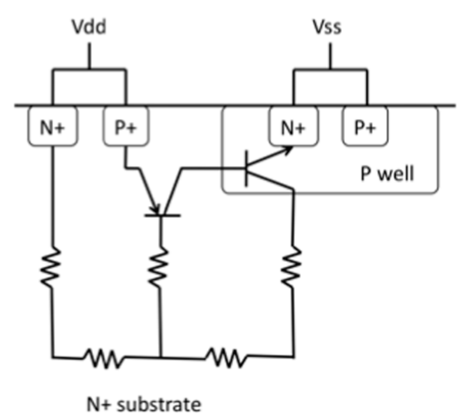
If the current resulting from ionization triggers the parasitic structure, a short circuit between power and ground lines is activated, resulting in a high current flowing in the device. In case such a current is not stopped promptly, permanent damage of the device is likely to happen.

2.2.2. Single Event Upset

As explained in (Dodd et al., 2003), DRAM technology refers to those devices that store bits as charge in a capacitor. In these devices no active information regeneration exists; therefore, any disturbance of the stored information provoked by ionizing radiations is persistent until it is corrected by a new write operation. Any degeneration of the stored charge that corresponds to a signal level outside the noise margin of the read circuit is sufficient to provoke an error. The noise margin is related to the memory critical charge, Q_{crit}, which is defined as the minimum amount of charge collected at a sensitive node that is necessary to cause the memory to change its state.

The most important SEU source in DRAMs is the SEE charge collection within each capacitor used to store bits in the DRAM. These errors are caused by a single-event strike in or near either the storage capacitor or the source of the access transistor. Such a strike affects the stored charge by the collection of induced charge (Dodd et al., 2003). Such error corresponds normally to a transition of the stored bit from 1 to 0 (May et al., 1979). However, the ALPEN effect (Rajeevakumar et al., 1988) makes transitions from 0 to 1 as well. SEUs can also occur in DRAMs due

Figure 1. The parasitic silicon-controller rectifies in a nMOS device



to charge injection in the bit lines (Dodd et al., 2003), or a combination of charge injection close to the bit capacitor and the bit line (Rajeevakumar et al., 1988).

SEUs are originated in SRAMs in according to a different phenomenon with respect to DRAMs. Indeed, in SRAM the information bit in restored continuously, by means of a two inverters forming a feedback loop. When ionizing radiation injects charge into a sensitive location in a SRAM, a transient current is originated in the affected transistor. The existing feedback counterbalances the injected current, trying restoring a correct (stable) configuration. In case the current originated by the injected charge is higher than the restoring current, a voltage pulse occurs that lead to the corruption of the stored bit (Dodd et al., 2003). In case charge injection affects multiple memory cells, the resulting effect correspond to multiple SEUs happening simultaneously; such event is known as Multiple Cell Upset.

2.2.3. Single Event Transient

The progressive decreasing of the minimum dimensions of integrated circuits, accompanied by increasing operating frequencies lead on the one side the possibility of using lower supply voltages with very low noise margins but on the other side it make integrated circuits (ICs) more sensitive to Single Event Transient (SET) pulses (Baumann, 2005). In details, the shrinking technology process decreases the manufacturing sizes reducing the charge required to identify a logic state. The result is that the parasitic current provoked by the ionizing radiation is inducing a pulse effect, also called SET.

The high-energy recoil and the proton-induced nuclear reactions are behind the SET generation mechanisms. In details, low-angle protons as well as heavy ions affect the silicon area close to a junction resulting in energy-loss of the signal and thus in observable SETs. The shape of SETs may be different depending on the source of the charge deposition and the conditions related to the tracks the considered high energy particle. More is the charge, more the SETs is characterized by peak heights and widths dependent from the space-charge effects (i.e. the heavy-ions generate this kind of effect).

The high-injection of charge provokes a variation of the external fields internally to the considered region. The carriers within the considered region are drifted by the ambipolar diffusion reaching the edge of the plasma edge, where they drift to the external region filed thus provoking a pulse of current (i.e. The SET effect). The pulse current is drastically smaller than the normal current induced by a logic-drift. Depending on the carrier levels and on the threshold level, the penetration within the external field may change thus resulting in a different SET width.

This phenomenon has been deeply investigated by experimental analysis where researchers control the radiation beam spot size, the intensity and the positions thus changing the charge injection of the particle strikes. The analysis of SET pulses has been obtained collecting datasets from pulse monitors or pulse shape analysis (PSA) that allow to generate the images of the induced SET measuring the charge and the maximum current, extracted over an area of interest.

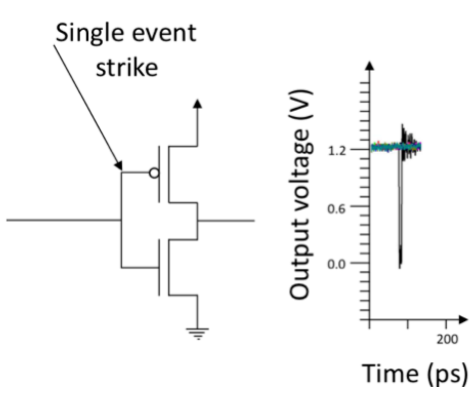
Many works investigated the nature of these events, measuring the propagation of the transient pulses through the combinational logic and routing resources in specifically designed circuits. These circuits have been demonstrated to be an effective solution for study SET effects in logic and routing resources of ICs ranging from ASICs to regular fabric such as FPGAs. In particular, for CMOS-based devices, energetic particle strikes can cause a transient voltage pulse that propagates through the circuits and may become an uncorrected data in case they are stored by a sequential element, causing disruption of the expected circuit operations. The upset rates due to SETs are dependent on the pulse width of the SET and the clock frequency of the circuit under analysis; in particular, with higher clock frequencies there are more latching clock edges to capture SET.

In particular, the SET pulse is originated by the energy loss released in the silicon structure characterized by the nMOS and pMOS transistors, as illustrated in the principal mechanism in Figure 2. The energy distribution is spatially uniform. This is due to the spatially non-variant loss of energy, thus it is assumed that the maximal peak of current as well as the rise and fall time are predominant. This is due to the electromagnetic field generation with runs with a specified angle with respect to the metallization.

The radiation environment, such as the one for space and avionic applications, is extremely stressing digital circuits for the generation and propagation of SET pulses, which have become a growing concern.

Depending on which is the affected circuit location, SETs may propagate through circuits and generate errors in digital combinational logic gates or a memory cells. Large distributions of SETs have been measured along combinational logic chains irradiated with heavy ions. The results reported large SET widths, up to 2 ns for simpler inverter chains. Several laser experiments demonstrated that SETs measured at the output of a logic gate chain undergo to pulse broadening effect induced by the propagation of SETs in long chains of identical inverters (Ferlet-Cavrois, 2007). This effect has been defined as Propagation-Induced-Pulse-Broadening (PIPB). It has been demonstrated that the SET pulse broadening is induced by the variation of the body potential, depending on the previous states of the transistor, this effect is related to the charge and discharge phenomenon of the transistor body that modifies the electrical response of the transistor to the current pulse propagation. Besides radiation experiments analysis, several other works investigated the nature of these events studying the propagation of the transients through the combinational logic and routing resources of ad-hoc designed circuits. These circuits have been demonstrated to be an efficient way of studying SET effects on logic and routing resources; however, they are extremely far from being representative of realistic designs. In order to study SET effects on real designs, three kinds of analysis approaches have been adopted. First of all, radiation experiments on complex circuits and real applications provide the behavior of designs implemented in such technology under radiation. In this case, the more is the desired accuracy to study precise effects, the more it is necessary to instrument and change the circuit. Secondly, laser techniques can be used to inject pulses in a desired point of the circuit at a precise energy and controlled pulse width. On the other hand, laser testing is an extremely accurate technique that can be used once the pulse lasers are focused on the active area and the energy is adjusted at the right threshold level. The original pulse width and amplitude generated either by radiation beam or laser test are almost impossible to be directly measured, therefore the two techniques cannot be directly used to precisely characterize the SET propagation effects. Between these two techniques, electrical pulse injection can be applied to the device under analysis with known pulse signal properties (width and amplitude). In case the electrical injection is performed externally to the integrated circuit, it requires a

Figure 2. A SET generation mechanisms on an inverter gate and the measured SET pulse output voltage



high-performance signal generator capable to provide appropriate SET pulses (shorter than 1 ns). However, this technique requires advanced characterization of the integrated circuits pads, since the injected pulse is applied to the external pad, the pulse shape is subjected to distortion effect due to the input buffer and the internal interconnections that stem to the injection location. Thus the shape of the injected SET may be modified before reaching the desired injection point.

The analysis techniques mentioned above allowed to determine that SETs pulse width and amplitude are intrinsically related to the numbers of logic gates traversed and the capacitive load of each logic gate. Researchers demonstrated that SET may be broadened or compressed depending on these parameters, and in particular the capacitive load plays an imperative role in the pulse width of the generated SET (Sterpone, 2009) (Kastensmidt Lima, 2008).

3. MITIGATION TECHNIQUES

Designers facing the problem of developing dependable systems (i.e., systems that operate without harming its users even in present on SEE-induced errors) need to adopt fault detection and compensation techniques. Indeed, as a matter of fact mainstream semiconductor technologies are prone to SEE, and radiation-hardened technologies insensitive to SEEs are too expensive for being widely adopted.

3.1. Detecting and Compensating SEL

SEL can be solved using two alternative approaches, one working at system level, and a second one working at layout level.

The first one uses current sensors at the system level to detect the excessive current flowing when the SEL is triggered to promptly shutdown the power supply. As the device is powered off, the SEL is stopped, and after a rest period sufficient for the injected charge to annihilate, the device can be power on again. The main drawback of this approach is that the circuit state is lost at power off and therefore a suitable synchronization phase is needed when the device is power on again.

The second approach uses SEL-aware design guidelines during the layout of transistors. By exploiting guard rings, the parasitic silicon controller rectifier is broken, so that SEL are likely not to take place (Troutman, 1983). To further improve such layout-based techniques, special manufacturing process can be exploited. To further reduce the SEL occurrence probability silicon grown on epitaxial layer, or silicon on insulator, is preferable over bulk silicon.

3.2. Detecting and Compensating SEUs, MCUs and SETs

This section presents techniques developed for detecting and compensating not-destructive SEEs. Several approaches are presented tackling SEUs, MCUs, and SETs; for the sake of clarity, the approaches are organized as a function of the component they aim at: processor, memory or random logic.

The presented approaches decline in different ways the well-known concepts of hardware, information and time redundancy (Pradhan, 1996).), i.e., the use of more hardware, stored data or computing time than actually needed for implementing the functionalities the system has to provide, to guarantee that the system operates correctly (or at least safely, i.e., without damaging the system user) even in presence of errors provoked by faulty system components

3.2.1. Processors

In this section we focus only on transient faults that may affect the processor the system includes. We thus assume that memories and other chips (e.g., input/output modules) located outside the processor chip are fault free.

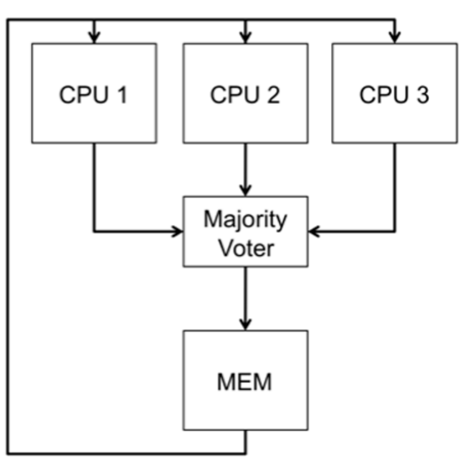
As far as techniques for detecting and compensating transient faults in processors are considered, we can classify them in two broad categories: techniques based on processor redundancy, which achieve fault detection and compensation using more than one processor chip, and techniques based on time and/or information redundancy, which achieve fault detection and compensation using one processor chip in combination with specially crafted software.

As far as techniques exploiting processor redundancy are considered we can further classify them in techniques exploiting passive redundancy, and techniques adopting active redundancy (Pradhan, 1996).

3.2.1.1. Passive Redundancy

The concept of *passive redundancy* consists in replicating the processor core three times, and in equipping the obtained processor module with a majority voter, according to the architecture depicted in Figure 3 that is known as Triple Module Redundancy (TMR) For the sake of simplicity we showed here only the interface between the processor and the memory. In general any bus exiting the processor has to be replicated three times and voted.

Figure 3. Passive redundancy architecture



The three processors of the TMR architecture are synchronized and execute the same software. According to this principle, every write operation toward the memory is executed three times; therefore, under the single-fault assumption, the majority voter (which is supposed to be fault tree) is able to decide correctly the address and the value of the memory involved in every write operation.

The most interesting property of the passive redundancy is the capability of providing a correct service even in presence on one error. Indeed, even in case one of the processor is behaving erroneously, the majority voter is able to decide the correct output that has to be sent to the memory. This property is known as fault masking, because every single fault affecting one of the processors will never have the chance to propagate to the voter output (Pradhan, 1996).

Although very effective in compensating the occurrence of transient faults, the passive redundancy architecture as presented so far does not produce any mechanism to remove the fault from the faulty processor. Considering the architecture of Figure 3, let us suppose that the tree processors are hit by a flux of ionizing radiation, and that CPU 2 experiences one SEU in its program counter. Since the modification of the CPU 2 program counter, the three processors are no longer synchronized. Indeed, CPU 1 and CPU 3 continue to execute the correct program sequence, while CPU 2 executes a different one. However, the system continues to operate correctly, as the majority voter is still able to decide the correct output using the values coming from the two fault-free processors. As the flux of ionizing radiations continues to hit the processors, it is possible that a new SEU hits either CPU 1 or CPU 3. In this event, the majority voter is no longer able to decide the correct output because two processors out of three are faulty. As result, passive redundancy should be enriched with suitable techniques to remove transient faults after their detection, to guarantee that the three processors are always synchronized.

The general algorithm for fault removal encompasses the following steps that perform processor synchronization:

1. Upon fault detection, the normal operations are stopped, and the three processors are forced to execute a procedure to save in memory their context (i.e., the content of the registers, program counter, and program status word). As the values are sent to the memory via the majority voter, a correct context will be stored.
2. The three processors are reset, and possibly powered off and on. As a result, all the memory elements are initialized to a correct value, removing any transient fault.
3. The correct context is copied from the memory to the three processors. At the end of this step, the three processors are synchronized, and the normal operations can be resumed.

Processor synchronization is a complex task that may be simplified by taking advantage of the peculiarity of the application where the system is employed in. For example, in case of cyclic tasks, processor synchronization can takes place at the end of each cycle by resetting the processors, and avoiding context savings.

During processor synchronization, the system is unavailable to the user, as normal operations are stopped. In case outages of service are not allowed, a more complex architecture based on N Module Redundancy, with N > 3, should be used.

Passive redundancy enriched with processor synchronization is currently used in a high-end processing module: the single-board computer for space, scs750, developed and commercialized by Maxwell technologies (http://www.maxwell.com/microelectronics/products/sbc/scs750.asp). The scs750 employs three PowerPC 750FX processors working synchronously, implementing the TMR architecture. The majority voter is implementing into a radiation-hardened FPGA that, being immune to radiations, guarantees fault-free operations. In case an error is detected, processor synchronization is performed in less then 1 msec.

3.2.1.2. Active Redundancy

The concept of *active redundancy* consists in tackling with faults in two consecutive steps: fault detection, followed by fault correction.

Fault detection, as the name implies, is the step during which the behavior of a system is monitored looking for symptoms of errors. While the system behaves correctly, the outputs it provides are forwarded to the user. As soon as, a fault is detected, a safe output is sent to the user, and the fault correction step is initiated. Safe outputs can be seen as output values not expected during correct operations, which are harmless to the user. As an example, a system designed according to the active redundancy concept may provide functional outputs, along with an error alarm output. The user of the system relies on functional outputs as long as the error alarm is not active. Whenever the error alarm is active, functional outputs are discarded until the error alarm is deactivated. Fault detection can be implemented in two ways:

- Instruction-level fault detection consists in monitoring each read/write operation the processor performs toward the external memory.
- Task-level fault detection consists in monitoring the values written in memory as soon as the processor completes the execution of a task (e.g., a sequence of instructions).

Fault correction is the step during which the fault is removed from the system, and its correct operations are restored. In case of transient faults, this may correspond to processor reset to bring all the memory elements to a known-good initial value.

As an example of active redundancy implementing an instruction-level fault detection scheme, we can consider the lockstep approach enriched with checkpoint and rollback recovery we introduced in (Abate et al., 2008).

Aiming at detecting errors affecting the operation of the processor, the lockstep technique uses two identical processors running in parallel the same application. The processors are synchronized to start from the same state. They receive the same inputs, and therefore they should evolve among the same states at every clock cycle, unless an abnormal condition occurs. This characteristic allows for the detection of errors affecting one of the processors through the periodical comparison of the processors states. Comparison of the processor states, called consistency check, is performed after the program executed for a predefined amount of time or whenever an activation condition is met (e.g., a value is ready for being committed to the program user or for being written in memory). In case of mismatch, the execution of the application is interrupted, and the processors must resume from an error-free state.

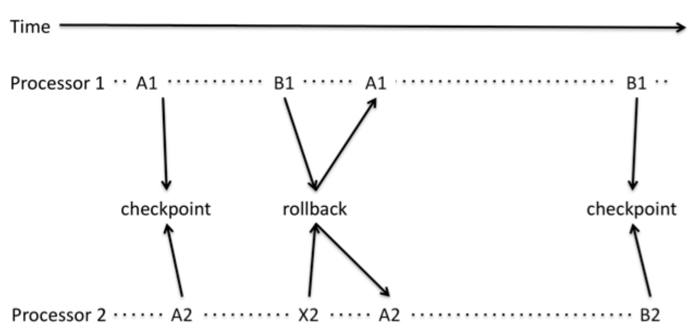
Checkpoints are used to keep a backup copy of the last error-free state in a safe storage. Whenever a consistency check signals a match among processors state, a copy of all information required to restore the processors to that state is saved in a storage device insensitive to ionizing radiation. This set of information is named context, and defines univocally the state of the processor (it can include the content of the processor's registers, the program counter, the cache, the main memory, etc.).

If the consistency check fails, rollback is performed to return both processors to the previous error-free state. The processors are reset, and the previously saved context is copied into them.

Figure 4 shows an example of application execution flow using lockstep coupled with checkpoint and rollback recovery. The arrow on the left indicates the timeline (T).

Initially, processor 1 executes the application until it reaches a predefined point. The context of processor 1 at this point is A1. Then, processor 2 executes the same application, reaching the same point with context A2. When both processors reached the same point, their contexts are compared and if they match a checkpoint is executed. Then, the execution of the application is resumed, with processor 1 performing another portion of the application until it reaches a second point, with context B1, and then processor 2 executes the same portion of the application, stopping at the same second point, with context B2. At this point a new consistency check is executed and, if no error is detected, a new checkpoint is performed, saving contexts B1 and B2, and so on, until the whole application has been successfully executed by both processors.

Figure 4. Example of execution of rollback recovery using checkpoint



Now, let us suppose that, as shown in Figure 4, one SEU occurs and causes one error while processor 2 is processing the second portion of the application. When it reaches the second predefined point and the consistency check is performed, the state of processor 2 is X2, instead of B2, which indicates that one error occurred and that a rollback is needed.

Rollback restores both processors to their last error-free states using the context saved during the last checkpoint, i.e., contexts A1 and A2. The execution of the application is then resumed as previously described, with processor 1 and then processor 2 executing the same portion of the application, and if no other error occurs the processors finally reach the correct states B1 and B2 and a new consistency check is performed, saving contexts B1 and B2. As a result, the error caused by the SEU was during consistency check, it is removed thanks to rollback, and it is corrected by repeating the execution application.

A particularly critical aspect in lockstep is the criteria used to define under which condition the application should be interrupted and a consistency check performed, as it can impact the performance of the system, the error detection latency, and the time required to recover from an error. Checking and saving processors context at every clock cycle provides the shortest fault detection and error recovery times. However, it entails unacceptable performance penalties. Conversely, long intervals between consecutive checkpoints may lead to catastrophic consequences, as the error is free to propagate through the system. Therefore, a suitable trade-off between the frequency of checkpoints, error detection latency and recovery time must be defined, according to the characteristics of the application, and taking into account the implementation cost of the consistency check as well.

A second issue is the definition of the consistency check procedure to be adopted. Considering that the consistency check aims to detect the occurrence of faults affecting the correct operation of the system, the consistency check plays an important role in the achievement fault tolerance.

In the definition of the processor context, designers must identify the minimum set of information that is necessary to allow the system to be restored to an error-free state when a fault is detected. The amount of data to be saved affects the time required to perform checkpoints and also rollback. Therefore, to achieve low performance overhead during normal operation, as well as fast recovery, the minimum transfer time for those operations must be obtained, together with a low implementation cost.

As an example of task-level fault detection scheme, we can consider the approach presented in (Pignol, 2006). In the DT2 architecture (Pignol, 2006), two processors execute in parallel the same task, as in the lockstep architecture. However, fault detection is performed only when the two processors completed the task execution, by checking the results produced. As a result, the architecture is less intrusive in the task execution time, as few consistency checks are performed compared to lockstep. On the contrary, error detection latency is higher than in the lockstep, as consistency checks are performed only after task completion. Upon error detection, the two processors are reset, and the whole execution of the task is repeated.

3.2.1.3. Information and Time Redundancies

Fault detection and compensation techniques that exploit passive/active redundancy entail a significant cost overhead, as they require at least two copies of the same processor. Moreover, additional hardware implies more power consumption, as well as additional volume and weight, which can be very critical factors for some type of applications (like for example electronic equipment on board of small-size satellites).

To balance fault mitigation capabilities with implementation costs, alternative approaches to processor redundancy have been proposed which exploit information and time redundancy. The basic idea consists in adding additional instructions to those actually needed by the application software to cope with fault detection and compensation. By spending more time in doing the needed computation, and storing more information than that actually needed, several authors showed the possibility of detection and correcting the occurrence of transient errors. As previously done, the techniques can be broadly classified as:

- Instruction-level redundancy techniques, where the instructions (assembly, or C, etc.) of the application source code are duplicated, consistency checks on the results of instructions, and error handling functions are added.
- Task-level redundancy techniques, where the tasks the processor executes are duplicated, consistency checks on the results of tasks, and error handling functions are added.

3.2.1.3.1. *Instruction-Level Redundancy*

Instruction-level redundancy can be roughly described as a technique that introduces additional instructions to the source code (at the assembly level, or at higher levels) of an application to perform error detection and compensation. The added instructions replicate computations, data structures, or perform consistency checks (of stored data, or taken branches) and, if needed perform error correction operations. For the sake of clarity it is convenient to distinguish among data-oriented techniques, to detect and compensate transient errors that affect the data the program manipulates, and control-oriented techniques that deal with transient errors affecting the program execution flow.

A basic method to achieve error detection by data and code redundancy exploiting a set of transformations on the high-level source code is presented in Golubeva et al., 2006. Errors affecting both data and code can be detected by the hardened code, where each variable is duplicated, and consistency checks are added after every read operation. Other transformations focusing on errors affecting the code are devised, corresponding from one side to duplicating the code of each write operation, and from the other to adding consistency checks after the executed operations. Placing the check operation after every read operation allows reducing the effects of possible error propagations.

A major advantage of the method lies in the fact that it can be automatically applied to a high-level source code, thus freeing the programmer from the burden of performing this task, and guaranteeing the correctness and effectiveness of the resulting code (e.g., by selecting what to duplicate and where to put the checks). The method is independent from the hardware that will run the code, and it can be combined with other already existing error detection techniques.

The transformation rules affect the variables of the program. By acting on the source code they are independent on whether the variables are stored in the main memory, in a cache, or in a processor register. The fault detection is quite high, as the transformation rules do not target any specific fault model.

The transformation rules are the following:

- Rule #1: every variable x is duplicated (let x_0 and x_1 be the names of the two copies)
- Rule #2: every write operation performed on x is performed on both x_0 and x_1
- Rule #3: each time x is read, the two copies x_0 and x_1 are checked for consistency, and an error detection procedure is activated if an inconsistency is detected.

Fault propagation is blocked by performing the consistency check immediately after the read operation. Variables should also be checked when they appear in any expression used as a condition for branches or loops, in order to detect errors that corrupt the correct execution flow of the program.

Any fault affecting a variable during program execution is detected as soon as the variable becomes the source operand of an instruction, i.e., when the variable is read; this minimizes error latency, which is equal to the temporal distance between the fault occurrence and the first read operation. Errors affecting variables after their last usage remains undetected (but they are harmless, too). Figure 5 reports an example of application of the described rules: a code fragment is shown, together with its hardened version.

To understand the methods developed to cope with errors affecting the program execution flow (named *Control Flow Errors* or *CFEs*), it is important to understand first how to represent the structure of a program.

A program code can be partitioned into basic blocks (BBs), which are maximal sequences of consecutive program instructions that, in absence of faults, are always executed altogether from the first to the last. A BB does not contain any instruction changing the sequential execution, such as jump or call instructions, except for the last one. Furthermore, no instructions within the BB can be the target of a branch, jump or call instruction, except for the first one. A BB body corresponds to the BB after the removal of the last jump instruction, if this is a jump instruction. Any program P can be represented with a Control Flow Graph (CFG) composed of a set of nodes V and a set of edges B, P = {V, B}, where V = {v_1, v_2, …, v_n} and B = {$b_{i1,j1}$, $b_{i2,j2}$, …, $b_{im,jm}$}. Each node $v_i \in V$ corresponds to a BB. Each edge $b_{i,j} \in B$ corresponds to the branch from node v_i to node v_j.

Considering the CFG P = {V, B}, for each node v_i we define *suc*(v_i) as the set of BBs which are successors of v_i and *pred*(v_i) as the set of BBs which are predecessors of v_i. A BB v_j belongs to *suc*(v_i) if and only if $b_{i,j} \in B$. Similarly, v_j belongs to *pred*(v_i) if and only if $b_{j,i} \in B$.

A branch $b_{i,j}$ is *illegal* if $b_{i,j} \notin B$. If a fault causes the program to execute a branch $b_{i,k} \in B$ instead of the correct branch $b_{i,j}$, then the branch $b_{i,k}$ is *wrong*. Illegal and wrong branches represent CFEs.

All instruction-level techniques to detect CFEs are based on the idea of adding instructions to verify whether transitions among BBs are consistent with the CFG (Golubeva et al., 2006). We can consider the method named Enhanced Control flow Checking using Assertions (ECCA) as an example of this idea.

ECCA assigns a unique prime number identifier (the *Block Identifier* or *BID*) greater than 2 to each BB of a program. During program execution the global integer variable *id* is updated to store the currently traversed BID.

Each code block is modified by adding two assertions to it:

- A SET assertion at the beginning of each BB, performing two tasks: it assigns the BID of the current block to the *id* variable and then checks if the execution came from is a predecessor BB, according to the CFG. As these tasks are performing resorting to arithmetic operations, a divide-by-zero trap is executed in case of CFE.

Figure 5.a) A code fragment; b) The hardened version of the code fragment

```
…
alfa = beta*k[i]+omega*w[j];
…
```

(a)

```
…
alfa0 = beta0*k0[i0]+omega0*w0[j0];
alfa1 = beta1*k1[i1]+omega1*w1[j1];
assert( alfa0 == alfa1 );
assert( beta0 == beta1 );
assert( k0 == k1 );
assert( i0 == i1 );
assert( j0 == j1 );
assert( w0 == w1 );
…
```

```
…
alfa = beta*k[i]+omega*w[j];
…
```

(a)

```
…
SET( id, BID_current );
alfa = beta*k[i]+omega*w[j];
TEST( id, BID_current, BID_succ );
…
```

(b)

- A TEST assignment at the end of each BB, performing two tasks: it updates the *id* variable taking into account the whole set of successors according to the CFG and then checks if the current value of the *id* variable is equal to BID.

Figure 6 reports a code fragment and its hardened version based on ECCA.

When inserting data- and control-oriented fault detection and compensation techniques in a program, particular care must be placed in preserving its CFG. Indeed, if additional branches are added as a consequence of the application of fault detection and compensation techniques, for example branches hidden in the assert() code used in Figure 5b, the structure of the resulting program graph will be different from the original one, and new CFEs are introduced. As a result consistency checks must be performed in such a way that the PG of the hardened program remains the same of the unhardened one, i.e., by using arithmetic functions that produce a divide-by-zero trap in case of error detection.

The adoption of information and time redundancies entail enriching the program with a number of additional instructions, as a result program execution time is reduced. Moreover, the compiler optimization options that modify the program structure should be disabled, otherwise the PG of the executable code will different from that of the source code, and hence the fault detection and compensation techniques will be ineffective. As a result, the execution time of the program obtained after information and time redundancies application is significantly increased with respect to that of the un-hardened program. This problem can be partially solved by demanding some of the operation of the robust program to special-purpose hardware, which is in charge of accelerating the most recurring (and thus time consuming) operations that information and time redundancies perform (Bernardi et al., 2006).

An example of real-life application of instruction-level redundancy can be found in the Proton series of single board computers manufactures by SpaceMicro (www.spacemicro.com), which exploits the patented Time Triple Modular Redundancy (TTMR). According to TTMR, each instruction is executed twice, being A_1 and A_2 the two instances of instruction A, and the two results compared. In case of mismatch, a third instance A_3 of the instruction is executed, and the result to be committed to the rest of the application is obtained by majority voting among the results of A_1, A_2, and A_3.

3.2.1.3.2. *Task-Level Redundancy*

Task-level redundancy techniques combine data- and control-oriented fault detection and compensation techniques by executing twice the same task, and then comparing the obtained results. In case of single-core processor, the two instances of the same task are executed serially, while in case of dual-core processors, they can be executed concurrently.

An example of task-level redundancy can be found in the DMT architecture (Pignol, 2006). A single-core processor executes two instances of the same task, which are assigned to two different, not overlapping, and isolated memory spaces.

When the results of the two tasks are available, a hardware module compares them, and in case of mismatch resets the processor, and force a new execution of the whole process.

3.2.1.4. Fault Coverage and Overhead Analysis

When considered the fault coverage capabilities of the different techniques we can conveniently talk about fault detection, defined as the percentage of faults the method is able to detect over the faults that may hit the processor, and fault correction, as the percentage of faults the method is able to recover from over the faults that may hit the processor. In Table 1, we report a fault coverage analysis for different techniques, assuming that a processor such as the PPC750FX is considered. Faults in the memory elements not protected by parity or ECC are considered, only (i.e., faults in user registers and control registers and faults in cache memory are neglected).

When analyzing the overhead of the considered techniques we should take into account the hardware overhead (e.g., the number of additional processors, and the area of the additional hardware expressed as a fraction of the processor area), the additional memory occupation, and the additional program execution time. Table 1 compares the overhead of the different architecture normalized versus a system that does not include error detection and compensations techniques. For computing the figures we assume a complex processor like PPC750FX, whose area is notably bigger than that of additional hardware that may be needed by fault detection and compensation techniques.

As far as the fault coverage is concerned, we can see that even the original, not robust, system is able to detect some of the faults that radiations may induce. Indeed, processors normally embed some error detection features (beside parity or ECC for memory banks like caches) that can provide partial transient error detection. As an example some faults may be detected through processor traps (e.g., invalid op-code trap). All methods offer complete fault coverage, thus guaranteeing at least the capability of recognizing an improper processor behavior. Among the

Table 1. Overhead comparison

Technique	Fault detection [%]	Fault correction [%]	Area occupation [#]	Memory occupation [#]	Execution time [#]
None (original system)	<10	0	100	100	100
Passive redundancy (TMR) to perform error masking	100	100	<305	<105	<105
Active redundancy (lockstep, with checkpoint executed only in correspondence of 10% of memory accesses) to perform error detection and removal	100	98	<210	<205	<220
Active redundancy (DT2) to perform error detection and removal	100	100	<205	<205	<210
Instruction-level redundancy, with data- and control-oriented techniques to perform error detection only	100	0	100	<400	<300
Instruction-level redundancy, with data- and control-oriented techniques+hardware acceleration to perform error detection only	100	0	<110	<210	<205
Task-level redundancy (DMT) to perform error detection and removal	100	100	<110	<210	<400

methods that offer fault compensation, fault correction is at least 98%, thus guaranteeing the possibility of resuming the correct operations upon fault detection of the vast majority of faults.

As far as area occupation is considered, all methods except purely-software ones entail some additional hardware, with complexity ranging from small watchdog up to one or two instances of the original processor.

Considering memory occupation, purely-software techniques are the most demanding ones, due to the replicated instructions a data. Similarly, software techniques are the most demanding as far as execution time is considered. Other techniques like DT2 and DMT show high execution time overhead, as a slack time equal to the original program execution time (DT2) or twice of the program execution time (DMT) are reserved for error compensation through task re-execution.

3.2.1.5. Final Remarks

The detection and compensation techniques to be used should be selected on the basis of the application the system is aiming at by evaluating carefully the magnitude of the problem transient faults induce. In certain type of applications transient errors may result in the modification of one pixel, and may occur once every year; as a result, it may be deemed more convenient to avoid any mitigation technique thus saving implementation costs. In other type of application, like the rendezvous with a comet, the system may have to remain operative only few minutes, during which no error is acceptable, otherwise the entire mission is lost; as a result, the most expensive fault detection and compensation technique should be used to guarantee 100% system availability.

Moreover, there is not a single best technique that solves all the problems. Certain types of effects induced by transient errors are either too expensive, or impossible to deal with certain techniques, and therefore a mix of different techniques is likely to be the best solution. Therefore, the general architecture of a reliable processor module should entail the processor that executes the application software, possibly enriched with information and time redundancies, plus additional hardware devoted to fault detection and compensation. This module can be as simple as a watchdog timer to reset and wake-up the processor that entered into end-loop due to very critical transient faults, or as complex as the hardware needed for implementing an NMR architecture.

3.2.2. Memories

Memories are increasingly critical components from the point of view of reliability. Their criticality is due to several factors:

- The high sensitivity of some semiconductor memory technologies (e.g., SRAMs) to radiations; in particular, CMOS based memories are especially prone to radiation-induced errors (Gong, 2003). This is mainly due to the fact that design rules are typically very aggressively pushed when designing memory arrays for area optimization. Moreover, the transistors used in memory cells are often optimized for area and speed and are therefore more sensitive to noise as compared to their logic counterparts.
- The high amount of memory existing in most of today processing systems; many complex Integrated Circuits currently on the market use a high percentage (from 50% to 70%) of the die area for embedded memory cores. It is projected that this percentage will soon increase to 90% of overall chip area on more demanding SoC designs. On the other side, the amount of semiconductor memory existing in most general-purpose systems (e.g., Personal Computers or workstations) already exceeds several GByte even for low-cost

products, making the frequency of faults affecting memories extremely high.

For the above reasons, several techniques for detecting and possibly correcting errors affecting memories have been developed in the past decades, and are now commonly adopted in many commercial products, even for non safety-critical applications (Slayman, 2005). However, the choice of the solution which provides the best trade-off between fault detection/correction capabilities, area and performance cost may significantly change from case to case, depending from many factors, such as the application characteristics, the available technology, the environment the product should work in, etc.

In the following, a summary of the most common techniques used to protect semiconductor memories against transient faults is presented. We did not consider here solutions based on special memory cells suitable designed for high reliability, which are out of the scope of this chapter.

3.2.2.1. Information Redundancy Techniques

This group of techniques is mainly based on error detection and correction codes, which are used extensively in memory arrays in order to reduce the impact of transient errors, whichever their origin. The main idea behind these codes is to use check bits in addition to the data bits to create a *checkword*. The simplest form of error detection is the use of a parity bit. Each time a word is written to the memory, an extra bit is computed and stored in the memory, which represents the binary sum (or its complement) of all the bits in the word (even or odd parity). If any bit (either in the data part or in the code) is flipped, the parity bit will no longer match the data and an error is detected when the word is read. However, in the case an error is detected the technique cannot provide the information about which bit has been flipped, so the error cannot be corrected.

Several solutions exist to implement detection mechanisms based on parity; they differ on which data bits are associated to each parity bit. When the whole memory is composed of different modules in parallel, it may be convenient to associate each parity bit either to a whole word, or to the bits of the word implemented by each module, or to a proper combination of them. The major advantage coming from these schemes, which are summarized in Figure 7, is that they allow detecting errors arising when a whole memory module becomes faulty. Finally, there have been some efforts to extend the parity method to detection of multiple bits (no matter their multiplicity) by proposing 2D schemes, such as the one shown in Figure 8 (Pflanz, 2002).

The adoption of more check bits per word allows getting more powerful detection and correction codes. Single error correct/double error detection (SEC-DED) codes were first introduced by Hamming (Hamming, 1950) and then continuously improved in the following years (Chen, 1984).

The number of check bits required to achieve a given goal (e.g., detection/correction of errors with a given multiplicity) is a function of the size of the data to be protected: this means that the percent area overhead for storing the check bits decreases when the length of the protected word increases. In some cases (e.g., for caches) entire lines are protected with a very reduced number of additional check bits, when compared to the number of data bits. In other cases (e.g., small caches) lines are much smaller, and the overhead required by the codes may be unaffordable: in this case, parity is often adopted, in conjunction with more complex techniques: in some cases, the cache line is simply flushed when an error is detected, and its correct content is then uploaded from memory.

Double-bit error correction/triple-bit error detection (DEC-TED) is another powerful error correction code. Obviously, the greater error detection/correction capabilities of these codes have a

Figure 7. Different parity schemes

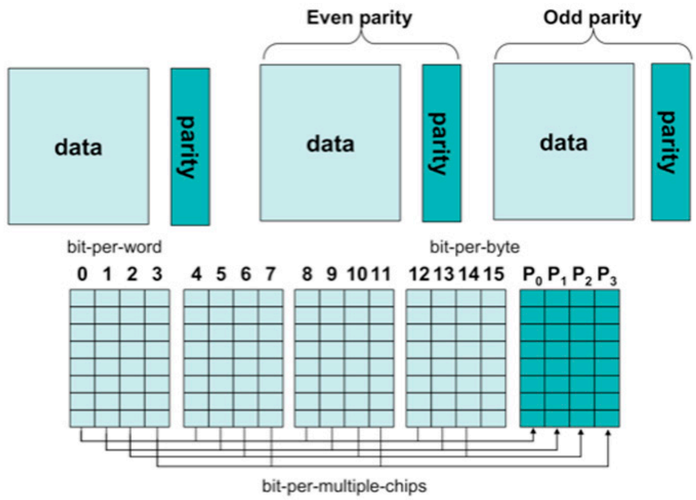

Figure 8. The cross-parity checking scheme

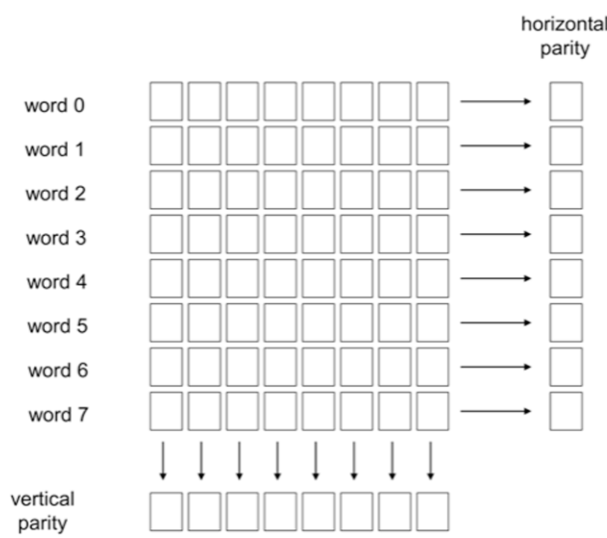


cost in terms of chip area, power required for the extra check bits, and latency for the computation required to encode and decode the check bits each time a word is written/read to/from memory. While sometimes adopted for space applications, DEC-TED codes are not commonly used in terrestrial workstation or server designs for several reasons. First of all, increased computational complexity leads to increased latency. Moreover, none of the word lengths, which minimize the cost for DEC-TED codes, are integral multiples of 8, thus forcing the designer to sub-optimal choices.

A further technique which is sometimes used to introduce error detection and correction capabilities to semiconductor memories is based on Reed-Solomon codes.

A Reed-Solomon code is characterized by the value of two integer parameters n and k (Blahut, 1983), where n is the number of symbols of m bits (with $n \leq 2^m - 1$) of a codeword and k is the number of symbols of the related dataword. A Reed-Solomon (n,k) code can correct up to $2E + S \leq n - k$ erroneous bits, where E is the number of erasures and S is the number of random errors. An erasure is an error whose location is known a priori (e.g., because it stems from a permanent fault). Transient faults (e.g., SEUs) can occur in unknown locations (i.e., bits) of a codeword; therefore, they can be effectively considered as random errors. Permanent faults (e.g., stuck-at 0/1 cells) can be located using either self-checking circuits, or on-line testing; therefore, they can be effectively considered as erasures.

Reed–Solomon coding is commonly used in data transmissions, as well as in mass storage systems to correct the burst errors associated with media defects. Reed–Solomon coding is a key component of the compact disc technology: it has been the first case of adoption of a strong error correction coding technique in a mass-produced consumer product, and DAT and DVD devices use similar schemes.

Reed–Solomon coding can also be used to harden semiconductor memories (in particular ROM, RAM and Flash) by adding a proper encoding/decoding circuitry on top of the memory module itself. The adoption of this technique may be convenient when the memory has to be used in particularly harsh environment (e.g., space), and has been boosted by the availability of efficient and compact Intellectual Property cores implementing highly customizable encoder/decoder functions.

Error detection latency is a major issue when designing a memory. In fact, latent errors can occur in both SRAM and DRAM due to bad writes (e.g., coming from noise in the system) or cell upsets from alpha particles or cosmic rays. These errors will remain undetected if no reads from the word occur. With a single-bit error already lying dormant, the check word is exposed to the risk of a second bit being upset, leading to an uncorrectable error in an SEC-DED design. In this case, scrubbing (Saleh, 1990) can be successfully exploited, if the application constraints allow its adoption. Scrubbing is a technique to prevent independent single-bit events from evolving into multibit events in memories: it is based on periodically checking (or scrubbing) the memory for correctable errors by traversing the entire address space. In the case of parity-protected caches, if a parity error is encountered, the data would be flushed and a re-read of correct data from main memory would occur. For SEC-DED-protected memory, a single-bit error would be detected and corrected. The probability of two statistically independent single-bit errors affecting the same word is inversely proportional to the time allowed for them to combine (i.e., the time between scrubs). Scrubbing eliminates this risk by removing the first error before the second one can arise. Clearly, scrubbing may significantly reduce the probability of failures by introducing some performance related to the time cost of the periodic scrubbing procedure.

3.2.2.2. Hardware Redundancy Techniques

The usage of triple modular redundancy even for memories is not uncommon for mission-critical avionic and space applications. On the other side, this technique is seldom used within commercial servers and workstations (and more in general for ground-level applications) because of the obvious power and area penalties. In almost all cases, judicious use of a ECC-protected cache and memory, combined with a good analysis of the Soft Error Rate (SER) of the different components, a careful design of logic elements, and a correct process-technology selection should be sufficient for commercial designs.

3.2.3. Random Logic

As described in the previous subsections, plenty transients effects may corrupt the circuits functionalities. Particular SEU and SET tolerance techniques must be taken in account in the design of fault tolerant integrated circuits.

3.2.3.1. Hardware Redundancy

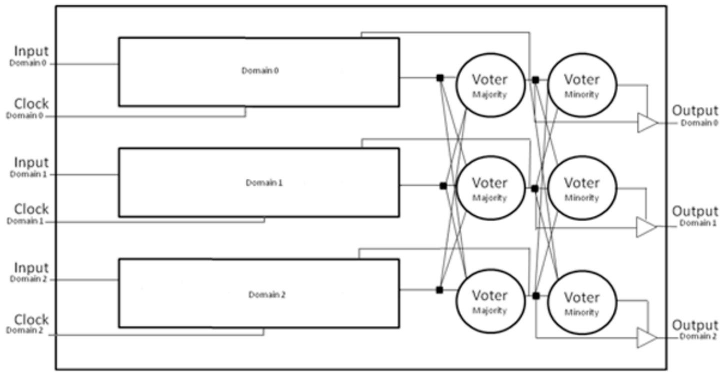
Hardware redundancy solutions can be adopted to protect the logic against transient faults. A commonly adopted solution is the Triple Modular Redundancy (TMR) which is generally used to provide design hardening in the presence of SEUs. All the circuit's flip-flops are replicated three times and a voter structure is used to the majority of the outputs, accordingly to the TMR scheme. The classical TMR scheme has been proved to be effective in protecting sequential logic against SEUs, nevertheless it brings high overhead on area. TMR techniques are based on the idea that a circuit can be hardened against SEUs or SETs by designing three copies of the same circuit and building a majority voter on the output of the replicated circuit. Implementing triple redundant circuits against SEU effects is generally limited in protecting only the memory elements. Conversely, in case SETs effects are addressed, full module redundancy is required because all the components such as memory elements, interconnections and combinational gates are sensible to SETs. This means that three copies of the user's design have to be implemented to harden the circuit against SEUs. All the logic resources are triplicated in three different domains according to the traditional TMR approach and voter elements are included at the domain's outputs. When any of the design domains fails, the other domains continue to work properly, and thanks to the voter, the correct logic passes to the circuit output. The TMR traditional architecture presents two major drawbacks:

1. The design is still vulnerable to SEUs in the voting circuitry. Nevertheless radiation-hardened voting circuits are available to protect against the permanent damaging of the voter induced by Single-Event Latch-Up (SEL), the CMOS devices adopting physical layout geometries smaller than 0.25 μm are still susceptible to transient effects.
2. There is no protection against the accumulation of SEUs in Flip-Flops (FFs). After an SEU happens, in the traditional TMR scheme, while the state machine is corrected through scrubbing, the state remains un-reset for the synchronization.

In order to protect the voters and input signals, all inputs, outputs and voters are triplicated, which avoid the presence of single points of failure. Besides, in order to ensure constant synchronization between the redundant state registers, majority voters with feedback paths are inserted. The resulting feedback logic of each state machine becomes a function of the current state voted from all the three state registers. The presence of the minority voters allow to protect the circuit outputs from SEUs affecting their resources, that represent a critical point, since they are directly connected to the device pins, as illustrated in Figure 9. The full TMR solution could not be the most harden solutions if critical harsh environments are considered. In details, if a higher level of protection against SEUs is necessary, several voter levels can be introduces into the circuit's random logic in order to increase the protection against transient effects. Nevertheless these solutions introduce a high routing congestion due to the interconnections coming from three domains to a single logic element. This has a severe impact on the delay of a design and the performance degradation may vary from 1.5 and 2.5 times with respect to the original un-hardened circuits.

A different solution, that reduces the dramatic overhead of TMR, is the Double Modular Redundancy (DMR). The main characteristic of DMR are the duplication of the storage cells and the correction elements used to output and keep the correct value of the redundant storage cells. The impact of the DMR structure on the area and on the delay is lower than TMR, while the tolerance

Figure 9. TMR architecture based on majority and minority voters



to SEU effect has similar level, in particular when sequential logic circuits are considered.

The principal DMR structure consists in doubling the storage cells of each bit and connecting the replicated outputs to the correction element. In case one of the redundant cells is changed by an SEU, the output of the correction element will maintain the right value. Then, at the next clock's edge, both the doubled storage cells will latch new data removing the possible errors. The DMR hardening solution allows saving one storage cell for each bit, therefore it is quite obvious that the area and the latency of the correction element is much less than a TMR-based voter. As a drawback, the DMR requires a physical design of the correction element, since the correction element used in DMR solution is a modified inverted latch, since the standard (symmetric) element are not able to decrease the SEU probability.

3.2.3.2. Temporal Redundancy

The traditional TMR structure that triplicates only the flip-flops can protect sequential logic against SEUs, however it cannot tolerate transient effects such as SETs in combinational logic. While a possible solution is to triplicate also the combinational paths, thus implementing a full-TMR approach, it does not protect completely the implemented circuits, since a SET glitch may pass through logic states and if multiple glitches arrive at the input of registers exactly at the clock edge, the redundant storage cells would latch incorrect values or go to undefined and metastable states. Therefore particular techniques have been developed to face SET effects. There are two common methods used for SET tolerant circuits, both are based on temporal concepts, pure temporal redundancy approach and SET filter.

The temporal redundancy (Mavis, 2002) is based on the TMR structure but it uses three shifted clocks to sample data at different time intervals. The approach is valid in case the SET glitches are shorter than the time interval, since at most one latch would sample incorrect value. A voter is used to forward the correct value to the output latch controlled by another clock domain.

The SET filter techniques are based on delaying the signals between sequential elements (Mongkolkachit, 2003). The idea behind SET filtering is to double the logical paths defining two signals: the original signal and the delayed signal, which are connected to the same correction element (which generally consists of a guard gate). Therefore SET pulses having a width shorter than the delay between the two signals would not be able to change the output of the correction element. In relation to the SET filtering, a particular kind of flip-flop has been developed: the DF-DICE cell structure is proposed to improve the aforementioned SET filter technique (Naseer, 2005).

Innovative techniques based on the broadening and filtering capabilities of logic gates are currently under evaluation. The idea behind such techniques is based on preventing the effect of propagation of SETs in combinatorial circuits. Two approaches are nowadays proposed: the first is oriented in the modification of the gate design to present balanced high to low and low to high propagation delays (Kastensmidt Lima, 2008), the second is oriented to the modification of the routing electrical characteristics by modifying the placement position of each logic cell within the integrated circuits. Both the approaches presented encouraging results.

4. CONCLUSION

The increasing usage of electronic systems for safety critical applications, and the growing sensitivity of semiconductor technologies to transient faults pushed towards the development of different techniques for developing devices and systems able to tolerate such a kind of faults. This chapter provides an overview of the main techniques that have been proposed and/or adopted for processors, memories and logic components. It is up to the designer, based on the specific constraints of its application and design flow, to combine and implement them in the proper way.

Chapter 97
Augmented Reality for Collaborative Assembly Design in Manufacturing Sector

ABSTRACT

Some speculations regarding the current issues existing in current assembly work have been brought out in this chapter. The theoretical basis behind the idea that Augmented Reality systems could provide cognitive support and augmentation is established. Hence, this chapter analyses the foundations for assembly feasibility evaluation and discusses possible innovative ways to provide an efficient and robust solution for these problems of realism and efficiency in design and assembly processes. The proposed platform considers the multiple dependencies in different manufacturing sectors that allow the work to be conducted in a simultaneous way, rather than sequential order.

INTRODUCTION

For a typical machine, one may look inside and find that it consists of accessories, modules and parts which have to be combined and integrated to fulfill its function. As the last step of mechanical manufacture to satisfy the technical requirements, assembly also includes the relative works such as regulation of assembly accuracy, inspection of tolerance, test of integration, painting and package other than the pure combination of components. During the process, correctly guaranteeing the assembly precision of machine and components is one of the critical criteria determines the product quality. Before shaping the finished product, the traditional assembly of mechanical components is mainly on the basis of parameters deriving from assembly drawings or some business software

DOI: 10.4018/978-1-4666-1945-6.ch097

such as CAD/CAM. Although being guaranteed a realization of strict assembly sequence and considerable assembly precision, such methods guided by assembly drawings or software also manifest their defects. Because of the lack of combination with the real environment, they can't provide a better understanding of different constrains and complicated plant environments in the real assembly circumstances while the after evaluation of assembly workload such as assembly cost, time consuming and hardship could not be easily commanded either. Moreover, concerning a large amount of components to be assembled, an obstacle to understand the assembly drawing between the designers and the assemblers has been introduced. Again, the repetitive assembly operation would also create a incorrect assembly because of the physical tiredness and the mental negligence. Accordingly, such a serious occlusion of information exchange greatly limits the development of the assembly level. To solve this problem, a concept of collaborative assembly design by using AR technology has been arisen, aiming at completing the interconnection of every character in the before-product period. This technology will allow designers, manufacturers and assemblers to collaborate in a distributed way.

This paper mainly focuses on a novel technology to evaluate mechanical assembly sequences, say, the Augmented Reality technology. Defined as the combination of the real and virtual scene, such a technology has been widely used in areas such as product maintenance (Feiner & MacIntyre & Seligmann, 1993), manufacturing (Curtis & Mizell & Gruenbaum & Janin, 1998; Sims, 1994), training (Back, 2001), battlefield (Urban, 1995; Metzger, 1993), medicine (Mellor, 1995; Uenohara & Kanade, 1995), and so on (Pope, 1994). Comparing with Virtual Reality (VR) which aims at totally mimicking the real world into the synthetic virtual perception according to the help of computer and separates the real and virtual environment, AR maintains a sense of presence in the real world and balances the perception of real and virtual world. With the help of a see-through head-mounted device, a data glove and a tracking system, the virtual components can be placed in the real one which can be seen from the head-mounted device. Wearing eyeglasses which are also called the HMD, an operator manipulates the virtual components directly and superimposes them on the real ones with the whole process can be seen from the HMD. Besides, during the operation process of integrating the virtual objects, the operator will detect the real interferences coming from the real objects and the ambient environment that would delay the assembly schedule or need to be further modified. What is more, because of the feedback of other "non-situated" elements like recorded voice, animation, replayed video, short tips, arrows, it could simultaneously guide the operators through the whole assembly operation, release their tension and even notify an error assembly (Raghavan & Molineros & Sharma, 1999). This way, the reality being perceived is augmented. In AR, two noticeable key techniques have to be mentioned. They are the generation of assembly sequence and the superimposition of virtual objects.

The planner, a key component in the system for creating the assembly sequence and reducing the impractical or impossible subsequences while manipulating the real and virtual prototype components in an assembly environment, allows an operator to cooperate with using the assembly graph which is also called the liaison graph (Molineros, 2002). The generation and the decrease of assembly sequence are coming from the mutual behavior between the operator and the planner. With the help of the assembly graph (liaise graph) which serves as the underlying control structure, the planner utilizes precedence constrains along with the liaison graph to input all the possible assembly sequences by planner, say, a state from FFFFF to TTTTT, and then generates all the possible sequences. Following that, a mutual intercommunication between the planner and the operator is used to reduce the impractical and impossible assembly sequences. When generating the assembly sequence, the planner initiatively provides information to the augmentation system on what to display using the liaison graph which detects the interference, the inappropriate sequences like the unmatchable inserts, connections and fixing, thus largely reducing the impractical and impossible assembly sequences. In the opposite way, according to visual sensing and augmentation, the operator provides the information perceived to the planner about what parts are being manipulated or what state has been reached in the assembly representation, simultaneously a liaison has been established when graphics and augmentation cues are correctly positioned and updated. The planner could delete the finished assembly notes in the liaison graph and reduce some assembly sequences. Again, the operator provides the information to the planner on the basis of how difficult the completed assembly sequence is and then this information is used to cumulatively compute the cost of the sequence under evaluation and to eliminate other sequences (Wilson, 1995). Another technique used for augmentation is the marker capture technique where the three algorithms were used, the thresholding algorithm, the region growing algorithm and Minimum Spanning Trees (MST) algorithm (Raghavan & Molineros & Sharma, 1999; Bolt, 1980). Considering computer vision techniques offer the potential to provide rich feedback, but suffer from problems like computational complexity, calibration, occlusion caused by lighting conditions, noise, etc. Accordingly, the assembly uses markers to simplify the computer vision algorithms and makes real-time implementation feasible.

BACKGROUND

Some assembly systems based on augmented reality have been produced by the researchers. The two most important AR systems were introduced by Molineros (2002) and by Azuma (1993), they developed AR system called the AREAS and AUDIT, in which they outlined in detail the components of their systems, the principle of each operational usages such as HMD (see-through eyeglass), Camera, planner, tracker, as well as image mixing. ESKUA which is based on tangible user interfaces and carried out by Zhang, Y, Finger, S and Behrens S, is another operational platform to interact with CAD software and replace the old CAD/CAM platform concerning the limitation of environment. The camera tracking technique rested with setting a series of markers was deeply investigated by Neumann, Cho (1996) and Liverani, Amati, Caligiana (2004) to supplement the object-tracking blank that the traditional computer graphics can't realize. To test the efficiency of the AR system, especially in the assembly in manufacturing industry, researchers have carried out a great deal of work in the last few years with the help of algorithms of automatically generating the assembly sequence (Wiedenmaier & Oehme & Schmidt & Luczak, 2001; Shin & Dunston, 2008). Despite the hardships and barriers in constraints management, especially in large batch assembly, great interest in other industries is still exhibited (Pellom & Kadri, 2003). More in general, there are some defects that should be noted. At first, when assembling in the real situation where only a few accessories should be assembled, it is better to obey the instructions in assembly drawings since their simplicity, time saving and low cost. Whereas the assembly drawings become very complicated or even can't be understood by the workers with obvious ease as soon as the machine includes a large amount of accessories. Under such circumstances, reading an assembly drawing for a long time could easily create a visual and physical tiredness which lowers the assembly efficiency in the issue. Accordingly, assembly using AR technique should be employed. But in the current AR system, we still can't utilize the computer to automate the sequence of assembly in view of the conditionality of colossal algorithm and computer Graphics (Tuceryan & Greer &

Whitaker & Breen & Crampton & Rose & Ahlers, 1995). Moreover, during the assembly, the mutual accuracy of position precision (straightness, parallelism and coaxiality), the mutual kinematic accuracy (driving precision and rotary accuracy) and the machining accuracy (matching quality and contact quality) must be guaranteed and if not, then rejects would be made in case the assembly accuracy can't be guaranteed.

ISSUES

Problem 1

To guarantee the possibility of high assembly accuracy, the proper assembly approaches should be employed. This way, it is significant to have the expert assemblers experienced in programming assembly path and solving assembly problem. To ensure accuracy in a multi-components assembly where includes lots of composed loops, an experienced expert assembler should design the ideal sequence of assembly by choosing the appropriate assembly approach among exchange, selection, modification and regulation approaches. Actually it often takes months or even years for a novice assembler to develop expert knowledge for assembling processes that have high complexity.

Problem 2

When assembling in the real situation where only a few accessories wait to be assembled, it is better to follow the instructions in assembly drawings due to their simplicity, time saving and low cost. Whereas the assembly drawings become very complicated or even can't be understood with obvious ease when the machine to be assembled includes a large amount of components. Under such circumstance, reading an assembly drawing for a long time could easily create a visual and physical tiredness which lowers the assembly efficiency in the issue. Accordingly, assembly using AR technique should be employed. But in the current AR system, we still can't utilize the computer to automate the assembly sequence in view of the limitation of computer graphics and colossal algorithm. Moreover, during the assembly, the mutual position accuracy (straightness, parallelism and coaxiality), the mutual kinematic accuracy (driving precision and rotary accuracy) and the machining accuracy (matching quality and contact quality) must be guaranteed and in case the assembly accuracy can't be guaranteed, then rejects would be made.

SOLUTIONS AND RECOMMENDATIONS

The Virtual Reality concept has been implemented in various business and industrial sectors. It offers a novel approach to human-machine interactions where information is displayed in the field of vision of human operators. This helps to visualize innovative ideas and user-activated visual programming processes. This concept also turns enterprises into a modern digital factory, particularly for the manufacturing sectors where users are often geographically distributed in different locations and collaboration is of paramount importance. Efficient sharing of product data is a crucial factor for the next generation of manufacturing.

In addition good collaboration is a key value for society. Working together in real time either together in one room or remotely is important for a flexible and fast planning process. There are a small number of existing technologies and systems which provide collaborative frameworks (Chryssolouris, et al., 2007; Constantinescu, et al., 2006) not only is collaboration between people important, but also collaboration between available systems is of significance. Important features such as common data exchange formats and a common look and feel for the given user interfaces must be considered in order to offer an easy-to-use technology that hides underlying technological diversity and complexity from users.

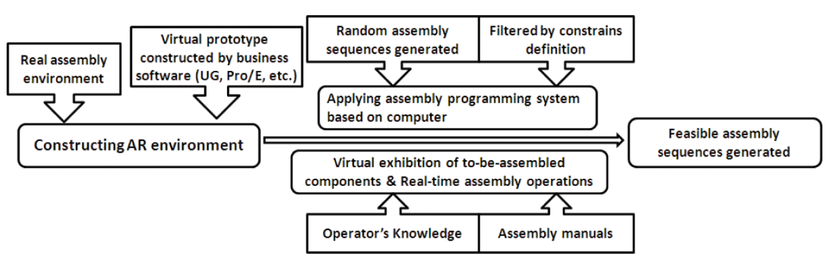
Concerning hardware ergonomics within the virtual technologies domain, a variety of devices are available which differ significantly in properties such as functionality, dimensions, weight and costs. Depending on the task and the needs of the user, the necessary hardware components have to be chosen accordingly. An example system for collaborative planning which is integrated in the Digital Factory for Human-Oriented Production System (DiFac) framework such as the IPA Collaborative Planning Table (Constantinescu & et al, 2006). It enables the collaboration of multiple involved persons, the so called "planners", for achieving the layout planning tasks. The assemblers, designers and engineers can operate with virtual objects and communicate easily and in a direct way. To collaborate with other remote users, a Multiuser Server can be employed. Files, text chat or interaction events for moving objects can be shared.

For the base components it is important to ensure the quality and robustness in order to have reliable devices for the interaction tasks. Therefore, it is envisaged that Augmented Reality (AR) systems are the most suitable for application assembly and design in manufacturing because AR ensures an efficient design, manufacture, and collaboration, as well as robust manufacturing techniques. In addition, the seamless interaction between the real and virtual world is of great importance for an easy-to-use and intuitive user interface. Again, tracking accuracy and precise registration of digital data are key issues. This chapter discusses the possibility to build an interaction platform which integrates different input and output devices like a Holobench System, DataGlove and Tracking System. Given such an interaction platform, the user is provided with a user-friendly interface for performing different tasks throughout the Digital Factory, such as designing a workflow, through direct manipulation by virtual human metaphors.

One of most difficult tasks for engineers is the assembly sequence planning for complex products (Bolt, 1980). Many automatic systems have been used to automate the sequences of the planning process, however, the problem is that it is very hard to formalize the assembly planners' knowledge. Automatic sequence planning systems are able to generate a set of feasible sequences based on identified constraints. Unfortunately, certain constrains are difficult to identify if a good and realistic feel of the assembly process is not in place. An Augmented Reality interface mixing the real and virtual prototypes provides a better perceptive environment for engineers to experience the realistic feeling of assembly operation and identify the assembly constraints. The AR assembly environment can be integrated with an automatic assembly planning system. As an example, the methodology developed by Pang et al. (2006) for assembly sequence optimization is shown in (Figure 1).

Different engineers and designers can view and verify feasible sequences in AR environments to identify new constraints and decide whether there is a need to change the optimization criteria

Figure 1. Sequence planning in AR assembly system (Adapted from (Pang, et al., 2006)).



(e.g., minimal cost, minimal number of orientations, etc.). Next, engineers can go back to the Automatic Assembly Planning System to re-plan the sequences no matter where they are located, so it is especially useful during a collaborative work.

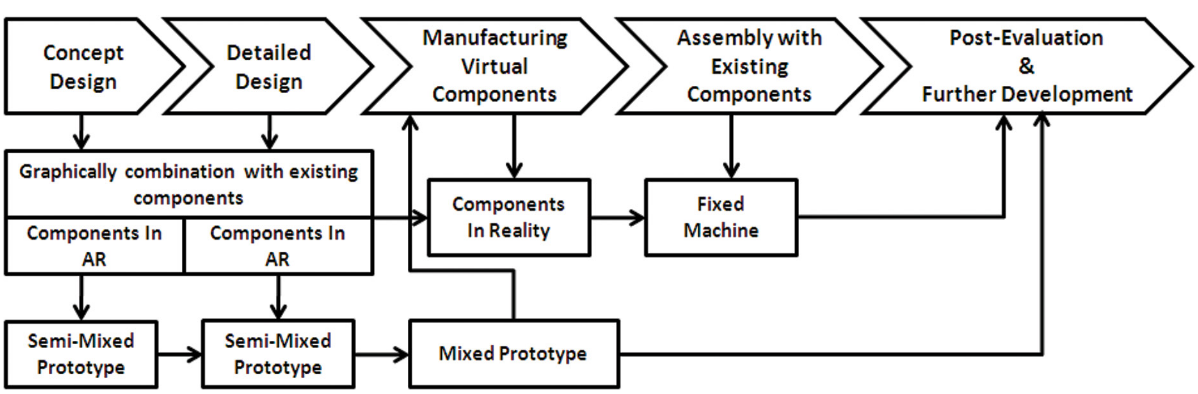
(Figure 2) describes the sequence for using the AR paradigm, starting from the concept design phase, followed by the detailed design phase, further design refinements and finally leading to building and assembly.

Concept Design phase: Business process re-engineering is increasingly becoming the focal point of attention in today's efforts to overcome problems and deficits in the automotive and aerospace industries (e.g., integration in international markets, product complexity, increasing number of product variants, reduction in product development time and cost). Deploying Augmented Reality systems often involves several interactive paradigms for assembly tasks (See Figure 2) in which engineers and designers can experiment naturally with the prototype. The figure shows a paradigm about how a single assembly can be done with the support of Augmented Reality systems. For example, the assembly process below illustrates how a designer would refer to an AR model (e.g. a design for an aircraft) to demonstrate the practicality of several designs and choose the most suitable option corresponding to existing components. An iterative process is applied in which increasing levels of detail and accuracy accumulates over the product design cycle. Initially, in the early concept design phases the AR model will be simplistic and lacking in detail (a rough draft of the desired end product). Gradually more and more component information is added and produces a more detailed design.

Detailed Design phase*:* Engineers can analyse the AR model and provide feedback. Here the AR model gives designers the freedom to quickly and easily make changes to the specifications of their model.

Modifying a real world prototype, such as an aircraft, following the traditional methodology of creating real world prototypes for each design introduces significant inefficiencies in the design and prototyping process. It can be prohibitively expensive due to costs of materials, man hours spent in and assembly of prototypes, and other costs associated with the increased timeframe required due to a slower design and prototyping process (e.g. loss of market share due to lack of competitive advantage).

Figure 2. A single interactive paradigm for an assembly task



Manufacturing Virtual Components phase: After the previous two phases the design is now starting to become relatively mature. Engineers will consult with the manufacturers of the various components (ie. component suppliers) and determine if further modifications to the AR model are required. Consultation between designers, engineers and with the component suppliers will take place in a more rapid timeframe. This promotes a more efficient form of collaboration between the interested parties.

The design cycle will move in a repetitive process of design, consultation, further design improvements, and so on. The design cycle is iterative and continually builds and improves on previous design efforts using feedback provided by engineers, component suppliers, and any other interested parties. There will be a negotiation between parties whose fields of expertise are within diverse disciplines, the AR design paradigm will facilitate better communication between these parties.

Assembly with Existing Components phase: The various parts are purchased from component suppliers and assembled by assemblers (e.g. engineers or factory workers) in order to produce the real world product based on the AR model. The product is ready to be used without need for the production of a real world prototype.

During this phase it is expected that the engineers or designers might wish to provide further feedback in order to improve the AR model so that the assemblers could follow the AR model easily rather than the schematics diagram and make the corresponding change to the real components. The virtual phototype (AR model) will help the assemblers to produce the real world product in a more efficient way, and will provide a visual representation that is more intuitive for them to follow.

Post-Evaluation & Further Development phase: After production of the prototype further testing and analysis will be carried out. This may result in further modification to the AR model. Due to the flexibility of the AR paradigm modifications to the AR model can be made more quickly.

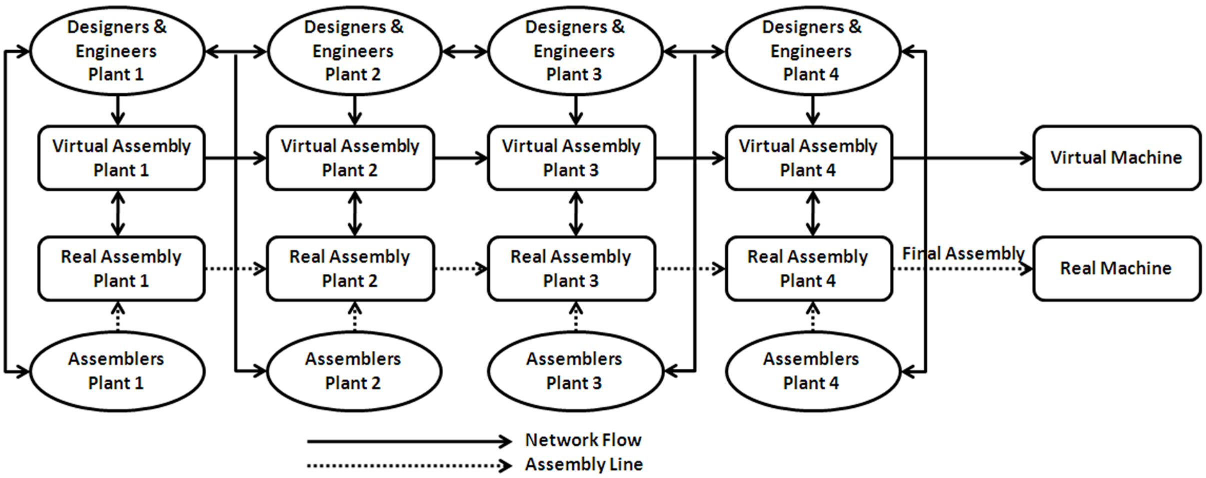
Fewer changes to the design will be required at this stage, and it will be quicker to finish the assembly tasks due to improved collaboration and feedback in earlier phases.

Practically all automotive companies separate different parts to various manufacturing factors. For example, if the object consists of four plants to be produced, then each manufacturing sector is in charge of one plant, but the important part is that the each component is required to be matched before any other steps to take further. The figure demonstrates a complicated process which using Augmented Reality concepts into a network with various departments for the components. Each sector has specialised workers in the particular domain knowledge with certain training. In the beginning the designer and engineer produce the concepts design, then with the aids of Augmented Reality systems, the virtual assembly could be formed. Meanwhile, the assemblers could see how the components should be assembled to match with some existing real components.

As an example, the assemblers of an automotive chassis in plant 2 are building the chassis based on the phototype. This plant is dependent on the production of parts from other manufacturing sectors, such as the supplier for the engine block. The manufacturer of the chassis can start to build with confidence without having to wait to receive a shipment of engine blocks from plant 1.

There are multiple dependencies between these plants, but with the network flow, each plant can monitor the other's plants' progress so there is no

Figure 3. A platform for collaborative work in assembly design simultaneously



need to wait until the previous plant to complete their assembly task, the work can be conducted simultaneously. In addition, the efficiency could be accumulated across the assembly line between all the manufacturing plants involving in the production.

BENEFITS

Reducing Mental Workload and Cognitive Load

There is a cognitive load present in the assembly process. In the assembly task, more and more assemblers get trained with different methods. Augmented Reality systems provide a more efficient way to train the assemblers, the cognitive workload will be reduced as they no longer need to exert cognitive effort when trying to visualise the component based on a traditional schematic. The AR phototype will help the assemblers by providing a more natural and intuitive phototype, requiring less effort to interpret, and helping to guide them in the assembly process.

Cognitive load theory addresses how to use elementary tools for training assembly workers. For example, users prefer a graphical user interface (GUI) that uses illuminated picture based icons in order to remember where specific programs and functionality are located in the user interface. Compare this to text based icons which are less intuitive and will increase the cognitive load. Providing visual cues decreases cognitive load even if a user knows where items are located. AR provides a superior visual stimulus to the end user. Picture based icons can be used instead of plain text icons as this provides a simpler more intuitive user interface with less cognitive load.

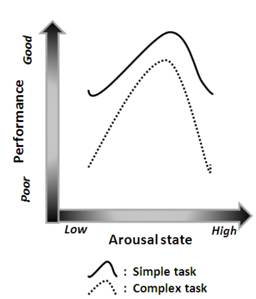
In performing complex manufacturing work such as assembly tasks, the assembler has to reach a certain level of performance while not exceeding the mental capacity he is willing to spend. A well-designed human-machine-interface like Augmented Reality might be helpful to the worker to achieve these goals. Some studies have reported that the AR environment was less mentally demanding (Tang, et al., 2003). A well-proven method of designing such systems is to arouse the workers, thus providing the visual cue is significant to the assembly task. The arousal level can be thought of as how much capacity you have available to work with. One finding with respect to arousal is the Yerkes-Dodson law (1908) which predicts an inverted U-shaped function between arousal and performance (See Figure 4). There is a certain relationship between the arousal level and the quality of performance. If the task is too simple or too complex, the level of arousal will go too low and too high. Only the optimal level of arousal, which is lower for more difficult or intellectually (cognitive) tasks, and higher for tasks requiring endurance and persistence, can improve the quality of performance. A visual stimulus is one of the significant senses for arousal and motivation of workers. In assembly tasks, workers often need to form the image of assembly sequences according to the drawings, this causes some mental workload for the workers. Although some cases may only have few steps to go through, but more often the cases are much complicated. Therefore, the Augmented Reality could allow the workers to visualize the parts rather than manipulating the objects in their mind. It has been proven that if the workers do not have to mentally transform objects and keep a model of the relationship of the assembly objects to its location in working memory, they would then experience less mental workload (Tang, et al., 2003). When the assembler is being trained to read the assembly drawings, there is a large quantity of information being presented in the drawings, it could easily overload the assembler's peak arousal level (producing stress) and this results in a situation where does not want to arouse them anymore. With the assistance of Augmented Reality systems, assemblers will not be fatigued easily since the visual aids could break down the complexity and maintain the arousal at an even level.

Reduced Design Time and Errors

Physical phototyping is traditionally the main method for assembly design. With physical phototypes, engineers, designers and assemblers can easily obtain direct feedback from their senses (visual, tactile, and force, etc) in order to decide if the parts have been designed properly. During the assembly operations, it is easier to identify any unexpected drawbacks to improve the design, but that usually is very time consuming and incurs a very high cost in past years, additionally, once being made, it is difficult, time consuming and expensive to modify the initial prototype. Hence, Augmented Reality can be potentially considered as a rapid prototyping and low cost system since the technology could generate the 3D graphical models which are used to manipulate and design products using existing (or novel) parts. Furthermore, usually the assembly designer tried to avoid the errors as much as possible. However, the design process is becoming increasingly flexible if the design process can be adopted with Augmented Reality systems since the design is changeable with changeable prototype, the 3D image will change according the manipulation from the designers so it is more efficient.

Furthermore, there seem to be two different understandings of what exactly virtual prototyping is: the "computer graphics" and the "manufacturing" point of view (Sims, 1994). During the verification between different disciplines such as designers, engineers, manufacturers and component suppliers, it is not avoidable to have some errors, some might be independent errors and some might be dependent ones. Previous study for assembly tasks have been proven that the participants who used the AR systems can produce far less dependent errors (Tang, et al., 2003). Since the visualizations provided by AR systems could help augment the assemblers' cognition and also be a more useful

Figure 4. The Yerkes-Dodson law



instructional tool compared to the paper drawings. In the past, proper design of instructional visualizations can reduce the time taken and errors made in performing a task (Molineros, 2002). To understand how to design effective visualizations, it is significant that Augmented Reality can give instant feedback, so the assembler could immediately decide if the next step should proceed before the errors to be produced.

FUTURE RESEARCH DIRECTIONS

In our future industrial case it can be aimed to enhance assembly work for sequence planning. In augmenting assembly work, the assembly worker is guided by virtual objects and visual assembly instructions.

As virtual reality has become more widespread, the demand for system developing has increased dramatically. Establishment of an AR assembly environment is an extremely complex and needs to consider many interdisciplinary issues from different domain knowledge such as design, engineering, AR technologies, assembly and manufacturing. Although there are some works which have been done in the AR assembly domain, the research in collaborative assembly design is still at the infant stage. Therefore, there are essential needs to investigate the realm of assembly process from the various disciplines in order to increase the work efficiency.

One key value for a comprehensive assembly evaluation is the physical interaction between real and virtual objects in an AR assembly environment, however there are still lots of limitations in this domain (Aliaga, 1994; Breen, et al., 19956; Vallino, 1998). For example, physical interaction between real and virtual objects in Augmented Reality should include collision detection and reaction which is significant for a comprehensive, realistic and feasible assembly and design process. If these problems cannot be solved, the AR assembly system would be hard to use in any complicated evaluation. On the other hand, at the current state of existing AR technology, the most realistic feedback can only be obtained from the direction of real object affecting the virtual components, but not vise-versa. Hence, the studies of the other way from a virtual object to the real object should be carried out as well and it has significant meaning for the future AR application in the collaboration.

CONCLUSION

This chapter discusses the current issues of assembly work and explain the reason that why the AR system could be the option to solve these problems with the potential for benefits. The proposed mixed prototyping concept from AR environment combines the advantage from the real prototype and virtual prototype which increases the efficiency and flexibility compared to the traditional method in the assembly work. In this way, it not only reduces the cost for the manufacturing industries, but also reduces the time and increase the accuracy during assembly process. The optimized solution also offers the opportunity for different manufacturing sectors to work in a same time. This innovative idea breaks down the sequential work process for collaboration in assembly and offers a platform which supports the features of overlaying and registering information on the workspace in a spatially meaningful way in AR. Moreover, it improves the human performance and relieves some of the workers' mental workload. The AR systems offer a real time collaboration and interaction between various enterprise units allowing a fast information exchange and letting the natural separation from designers and manufacturers to be overcome.

KEY TERMS AND DEFINITIONS

Augmented Reality: A field of computer research which deals with the combination of real-world and computer-generated data such as the computer generated scene overlaid on the real world.

Virtual Reality: A technology which allows the users to interact with a computer-simulated environment, whether that environment is a simulation of the real world or an imaginary world.

This work was previously published in Virtual Technologies for Business and Industrial Applications: Innovative and Synergistic Approaches, edited by N. Raghavendra Rao, pp. 105-117, copyright 2011 by Business Science Reference (an imprint of IGI Global).

Chapter 98
E-Business/ICT and Carbon Emissions

Lan Yi
China University of Geosciences (Wuhan), China

ABSTRACT

The high-tech industry, its associated Information and Communication Technologies (ICT), and subsequent e-business and Internet applications, have had profound effects on our economic lives, social development and environment. This revolutionary change is not only appreciated by computer gurus, but also by private and public organisations. This chapter attempts to focus on the relationship between the e-business/ICT and carbon emission–one of the causes of global warming. Aspects to be considered include energy consumption and CO_2 emission associated with the Internet throughout its lifecycle-from manufacturing of Internet equipment/hardware to its usage and final disposal. On the other hand how Internet technology facilitates environment management and benefits industries via, for example Carbon Trading, will be discussed. The aim of this chapter is to provide a clarification and comprehensive picture of the carbon impact of ICT/e-business to private and public organisations as well as individuals, especially some "behind-the-scene" type of facts. Therefore environmental factors can be taken into account for more informed decision-making during business conduction.

INTRODUCTION

"In 1965, Gordon Moore, one of the visionary founders of Intel, predicted that the high-tech industry could double computing speed and power every two years. This vision, referred to as 'Moore's Law', has been realised" over and over again (SVTC, 2006a). This revolutionary change is not only appreciated by computer gurus, but also the whole society. Through one touch of a mobile phone, one can surf the Internet, send SMS and emails, or shoot 5-mega-pixels resolution photos and share them with the whole world, at a matter of seconds literally. What's more, these devices are improving constantly, becoming faster, smaller, cheaper, increasingly powerful and more

DOI: 10.4018/978-1-4666-1945-6.ch098

advanced. However, what shouldn't be ignored also is - they have shorter and shorter lifecycles. Taking pleasure in the revolution exultantly, few of us have noticed what sacrifices have been made to reach this achievement and what side effects are coming along.

Information and Communication Technologies, supported by the high-tech industry, and subsequent e-business and Internet applications, have made profound effects on our lives. The inevitable growing usage has marked it as digital economy era. On the other hand, with the recent Copenhagen Climate Change summit happening during a global recession, how to achieve a low carbon economy has also been on the top agenda of most governments. The further growth of these two trends seem unavoidable, however, are these two going to contribute or contradictory to each other? Study on the interaction between the environment and ICT is relatively new. And very few people really understand the full picture. The obvious links can be exemplified via, just to name a few, teleconferencing reducing carbon emission, online shopping replacing shopping malls, mp3 files substituting CDs, e-commerce deliveries causing additional transport pollution, extra packaging and increasing WEEE (Waste Electronic and Electrical Equipment) issues. Researchers have started to review these impacts from different angles using various methodologies. As can be expected from an emerging field of research, awareness and understanding of this topic is rather limited. Previous studies have presented mixed results.

This chapter attempts to focus on the interactive relationship between the Internet and the environment, energy consumption and carbon emission particularly. Further information regarding the broader linkages between the ICT/e-business and sustainable development (economic growth, environment protection and social development) can be found in the materials provided in the additional reading section at the end of this chapter.

The specific interaction between the e-business/ICT and carbon emission has been mostly looked at from the angle of "the Internet is associated with how much electricity". Rather than assessing the issue from this macroeconomic point of view, which is the most common approach, this chapter attempts to analyse it from a more detailed perspective, at the operational level. The aim is to provide a clearer and comprehensive picture of the carbon impact of e-business/ICT to private and public organisations as well as individuals, especially some "behind-the-scene" type of facts. Therefore they can take the environmental facts into account to make more informed decisions while they conduct business.

Aspects to be considered include (i) energy consumption and carbon emission associated with the Internet throughout its lifecycle, from manufacturing of Internet equipments/hardware to its usage and final disposal, and (ii) how Internet technology facilitates environmental management and benefits the energy industry via, for example Carbon Trading.

BACKGROUND

Mark P. Mills, one of the earliest to study the environmental impact of the Internet, claimed the energy consumed by Internet totalled about 8% of all US electricity use in 1998 and predicted it would grow to half of all electricity use in the next decade (Mills, 1999). These figures were claimed to be "significantly overestimated" by the Energy End-Use Forecasting and Market Assessment Group at Lawrence Berkeley National Laboratory (LBNL) (EUF, 2004). The debate reached an unprecedented level when the US House Subcommittee on National Economic Growth, Natural Resources, and Regulatory Affairs held hearings on "Kyoto and the Internet: the Energy Implications of the Digital Economy" on February 2nd 2000. At that hearing, Jay Hakes, Joseph Romm, and Mark Mills, the most authoritative and active figures in this research field testified. However, no unanimous conclusion was drawn as everybody looked at the problem from different angles and considered different system boundaries. Following this hearing, there were a few rounds of debates and rebuttals between Mills, LBNL etc, which received lots of attention in the media.

In 2005 LBNL published a final report for the PIER (Public Interest Energy Research) programme for the California Energy Commission (Masanet, Price, Can, Brown, & Worrell, 2005). Conclusion was made that despite the ubiquity and importance of PCs in industrialised economies, few data have been published - particularly data that characterise the life-cycle energy consumption and Greenhouse Gas (GHG) emissions of PC. This lack of data is due in large part to the extremely complex nature of the PC production system, which typically involves hundreds of different manufacturing processes, raw materials, and process chemicals, and is often dispersed among a vast global network of suppliers.

Though the results are rather inconsistent, these disputes aroused more interests than ever and triggered researchers and organisations to attempt to find the answer. Even though no conclusions have been made, the scientific value of this topic to researchers as well as the economic interest to industries and governments have been well exhibited. Yi and Thomas have provided a relatively comprehensive review of research on the environmental impact of e-business and ICT till 2007 (Yi & Thomas, 2007), including a review of related papers and thesis published, projects, comparisons of methodologies, conferences and symposiums. In this article, some of the most important development were mentioned and assessed, for example:

- Jokinen et al. examined the relationship between the information society and sustainable development on theoretical and conceptual levels (Jokinen, Malaska, & Kaivo-oja, 1998).
- Miller and Wilsdon published a paper entitled "Digital Futures — An Agenda for a Sustainable Digital economy" in 2001. This paper was one of the major products of the Digital Futures project, one of the most significant projects in this research field. In this paper, findings were summarised in the form of ten headline principles - what they call the ten 'dot-commandments' (Miller & Wilsdon, 2001).
- Matthews et al. compared the environmental and economic performances of traditional retailing and e-commerce logistic networks in the United States and Japan, using book retailing as a case study (Matthews, Williams, Tagami, & Hendrickson, 2002).
- In 2002, Romm published a journal paper entitled "The Internet and the new energy economy" (Romm, 2002), based on work first published in 1999 in a working paper (Romm, Rosenfeld, & Herrmann, 1999). These two papers have been the most frequently quoted and referred papers in this field.

With a glance of these titles, one can see previous efforts have been made from quite different perspectives. It is not feasible to conduct a direct comparison of the results as past work have chosen very different scopes in assessing the problem. Researches range from relatively small-scale case studies to very large pan-European projects. The range of the relationship also spans from strictly e-commerce to all encompassing digital technologies and electronic business platforms, and from a sub-sector of the environment, e.g. energy prospect, to general economic, social and environmental sustainable development. Nevertheless, past efforts have made significant contribution to the possible quantification of the issue in the future and set the background for this chapter.

The complexity of this topic originated from the complication of the Internet structure itself as well as the difficulty to define a clear-cut boundary for the input-output (economic as well as environmental) of the life cycle analysis. One simple network comprises large number of telecommunication equipments and terminals, from hub, router, gateway, server to PCs and peripherals, while every stage of the supply chain could involve energy consumption and CO_2 emission, from production to waste disposal. Furthermore, expertise needed to understand this issue incorporates a range of fields including computing, economics and environment science. Therefore the multi-disciplinary nature of the problem has also made the situation more complex.

Along the life cycle of e-business/ICT related physical existence, the next section of this chapter will provide (i) a review of how relevant e-business/ICT physical elements contribute to energy use and carbon emission in different stages and (ii) why e-business/ICT has contributed to data sharing and transactions on energy derivatives particularly the establishment of carbon trading platform.

ICT RESULTED CARBON EMISSION

This section attempts to break down the Internet associated energy consumption into the following levels along the life cycle of e-business/ICT related physical existence:

- The first section is related to the production which includes energy used in the production of Internet equipment/hardware, e.g. manufacturing of semi-conductors, PCs.
- The second section discusses energy related to and carbon emission resulted from shipment and distribution of components and equipment, e.g. overseas outsourcing.
- The third section presents energy consumption by the usage of hardware.
- The fourth section explains energy and carbon emission related to Internet and e-business applications, e.g. energy saved/used during usage of tele-conferencing and home-working.
- The last section reviews energy consumption and carbon emission related to the final disposal of the hardware.

Production

Along the life cycle of e-business/ICT related physical existence, this section discusses energy used in the production of Internet equipment/hardware, e.g. manufacturing of semi-conductors, PCs.

Researchers have considered different units in studies of computer related resource and energy consumption during the manufacturing stage, with reference to different mixes of processes in different regions. In general, it is agreed that computer related electronics manufacturing is a complicated process involving hundreds of natural resources and chemicals, requiring enormous amount of energy. Some compare the making of a single computer chip to boiling 10 gallons of water to make a cup of tea, as the Silicon Valley Toxics Coalition (SVTC) described. For example, the annual materials usage of a typical semiconductor facility (a semiconductor is an electronic component that is essential in many electrical devices from computers to mobile phones) includes: 832 million cubic feet of bulk gases, 5.72 million cubic feet of hazardous gases, 591 million gallons of deionised water, 5.2 million pounds of chemicals, and 8.8 million kilowatt hours of electrical power (SVTC, 2006b). This energy intensive process also results in large amount of carbon emission.

In 2002 Williams et al studied energy associated with manufacturing a 2-gram microchip in Japan (Williams, Ayres, & Heller, 2002). They stated the fossil fuel and chemical inputs to produce such a chip is estimated at 1600g and secondary materials used in production total 630 times the mass of the final product. This is an order of magnitude much larger than the factor of 1-2 for many other manufactured goods, such as automobiles and refrigerators.

The European Commission study (Atlantic-Consulting, 1998) broke down the assessment to components of a PC – control unit, keyboard, monitor etc and presented the results within the geographic boundary of the European Union as in Table 1 (unit: g CO_2-eqv). These results are however inconsistent. Furthermore data cannot easily be compared to others. Also, what shouldn't be ignored is that a PC or a PC component is just one part of an overall network. And the Internet is a vast collection of different networks that use certain common protocols and provide certain common services (Tanenbaum, 2003). So first of all, what physical elements (components/hardware/devices) are associated with the Internet that are contributing to carbon emission during their lifecycle?

The interconnected networks transmit data packets through guided transmission media (fibre-optic cables, twisted-pair copper wire or coaxial cable), or unguided media (e.g. wireless LAN or a digital satellite channel) (Kurose & Ross, 2003). The Internet's end systems normally include desktop computers (PCs, Macs, and UNIX-based workstations) and mobile computers (portable computers, PDAs and mobile phones with wireless Internet connections), as well as indirect servers (web servers, e-mail servers etc). An increasing number of alternative devices such as thin clients and household appliances, web TVs, set top boxes and digital cameras are also being attached to the Internet as end systems. Furthermore, there are devices which connect network segments between different layers, including repeaters, hubs, bridges, switches, routers and gateways. These switching devices are in common use but they operate in different layers in the OSI (ISO Open Systems Interconnection) reference model (Tanenbaum, 2003).

Also, some computer peripherals are likely to be attached for certain tasks. For example, in relation to e-business for the travelling sector, say a customer buying an e-ticket online, normally would be required to print the reference number/e-ticket or to save the webpage in a mobile. Therefore a printer or a mobile phone is considered to be part of the network.

Although different types of computer networks (e.g. LAN, WAN, MAN…) are available, the hardware and equipment involved are mostly a combination of elements mentioned above, which have carbon emission associated with each individual lifecycle. Nevertheless, the scope of elements involved far exceeds one type of equipment, e.g. PCs.

According to the US census, along with around 26.9 million electronic computers produced in 2006 in the US (US-Census-Bureau, 2007a), over $18,562 million (value of shipments) worth of wireless voice and data networking equipments were also produced, including for example, over $1,081 million worth of enterprise routers (US-Census-Bureau, 2007b). Thus if all Internet related hardware is considered, the contribution to global warming by manufacturing and using these devices will be significantly increased from earlier studies.

Calculation of these figures would be a confusing and daunting task. It is possible to collect data from a macroeconomics point of view, though it

Table 1. Emission of CO_2 equivalent from PC components

Components	Material production	Manufacture	Use	Distribution	Disposal	Total
Control unit	2.98E+04	5.32E+04	3.09E+02	1.68E+05	1.34E+03	2.49E+05
keyboard	3.21E+03	2.96E+03	4.35E+01	0.00E+00	6.07E+02	6.66E+03
monitor	1.64E+04	**7.69E+04**	**4.46E+02**	**2.80E+05**	**2.52E+03**	**3.75E+05**

will require data from different sectors including manufacturing of electronic computers, telecommunications equipment, semi-conductors, wiring devices and supplies etc. Nevertheless, when we sit in front of a PC either for personal or business purposes, we should bear in mind the long route taken by this unit and associated environmental impacts.

Shipment and Distribution of Components

Due to cost issues, technology availability and environmental regulations from different countries, e-business/ICT involved hardware are rarely locally manufactured. The material consumption and manufacturing process associated with the Internet hardware are rather energy intensive. On top of that, outsourcing and transportation of the hardware beyond geographical boundaries has made it more difficult to track the life cycle emissions. One PC could have components manufactured in hundreds of different locations and assembled elsewhere.

The reason for the migration and outsourcing of the hi-tech industry has gone beyond being a cost problem. After the discovery of massive groundwater contamination caused by toxic solvents from a computer chip factory in Silicon Valley of Santa Clara County, US in 1980s, hundreds of workers were found to develop cancer, reproductive problems, and other illnesses due to exposure to hazardous chemicals (SVTC, 2006c). The US Environmental Protection Agency had to deem 29 areas toxic Superfund sites, requiring priority environmental cleanup. As of 1996, 20 out of the 29 superfund sites were caused directly by the high-tech electronic industry and 5 were caused by related industries. Therefore, the electronic companies began outsourcing and moving their facilities overseas where labour is cheap and environmental protection laws are weak. "Today, behind any brand name electronic product a consumer buys off the shelf, there may have actually been 30 different companies involved with the making of that product" (SVTC, 2006c).

However, before considering the carbon emission involved in the transportation of computer related products, just how many computer related products are outsourced? Most well known electronic manufacturers such as Intel, AMD and Cisco are actually supported by many components makers worldwide. The quantities of outsourcing products can probably be reflected by the revenues of the overseas computer hardware markets. One of the most important outsourcing countries is undoubtedly China due to its cheap labour cost. China Development gateway, a Chinese NGO originally launched within the World Bank, stated that exports of computer products grew from $200 million in 1990 to $3.78 billion in 1995 (Chinagateway, 2004). In 1990 the Chinese computer industry had 191 hardware manufacturers and a total workforce of 100,000 people. By the end of 1995, a total of over 300,000 people worked for 1,000 hardware manufacturers. China's computer industry grew in output value from $921 million in 1990 to $6.37 billion in 1995. When moving such a large quantity of products across the world, no matter what transportation means is used, related carbon emissions are undoubtedly going to be significant. In addition, the market has grown considerably since 1995.

The calculation of freight related emission would require standardisation of indicators, measurements and units. However, just to give an idea of the scale of the problem: flying a fully loaded freight A727 (capacity 19 tonnes) just over 300 kilometres (less than the distance from the Midlands to Brussels) or running an articulated lorry over 9,000 kilometres could generate 10 tonnes of CO_2 equivalent emissions (DEFRA, 2000). So for export from China alone, how much carbon emissions would be involved in moving $3.78 billion worth of computers across the globe every year?

It's nearly impossible to calculate the amount of carbon emission coupled with shipment and outsourcing of Internet components, nonetheless, the above will give some idea of the magnitude of the problem.

Furthermore, Internet supported electronic commerce has facilitated online transactions around the world. The fact that a consumer can order almost anything from anywhere in the world at any time, which will most probably be packed and delivered individually the next day, changes the traditional shipment pattern and correspondingly deteriorates the environment and accelerates carbon emission. This will be discussed further in the Applications section.

Usage of Hardware

Once the hardware are shipped and distributed through warehouses and retailers, the transportation process temporarily stops. The hardware finally reach consumers and are ready to be used. This section provides a simple equation on how to calculate energy consumption during usage of the hardware.

According to the UK's Department for Environment Food and Rural Affairs (DEFRA), powering 86 PCs for a year uses 23,000 kWh of electricity and could generate 10 tonnes of CO_2 equivalent emissions (DEFRA, 2000). To calculate the electricity use of a particular computer or equipment is theoretically straight forward – just multiply its power with the usage time and sum the results from all the units involved. However, the process becomes more complicated as different makes, brands, and modes of operations (e.g. stand by, power save mode…) are involved. LBNL set an equation to calculate the average annual energy used by each piece of equipment as (Kawamoto, et al., 2001):

$$UEC_i = (SPM_i \times (PA_i \times HA_i + PL_i \times HL_i + PO_i \times HO_i) / 7) \times 365/10^3 + ((1\text{-}SPM_i) \times (PA_i \times (HA_i + HL_i) + PO_i \times HO_i) / 7) \times 365/10^3 + EPC_i$$

where

UECi = Unit Energy Consumption for equipment type i (kWh/year)

i = index for equipment type

PAi = Average active mod e power for equipment type i (W)

PLi = Average low- power mode power for equipment type i (W)

POi = Average off mode power for equipment type i (W)

HAi = Hours of operation in active m ode for equipment type i (hours/week)

HLi = Hours of operation in low-power mode for equipment type i (hours/week)

HOi = Hours of operation in off mode for equipment type i (hours/week)

SPMi = Power-management-enabled rate for equipment type i (%)

EPCi = Extra energy for printing or copying for equipment type i (kWh/year)6

365 = days per year

7 = days per week

The results from LBNL are based on a few assumptions including: the average lifetime of all types of network equipment is 4 years; Cisco products are selected as the representative model.

With regards to whether energy use and other environmental impacts in the manufacturing phase of PC equipment outweigh the usage phase, there have been controversial statements made in the past. Williams et al have claimed that for energy, the production phase becomes more relevant than the use phase, a reversal of the situation for products such as automobiles and many household appliances (Williams, Ayres, & Heller, 2002). Williams (2004) stated life cycle energy use of a computer is dominated by production (81%) as opposed to operation (19%). However the European Commission study claims the characterised data for global warming shows that the largest environmental contributions of PC come from the use stage where they are caused by the electricity consumption (4.47E+5, unit: gCO_2-eqv), which is over three times of the second largest contributor

- the manufacture stage (1.33E+5, unit: gCO_2-eqv) (Atlantic-Consulting, 1998).

Despite the disagreement among different studies, available research has mainly focused on the energy consumption of PC units, which are only one type of equipment running within the overall network. Other Internet equipment also consumes significant amounts of energy, e.g. the constant running of Internet routers, switches, servers etc. Unlike PCs, these equipments don't really have low-power, standby or power-saving mode. Due to their functions in the Internet structure, these equipments mostly have to be fully powered on 24/7, which means that the associated energy consumption is not negligible.

At the organisational level, it is relatively easy to calculate the electricity consumption and carbon emission associated with PC units. The figure could potential help an organisation's bottom line as well as its environmental performance.

Internet and E-Business Applications

The above section presented energy consumption related to the usage of e-business/ICT physical components. Calculation is rather straightforward. However unlike refrigerators or televisions, energy consumption of e-business/ICT equipments is not just self-resulted. Internet and e-business applications, for example, tele-conferencing, online shopping have significantly changed our life-style – in many ways have contributed to considerable energy saving and reduced carbon emissions compared with traditional life-style. Differentiated from previous section where the focus was on the primary impacts from e-business/ICT involved physical components, this section mainly focuses on the secondary effects created by the ongoing use and application of e-business/ICT.

Some claim that increasingly complex products, such as microchips, require additional secondary materials and energy to realise their lower entropy form, which offsets their dematerialisation contribution – the secondary materialisation proposition (Williams, Ayres, & Heller, 2002). However many still believe that Internet supported applications have been making a positive contribution to resources and energy saving in many areas and consequently to carbon reduction.

For example, the substitution of air travel with tele-conferencing has significantly reduced transport related carbon emissions. DEFRA stated that flying 14 international long haul trips or 110 short haul trips, or travelling 165,000 km on a train could generate 10 tonnes of CO_2 equivalent emissions (DEFRA, 2000). According to the Financial Times, the average transatlantic business flight uses 80,000 to 100,000 pounds of fossil fuel, which could easily be avoided by the use of teleconferencing (Cohen, 2000). Compared with these figures, the electricity consumption of tele-conferencing equipment and associated carbon emission are almost negligible.

Many companies have also started implementing Intranet based home-working schemes, which significantly reduce office space and related energy consumption. The construction, heating and lighting of buildings in the UK accounts for half of all energy consumed, half of carbon emissions and 40% of raw materials. But office space is only actually used for 22% of the average week (Goodman, Alakeson, & Jorgensen, 2004). Many organisations have seen huge savings through tele-working, e.g. British Telecom's flexi-working programme has enabled a 50% reduction in floor space since the mid 1990s; Sun Microsystems' iWork has reduced office space needs by 25% in four years (Goodman, Alakeson, & Jorgensen, 2004); At&T estimates a US $25 million per year saving in real estate through its virtual office programme (Allenby, 2001).

E-commerce related Internet shopping has also replaced physical shopping malls to a certain degree. In contrast to traditional business, some pure online businesses offer even more potential to eliminate retail space completely. C2C (consumer to consumer) e-commerce, for instance EBay, serving over 100 million users with more than 1.4 million items up for auction each day, is maintaining a virtual website rather than a huge retail store. Romm et al predicted the Internet economy could also render unnecessary as much as 3 billion square feet of buildings – some 5% of the US commercial floor space – which would save a considerable amount of construction-related energy (Romm, Rosenfeld, & Herrmann, 1999).

Other Internet facilitated applications, for instance, e-procurement has saved BT 5.8 tons of paper from 100+ page catalogues that were previously circulated and 1 ton of paper from 24,500 order pads that were previously printed (BT, 2003). Furthermore, the internet has made virtualisation of products and digitisation of information possible. Taking the music industry as an example, physical products such as CDs could easily be replaced with musical files downloadable from the Internet. Production as well as related warehouse, transport, etc. could be eliminated. The digitisation of standard business transactions is also changing office paper use (Yi & Thomas, 2006). Transformation of the earlier physical form of these products to virtual format has obviously made a saving in energy across their life-cycles.

Though on the negative side, the "Harry Potter" event – one of the milestone in the e-business history – was strongly criticised because of its environmental impact. On a single Saturday in July 2000, 100 airplanes and 9,000 trucks delivered more than 250,000 copies of 'Harry Potter and the Goblet of Fire' to Amazon.com customers all over the USA. This event had set a record for the online provision of goods in volume, but it probably also set a record for the quantities of empty shipping boxes and packaging that would wind up in landfills, let alone the energy used, transport pollution and carbon emission caused in the deal (Matthews, Hendrickson, & Lave, 2001).

The net impact on energy during the Internet application phase is yet to be further explored. However, in general the positive aspects are believed to outweigh the rebound effects. Realising and analysing each possible detailed aspect, where and how much energy is associated with, is a start.

Disposals of Hardware

During the life cycle of e-business/ICT hardware, the last stage would be the final disposal. Unlike other consumer electronic products such as refrigerators, consumers couldn't be busier throwing away outdated PCs and replacing them with newer versions. The increasingly shorter life cycle of these PCs and other related products (mobile phones, PDAs etc) has induced a unique market with unprecedented amount of demand, compared with products involved in previous major revolutions such as radios and TVs. The enormous appetite for PCs inevitably leads to a high PC disposal rates: for example, an estimated 10,000 PCs become obsolete in California alone each day (CAW, 2004; Masanet, Price, Can, Brown, & Worrell, 2005). On the other hand, despite the massive resources and energy used in manufacturing a relatively small-sized item, the hi-tech industry has designed the computers in such a way that it is more difficult for customers to upgrade than to replace the whole unit.

The EC Directive on Waste Electrical and Electronic Equipment (WEEE) (European-Commission, 2000), was agreed upon in January 2003 and entered into force in January 2007. The Directive aims to minimise the impact of electrical and electronic goods on the environment by increasing re-use and recycling, hence reducing the amount of WEEE going to landfill. IT and telecommunications equipment is among the 10 categories listed and accounts for a considerable portion of the total. WEEE now constitutes one of the fastest growing waste streams in the EU, with current estimates indicating a rate of growth three times that of average municipal waste.

In addition, the process of incineration or recycling of WEEE is not carbon emission free, especially taking into account this amount of WEEE produced. In a report produced by

Earthworks and Oxfam America, Farrell et al. stated that PCs alone contain a medley of metals, including gold, silver, aluminium, lead, copper, iron, zinc, and tin. Many of these materials could be salvaged at the end of the computer's life and recycled. But currently, most discarded computers are dumped in landfills or incinerated. Incineration of e-waste releases heavy metals and dioxin into the atmosphere. Some of the larger and older smelters have done extensive ecological damage. Worldwide, smelting adds about 142 million tons of sulphur dioxides to the atmosphere every year, which is 13 percent of total global emissions. And since smelters burn huge amounts of fuel, they also release substantial quantities of GHG, such as CO_2 and perfluorocarbons (Farrell, Sampat, Sarin, & Slack, 2004).

Furthermore, much of the e-waste produced in developed countries is actually shipped to developing countries to recycle. It is estimated that 50% to 80% of the "made-in-USA" e-waste is not recycled domestically but placed on container ships bound for destinations like China due to cheaper labour and lack of environmental standards in these countries (Puckett, et al., 2002). The process of transfer and transportation will cause another round of carbon emission.

CARBON TRADING PLATFORM

The previous section has presented the carbon emissions that Internet and related hardware manufacturing and usage have caused. On the other side, the Internet has enabled effective data sharing and ICT have been making positive contributions on energy issues in various industries. For example:

- The design of intelligent energy efficient products and systems has been facilitated, e.g. intelligent transport systems, environmental management systems, and energy management in housing.
- It can be conducted more effectively to monitor energy flow and other environmental indicators in the supply chain process: from production, distribution to disposal.
- Tools, software/application and platforms for energy trading, especially across countries, have been provided.

In particular, digital technologies supported carbon trading platforms have also created new markets online and is becoming an emerging and fast growing global phenomenon.

Background

Driven by the Kyoto Protocol signed in 1997, governments have committed to reduce carbon dioxide emissions by 20% by 2020. Carbon dioxide is one of the major GHG - the commonly known causes of global warming. Carbon emission has stretched its impact on our economies beyond being a simple environmental issue. On 30 October 2006, the UK government published a 579-page report on the economics of climate change by Sir Nicholas Stern. According to Stern (Stern, 2006), the overall costs and risks of climate change will be equivalent to losing 5% to 20% of GDP. In contrast, the costs of action – reducing GHG to avoid the worst impacts of climate change – can be limited to around 1% of global GDP each year. With no action, each tonne of carbon dioxide we emit will cause at least $85 (£45) of damage.

The British Government has introduced a tax on industrial energy as well as a cap and trade scheme. Companies are granted with an annual allowance of CO_2 emission (the cap). Whoever exceeds the cap will be fined; alternatively the company can buy allowances from other companies who have surplus. In short, industry societies now have to pay for their pollution, e.g. the price of 2005 CO_2 allowance rose to a record of €29.50 a ton on July 7th in the European CO_2 rights market (Levy, 2005). Due to immaturity of the system and policy, the price has fluctuated significantly during the first phase (2005-2007) as well as the recent recession.

The Market and Concept

Carbon is taken by the financial professionals as a form of energy derivatives, which is not a new concept. However, carbon does bear certain unique characters. Since European Commission and national governments still allocate free allowances to industries, only companies that exceed this free allowance needs to buy credits. The accuracy of this initial allocation has significant impact on the subsequent price. The price of carbon also fluctuates under influences of politics, country policies, other energy markets and so on. There are increasing number of regional, national and international systems for trading and transfer of GHG allowances and emission reduction credits. Hasselknippe reviewed a total of 47 systems for GHG trading and transfer included in the International Emissions Trading Association (IETA) Trading Schemes Database (Hasselknippe, 2003).

Various electronic platforms established domestically and internationally include the Climex Alliance (a pan-European market for trading Carbon Emissions Certificates within the EU's Emissions Trading Scheme), the Intercontinental Exchange (ICE), SENDECO2 (the Spanish CO_2 exchange expanding to Italy, Greece and Portugal) etc. The European Union Emission Trading Scheme (EU ETS), the largest multi-national GHG emissions trading scheme in the world and the main pillar of EU climate policy, commenced operation on 1st January 2005. All 27 member states of the European Union participated. In its first year, 362 million tonnes of CO_2 were traded on the market for a sum of €7.2 billion.

The international carbon market in 2005 transacted a total of 799 million tonnes of CO_2 equivalents worth approximately €9.4 billion (Point-Carbon, 2006). The carbon market grew in value to an estimated US$21.5 billion in the first three quarters of year 2006, more than doubling in value over the previous year (Capoor & Ambrosi, 2006). For such a large market to survive and the second phase (2008 ~ 2012) of the ETS scheme to proceed, technological support by ICT will play an important and growing role. Therefore how to integrate all these different systems presents a challenge. The communication and harmonisation of the systems as well as security control, can only be implemented probably with the support of the Internet and other Information and Communication Technologies.

Reduction of carbon emission has become an unavoidable issue for industries and governments. Carbon trading has been developed beyond the single purpose of protecting the environment with the involvement of international financial industry. With more participants and engagements, the mechanism and systems have become more and more complicated. Some even expect the system will further expand from energy industry to cover local government, retail sector, or even individual citizens. One day a carbon credit card for individuals to pay for electricity, gas and petrol might become reality (Sustainable-Development-Commision, 2006). No matter the future of the trading is a global central exchange or over-the-counter mechanism, it wouldn't succeed without the support of ICT – which helps to overcome the barrier of geographical boundaries and the challenge of large amount of data flowing around the globe.

The Case of EU

PriceWaterHouseCooper has reported the state of art of potential expanded use of IT in EU-ETS (PriceWaterHouseCoopers, 2006). It summarised that in the current EU-ETS, IT is restricted to support monitoring, reporting and registry activities. Verifiers and competent authorities use non-standardised software for internal purposes only. For example in the case of the UK, in the Verification Reference Model of EU ETS, IT is used as (i) a template for reporting, (ii) a template for verifiers and (iii) the home developed registry. No software application is currently used in the monitoring stage and the electronic media for reporting is not currently web enabled. The vision of British regulators is to have a web enabled reporting system with different levels of access for regulators, operators, verifiers and the public and a standardised system to be shared across the EU.

The national registry in the UK is accessed via the Internet and has been developed using DEFRA's technical design standards in Microsoft.NET 1.1 and SQL Server. By using web services the registry is able to communicate with the EU Commission's Community Independent Transaction Log (CITL). Currently the communication is secure and processed as real time transactions. The UN Data Exchange Standards (DES) specifies the use of TCP/IP connections using encrypted messages over the Internet in order to protect communications from modification or interception in transit (PriceWaterHouseCoopers, 2006).

During the trading phase, DEFRA (UK) and the French Registry developers, Caisse des ustus et consignations (CDC), are working together to enable trading platforms to interface with the registry systems. DEFRA hopes that the creation of international data exchange standards will facilitate the development of electronic interfaces by end users allowing trading platforms and electronic accounting systems to communicate automatically with Registries (PriceWaterHouseCoopers, 2006).

In order to accommodate growing usage and future demands, transparency, reliability, speed, capacity, adaptabilities, upgradeability and security of these online platforms are critical for the trading to operate effectively and efficiently. Development of a sound IT infrastructure and harmonised interfacing between different systems will be fundamental to the overall success of the programme.

CONCLUSION

ICT and related Internet usages have made profound effects on our economic lives, social development and environment. Research on the environmental impacts of the ICT is relatively new. This chapter attempted to explore the interaction between Internet technologies, energy consumption and carbon emission. The objective is to give a detailed, however not exhaustive, summary of various stages of how the Internet and e-business contribute to the energy issues. Private and public organisations can therefore more clearly understand the environmental impact of their usage of related technologies in their business.

As expected, research that has made a significant difference is limited and is far from finding any definitive conclusions or solutions. Also the depth of research is not enough. However on the positive side, significant interest has been provoked. Awareness of issues involved has also been raised not only with academics but also with policy makers and industries. Some results have paved the way for future research in this field.

With reference to the manufacturing of Internet hardware and equipment, past research has considered different system boundaries with different mixes of processes in different regions. Nevertheless it is agreed that computer related electronics manufacturing is a complicated but clearly energy intensive process. Outsourcing and transportation beyond geographical boundary has made it difficult to track the life cycle of Internet hardware. The usage stage is claimed to involve large amounts of energy due to the constant running of networking hardware but relatively easy for individuals to calculate. Fortunately subsequent Internet supported applications have been making a positive contribution to resources and energy saving in many areas and consequently to carbon reduction. These include home-working, tele-conferencing and dematerialisation of physical products. Finally, the creation of e-waste and its transfer to developing countries has however caused another round of negative ecological impacts.

Additionally, the chapter has also looked at the importance of ICT in facilitating the emerging carbon trading systems. In order to accommodate growing usage and future demand and for the trading to operate effectively and efficiently, the systems have to be transparent, reliable, adaptable, upgradeable, and secure. These critical requirements will all largely depend on advanced ICT and web-enabled technologies.

Understanding of the relationship between the Internet and carbon emission has demonstrated substantial impact on environmental monitoring and protection. Quantitative standardised methodologies are currently under development and will be beneficial in realising the full picture. Nonetheless, presenting a full picture of the interaction hopefully can help both private and public organisations see the facts behind the scene, and therefore manage their purchase of IT equipments and integrate IT into business more sensibly.

SOLUTIONS AND RECOMMENDATIONS

This chapter essentially tries to provide a picture of and reference on how ICT and e-business interacts with the environment, particularly the carbon and energy side along the life cycle of the ICT physical elements. A literature review and survey of the current status is expected to facilitate future research and further understanding.

It is recommended that private and public organisations devote appropriate amount of time and resources to measure the environmental impact such as GHG emissions associated with their general business operations – including ICT and e-business usage. Many industry sectors including mining, utilities, and infrastructure have seen the business value and opportunities of conducting business in an environmentally sound and socially responsible manner.

Organisations are suggested to take on the positive contribution from ICT sector and e-business platforms and to carry out business more sustainably. This includes not only optimising internal operations (such as management of electricity, water, gas use, transportation and waste), but also making the choice of having more sustainable partners. Examples of achieving a greener business might start with a business manager taking a video-conferencing instead of flying across Atlantic, or simply mean reusing or recycling an old PC. Different organisation/company may have different operational strategies, but raised awareness and taking account the environmental factor into business decisions, will only help the planet as well as individual's bottom line.

FUTURE RESEARCH DIRECTIONS

Current dominant approach of analysing the problem is either a micro-level case study approach or a macro-level statistical approach. Traditional assessment approaches are found to be insufficient to accommodate the digital technology revolution and cannot accommodate the challenge of measuring the impacts of ICT on environmental sustainability. New innovative methods need to be created to fill this gap. It is suggested that a more predictive and empirical model, which can be applied within a sector of society, should be more beneficial in the long term. This approach should help simulate potential impacts resulting from changes of indicators, so that positive effects can be promoted and negative ones alleviated proactively, rather than knowing and accepting outcomes passively (Yi & Thomas, 2007).

The challenge of any research does not stop at recognising the problem, but to know: how to solve the problem, alternative solutions with corresponding risks and benefits, and how to choose the best solution. It is not enough to know ICT/e-business has been changing our daily life, economy, transport, air, water, forests, etc., it is not even enough to understand how it is changing everything, ultimately an approach which can influence the behaviour, say of a private organisation for example, is needed.

KEY TERMS AND DEFINITIONS

Carbon Market: Refers to the Emission Trading market, is one of the three mechanisms designed in the Kyoto Protocol. The other two are namely Clean Development Mechanism and Joint Implementation. The term is also called the cap and trade market, since normally a government sets the limit / cap on the amount of Greenhouse Gas (GHG) that can be emitted. Essentially it is an approach designed to control GHG emission through economic mechanism. Companies are issued with specific permit to emit certain amount of GHG. For those who exceeds the allowance, they either have to pay a fine, or they can buy the allowances from another company who emits less than its assigned allowances. The transfer of the allowances therefore becomes a trade. Transfers and acquisitions of these allowances are tracked and recorded through the registry systems under the Kyoto Protocol. An international transaction log ensures secure transfer of emission reduction units between countries.

DEFRA: The UK government department responsible for policy and regulations on the environment, food and rural affairs.

Electronic Business (E-Business): Is the application of Information and Communication Technologies in any essential activities of a business throughout its (external and internal) supply chain. The term can be confused with the other concept "e-commerce", which is a subset of e-business and normally only includes conducting business via online platforms.

Greenhouse Gases: The atmospheric gases that contribute to the greenhouse effect, including water vapor, carbon dioxide, nitrous oxide, methane etc. These gases are believed to be able to trap heat therefore affect the temperature of the earth.

Information and Communication Technologies (ICT): Is a term used to encompass computing, telecommunication, digital technologies that intend to facilitate the processing, analysing, transfering, exchanging, distribution of information.

Kyoto Protocol: Is an international agreement linked to the United Nations Framework Convention on Climate Change. The Protocol was initially adopted on 11 December 1997 in Kyoto, Japan and entered into force on 16 February 2005. The major feature of the Kyoto Protocol is that it sets binding targets for 37 industrialised countries and the European community for reducing Greenhouse gas (GHG) emissions.

Open System Interconnection (OSI): Reference Model: Is an industry wide protocol and international agreement for layered communications and computer network. It divides network architecture into seven layers as: the Application, Presentation, Session, Transport, Network, Data Link, and Physical Layers. It is therefore often referred to as the OSI Seven Layer Model.

Peripheral: Is a device that attached to a host computer. It normally does not constitute as the core component but it extends the functions of the main computer. Examples include printer, scanner, speaker, webcam.

Silicon Valley Toxics Coalition (SVTC): Created in 1982, Silicon Valley Toxics Coalition is a non-profit organisation engaged in research, advocacy and grassroots organising to promote human health and environmental justice in response to the rapid growth of the high-tech industry. It is based in San Jose, California, the United States.

Superfund Sites: According to United States Environment Protection Agency (EPA), a Superfund site is an uncontrolled or abandoned place where hazardous waste is located, possibly affecting local ecosystems or people. It is also the name of the fund established by the Comprehensive Environmental Response, Compensation and Liability Act of 1980, as amended (CERCLA statute, CERCLA overview). This law was enacted in the wake of the discovery of toxic waste dumps such as Love Canal and Times Beach in the 1970s. It allows the EPA to clean up such sites and to compel responsible parties to perform cleanups or reimburse the government for EPA-lead cleanups.

Chapter 99
Building for the Future:
Systems Implementation in a Construction Organization

Hafez Salleh
University of Malaya, Malaysia

Eric Lou
University of Salford, UK

EXECUTIVE SUMMARY

This chapter provides the IT readiness assessment for before and after scenarios of IT systems implementation in a construction consultancy company providing multi-disciplinary services for the construction industry throughout the United Kingdom. The services offered include building surveying, quantity surveying, project management, civil and structural engineering design, and mechanical and electrical engineering design, among others. On application of the maturity model it was found that the overall processes for managing information are improving since the introduction of the new IT system. Prior to the project, the development of IT/IS was driven to perform daily work tasks that required the company to run a business. The new systems has streamlined the organization-wide communication, which the previous system did not have the capability to do, and to reduce cost for document reproduction. The level of IT skills prior to the project was relatively low; the introduction of the new system has helped the company to increase their staff's IT skills.

BACKGROUND AND HISTORY

Organization B is a construction consultancy company providing multi-disciplinary services for the construction industry throughout the United Kingdom. The services offered include building surveying, quantity surveying, project management, civil and structural engineering design and mechanical and electrical engineering design, among others. Organization BBBBB was established in 1941 and operates from their offices in four different cities. The organization turned into a Limited Liability Partnership (LLP) in April 2006, with an annual estimated turnover of £12 million. Organization BBBBB employs 220 staff across 4 offices, of which 120 staff are

DOI: 10.4018/978-1-4666-1945-6.ch099

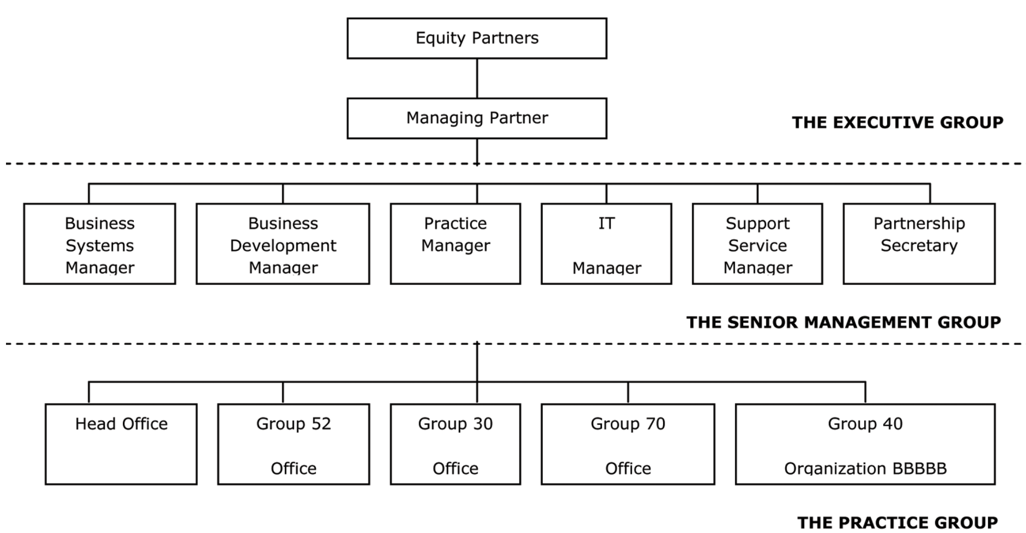
located at the Head Quarters of the company. No specific department exists in their organizational structure. Instead, the organization operates in groups, but not strictly by discipline. For example, one group consists of multiple disciplines, and anyone can be a group leader. The disciplines are as follows: Building Surveyor, Quantity Surveyor, Project Manager, Employers Agent, Architect, CAD, Mechanical and Electrical Engineers, Civil and Structural Engineers, Planning Supervisors. There are three layers of management within Organization BBBBB's organization structure; The Executive Group, The Senior Management Group and The Practice Group. Organization BBBBB's organization structure is shown in Figure 1.

Sequence of Events

In November 2004, the management of the company discussed the need to replace their existing Database Management System (DMS), which had reached the limit of its development potential. In doing this, they had to recognize the need for a coherent approach to their IT, and the need to bring all systems under one control.

In 2004, the management wanted to have access to all parts of the knowledge system through one front end. Further discussions established that they wanted to include a Knowledge Management System (KMS), and added Human Resource (HR) functionality to the proposed system. The organizational business system managers suggested what the practice really needed was a single piece of software that had the capability to manage all the functions within the organization. The management agreed, and asked for a time frame. The project team was then established and comprised of a business system manager as head, and IT manager, a database programmer and a business development manager; and started to evaluate the products available in the market. During the product evaluation, the project team identified products which could do more than just DMS functions, and in fact provide them with a Client Relation Manager (CRM) which is essentially an advanced address database with functions that make the information both accurate and usable, and also an extranet function which makes all documents retrievable from remote locations and an intranet for internal information distribution. The whole function combined to provide a sophisticated Knowledge Management System (KMS). This is what they thought many people had been requesting for some time. The project

Figure 1. Organization BBBBB's organizational structure



team identified the preferred vendors, and five vendors were invited to present their products. One of the products that impressed the project team was the product from Vendor B, and this vendor was invited to present one of their products called Workspace ™. The presentation was attended by the managing partner, business system manager, IT manager and the database programmer. In addition to Workspace ™, the project team also reviewed other products by attending seminars, conferences, and seeking views from the companies who had implemented similar systems.

The product evaluation process took up to a year (then 2005). Finally, the project team decided to select the product from Vendor B as it met the specification of the required system for the company to bring all systems under one umbrella. A payment was made to Vendor B of about £200,000 and internal development costs were going to be added to this later. After signing the contract with the vendor, the business systems manager came out with a methodology (programme) of software development, including the necessary adjustments to the software and the time frame. Both these were represented in terms of business processes.

- **Initial phase**
    - looking at the corporate appearance of software
    - In house staff designed this corporate appearance
    - Looking at the extra functions to be added to the software
    - Within three months after that the management decided there was an urgent need to be looking at a human resources (HR) package
- **Second phase**
    - Started to evaluate a few human resource (HR) products to include human HR functionality to the workspace.
    - Started to load data into the HR product
    - Human resource managers complained the software was not functioning as expected.
    - The vendor who was supplying the HR product was very unhelpful, and imposed extra charges on every extra hour they spent on it which totally contrasted with Vendor B.
    - Vendor B put in a lot of time to put the system in order without extra charges
- **Third phase**
    - Terminated the contract with the vendor that supplied the HR product
    - Asked Vendor B to incorporate the HR function to their product
    - Started the development process
    - Steering committee (SC) formed to represent all functions and levels in the practice
    - Gave a presentation to SC about what the team had been doing with Vendor B so far, and sought their comments and agreement.
    - The SC were asked to look at and test the system, but it did not go well
    - There are several stages of testing
        - The in-house staff renamed the product as 'System Y' (for corporate appearance)
        - Selected staff tested the system – open, enter and save documents
        - It started in the Winchester office
        - Management expressed concern over time delays and fears of the system crashing if large numbers of users used it simultaneously
        - The business development group also participated in testing the system and commented on it.
        - Training managers went to each office branch and provided one

to one training to each member of staff

- All the members were trained to create and save documents in System Y. This is a basic level of training, and staff were certified to use the basic operations of System Y.
- Some of the partners said they wanted to work remotely, for example at home. The business system manager suggested it would be possible if a scan function could be added to the system in order to review documents off site.

- **Fourth phase**
  - This phase focused on the issue of how to maximize the capabilities of the system, particularly involving people issues
  - All suggestions and feedback were reviewed
  - A business case and future priorities were produced
  - Final specifications were then produced

2006

- System Y went 'live' in February 2006 with basic functions.
- System Y was a document management system (DMS) designed to facilitate the management and administration of corporate documents within Organization BBBBB.
- There were 4 main entities/zones that were used within System Y (see Figure 3):
  - Documentation – all the documents produced were stored.
  - Contact – all contact information held on both internal staff and external clients.
  - Project – all information to projects was stored.
  - Organization – all company information was stored.

2007

Figure 2 illustrates the timeline for System Y's development.

Figure 3. System Y

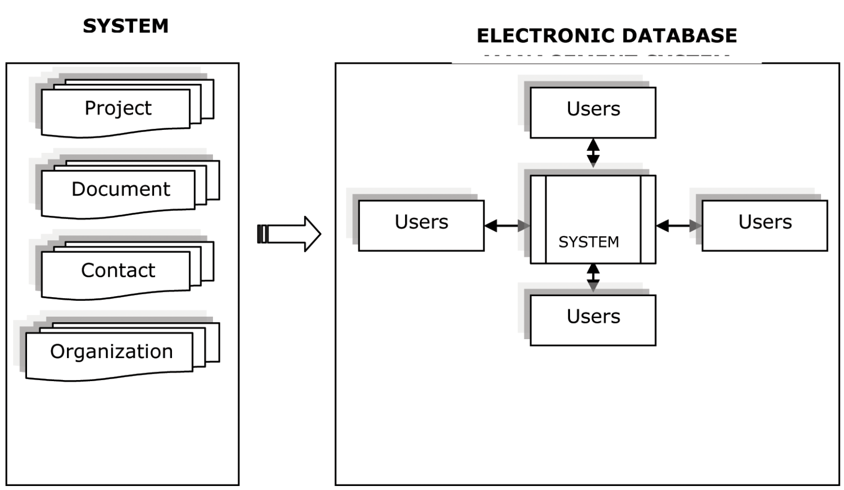


Figure 2. System Y's development timeline

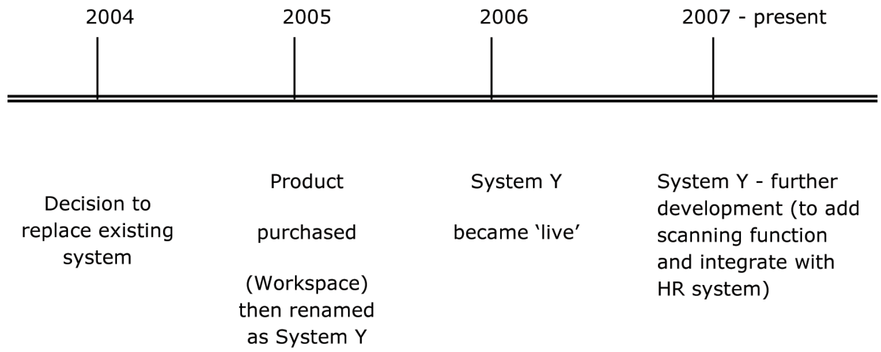

ANALYSIS AND DISCUSSION

The following section addresses each attribute of the four domains of the readiness model within the context of Organization BBBBB.

IT INFRASTRUCTURE

Top Management Perceptions

The management of the company which includes the executive group and senior management group established the vision of strategic thinking towards the general current and future business plan, and the level of resources needed, including staff, training, IT system development, equipment, and identifying opportunities and risks to the business, etc. In addition, any project including construction development and IT system development was planned in terms of its own individual requirements. In terms of IT system development, the business systems manager was responsible for ensuring that IT systems were suitable with business needs and were properly administered and maintained. Once Organization BBBBB became a Limited Liability Partnership (LLP) in April 2006, it facilitated more staff participation in decision making in the company's strategic planning. The *status prior to project* refers to the period prior to 2006 in which the existing Database Management System (DMS) was still in operation. The *current status of the project* refers to when System X became 'live' in 2006 and up to the present day. *Target status* refers to the readiness level that organizations desire to be at in the future.

Status Prior to Project

Drivers

The development of IT/IS is purely to support task requirements and to improve the internal efficiency of various workgroups such as designing, costing, procurement, programming and reporting that is required for the company to be in business. The other IT systems (word processing, spreadsheets, CAD and visualization, computer aided cost estimating and planning and scheduling) are solely independent, off-the-shelf, and primarily related to support individual work tasks. The decision to purchase any system/application was according to the necessity to perform single work tasks. No feasibility study towards the direction of IT/IS development within the company had been done. The need to purchase the system/application was also triggered by looking at systems used elsewhere. A very small IT/IS plan was developed, however its nature was on an ad-hoc basis.

Systems Requirements Definition

The product vendors played an important role in influencing the company to purchase the system/application. The company heavily depended on the vendor to set the functional requirements of the system purchased, while the management determined its non-functional requirements in terms of speed, quality and cost. The applications/systems used within the company were solely dependent on standard featured software and hardware vendors, and operated on a DOS platform. The company did not have any possibility to make alterations or enhancements to the original product they used. The planning, designing and installing of the products was done mostly by vendors.

The Criteria that Relates to the Readiness Model in Level 1

- Driver; copying/work task requirements
- Systems requirements definition; heavily depends on vendor.

Current Status of the Project

Driver

There is an issue relating to the consistency of information storage and retrieval organization-wide. Everyone has their own separate directory and lack of information sharing is obviously emerging. Information queries from the London office take time for a response. The other issue was that all the documents were saved in individual standalone PC, and therefore it took time to get the information needed, and the possibility of lost documents was relatively high. To solve this problem, the management decided to develop a centralized database that was accessible within the company. In doing this, the company recognized the need for a coherent approach to their IT, and the need to bring all the systems under one central control. There was also a space issue regarding the allocation of the filing cabinet for storing the file documents. Cost of reproduction for project documents was also high. The company then decided to develop systems that have access to all parts of the knowledge system through one front end, and be managed by a central database administrator located in Orpington. For example, the applications used Quatopro, Auto CAD, Word, Excel, Visio, and Microsoft Project, and these would be linked together which could then be opened in a single application, 'System Y'. With this feature, the sharing of information and streamlining of communication and inter workgroups co-ordination became more efficient. The main reason to develop System Y was to streamline communication organization-wide, which previous systems did not have the capability to do, and so reduce the costs for document reproduction.

System Requirements Definition

A lot of customization needed to be done to 'Workspace' TM. Organization BBBBB produced a methodology of software development including the necessary adjustment and customization to the software and time frame including renaming the product 'System Y'. The major customization of Workspace TM was to fix the scanning function which facilitates document scanning and viewing. The customization work was done by Vendor B. All the functional requirements and non-functional requirements of System Y were compiled by in-house experts with vendor assistance, and the role of Business System Manager in System Y's development was interpreting the needs of the practice into the technological solution. Vendor B had a project manager dedicated to this practice and information flowed freely between them; there was also a helpdesk function built in. The development of IT/IS started to increase in a planned manner with management support.

The Criteria that Relates to the Readiness Model in Level 3

- Drivers; cost reduction, organization communication
- System requirements definition; mainly in-house with intervention from the vendor.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Driver

There is great demand from the clients and project team members to monitor the progress of construction projects more closely and transparently. The future situation was to meet this demand by extending System Y's accessibility to the clients and project team members, and the clients and project team members were given access to System Y to track down the project progress and status. There was also demand from the clients to integrate System Y with their system. Along with these improvements, the agenda to increase internal efficiency was still moving by integrating System Y with the Staff Management System (Human Resource Management System). The future improvement was to add value to System Y by extending its accessibility along the company information supply chain project – this function will increase the organization's competitive advantage.

System Requirements Definition

The company was planning to expand their IT Department by employing more technical staff, particularly the systems analyst, business analyst, and programmer. In the future, the company intended to get full involvement of internal expertise throughout the system's development. The design and set-up of the IT infrastructure such as the operating system, networking, security and telecommunications, was the responsibility of the vendor.

The Criteria Relating to the Readiness Model in Level 5

- Driver; information supply chain project
- System requirements definition; Full in-house with intervention from vendor

The results of top management perception analysis are shown in Table 1.

Systems and Communication

Before 1996, the company had a basic network system but only secretaries had access to it. Quantity Surveyors used stand alone PC's for measurement, etc. There was no internet access or email. Telephones were basic switchboard type and dictaphones were tape type. Photocopiers and faxes were also basic. In 2000, all computers were fully networked and the practice had 80% of staff using computers. Currently, the company has 100% computer access. The telephone, fax and scanner systems are all integrated and managed centrally.

Status Prior to Project

Focus

IT/IS development is to support processes that are required for the company to be in business.

These business operations are primarily related to accounting, designing, procuring, documenting, etc. IT is not critical to any aspect of the company business strategy. The development of IT/IS is purely basic and to support operational tasks and performing similar activities such as typing

Table 1. IT Infrastructure: Top Management Perception Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	1	3	5	2,3,4,5

documentation, payroll, accounts, and human resources. The applications that performed single activities are solely independent, off-the-shelf, and primarily related to the core business such as CAD and visualization, computer aided cost estimating, planning and scheduling.

Network Communication

All the PC's are connected, limited within the group, all employees used their own/shared IT services such as printing and scanning, and all had their own directory to save documents in, that could not be shared by another. However, the documents were exchanged on a manual basis.

The Criteria Relating to the Readiness Model in Level 2

- Focus; co-ordinate project and business information
- Network communication; networks within workgroups in business unit

Current Status of the Project

Focus

IT development is devoted to centralized information activities, company wide. Current goals for IT focus are on cost reduction, improving quality and speed, and enhancing overall company effectiveness. The main aim is to store a document into a single database that is accessible by all staff within the company.

Network Communication

System Y provides a collaborative network for project management through a single login. It authorizes people at all branches/remote locations and the design team involved in the project to access all the information they need, regardless of where the information is actually located. Every PC is connected to each other and shares some common IT services such as printers, scanners and servers, and now the exchange of documents is mostly electronic.

The Criteria Relating to the Readiness Model in Level 3 / 4

- Focus; fully integrated software applications organization-wide
- Network communication; networks are used organization-wide.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Focus

IT developments that extend services to support managing the supply chain to the customers and the design team. The IT/IS goals for IT focus on extending the market and the geographic reach. The focus is to make everyone use the same documents such as email, scanning documents, word application, spreadsheets, and drawings to fit around highly organized business processes.

Network Communication

The accessibility to the company database in System Y is extended to the clients and design team.

The Criteria Relating to the Readiness Model in Level 5

- Focus; manage information supply-chain
- Network communication; networks are used to improve supply-chain performance.

The results of system and communication analysis are shown in Table 2.

Table 2. IT Infrastructure: System and Communication Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	2	¾	5	3,4,5

PROCESS

Practices

The overall processes within the organization were not defined and documented prior to the project. Also, prior to the project, everyone followed the same process (scope identified) in managing information; however the processes were unable to ensure quality and standards. Currently the information management has been standardized and everyone follows the same processes, which establishes quality and consistency organization wide.

Status Prior to Project

Practices

The process involved document processing over the whole lifecycle, consisting of incoming documents and 'in house' documents being held in hard copy and kept in dedicated file folders on the filing cabinet with a unique indexing system, documents being scanned when the job finishes, and held on optical disk. When the document was requested, staff could simply search in the filing cabinet according to the unique indexing system and make another copy of it using the photocopier and then the requested document was distributed to the particular staff member. Where documents or data existed on the computer then it could be accessed by anyone with the software on their computer, but searching for it was cumbersome and often required an email to staff members to find out where it was located. The process was repeated every time the same document was requested. There are several issues, which can be highlighted from this process:

- No document to record the document life processing.
- No assigned responsibility and authority for performing the tasks.
- Policies and procedures for managing project information throughout the company were identified and improved based on experience with similar projects.
- The organization typically did not provide a stable environment for managing project information, for example it lacked sound management practices and had ineffective planning.
- The process was unpredictable and constantly changed particularly when dealing with time and cost. The information process capability of the organization was unpredictable, because the management of project information was constantly changed or modified as the work progressed.

The Criteria Relating to the Readiness Model in Level 2

- Practices; business processes scope identified and improved as the work progresses.

Current Status of the Project

Practices

System Y can hold electronic copies of all documents, either in which they were created or in a scanned/pdf form and allows users to create, edit and manipulate documents with the same process and single resource as follows:

- The Find Zones within system Y enable the users to search for and manipulate data. The users are also able to create new projects, edit existing projects, create and edit documents, as well as create and edit contact information.

- The My Zone within System Y gives users access to the latest news, information, and correspondence, active files that users are currently working on, live projects, favorite links, and a list of all documents published, authored, or sent to the current users.
- There are a number of different ways the users can create new documents in System Y; firstly, a new document can be made with the listing templates according to their category, i.e. letters, reports, memos, etc. Secondly new documents can be created via the Project links. Thirdly, by creating a document based on an existing document within System Y; and fourthly, by using an existing document outside System Y as a basis for a new document by dragging a file from Windows Explorer into the Working Files area of System Y.

The process can be summarized as follows:

- The standard process for managing projects information throughout the company are documented and standardized.
- System Y is created with the intention for everyone in the company to be able to store their work and record their activities in a controlled and standard way. For example, every document created such as emails, contact details, word applications, drawings and spreadsheets saved into a single repository can provide a simple and searchable interface to every document. This includes a full content index of most document types. That means the users can search everyone's work to see if something similar has been done before. Also, System Y keeps track of all information relating to the distribution process, thus, it is possible to find out when, how and why documents and drawings have been sent out. Apart from that, global views of all staff and their percentage utilization are also provided to allow the management to monitor the utilization for the entire company. Login and logout functionality exists in System Y, ensuring that two people cannot edit the same document at the same time.

The criteria relating to the readiness model in Level 3

- Practices; business processes documented and standardized

Target Status (Readiness Level that Organizations Desire to be at in the Future)

Practices

The future of System Y's development is to extend its accessibility to the external parties such as clients and project team members to get access into the system. With this function, the clients and project team can track down the progress of the related project, such as variation orders (changes of design, cost increase, extensions of time), payments, purchase orders, valuations, letters, minutes of meetings, etc. This would increase the client and project team member satisfaction and transparency of service being provided by the company, and would increase the level of harmony across the supply chain. Due to its transparency function, a project team is able to make complaints and enquiries in a more efficient and effective manner. A number of customer complaints and enquiries regarding the project progress might be set as a quality measure. However, the external parties' accessibility is limited to the 'project function' area only, which means they cannot view the other functions such as organizational documentation. The future of System Y's development is also intended to integrate with human resource system management for the efficient and effective management of human capital. The human resource management system functions as a single source of information, giving the employees' details such as personal histories, educational background, skills, capabilities, personal experiences, project handling experience, workload to payroll records. This therefore reduces the manual workload of administration activities, such as employee time and attendance, employee tax reports, pension plan to profit sharing and the capability for training and development, skills and capabilities management.

The Criteria Relating to the Readiness Model in Level 5

- Practices; business processes capable of setting quality and measuring the products/services

The results of business process analysis are shown in Table 3.

Table 3. Process: Business Practices Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	2	3	5	3,4,5

PEOPLE

Skills

Most staff gained basic IT skills; however, there are differences between junior and senior staff. The junior staff often request more IT facilities within the company, whereas the senior staff have the opposite view. The company is starting to employ young, dedicated people to fill the IT related positions. Network communication skills are becoming more essential due to great demand from staff and clients to invest in advanced telecommunications.

Status Prior to Project

Type of Skills

Most applications and systems within the company were off-the-shelf and developed by an external consultant/vendor. The in-house IT staff did not have the expertise to develop systems, and in-house staff did the installation of off-the-shelf and low level maintenance. The complex IT maintenance was done by an external consultant/vendor. Most application systems use basic IT functions such as switch on/off computer, creating, saving, and printing documents. The application use is simple and basic and does not require much IT skill. Daily operation of applications such as word perfect and spreadsheets for creating letters, documents, correspondence, specification, project planning, estimating, bills of quantities, etc. Design drawings were done manually. Obviously, no networking and electronic communication skills were required since all the information was distributed through hard copy. The users and even technical staff required assistance from an external consultant in resolving unexpected computer problems.

Capability Building

There was no formal IT training conducted to improve staff IT skills. Users took their own initiative to improve their own IT skills such as learning among themselves and learning through job experience. Some even took external courses on their own. The company only sent technical staff for external training to improve their programming and analytical skills.

The Criteria Relating to the Readiness Model in Level 1

- Type of skills; basic skills
- Capability building; individual effort.

Current Status of the Project

Type of Skills

The original system Workspace ™ (renamed System Y) has multiple functions that were defined by Vendor B. The customization tasks of System Y, such as defining functional and non-functional requirements, were mostly done by in-house expertise along with Vendor B's expertise. In-house expertise was gained with the system development experience during System Y's development. It has to be appreciated that System Y operates for all level of users including senior management, middle management, administration, and site management for Organization BBBBB. Most users, particularly the surveyors, utilize and benefit from the functions within System Y that support many tasks for project management, such as:

- Anyone involved in the project can access the information such as drawings, specification, bills of quantities, letters, etc., with a single source database.
- A project directory stores all the information on parties involved in the project.
- There is a 'template' function for producing all project correspondence including letters, reports, fax's, etc. This ensures the quality of outgoing documents for all projects are maintained.
- Key events for every project such as the start and completion date can be created for monitoring the progress at different milestones.
- Due to the increase in information intensity of the construction process created and used by project members, the company began to realize they could create an environment in which various forms and formats of information could be linked together for easy access and distribution.

Capability Building

The training was conducted throughout the organization including branches, and open to all staff, this consisted of half-day training for all staff to use the basic functions of System Y. Each level of a module is a separate training exercise. When staff successfully complete the basic level of training, they move to the next, more advanced level. Their access to System Y also depends on their training achievement.

The training also conducted for System Y includes

- Series of 18 emails distributed to all staff
- One to one training
    - This is more on an ad-hoc basis and upon request.
    - This is personal one to one training provided to the staff who need more attention about the uses of System Y.
    - The Assistant Training Manager handles this type of session.
- Workshops
    - This is a hands-on workshop about the uses of System Y.
    - The Training/Assistant Manager and Vendor B's trainer conduct this workshop.
    - This workshop is divided into three stages: beginners, intermediate, and advanced.
    - Half day training of all staff to use the basic functions of System Y. Each level of a different module has separate training exercises when the staff successfully complete the basic level of training.
    - All staff were required to pass a lower level training module in order to get to the advanced level. Their access to System Y also depended on their training achievement.

- ◦ Upon completion, the certificates were awarded to the successful trainee.

Training managers give induction courses to new staff, according to the multilevel needs.

The Criteria Relating to the Readiness Model in Level 3 / 4

- Type of skills; considerable technical and project management
- Capability building; centrally integrated training within organization.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Type of Skills

Everyone, including the surveyors and administrative staff, expect work under general direction and receive work tasks in the form of project objectives, and are able to plan their own work to meet target costs, time, and quality. Everyone has a good understanding of the relationship between their own area of specialization to other areas. The accounts department is able to understand and appreciate the valuation process.

Capability Building

The existing training methods are expected to be applied for the future and to establish collaboration and knowledge sharing within the company and design team.

The criteria relating to the readiness model in Level 5

- Type of skills; cross disciplinary experience
- Capability building; based on knowledge sharing.

The results of skills analysis are shown in Table 4.

Roles and Responsibility of IT Staff

There are misconceptions about who is really responsible for managing IT within Organization BBBBB between the Business System Manager and the IT Manager. The newly appointed IT Manager was appointed at senior management level in the organization structure. However, the size of the IT Department is small and too inexperienced to cope with a high level IT system.

Status Prior to Project

Position of IT/IS Head

The company had an IT Manager with senior management status.

Roles

IT/IS strategy

The Criteria Relating to the Readiness Model in Level 5

- Position of IT/IS Head; IT Manager with senior management status
- Roles; IT strategy.

Current Status of the Project

Position of IT/IS Head

The company has a dedicated IT Manager, but who is still under the Managing Partner. In addition, the Business System Manager is also in a senior management position.

Table 4. People: Skills Analysis

Status	**Prior to**	**At termination/Current**	**Target**	**Gap**
Maturity Level	1	¾	5	2,3,4,5

Roles

The role of the IT Manager is to deal with all technical matters in IT/IS including the development of the IT/IS infrastructure (hardware, networking and security) and application.

The IT Manager reports directly to the Managing Partner and the staff of the IT Department consists of 7 employees:

- The IT Manager
- 3 technicians
- 1 programmer/analyst
- 2 trainers

The Criteria Relating to the Readiness Model in Level 5

- Position of IT/IS Head; IT Manager at senior management status
- Roles; IT strategy.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Position of IT/IS Head

The position of IT Manager is expected to remain the same in the organizational structure.

Roles

The role of the IT Manager is expected to replace the position of Business System Manager in parallel with the expansion of the IT Department and is to help the senior management align the IT/IS strategy with the business strategy.

The Criteria Relating to the Readiness Model in Level 5/6

- Position of IT/IS Head; IT Manager at senior management status
- Roles; IT/IS strategy and business strategy.

The results of roles and responsibility analysis are shown in Table 5.

User Involvement

The awareness of the importance of user involvement is increasing among the senior management. The users did not participate in the decision making to purchase System Y and only participated in System Y's development.

Status Prior to Project

User Involvement

The role of the users is to define the needs and requirements of the proposed system, and only selected users were consulted to give input. No user group was formed to perform tests and the 'champion' of the proposed system normally made all the major decisions.

The Criteria Relating to the Readiness Model in Level 2

- User Involvement; Individual consultation.

Current Status of the Project

User Involvement

A group of users have been selected to be a member in the Steering Group, led by the Business System Manager. Members of the steering committee consisted of over twenty staff members from different levels, with a spread of skills and aptitudes, and from all offices (including the partners to administrative staff) of the practice.

Table 5. People: Roles and Responsibility of IT Staff Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	5	5	5,6	6

The role of the users in the Steering Group is the identification of user needs, including functional and non-functional requirements. The Steering Group had one central meeting then were consulted and involved in specific skills areas up to installation, and the committee exists only for the large IT/IS projects and will be dispersed after the completion of the projects.

The Criteria Relating to the Readiness Model in Level 5

- User Involvement; ad-hoc user group (steering committee).

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

User Involvement

The users are expected to be involved in the systems development by contributing to most of the major decisions, identification of users' needs and requirements, testing the prototype, and approval of the system. However, there is no intention to set up a permanent user group as the practice plan is to go for vendors for full implementation of the future system.

The Criteria that Relates to the Readiness Model in Level 5

- User Involvement; ad-hoc user group (steering committee).

The results of user involvement analysis are shown in Table 6.

Table 6. People: User Involvement Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	2	5	5	3,4,5

WORK ENVIRONMENT

Organizational Behaviour

Prior to the project, the practice saw IT/IS as a tool for performing their work tasks. The IT system and applications purchased developed more focus on specific groups and individuals, and not on the organization as a whole. IT skills and knowledge were measured through the user's competency at using the system, and the relationship between groups was improved in terms of solving the problem. However, there were gaps between the two main groups of users existing in the practice; the 'younger' group who continuously demand more advanced IT systems, compared to the more 'old fashioned' group which preferred the previous practices and systems and were not welcoming towards the new system.

Status Prior to Project

Characteristics

Everyone had their own way of managing information and used a different approach in performing common work tasks such as storing project information in different files and directories. The dissemination of information within the practice took a long time and was mostly done manually which lead to a non-data sharing culture within the practice. The different work processes used in many workgroups within the practice made it even harder. The process also depended solely on individual efforts, such as how long they kept the document until it was filed away, and also how they managed the filing system. Consequently, the company fell into a crisis when a member of staff left the company.

The possibility of document loss was also high. Members of staff without authority were able to take confidential documents without prior consent. The management saw IT as helping to perform business operations, and not as a strategic use; and saw the performance of IT systems in terms of technology delivery (speed, accuracy and quality).

The Criteria Relating to the Readiness Model in Level 2

- Characteristics;
  - Technology led,
  - IT success measured in IT terms rather than impact made on the business.

Current Status of the Project

Characteristics

The practice started to develop a data sharing culture, and there is an improvement of work co-operation within and between workgroups. Everyone has knowledge of what the others are doing. The practice share processes for common tasks such as creating, storing, retrieving and disseminating information inside and outside the organization – such practices have become more transparent. System Y does not change the way people perform their job but just makes the processes easier. IT success is mainly measured in terms of its efficiency, such as how it can make processes run more smoothly. For example, they measured the benefits of System Y by the number of complaints, less time searching for documents, and fewer filing cabinets (operation efficiency).

The Criteria Relating to the Readiness Model in Level 4

- Characteristics;
  - Sharing processes
  - IT is vital for streamlining business processes.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Characteristics

The senior management plan to create an IT system environment towards a customer focus and centralized knowledge. The practice sees IT as one of the vital elements that lead to competitive advantage by producing better products and services for the customer. The practice also encourages more user participation in IT system development in the future and users are expected to become a main reference during IT system development projects. The interaction and relationships between the users and IT staff is improving in parallel with the plan for IT department expansion in the future.

The Criteria Relating to the Readiness Model in Level 5

- Characteristics;
  - IT/IS used to provide better products and services to customers
  - Staff encouraged to input ideas.

The results of organization behaviour analysis are shown in Table 7.

IT Policy

Organization BBBBB centralized all of their IT/IS activities including purchasing and managing the IT infrastructure and applications. Previously, prior to the establishment of the IT department,

Table 7. Work Environment: Organization Behaviour Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	2	4	5	3,4,5

the quantity surveyor (currently appointed as Business System Manager) controlled the management of IT across the organization. Currently, the IT department controls the IT/IS activities across the organization. However, the IT Manager has to report to the Business System Manager on every decision they make. The Business System Manager is the 'champion' of the IT/IS management across the organization and the management is expected to practice the current policy on managing their IT/IS activities in the future.

Status Prior to Project

IT/IS Activities Control

Mostly controlled by Business System Manager.

The Criteria Relates to the Readiness Model in Level 3

- Centralized IT infrastructure and application policy.

Current Status of the Project

IT/IS Activities Control

The IT department controls all IT/IS activities (centralized IT infrastructure and applications). Every time the business units want particular applications they have to submit applications to the IT Manager, making a business case. If it is not considered expensive, then the IT Manager will discuss with the group leader and then get approval and install. Otherwise, the IT Manager will require approval from the Managing Partner.

The Criteria Relating to the Readiness Model in Level 3

- Centralized IT infrastructure and application policy.

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

IT/IS Activities Control

The IT department controls all IT/IS activities (centralized IT infrastructure and applications).

The Criteria Relating to the Readiness Model in Level 3

- Centralized IT infrastructure and application policy

The results of IT policy analysis are shown in Table 8.

IT Policy

There was a lack of senior management awareness towards the potential of IT for their organization. Previously, the IT development was organized on an ad-hoc basis. System Y implementation was the first time the IT development in the practice had gone through the proper planning process. The senior management sees IT/IS as tools for smoothing the business processes, and the Business System Manager plays a vital role in representing senior management's views.

Status Prior to Project

Communication

The communication regarding the IT/IS activities was mostly done through manual methods such as through memos, letters and meetings. Most communication between senior management and

Table 8. Work Environment: IT Policy Analysis

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	3	3	3	Improvement

staff was through the Business System Manager, and the communication between the vendor and the users was also through the Business System Manager. No communication planning existed and everything was done on an ad-hoc basis.

Participation

There was little participation of senior management in IT/IS activities and the senior management were mainly concerned with the IT/IS expenditure.

The Criteria Relating to the Readiness Model in Level 2

- Communication; no established standard for communication (ad-hoc)
- Participation; ad-hoc participation.

Current Status of the Project

Communication

The communication regarding the IT/IS activities including IT/S project is mainly done through emails and during training. Apart from that, communications through memos, letters and meetings is still popular. The senior management began to communicate to the users directly through emails and meetings. The senior management comment on, and answer, any question from the users through email. E-mail played a major role as a communication channel during System Y's development. For example, the introduction and guidelines on using System Y were done through a series of 18 emails. The vendor also conducted an interview with the users to seek out their needs and expectations towards System Y. However, only selected users were chosen to participate in the interview. The practice started to have a communication plan for IT/IS development.

Participation

In addition to the expenditure on IT/IS, the senior management were concerned with the disruption caused during System Y implementation to the business process. The senior management also started to express their concern regarding the improvement/enhancement of a future System Y to improve client satisfaction, while the Business System Manager participates actively in System Y development.

The Criteria Relating to the Readiness Model in Level 3

- Communication; organization-wide policy and standards for communication
- Participation; Participate only on large scale and high cost IT projects

Target Status (the Readiness Level that Organizations Desire to be at in the Future)

Communication

The practice expected to develop communication planning across the organization for their IT/IS activities, from the experience gained in System Y's development.

Participation

For System Y to successfully satisfy the clients, the senior management have to play a vital role to participate in measuring the performance of the IT/IS project from the strategic perspective.

The Criteria Relating to the Readiness Model in Level 4/5

- Communication; a communication plan is expected for all activities
- Participation; Participation in performance measurement of IT/IS project.

The results of Organization BBBBB behaviour analysis are shown in Table 9.

Table 9. Work Environment: Leadership

Status	Prior to	At termination/Current	Target	Gap
Maturity Level	2	3	4/5	3,4,5

SUMMARY AND FINDINGS

Overall processes for managing information are improving (level 2 to level 5 - process) since the introduction of System Y where;

- Overall processes were not defined and documented prior to the project.
- Also, prior to the project, everyone followed the same process (scope identified) in managing information; however the processes were unable to ensure quality and standards.
- At the current status, the information management began to be standardized and everyone followed the same process which established quality and consistency organization-wide.

Prior to the project, the development of IT/IS was driven to perform daily work tasks that required the company to run a business. Examples of those work tasks are designing, costing, procurement, programming and reporting (level 1 – top management perception). Organization BBBBB then developed System Y to streamline communication organization-wide, which the previous system did not have the capability to do, and to reduce cost for document reproduction (level 2, 3 – top management perception). System Y development is currently continuing to achieve its target for managing the information supply chain within industries (level 5 – top management perception).

The level of IT skills prior to the project was relatively low (level 1 - skills). This was due to the fact that most of the application systems used basic IT functions such as switching the computer on/off, and creating, saving and printing documents. The application use was simple and basic and did not require much IT skill. The daily operations were of applications such as word perfect and spreadsheets for creating letters, documents, correspondence, specifications, project planning, estimating, bills of quantities, etc. The introduction of System Y has helped the company to increase their staff's IT skills. For example, the customization tasks of System Y such as defining functional and non-functional requirements are mostly done by in-house expertise, along with Vendor B's expertise. The in-house IT/IS experts also gained system development experience during System Y's development. The staff's IT skills are expected to improve in the area of using IT for decision making, and across disciplinary skills, parallel with the further enhancement of System Y in the future (level 2,3,4,5 -skills).

Prior to the project, the position of the IT Manager was at senior management level to set up IT/IS strategy. The Business System Manager was also at the senior management position (level 5 – roles and responsibility of IT staff). The position of the IT Manager remained the same during System Y's implementation and then remained so, but the role of the IT department is now to set up IT/IS and business strategy (level 5, 6 - roles and responsibility of IT staff).

There was no improvement in IT/IS activities control since it remained centralized, for all of their IT infrastructure and applications(level 3 – IT policy). In the improved system, the users get involved in the IT/IS development, which is an improvement from the ad-hoc individual participation of the previous system (level 2 – user involvement). They get participation in the steering group led by the Business System Manager in System Y's project (level 5 – user involvement). However, the Steering Groups only exist for the large IT/IS projects, and will be dispersed after the completion of the projects.

Two groups exist within the company. There is a gap between the two main groups of users existing in the practice. They are the 'younger' group which continuously demand a more advanced IT system, compared to the more 'old fashioned' group which prefer the previous or current practice. Prior to System Y's implementation, the management saw the performance of IT systems in terms of technology delivery, i.e. speed, accuracy and quality (level 2 – Organization BBBBB behaviour). However, this perception changed after System Y became 'live'. The management sees IT/IS as vital for smoothing the business process and as a tool for achieving competitive advantage (level 4,5 – Organization BBBBB behaviour).

The summary of the assessment of System Y's implementation according to the readiness model can be found in Figure 4.

ABSTRACT

Full traceability of products is extremely difficult, although it has been sought after for as long as production, distribution and sales chains exist. Electronic traceability methods, such as RFID technology, have been proposed as a possible solution to this problem. In the specific case of RFID, the number of applications that promote innovative solutions in retail and other areas has been continuous growing. However, RFID tags are mostly placed externally on a surface of products or their packages. This is appropriate for logistics, but not for other applications, such as those involving user interaction. In those, not only is the placement of the RFID tag more complex, but it is also necessary that the tag is not visible or not directly accessible, to prevent accidental damage and intentional abuse. This certainly imposes challenges to manufacturing, but mainly creates new challenges to the development of new products and re-design of existing ones. This chapter presents some insights and what we consider to be the two main approaches to incorporating RFID technology into consumer products.

INTRODUCTION

RFID technology has attracted an increasing interest from companies and R&D institutions around the world in the past few years. Some of the application areas of this technology can be seen in the automotive, retail, logistic and health industries. The benefits can go from increased productivity and cost reduction, to more indirect factors– difficult to quantify – such as improved post-sales consumer service (Hodges & McFarlane, 2005). This technology is seen as a potential new phase

DOI: 10.4018/978-1-4666-1945-6.ch100

in the development of the information society, in which the overall day-to-day objects will be inter-connected to other objects, data, etc. This will lead to a considerable impact in some value chains, resulting in a plethora of new applications (Gellersen, Schmidt & Beigl, 2000).

However, this trend represents a challenge that has limited the feasibility of applying RFID technology. The fragility of these electronic devices, associated to the great variety of products and the processes to which these are submitted through their life cycle, restrict the adoption of these technologies (Deavours, Ramakrishnan & Syed, 2005), Moreover, the development of solutions to incorporate an RFID tag in a product and/or packaging in molded components with the minimum impact on the manufacturing process still remains a difficult task (Hodges & McFarlane, 2005).

Despite recent evolutions in design and development processes, that cover the necessary modular product architecture (e.g., Grady, 1999; Ulrich & Eppinger, 2007), these present themselves as processes for new or re-designed products. None of these new processes have been optimized for the development of products that need to perform their function coupled with another product that already exists, being therefore conditioned by that existing product's form, size, and other physical and functional characteristics.

Thus, the challenges posed by introduction of RFID technology into consumer products can be divided into two types: those related to the manufacturing process (the ability to embed the RIFD tag into the product), but also those related to the required changes to the product form and possibly its architecture (where in the product should the RIFD tag be placed and how much does the product need to change to accommodate it). For the former, we can expect industrial processes to improve to meet the demands of the market. As RFID technology becomes more widely adopted, advanced processing technologies (such as non-conventional injection molding) will enable new solutions for embedding the tags into products during the manufacturing process. However, for the later, which is the focus of this work, it will clearly be necessary that appropriate design methodologies be identified and, if necessary, developed, for seamlessly adding RFID tags to products.

In this chapter, we discuss that to successfully incorporate RFID technology, the design and development of products will demand an effective analysis of existing products, following a modular product architecture philosophy, which will create a significantly different development process. We also discuss what those changes may imply in the overall process and which type of product architectures offers competitive advantages for such solutions.

RFID TECHNOLOGY OVERVIEW

RFID is a wireless tracking technology that allows a reader to activate a transponder on a radio frequency tag attached to, or embedded in, an item, allowing the reader to remotely read and/or write data to the RFID tag (Das, 2009). Essentially, an RFID system comprises an RFID tag, also called transponder, a reader, also called transceiver, and the supporting IT infrastructure. An RFID tag embodies a built-in antenna connected to an electronic microchip. These tags carry on a unique identifier that relates the tag with the precise tagged object, allowing unique product identification. A tag receives and retransmits signals on a set of predetermined frequencies, in other words, in response, a tag transmits a predetermined message to a predefined received signal.

RFID tags can be read-only or read-write. A read-only tag includes a programmed identification code, recorded at the time of manufacture or when the tag is allocated to an object. Once programmed, the data cannot be modified but may be read multiple times. Read-write tags can have their memory changed, or written many times; in

Table 1. A general overview of RFID tags

	Passive	Semi-Passive	Active
Power Supply	External	Internal battery powering only processing units and sensors	Internal battery also powering radio chip
Typical read Range Requirement	1-3 meters	Up to 30 meters	Up to 120-150 meters
Typical Type of memory	Read-only	Read-write	Read-write

this way, they offer greater functionality. RFID tags can be categorized in three general varieties: passive, semi-passive and active tags (Table 1).

A passive RFID does not contain an internal power supply. This tag transforms the energy of radio-frequency it acquires from an RFID reader to answer by sending back information. Drawing power from the reader makes them cheaper and smaller than active tags, which have a battery used to broadcast the signal to the reader (Teixeira & Piçarra, 2007). Active tags are also more reliable than passive tags, because they have an internal read and write capability, and can transmit their signals over a longer distance. Depending upon the size of the tag and the frequency used, the current range of reception, or read range, of the reader is limited. Semi-passive tags use an internal battery to ensure data integrity, however the signal sent from the reader generates the power to transmit the signal from the tag.

The fast, automatic, pervasive and ubiquitous identification of objects is one of the challenges of today's business corporations. RFID's ability to read objects in motion and without a direct line of sight gives it the edge over traditional bar-coding methods. It can be said that the difference between RFID technology and bar-coding comes with the sensing capabilities that RFID offers in an increasingly dynamic, mobile physical world (Teixeira & Piçarra, 2007). Even if the main differences between these technologies may be seen as minor, other differences are opening the path for new applications. If we imagine that any product could have an RFID tag and that we could track this product with a computer-reader, this can be translated in an incredible number of applications in various domains, such as access control, logistics, or animal tracking. Some of the most interesting applications of this technology are: (a) the counterfeiting battle, which is huge threat to global business and concerns all kind of products and companies (e.g. pharmaceutical, luxury goods), as RFID technology allows the products to authenticate themselves to the user; (b) the reducing of crime, under the Design Against Crime program (Learmount, Press & Cooper, 2000; Design Council, 2002), which has been producing some interesting examples since 1999, such as the *Bike-off* project (Bikeoff, 2009) and *The Chipping of goods Initiative*, to show how property crime can be reduced through RFID technology (Adams & Hartley, 2000); (c) e-Government, as there is a growing demand for higher security standards and governments requiring secure identification of individuals, such as electronic passports; (d) e-Health, with healthcare being one of the most enthusiastic sectors adopting this technology as it offers multiple possibilities of tracking medical devices and; (e) Waste management. It is precisely this last example that emphasizes another important factor in the development and implementation of RFID technologies. Nowadays, as sustainable development is increasing in importance and every company must worry about their products throughout the end of the product lifecycle. It is very difficult to create a disassembly system for any kind of a product. It would be better if every company could trace its products and find out where they are at the end of their lifecycle. As stated, while being an innovative solution itself, it can be said that RFID triggered further innovation in products, services as well as in development processes.

RFID IN CONSUMER PRODUCTS

Incorporating RFID tags in products might seem like a trivial task. To support that hypothesis, one can even showcase the large number of products which already include RFID tags. However, a careful analysis shows that this is not the case. First, the large majority of current RFID-tagged products are containers (e.g. boxes, palettes) with very simple geometries. Second, in almost every case of currently tagged products, it is actually the product package which is tagged, and although packaging is a major application of RFID, and many products have and will continue having a package, it is important to be able to place tags in products that are commercialized without a package. Due to these two factors, until now there has not been a serious need to develop and implement efficient methods to place RFID in a wide variety of products. With the massive increase in RFID deployment and expansion to new applications/ products, this situation must change very soon.

The two main reasons why it is important to start studying in much greater detail the placement of RFID tags in products is due to: a) technological issues related to the RFID technology itself, and b) the variety in products to be tagged. Other very important aspects of RFID incorporation into products are cost and sustainability, but these are outside the scope of this work and will not be explored.

The main RFID technological issues/limitations are signal attenuation and electromagnetic interference. Signal attenuation in RFID is related to losses in the energy reflected by the tag back to the reader which sends the signal. If less energy is able to reach the tag, then the tag must be closer to the reader to be read. The reflected signal decreases as the inverse fourth power of the distance between tag and reader. Since most tags are passive, the energy levels are already small to start with, and if losses occur, read distances can become a problem. Attenuation can occur from the environment or product characteristics. Water (thus, also products with high water content, including fruits, soft drinks, or moist goods) and carbon will absorb ultra-high frequency RFID signals (the most common passive RFID tags). In the case of metals (canned goods and metal objects), the RFID signal will bounce off the metal surface, typically causing the signal to be blocked. EMI (electromagnetic interference) is essentially noise that will affect the RFID signal travelling back to the reader. This can result from interference from motors, conveyors, old wireless networks, and other sources. In most cases, the source of the interference needs to be shielded in order to allow RFID system to work properly.

Signal attenuation requires particular attention due to the large variety of materials currently used, both in the product itself as well as its package. The development of consumer goods has evolved to take advantage of materials engineering, and thus contemporary products use materials such as wood, plastics, metal, paper/cardboard, composites, laminates, glass/ceramics, and often include several parts made of different materials. Without understanding the influence of the materials on RFID performance, it is not possible to ensure adequate implementation of this technology.

The second reason listed above for studying RFID placement in greater detail was the large variety of existing products. The diversity of materials has already been discussed, but product shape and other characteristics are also an issue. For example, a material might be relatively impervious to the RFID signal but only up to a certain wall thickness. Regarding shape, qualitative and quantitative criteria must be defined for where to place the tag on a product, and where along the production line the tag should be incorporated (possibly, but not highly likely, at the end). Trends towards more complex or more organic product shapes will affect where a tag can be placed, and specific inner features might be required to accommodate a tag. This becomes even more important due to the fact that specific design solutions can solve some of the signal attenuation issues listed above. For example, although metals can create serious problems for direct tag placement, introducing an air gap between the tag and the metal surface can increase its performance, in some cases, bringing it close to the level of performance expected in materials to which the RFID signal is impervious.

Other issues can also affect the RFID performance, for example the proximity of neighboring tags and the angle between the reader antenna and the tag. If RFID is being used for automated inventory upon delivery of goods to a store, adequate planning of the position of the tag in the product and the way multiple products stack inside a box can optimize the performance of the system.

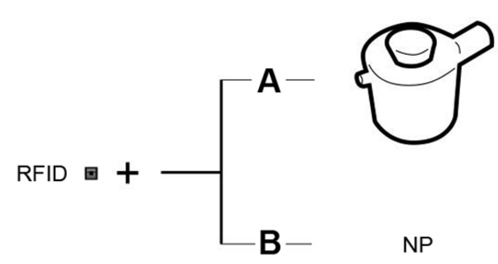
It is also interesting to notice that different sectors of activity have been employing RFID technology in very different degrees. In retail, one can assume this to be highly related to considerable differences in the type of product of each sector. For example, textiles, consumer electronics, shoes, food packaging, all require considerably different implementation solutions, and a common platform is difficult to achieve. Due to this, the massive deployment of RFID in consumer products that has been advocated in the past decade is taking much longer than expected to come to pass. This situation results mostly from the inexistence of adequate methods to plan RFID tag placement in products, prevent knowledge-based development.

How to incorporate RFID tags in products in the most efficient way is a problem that needs to be solved. Two main approaches can be used for this. Externally attach the RFID tag to the product in some way, or make the RFID tag part of the product itself.

THE PRODUCT DEVELOPMENT PROCESS: TOWARDS THE INCLUSION OF RFID TECHNOLOGY

In the general trend towards wider application of RFID technology in products, we can envision two different roles that product development will assume. If we can think that tagging will move from being something attached to an object to become part of the object itself; for this to happen we will inevitable see changes take place in the design and product development process. Nevertheless, tagging any product is not a simple task and, thus, the shift from tagged to RFID-embedded products will be a necessary evolution. As stated before, product design and development processes present them as process for new or re-designed products. However, none of the traditional processes meet the requirements of developing products that support the incorporation of an RFID tag. During the product development process that absolutely requires the inclusion of RFID technology, we need to develop secondary products that have an embedded RFID and can be coupled to existing products. For this we need two product development processes: one that can add RFID technology to products that already exist (product development process – A), and a different process that has the incorporation of RFID technology in the product as one of its primary concerns (Product development process - B). These are schematically represented in Figure 1.

Figure 1. The two possible RFID product development process. NP stands for "New Product"



Defining the development process as the specific series of events and methods by which a procedure or set of procedures are followed, in order to achieve an intended purpose, goal or outcome (Best, 2006), the development process consist in a series of activities and methods that are grouped in phases that tackle a complex problem by decomposing the overall complexity in smaller, more manageable sub-problems (Simon, 1969). Dividing a problem into simpler sub problems is called decomposition and there are many schemes by which a problem can be decomposed. One of them is functional decomposition (Ulrich & Eppinger, 2007). In product development, a part of the problem-solving activities consists of discovering unknown types of interdependencies between different design solutions. A decomposition of the product into nearly independent functional components is a way to clarify the overall problem and test the feasibility of different design solutions. A product can be thought in both functional and physical terms. The functional elements of a product are the individual operations and transformations that contribute to the overall performance of the product and the physical elements of a product are the parts, components, and subassemblies that implement the product functions (Ulrich & Eppinger, 2007).

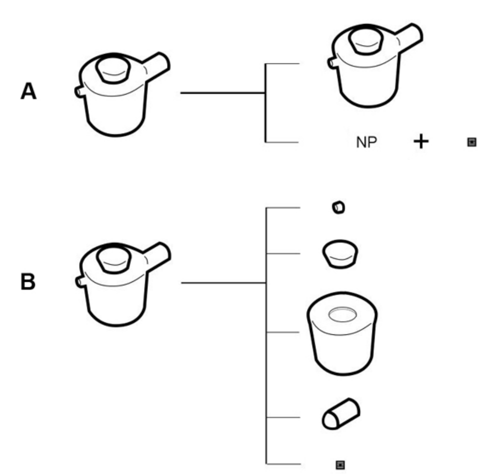
Allocating a function of a product to a physical component is called product architecture. Roughly formulated, product architecture concerns the design and layout of the physical building blocks of a product. Product architecture is an abstract way of looking at a product and is usually determined before a product is actually designed into detail (Ulrich & Eppinger, 2007). Likewise, abstract terminology is used to refer to properties of components in products and the way these components interact. Ulrich and Eppinger (Ulrich & Eppinger, 2007) specified product architecture more precisely as: (a) the arrangement of functional elements; (b) the mapping from functional elements to physical components, and (c) the specification of the interfaces among interacting physical components.

The importance of problem decomposition and the subsequent product architecture to the inclusion of RFID technology is very high. Once again, if we need to place an RFID in existing product and further start to embed this technology in new products, we need to understand the existing products, their shapes, forms and functions to design a way to incorporate the RFID tag. Rethinking the product architecture is the best strategy to attach a new physical component, with a specific function, to an existing product.

In other words, when we need to attach an RFID tag to an existing product, and we begin with functional product decomposition, the existing product becomes one functional element itself. What is new in that architecture is the RFID tag. To attach the RFID tag to the product we need to develop a new complementary product (NP) which contains the RFID tag (process A in Figure 2). This new complementary product will attach itself to the existing product, which ensuring adequate physical support to the RFID tag.

On the other hand, process B in Figure 2, illustrates the functional product decomposition of a product which is being developed and in which we need to incorporate the RFID technology. The

Figure 2. Functional product decomposition



fact that we have a considerable degree of control over each of the physical elements, with the exception of the RFID tag, will allow us to embed the RFID tag directly in the product. Independently of the product development process employed, one of the physical components will have the embedded RFID tag, ensuring traceability for the entire product. This, of course, will lead us to modular product architecture.

THE MODULAR APPROACH

According to a widely accepted definition (Ulrich & Eppinger, 2007), a product architecture is modular when components are functionally independent. A modular architecture includes a one-to-one mapping from functional elements in the function structure to the physical components of the product, and specifies de-coupled interfaces between components (Ulrich & Eppinger, 2007). Functional independence has a deep impact on the supply chain, since components may efficiently be developed and manufactured separately by different organizations, as well as on marketing, since product customization may be achieved with greater ease by simply swapping components (Cantamessa, 2005) One of other characteristics of product modularity is the ability to mix and match independent and interchangeable product building blocks with standardized interfaces and products in order to create product variants.

Modularity is an effective means to control complexity. Once the modular architecture is fully specified, the uncertainty in product development is confined to problems of identifying feasible solutions that will improve the functionality of the product, allowing at the same time the firm to minimize the physical changes required to achieve a functional change (Ulrich & Eppinger, 2007). Furthermore, it enables the production of variety while facilitating the achievement of economies of scale. Modularity is vital to responsive manufacturing and creates the opportunity of producing a huge variety of products that satisfy various customer requirements. A firm that offers several variants of a product can, at the same time, postpone the differentiation of a product until the very end of the supply chain. This is because products manufactured with a modular architecture can be easily modified without causing significant changes to the manufacturing system, because of the possibility of sharing components amongst various products.

The provision of product variety is often based on the concept of product platform. Since the effort, in terms of time and money, to implement a product platform is larger than a traditional development process, it is not possible for any new project to necessarily be a platform project. Product platforms are closely related to the technology development efforts of a determined firm, and to decisions about which technologies to employ in new products (Cantamessa, 2005). The technologies and the variable products needed, or possible, are expected to be planned in the beginning of the development process. This is the case of the inclusion of RFID technology in products. With the product platform being the set of assets shared across a family of products (Robertson & Ulrich, 1998), RFID technology is one of the assets shared, and needs to be planned in a way that achieves the overall performance of the technology. In other words, RFID technology could be the base for a new product platform, independently of the strategic development process chosen.

Notice that in the framework of the two distinct product development processes discussed above, the practical implementation of the integration of RFID technology in products can range anywhere from process A to process B. The process which can be implemented more rapidly and more straightforwardly is Process A, since it does not imply changes to the product itself. However, on a longer time scale, Process B will most often be employed, due to its inherit advantages.

If we assume that RFID technology will be the support for one or several product platforms, the planning of these platforms will necessarily involve managing a basic trade-off between distinctiveness and commonality. These trade-offs can be formalized in the differentiation plan and the commonality plan (Ulrich & Eppinger, 2007). The differentiation plan explicitly represents the ways in which multiple versions of a product will be different from the perspective of the market or the customer. These differences are normally diverse specifications of the final product with the objective of satisfying the needs of the customers in a specific market target. Conversely, the commonality plan explicitly represents the ways in which the different versions of the product are the same physically and, sometimes, functionally. It is clear that in both product development processes discussed in this chapter, establishing the architecture of the product and its inherent modularity is a primary concern in the overall process. Nevertheless, turning to a more specific modular philosophy will necessary inevitably lead us to planning a product platform around RFID technology. In the case of the product development process A, it is necessary to take into account that developing a complementary NP that only works for one existing product is (aside from exceptions) unreasonable in terms of an economy of scale. So the inclusion of an RFID tag through this product development process will require a profound analysis of the shape of a variety of products (probably in the firm internal product catalogue) with the purpose of finding similarities that make it possible to develop a unique NP with an embedded RFID that can attach itself to as many products as possible (Figure 3).

From Figure 3, one can see that one of the possible similarities in the four products illustrated is the handle. Thus, to insure the possibility of incorporating RFID technology, it is necessary to create the NP with the embedded RFID in such a shape as to allow it to attach to all the handles of the considered products. This could be done with, as an example, a flexible polymeric bracelet.

On the other hand, product development process B (Figure 4), considering the development of new products from start, it is not restrained to any shape, form or style, but only to the functional elements needed. As in process A, several possibilities can be identified to achieve the goal of developing a new product that already features an embedded RFID. After decomposition of the functional elements, one needs to identify which functional element is going to have the embedded RFID; in the case shown in figure 4, that element was the cap.

Thus, in this case it is possible to talk about a functional element (asset) common to all products, and which already has an embedded RFID tag. It can also be planned to perform its function in other product families.

Figure 3. Possibilities of product development in the scope of Process A

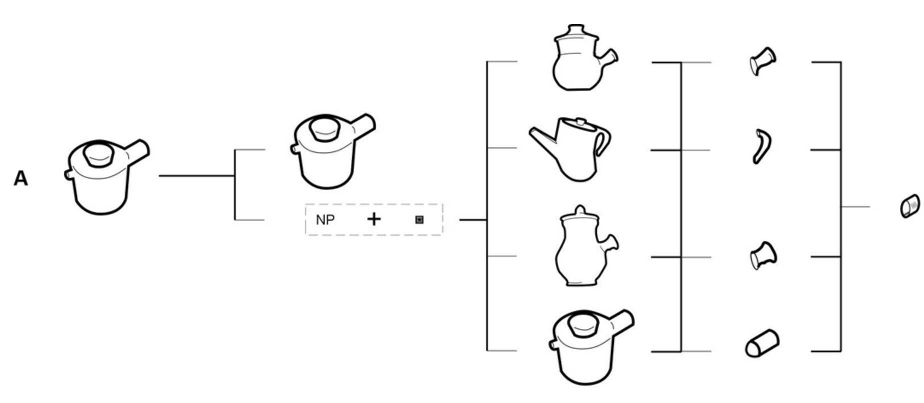


Figure 4. Possibilities of product development in the scope of Process B

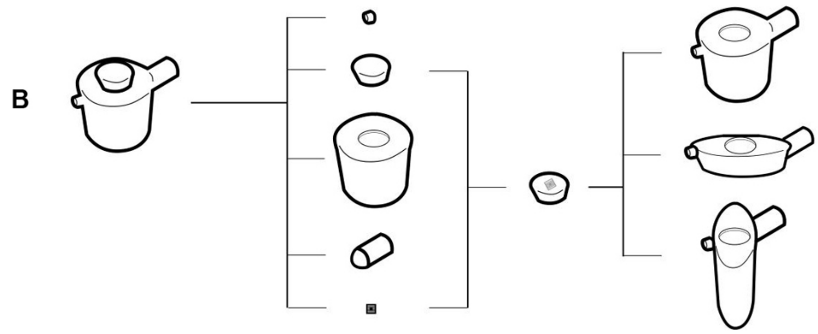


CASE-STUDIES

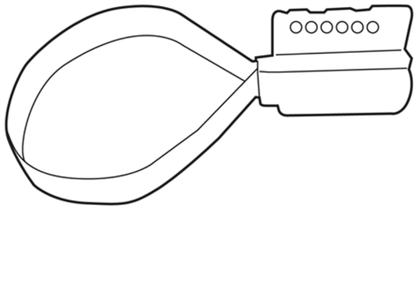
To better illustrate the two concepts being the product development processes discussed in this chapter, we shall use two case-studies of commercial products. The two products are mass-produced by the Daily RFID Co, Ltd. (2009).

The first example (shown in Figure 5) is a bracelet-like product that was designed to attach RFID tags to existing products, following the approach of product development process A.

The shape of the existing product to which this device will be attached must include some feature around which the bracelet will go (e.g. a tubular or quasi-cylindrical feature). It is a one-off seal, and once attached, cannot be removed without damaging the seal and leaving evidence of tampering.

As is well known, the most pervasive current application of RFID technology, and the one that still represents the large majority of tags in use, is logistics. Essentially, RFID tags are placed in boxes, cases, pallets, carts, and more recently, envelopes, books, magazines, and many other objects which have very simple shapes, and, almost without exception, offer a flat surface for placing the tag. For all those applications, the typical tag offers an adhesive layer so it can be stuck to the surface. The type of device in Figure 5 (which is only representative of a large number of devices with encapsulated RFID tags), appears from the need of placing tags in more complex products. If a retail store wishes to track its products that are not enclosed in a box (e.g. bicycles, toys, kitchen accessories, etc), they must find a way to ensure the tag can be safely placed on the product and that it will not come off when colliding with other objects. When there are no flat surfaces or when it is not allowed to leave residues of the adhesive on the object, the type of device in Figure 5 can be an excellent solution. It also prevents malicious users to simply peel off a tag placed externally on a surface of the product.

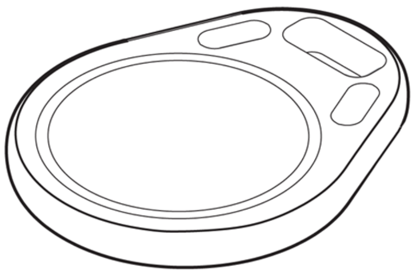
Figure 5. RFID embedding solution for external coupling to existing products



The second example is a key-chain (Figure 6). Designed from the start to include an RFID tag (following the approach of product development process B), using adequate materials and some planar surfaces, it becomes possible to use the key-chains for access control, security, and many other applications. The key-chain can even allow information (e.g. a logo) to be printed on its surface.

In this case, the fact that the RFID tag is not detectable by users is a vital advantage. At the

Figure 6. Key-chain with embedded RFID



early design stages, aside from all the product design specifications that one would typically consider for such product, the shape of the key-chain must be set taking into consideration physical requirements of the RFID tag as well as its placement. This implies finding the optimum way to enclose the tag inside the key-chain.

There are many technological options (fabrication solutions) to enclose the tag inside the key-chain, such as making the keychain in two parts that are locked together only after placing the tag between them in an appropriate hollow space, or finding a way to place the tag actually inside the polymeric material during processing. Notice that, in practical terms, the mechanism through which the tag is embedded in the product is not critical, since the end result is essentially indistinguishable by users.

CONCLUDING REMARKS

RFID technology is at a crucial point, in terms of the adoption exceeding current applications. As this technology becomes ever more deeply embedded in everyday life, it can no longer be seen as a simple appendix to increase traceability in the supply-chain, but as a technology that can be embedded in every existing product. The technical issues of tag reliability and the effect of liquids and metal surfaces are challenges and not true problems. One of the most important issues in the implementation of this technology is that the RFID will necessary transform the way in which we develop products and the way we identify potential advanced features of products. One can say that very little RFID novelty will be achieved from changes in the technology itself. Instead, it will arise from innovative use. When it comes to finding new ways to use RFID to create and build product value, user experimentation will inevitably bring original interactions.

In a trend towards a more effective use of this technology in product design and development, RFID tag incorporation needs to be an important specification of the development process. This, of course, will be an evolutionary process, and will range from the previously described development process A, where no changes are made to existing products, through development process B, where products are developed from start considering embedding the RFID tag. The endgame in any of those processes will be the increasing use of RFID technology in products, increasing the interaction of products with their environment and their users. A time will come when RFID will vanish from the mind of the consumers, becoming impossible to distinguish it from the product itself. As espoused by Weiser (Weiser, 1991, p. 94), "the most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it".

Although the discussion about the examples provided in previous sections illustrates the need for manufacturing processes optimized for embedding RFID technology, processing technologies exist that can be adapted for that purpose, and the real challenges still clearly reside on appropriate product design and development methodologies.

It is also important to mention that RFID is only one example of the growing number of microelectronic devices incorporated into products, following the current trend of technology-driven product development (Simoes & Sampaio, 2008). However, many of the challenges are the same, and conceptual solutions can be reused for different scenarios.

KEY TERMS AND DEFINITIONS

Electronic Product Code (EPC): Is the basis for the information in the network. Each RFID tag has a unique EPC.

EPCglobal Network: A computer network used to share product data between trading partners.

Integral Architecture: Architecture in which the number of functions is considerably larger than the number of components, which implies that some components are involved in delivering multiple functions.

Modular Architecture: Architecture in which the number of functions is approximately similar to the number of components, where usually the interactions (as well as the interfaces) between components are relatively simple, and where each module is intended to be the main (often the only) responsible for providing a given function or sub-function of the product.

Product Architecture: The conceptualization, design, and description of a product, its components, the interfaces between components, and the relationships with internal and external entities, as they evolve over time.

Radio-Frequency Identification (RFID): Is the use of an RFID tag applied to or embedded into a product, animal, or person for the purpose of identification and tracking using radio waves.

Chapter 101
Future Trends in SCM

Reza Zanjirani Farahani
Kingston University London, UK

Faraz Dadgostari

Ali Tirdad
University of British Columbia, Canada

ABSTRACT

The field of supply chain management (SCM) has experienced radical changes in its short life period. Originating from 1980 and 1990s management trends and techniques of operations management, passing process oriented and system oriented approaches in the 1990s, and now attracting the attention to behavioral approaches have all caused SCM to be largely vertiginous. So dealing with its future requires a more accurate method than common predicator fashions. Therefore, the chapter first considers SCM as a body of knowledge in which evolution is based on its theoretical foundation, and therefore, prevalent research paradigm(s), research methodological base(s) used by developers, and also real world challenges that motivate it. Consequently, the authors review current status of SCM from standpoint of the discipline's theory, its conceptualization process, and most used research methods and approaches. Then the authors will be able to use its implications to adopt an appropriate model of philosophy of knowledge for scientific change and knowledge growth of SCM. This can be used as a guide to the future of supply chain management.

AN EVOLVING CONCEPT

Supply chain Management's definition is seriously contentious. Kathawala et.al, (2003) indicates that supply chain management is defined poorly and its meaning has a high volume of variability in the minds. Also definitions provided in literature (such as New, 1997; Mentzer et al., 2001; Kauffman, 2002) shows little consensus on the definition of supply chain management. Burgess et al., 2006 have reviewed the literature of supply chain management from the standpoint of its prevalent definition status to evaluate the maturity level of the field. Their review reveals that almost 20 percent of researches use existing definitions, 15 percent develops their own definition and in half of them no definition is used. More concentration

DOI: 10.4018/978-1-4666-1945-6.ch101

shows even existing definitions which is used in some research have little consistency and there is no specifically accepted definition. Besides this considering that 10 percent of researches incrementally changes existing definition can tell us the definition of supply chain management is still open and challenging.

To realize the researchers and practitioners understanding about the concept we can investigate framing of supply chain management in their works. Its large bearing on the qualities of the way it conceptualizes will make the future trends more clear. Burgess et al. represents four categories in which Supply chain Management is conceptually framed. These four categories; “activity” category (described as a function of a process), “process” category (described as a chain of associated activities), “system” category (described as a chain of associated processes) and “other” category (described as kind of analysis which deal with, interdisciplinary, behavioral, sociological, psychological and philosophical aspects); describes four ways with which the researchers and practitioners deal supply chain management. For example assuming supply chain management an activity makes it something minor which can be treated as an operational function. On the other hand perceiving it as a process makes or prospective wider and understanding it as a system represents supply chain management as an all-embracing management framework. At last describing supply chain management considering its behavioral aspects leads to a holistic point of view. Investigating the conceptual framing which is used by researchers and organizations reveals the current construct of supply chain management and help us to understand its evolving trend. Burgess et al. show the majority of more than half of researches viewed supply chain management as some form of process. More than 20 percent framed it as a system and less than a tenth saw it as a simple activity.

Also presenting the conceptualization of supply chain management successfully depends on the construct with which we logically group supply chain management as a management concept. Constructs are about the higher order absolute immeasurable variables, but give us a clearer definition of the concepts (Nunnally, 1978, cited in Burgess et al 2006). The set of generally accepted constructs doesn’t appear to exist. In regard to the commonalities between the proposed sets of constructs for supply chain management by several researchers such as Chen et al (2004), Min et al (2001) and Tracey et al. (2004), Burgess et al conclude a set of seven constructs. This set includes “leadership” (in regard to strategic aspects of supply chain management; (see Shapiro,2004)), “inter organizational relationships”, (concentrating on the connections within the organizations), “intra organizational relationships” (concentrating on the connections between the organizations, based on joint social and economic responsibilities and interests)”logistics” (focusing on the issues which address material handling in a supply chain),”process improvement orientation” (in regard to continuous improvement of processes within a supply chain),”information system”(focusing on systems which facilitate communications within a supply chain) and “business results and outcomes”(concentrating on the economic benefits and outcomes of adopting an appropriate supply chain management aims). As other discipline within management field constructs of supply chain management can be divided to two general categories of “soft” and “hard” constructs. Soft constructs deal with behavioral and social issues of the field and hard constructs are about infrastructural and technological aspects of the field. Therefore the first three construct can be categorized as the soft ones and the others can be categorized as the hard ones.

Based on the researches done on the constructs of supply chain management and these categories by Burgess et al, even in soft construct which is expected to be concentrated on people related and behavioral issues, the research have been on technical aspects. Most of research in soft constructs is carrying on about inter-organizational relationships and almost two thirds of the research in hard construct is about process improvement orientation. Other constructs have been researched lesser but they haven't been neglected.

Every field's maturity level can be indicated by its definitions status. As described, Most of the researchers and practitioners uses newly developed definitions or develops new definitions themselves. Even existing used definitions have no convergence on a single one. A matured developed field uses few or even single definition.

Therefore and also as other researchers acknowledged (New, 1997; Cox et al., 2001; Kauffman, 2002; Quayle, 2003) supply chain management is an immature field of research and practice and should be considered as an evolving concept. Additionally the portions divided between supply chain management's constructs shows the importance of process based point of view. It's basically because of the field's Originating from 1980 and 1990's management trends and techniques of operations Management in which technical and even mathematical methods play the main role. In regards to the emphasis of many authors on the importance of system based point of view, supply chain management's social aspects, people related issues which extends cooperation and organizational trust within the chain, soft construct (concentrating on behavioral and cultural issues) can be a main pivot of maturing of the field's definitional aspects which can make it more integrated, more comprehensive and therefore more acceptable by most of researchers and practitioners. Without existence of such a definition, theoretical development of supply chain management could be deformative and even impossible and accordingly the questions such as: "how does an organization's dominant culture can form the way with which that organization uses internal rules and external standards to coordinate with the other partners within the chain.?" (Dowty et.al, 2010) Not only doesn't find any answer but even won't be on the table.

THEORETICAL DEVELOPMENT

For any field of science and practice theoretical development is a fundamental requirement for an integrated and triangular development (popper, 1961; Wacker; 1998 cited in Burgess et al). In the matter of supply chain management several disciplines claim the ownership of it and therefore they assume their theoretical basics can be used for the field's scientific and practical development. They suggest that supply chain management doesn't require an independent self motivated theory and other disciplines' theories are adoptable for theoretical development requirements. Others think an independent self motivated theory should be developed and proposed (Van Maanen; 1995). If we consider that the field's development requires a "clear line" from definition to theory and then to the research methodologies, the importance of theoretical status of the field and its trends is undeniable. Also the two way influence of development in theoretical term and development in research methodological term should be considered and therefore the research methods which are applied in the field and their paradigmatic stance should be investigated and consequently should be used aptly to scheme the future of the field.

Any discipline is based on some infrastructures which create knowledge and transfer it within a specific field. Such infrastructures should contain defined theories, applicable research methods and practicable tools. While the dominant discipline which is leading supply chain management's research and practice is Operations Management, a multitude of the other disciplines are emerging to contribute in the future of the field (Sachan et al). It means that these disciplines' researchers tend to use theoretical basics and research methods of their disciplines to develop the field.

Burgess et al recognize nine disciplines relevant to supply chain management including, "Marketing", "Purchasing", "Strategy", "Finance/Economics", "Sociology/Psychology", "Information", "Logistics", "Operations Management" and "Others". Based on their findings, operations management, strategy and purchasing are the disciplines which are accomplishing most of the research activities (and therefore have the biggest portion in the developing of supply chain management, based on the theoretical basis of their discipline) in the field. Also in this research have been shown that multidisciplinary researches have small role in the developing the field's body of knowledge. Also as Voss et al (2002) mention, the supply chain management's body of knowledge is developed leading by practitioners and is following by the researchers. Accordingly low presence of researches focusing on the soft type, psychological and sociological aspects of the field and the importance of them in practitioners' success in the business shows future potentials of these disciplines' contributions in the supply chain management growth. But to understand the reasons causing the incoherence of researches has done till now we should back to the theoretical concerns and research methodological stands of the field.

As the same as the research methods which have applied in the field, practitioners and researchers have used the same point of view about assumed theoretical basics in the research and practice. Most used theories respectively are strategic management related theories (about 40 percent), transaction cost theory of economics (about 30 percent), and psychological/sociological related theories (about 10 percent). But 25 percent of the researches don't use discernable theory. Also there is no supply chain management specific theory, used in any published research. Furthermore no multi-theoretic based research has accomplished yet (Burgess et al).

Despite the multidisciplinary basics of supply chain management and usage of different type theories by researchers and practitioners it seems in future there should be trends to fill these gaps. Thus the researchers and practitioners need to develop and use supply chain management specific theories, multi-theoretic basics and also multidisciplinary approaches. Otherwise these gaps, current incoherency can inhibit the field's regular development and can't logically be persuaded. Also theoretical contributions are more descriptive than other types. This indicates that supply chain management is an immature field from standpoint of the theoretical basics. Additionally while theoretical contributions aren't developing the conceptual aspects of supply chain management by theoretical validation, theoretical development and theoretical refinement, supply chain management can't extend its theoretical basics and therefore can't face emerging challenges. Accordingly the field's conceptualization should use more sophisticated and higher-level theoretical contributions to encounter the face the challenges.

Burgess et al shows that supply chain management needs a Meta-Theory to overcome the theoretical difficulties. Meta-theory is a "theory of theories" which firstly developed by Tsoukas 1993 for Management. It creates an appropriate theoretical foundation for the fields which have developed based on different theoretical basics, within various disciplines and belongs to distinct traditions. It is suited for the areas which epistemological and ontological diversity is high and single theory can't serve the fields development.

Considering the above and based on Tsoukas, an appropriately developed Meta-Theory can merge the ontological and epistemological principles, which can explain the foundations of the field and therefore the existing and possible body of Knowledge within it.

PROSPECTIVE BODY OF KNOWLEDGE

What mentioned before shows supply chain management has conceptualized as a "science" and positivist paradigm is dominant in its theoretical and research methodological aspects. Relative lack of non-positivist approaches and absence of Mixed-Multi-paradigmatic research methods can prevent triangulation to Body of Knowledge

Development in the field. These issues can be caused by practical difficulties in extending these type methods and also given the wide opposing assumptions that are made (Burrell et.al, 1979; cited in Burgess et.al).

Considering the above, development of the Body of Knowledge of supply chain management should be fill the mentioned gaps and overcome the preventing difficulties. From standpoint of the Philosophy of Knowledge the appropriate way to describe a body of knowledge is considering a fundamental theory is phenomenology. Phenomenology in Husserl's perspective basically is related to the systematic reflection on and analysis of the structures of the consciousness and how a phenomenon appears in acts of consciousness. It seeks through systematic reflection to determine the fundamental attributes and structures of conscious experience and also consciousness itself (Husserl, 1973). He believed that phenomenology provides a foundation for scientific knowledge, and ground philosophy as a "rigorous science" of measurable perception. In this manner Lakatos proposed that there is something named "research program" with which researchers study a phenomenon based on different theories and these theories operates within it. In the Lakatosian research program a "hard core" that contains some theories which are informed positively provide some foretelling quality about a phenomenon.

On the other side in this research program there is a "protective belt" which tends to coalesce with hard core and progressively helps the field's growth by the discovery of astonishing novel facts, development of new experimental Methods, more accurate predictions and also by introducing new and applicable aspects of definitive and theoretic point of views to the field. Also the researchers who are engaged in the program try to prevent the hard core from falsification endeavors behind the hypotheses of the protective belt. This provides us a Model to understand how the knowledge of a field of science and practice grows.

Based on finding of Burgess et al hard core in the supply chain management's body of knowledge is based on "operations management, manufacturing, analytical school, process and positivist paradigm". Also the protective belt contains several other activities which aren't defined clearly and need to more attention and can be the basics of future trends. Behavioral approaches concentrated on Psycho-social dimensions of the field and also multi-disciplinary and Multi-theoretical aspects should be considered to describe the most realistic identity of protective belt related activities. Based on it and applying Lakatosian approach we can aptly describe how knowledge growth appears to be conducted in the field facing the emerging challenges. It provides a logically framed analytical way to perceive the way which the SCM's body of knowledge is evolving rather than simply using common predicator fashions.

Accordingly supply chain management is a young immature field of research and practice which its evolving path should make a serious conceptual growth based on a defined meta-theory which can overcome theoretical, research methodological and other knowledge empowering related basics difficulties and also can fill gaps caused by incoherencies and lack of integrated clear path of insight in the research methodological stand point.

This exponentially growing field should develop and apply research methods, theoretical basics and methodological stand points of the protective belt to help to reduce dissociations in the field and interacting with novel contents and methodologies, along with staying connected with the theoretical core of supply chain management in contents and methodologies.

FUTURE OF THE REAL-WORLD APPLICATIONS OF SCM IN THE INDUSTRY

We are going to talk about different research directions for SCM which have been interested for industry and business and still there are lots of works to do in these areas. We will go through the following topics: New Public-Private Partnership Trend, supply chain design and redesign, supply chain coordination, supply chain risk management, and at the end we are going to provide some case studies from real world problems.

New Public-Private Partnership Trend

In general we tend to optimize the supply chain. In a stable set of supply chain network it is possible to model and optimize the network and we can have a supply chain coordinator. But the current environment of dynamic demand-driven supply networks, most of time leads to emerge of the temporary supply chains. The lifespan of these supply chains directly depends on the market opportunity. In such dynamic networks the speed of execution is usually more important than the finding the optimum of the network and the speed of execution is directly related to the coordination of partner. The excellent examples of the extreme dynamic environment are war and disaster relief (Kumar, 2001). For a special case we can mention the weak performance of the governmental agencies in Hurricane Katrina in States, in delivery of supplies and equipment. Wal-Mart was the fastest organization which handled delivery of the goods like food, water and etc. to the victims (Dimitruk, 2005).

So the old-school model of the government as the "Lord of the Supply Chain Network" is not working anymore in this environment. That's why the tendency observed in the developed countries to reconsider the pubic-private partnerships.

The other concern about reconsidering the public-private relationship emerged after September 11th, 2001. The SC managers challenged to adjust their relationship with others in the network. The security and being prepare for dealing with problems after the terrorist attacks are the main challenges that effect on the public-private relationships (Sheffi, 2001).

Designing and Redesigning the Supply Chain Networks

Supply chain configuration for mass customization and supply chain quality modeling are two major concepts for designing a supply chain networks. We will go briefly to the main works which talk about these two topics.

Salvador et.al, (2004) discuss about the problem of supply-chain configuration for mass customization and suggest an answer. From their work, other questions arose for the further research, for example "do modular products need a modular supply chain network or non-modular ones work for them either?"

Batson and Mc Gough (2007) talk about how the network model can enhance the quality in manufacturing supply chains. They outlined these future research topics in supply chain quality modeling:

- **Multi-company adaptations of Experimental:** For reaching to the better quality (closer to the real optimum of the network) the planning, coordination, execution, and data analysis should perform across multiple levels in the supply chain network. This concept arise new research topic to combine the design of experiment (DOE) and supply chain management.
- **Performance analysis:** Supply chain performance analysis (e.g. multi-level tolerance analysis) should perform before the production. Cost and quality are regularly achieved worse than the optimum values in multi-level environments. How can these be avoided? That's another topic for further work.
- **Statistical process control:** Woodall and Montgomery (1997), they discuss that the quality improvement (QI) is a challenging work in the multi-level environments like supply chain networks.

By redesigning the supply chain network, we mean the investigation of process efficiency and process effectiveness. Redesign can result in increasing the operational efficiency or effectiveness of the supply chain network (Hewitt, 1994). Moreover, rapidly changing business situations make it necessary to redesign the supply chain management time to time. The example of the rapidly changing supply chain networks are large networks; because small change in one of the suppliers can results in a huge changes in the whole network (bullwhip effect) (Van der Vorst,2002). Van der Vorst et.al (2002) claim that the uncertainty in the supply chain network is the one of critical criteria in redesigning. So based on this claim, they provide a research approach to supply chain redesign and declare that this approach is applicable for large chain network either.

Service Supply Chain

The service operations should be considered differently from manufacturing products; because they have different characteristics which you cannot find in manufacturing materials. The service operations are intangible, labor intensive, heterogeneous, we are not able to store them or transport them and the quality of a service is hard to determine in comparison to the manufacturing products (Slack, 2001).

So based on the different, the service supply chains inhere the different from manufacturing supply chains. In designing service supply chains effectively, we can still use the experience and guidance from manufacturing supply chain. In fact, manufacturing supply changes are more understandable, because they are tangible and there is a rich literature on it over the past 20 years.

Akkermans et.al, (2003) show that part of the available knowledge from manufacturing supply chains can be use for service supply chains as well, with some remarkable exceptions and some additions. These exceptions come from this fact that services cannot be stock but can be ordered. So first obvious result is no inventory level but they have workload levels. The other result is the known measures of inventory do not apply for services.

Supply Chain Management and Facility Location

Context of supply chain management contains problems which can be discussed with the facility location problems structure. Using facility location concepts and models to address supply chain management problems should have characteristics which meet needs of supply chain management problems. Considering this assumption facility location can extend its future in this context in different directions. Developing models which can consider uncertainties of supply chain management, which can address multi-layer networks and stochastic constraints and Modeling parameters such as researches of Miranda et.al. (2008) will extend applicability of the facility location problems in this context.

Concentrating on vehicle routing problems along with the transportation systems that are used trough the chain such as works of lee et.al, (2008), aksen et.al, (2008) and many other relevant tactical/operational systematic decisions such as procurement, reverse activities, postponement decisions and backorders are getting more critical. Also considerable simplifications have been done on the models to make them efficiently solvable. Developments in computational infrastructures lead to more realistic and more complicated modeling contributions and more accurate solution methods. The coming capabilities of the optimization applications and expected computation power of coming hardware makes the future models more complex and comprehensive and will enhance the possibility of solving real-world problems of supply chain management. Modeling procedures relevant to facility location tend to use multi-objective type models (such as Farahani et.al., 2007; Du et.al, 2008 and Mansouri et.al, 2010) along with new type of objective functions such as maximizing the potential return of the investments (see sheu, 2003; ReVelle et.al., 2008; Mirchandani et.al., 1990) or profit oriented objective functions to add the idea of revenue management to supply chain management context. Also lack of attention to planning for distribution in supply chain management can cause serious risks. Accordingly, it is essential to consider disruptions during the modeling of supply chains so that they perform well even after a disruption. Resulting models made substantially more reliable with optimum additional investments (Snyder et. al., 2005).

The integration of strategic and tactical aspects of supply chain management is growing and therefore the application and role of facility location related concepts of features are getting more important. Considering various aspects of supply chain management simultaneously, modeling real world problems makes the body of Knowledge of the facility location more applicable in the future of strategic supply chain management planning.

Reverse Supply Chain Management

Recent trends shows the newly emerging practical issues which are getting more serious and the researchers and practitioners should consider them to develop appropriate managing approach in the supply chains. Reverse logistics is one of those and its applications are getting broader and more unavoidable. One of the most effective reasons to this is the environmental law constraints which are being imposed in the word with fast growing trend and is being considered by practitioners and researchers seriously (see Jalali Naini et.al, 2010). Accordingly it leads to the need for safe return of products from the end of the chain or even from the middle of it. Therefore supply chain management should now consider both forward and return flows of products, parts, subassemblies, scrap and containers. These completely new spectrum of goods should be managed at where was considered the end of the chain. There may be occasions for most of the chains when the goods they have produced and supplied to the market should be returned through the reverse chain function. These may include the products which have failed or become absolute but aren't useless yet, also the unsold or recalled products should be brought back to the chain and at last the containers which should be brought back to be used again. These examples shows the importance of the reverse supply chain management and the efficiency which can be lost by ignoring it. (Helms et.al, 2006; Du et.al, 2008)

Broader economic perspective illustrates the beneficial of reverse logistic systems such as recycling systems and infrastructure for recyclable materials to communities. Of the many practical factors technical issues pertaining to reverse supply chain management such as facility locations, distribution points, scheduling issues and operational inventory levels, have been investigated widely and should be investigated in the future further. In fact these are important issues in the design of any reverse logistics network. Organizations are feeling the pressures from the regulatory or from the social opinions. Also competiveness is another reason which stimulates the organizations to assign optimum recourses to manage reverse logistics. Therefore this field is becoming prominent in the research and practice of supply chain management. Considering the robust nature of the researches which have been conducted yet, the researchers have opportunity to develop the theoretical foundations and also the technical aspects of the area. They can focus on the final stages of organizational management. Also theoretical and methodological standards should be developed to describe the phenomena, advance the practice of reverse logistics and as a result broaden the methodologies to improve incorporation within the supply chain. (Meade et.al, 2007)

Reducing Bullwhip Effect in Supply Chains

Small fluctuations in consumer demand extremely get larger when they go up through the supply chain from retailers to main suppliers. In general the variance of consumer demands sometimes can get larger than the demands; this is called “Bullwhip Effect” (Lee et.al, 1997). There are four main reasons that the Bullwhip Effect happens (Lee et.al, 1997):

- Consumers’ interpreting demands,
- order in batches,
- promotions which changes the artificial demand (not the real demands) and
- Shortage in supply which results in emergence of the demand artificially either.

There are several papers who worked on reducing the Bullwhip Effect in supply chains. Warburton et.al, (2004) provide ordering policies to reduce the Bullwhip Effect and improve inventory management. Lee et.al, (1997) suggest the followings for reducing the Bullwhip Effect: Choosing the combination of sell according to data, sharing the inventory status information between the different levels in supply chain, ordering with coordination in advance and finally using simplified pricing rules. A number of methods of mitigating Bullwhip Effect have been reviewed by Towill (1997). These methods work in the real world problems properly. They showed that the Bullwhip Effect can be reduced via Business Process Reengineering (BPR) up to 50%.

Vendor Management Inventory (VMI) and Reengineering in Supply Chains

Vendor Management Inventory (VMI) is a strategy which allows the retailer to manage the customer’s stock on his own (the supplier does not get involved with this responsibility). VMI has become more popular as retailers get more powerful recently. The great example is Wal-Mart which in the grocery sector in the last 15 years has VMI strategy and has a successful performance (Disney et.al, 2003). Moreover, we can say somehow recently the necessary ICT has become available in acceptable cost to enable this strategy. However it has been shown that it can be performed via fax or emails and spreadsheets (Holmstrom, 1998). VMI have been showed up differently in the literature. Quick response (QR), synchronized consumer response (SCR) and centralized inventory management (CIM) are the applications of VIM strategy (Disney et.al, 2003).

Supply change reengineering usually means improvement in processes of the supply chain in terms of the cost and quality of service in general. This need of improvement can arise from the competition, increasing in customer expectation or etc (Swaminathan et.al, 1998). One of the main drivers for reengineering the supply chain is to reduce product life-span. Since the early 80’s supply chain reengineering strategies has been performed by companies. Before that, the idea of reengineering had existed in the supply chain but not in a proper way. Just in time (JIT) strategy was the one of the closest idea to the reengineering in the early 1980s (Naylor et.al, 1999). Nowadays, by extremely competitive environment, tendency to implement the reengineering more frequently for increasing the quality of service and lowering the costs has a upward direction.

Multi-Channel Cooperation in Supply Chains

By improving the supply chain concept every day, there is the need for companies to look outside of box and look for opportunities to collaborate and coordinate with partners. This helps them to have a more efficient supply chain for demands with high variances. However, these opportunities lead to new challenges and concerns; like huge supply chain scale and possibility of conflicting between the sides of the cooperation (Balakrishnan et.al, 2004).

Providing products or services to consumers via different channels of suppliers or even retailers is called multi-channel supply chain. It leads to increase of levels of quality of service, or on the other hand it results in challenging issues like complexity and more responsibility for supply chain managers. In other words, the more channel options we have, the more complex supply chain will emerge. Synchronizing the channel of supply chain in the way that the consumers' need will meet independent of which channel is chosen to serve the consumer, needs the latest ICT technology and management experts. Radio frequency identification (RFID) is one of the technologies that can help multi-channel supply chain management a lot (Rosenbloom, 2006). Journal of "Industrial Marketing Management" Volume 36, issue 1 (2007), have a good collection of papers about the multi-channel coordination supply chains, the problem to handle them, some approaches to obtain the optimal channel and etc. Moreover, Stadtler (2009), provides a review on collaborative planning in supply chain networks.

Supply Chains and Risk Management

The business environment is expanding every day and as a result, rougher and more frequent natural and human-made disasters make supply chains more vulnerable (Wagner et.al,2010). Today supply chains are getting more complex and therefore to have an efficient supply chain and also to keep the market consumers satisfy, we need to apply risk management concepts and Models. In other words, it is necessary for the supply chain managers to identify, evaluate, sort, and manage any kind of risk which threat the network.

The dynamicity of a supply chains means that the decision model for risk management should reflect the interaction and relationship between managerial elements and factors of the risk (Xia et.al, 2011). Risk consists of uncertain outcomes with known possibilities. The sources of risks can be from inside or outside of supply chain. The role of risk management is to recognize the risks who endanger the network and find the way to minimize the effect of the on the outcomes of supply chain (Faisal et.al, 2006). Mainly there are two types of risks for the supply chain networks; disruptions and delays (Craighead et.al, 2007).

In the today's business environment, survival is not an issue for companies against each other; it is supply chains' issue. So in such environment, the importance of risk management can be felt increasingly (Craighead et.al, 2007).

Real-Time Supply Chain Management

Collaboration within the supply chain in the current market of competitiveness and dynamicity is critical. Relationship among supply chain competence and supply chain agility in the current and emerging global supply chains are undeniable (Ngai et.al, 2010). New technologies such as radio frequency identification (RFID), electronic sensors which can be used to control material flows, GPS receivers and the Navigation systems are being used to process the information within the chain in the real-Time manner. These advances in IT and ICT make us capable to address and solve new decision making problems which can be cross-enterprise or even cross-functional and improve the firms performance by improving the supply chains agility (Ngai et.al, 2010). From standpoint of mathematical modeling of supply chain management problems, Real-Time Modeling can be used instead of dynamic or Stochastic Modeling. In fact real-time management aims to empower operations research capability to Model uncertainty and to solve dynamic decision making problems. Therefore real-time flow of information through the supply chain makes us capable of modeling new type of problems in which incomplete or unknown data are be known concurrently with the solution process and as the result we can make more accurate decisions on-line. This simply can improve efficiency by enhancement of traceability and visibility of products and processes, enhancements in the efficiency of the processes, improvements in the accuracy of information flow, reductions in the delays, Reductions in the losses of the inventory and also Facilitation of management through real-time information (sarac et.al, 2010).

Newly developed technologies and also the companies' necessity to manage their operations in the real-time manner have made the research and practice of the real-time supply chain management flourishing. Dynamic problems as Psaraftis (1995) indicates differ from the static problems at least in 12 aspects and therefore, considering these aspects not only affect the strategic policies but even can improve simple decision making procedures.

Recent works on dynamic routing problems (Larsen et.al.,2007), dynamic pricing in the real time supply chain management (Burke et.al.,2008), modeling dynamic demand in supply chains (Sodhi et.al,2009; Toktas-Palut et.al,2011) and even on integrated framework to develop RFID technology in the logistics and supply chain management (Lin,2009) show the vast trend of researchers and practitioners to develop the theoretical foundations and also the applications of the concepts, the tools and the technologies which can be used in the real-time supply chain management.

Supply Chain Management and Scale Economies

Considering economies of scale in designing a supply chain is critical. If someone does not consider scale economies in supply chain, it can lead to significantly higher costs rather than the optimal design. One of the practical examples of importance of economies of scales is provided by Baumgartner et.al, (2009). Supply chain management's complexity (Bozarth et.al, 2009) complicates finding suitable measures for supply chain. In the other words supply chain performance evaluating is complex, because this is a crossing process containing various factors cooperating to achieve the logistical and strategic objectives (Estampe et.al, 2010). Cohen et.al, (1990) present a review of the performance measures and provides a framework for the selection of measures for manufacturing supply chains.

In practice the performance of the supply chains is measured by the customers' level of satisfaction and the expenditures. These evaluations can be especially important in the case, where supply networks are being considered a critical factor of the organizations' success (Estampe et.al, 2010).

PROBLEM MODELING

Most of the time, supply chain models are really huge; because they should consider the large number of materials, suppliers, retailers and etc. and they require a huge data collection. If we want to categorize the supply chain designs by modeling approaches, it is possible to categorize them in four general classes: (1) deterministic models (2) stochastic models (3) economic models, and (4) simulation models (Beamon, 1998). We are going to review the literature briefly for each of these classes.

Deterministic Supply Chain Models

In the deterministic models, all the parameters of the problem are known and there is no uncertainty in their value. Like most of the other problems, the very first approach for this type of problems is heuristic algorithms. Williams (1981) provides seven heuristics with a minimum cost of production and distribution as the objective function. The only constraint considered in this model was satisfaction of the consumers' demands.

Dynamic programming was the next approach for solving deterministic models (Williams, 1983). In this model additional to the above objective function, holding cost is considered either at each node of supply chain network.

A mixed integer, non-linear mathematical model, is provided by Cohen and Lee (1989). The objective function was maximization the total profit for all the participants in the supply chain network. They consider two types of constraints: boundary conditions which talk about the maximum of the available resources and limitation of demands which determine that each demand cannot be more and less than certain amount. Cohen and Moon (1990) extend the previous work and survey the effect of different types of factors on the total cost of supply chain network. In this extended model, multiple products are acceptable and transportation cost is considered either. The objective function was the somehow same as before, but they consider more constraints including requirement of materials at each node, capacity and assignment limitations. (see Chan et.al, 2011)

A Two-phase approach is represented by Newhart, et. al. (1993). This approach first minimizes the number of product classes in inventory using a hybrid method of mathematical and heuristic model and then it provides the alternatives with the minimum value for required safety stock in a feasible way. Finally we should choose the option with a minimum cost, obviously.

Generally, it seems that using mathematical programming have been become more popular after this point. Arntzen et. al. (1995) design a mixed integer model considering multiplicity in most of the features of the network, e.g. products, transportation options, levels of the network and etc. Voudouris (1996) builds a mathematical model with considering efficiency and flexibility as part of objective function to maximize. Chan and Chung (2004) provide multi-criterion genetic optimization technique using analytical hierarchy process for a large supply chain network.

Stochastic Supply Chain Models

Stochastic supply chains models include models with at least one unknown parameter. Usually in these cases it is considered that the unknown parameter has a specific probability distribution for its possible values. First stochastic parameter which comes to the mind in supply chain problems is demand. In Beamon (1998), lots of papers which discuss about stochastic demands are provided in literature review. For example, Lee, et. al. (1997) design stochastic mathematical models which can reveal the effect of different factors of the Bullwhip effect.

We should not forget that the critical parameters of most of supply chains, like demands, resources and prices have uncertainty, somehow. But the problem is that most of the works in the literature consider these parameters as a deterministic parameter and some stochastic mathematical models are not applicable in the realistic scale of real world problems (Santoso et. al., 2005). So it is time to consider this aspect in the future researches. Santoso et. al. develop a stochastic mathematical model for supply chain networks and provide a solution for that by Bender's decomposition method.

Goh et. al. (2007) provides a two-stage stochastic model for the multi-stage supply chain network problems with objective of maximizing the profits and minimizing the risks. They mention the large scale supply chain network of this type for the future research. Also Defaults of companies in the multi-stage supply chain networks have been modeled in Mizgier et.al, (2010) in which the stochastic elements of supply chains are introduced and how local events can affect the global performance of the chain has been shown.

Also uncertainty can be considered and modeled in other ways instead of stochastic optimization paradigm. Especially strategic level supply chain management deals with uncertainty with modeling the relationships of strategic level decisions and selected product, operational and demand variables. (see Wanke et. al.2003)

Economic Supply Chain Models

By economic models we address to the models which use mostly game theory concepts for modeling the supply chains. The two sides of the games are usually buyer and supplier (Beamon, 1998). The evolution of the supply chains in the recent decade reveal important challenge to supply chain managers; every business process contains several decentralized organizations which final decisions of these different firms impact profit of other firms. It means that the entities in the supply chain network are like the players in a game. So for being able to model and analyze strategies in this environment, game theory is a logical choice (Nagarajan and Sosic, 2006). Cachon and Netessine (2006) is a valuable reference for the application of game theory in supply chain analysis.

Simulation Supply Chain Models

Simulation plays a significant role in either modeling the supply chain network or in the validation of the mathematical models for the supply chains. Terzi and Cavalieri (2004) provide a great survey on the application of the simulation in the supply chain network over the 80 articles. It can be a suitable reference for anyone who interested.

CONCLUSION

It looks there are various ways for future of supply chain management. First of all, the models are going to get more complicated for lager supply chains. Because the aim of SCM is going to hit the larger targets and analyze more inclusive networks. Therefore they are more difficult to solve. Hence the need of faster and more efficient solution methods is tangible. Another topic is the modeling of supply chain networks considering reassigning demands or re-routing flow of materials after a disruption and their costs. Moreover, risk mitigation is important concern in the nowadays competitive business environment. In the competitive environment, most of time it is enough to make sure that the objectives of our competitors are not better than us. This idea rings the bell of using game theoretic models to approach supply chain networks. Speaking of the objective of supply chain networks is mostly about the cost, But there are especial cases in the public services such as emergency post-disaster supplies, which their reliability have a significant role. This can bring a challenge to modeling and applying this kind of problems (Snyder, et. al, 2005). The very last case is one of the applications of the mixture of facility location and supply chain management. Melo et.al, (2008) provide a good review about this topic. They mentions that stochastic SCM is one of the areas in SCM which needs an intensive research work on it. The other hot topics in SCM mixed with facility location problems are the cases with procurement, routing and the choice of transportation modes.

Another concern which is not considered properly in the supply chain management researches is formulation of regulation to societal and ecological concerns. These frameworks are called environmental or green supply chain management. Srivastava (2007) makes a review on this topic and provides some directions for future research in this area. Shen (2007) discusses about the other interesting topics of the future researches. Considering limitation for the capacity of demand, developing new algorithms to efficiently solve the large-scale networks, game theoretic approach to competitive supply chains and including robustness, reliability and risk management in designing supply chain networks can be the ways to the future works. Aside from these, definitive, theoretic and methodological difficulties of body of knowledge of supply chain management are getting more challenging and therefore future researchers and practitioners are to fund new basics to overcome the theoretical shortages and therefore to develop supply chain management as it becomes able to face the time concerns and challenges.

Extensive challenges are emerging as it mentioned before. Different applications of supply chain management are getting more serious roles in the future of the industries or even in the future of the world. Economic challenges as environmental threats such as global warming are making supply chain management a leading state of the art in the humans' hands which can help to build a better life for us and also the coming generations.

Chapter 102
Green Computing as an Ecological Aid in Industry

Ecole Polytechnique Fédérale de Lausanne, Switzerland

ABSTRACT

This chapter concerns the use of computing for ecological evaluation in the manufacturing industry. Here, ecological evaluation means identification and quantisation of various manufacturing process characteristics from the point of view of the environment. Manufacturing is a complex process with many different interactions between the parameters controlling the manufacturing machine tools. In the past, manufacturing planners and operators have set these parameters without understanding the consequences, leading to waste of energy, cutting fluid, and so on. This chapter presents a computer tool for evaluating and quantifying the effects of different manufacturing choices using chosen criteria. The tool was implemented as part of the work for a European project. It is based on an extensive analysis of machine tools to provide a way of handling the complexities of understanding the use phase of products.

INTRODUCTION AND BACKGROUND

The aim of this chapter is to explain the use and practice of one aspect of green computing in the manufacturing sector. The contents of the chapter concerns work done for a doctoral dissertation (Avram, 2010) performed as part of a European project on the next generation of machine tools (the NEXT project). The work is important for manufacturers to evaluate the consequence of different manufacturing strategies and to quantify the effects of these on the environment. Manufacturing is a very complex task with many interactions making it difficult or impossible to understand the consequences of manufacturing decisions.

The major environmental aspects of machine tool use come during the use phase of the machine tool. At the same time, existing evaluation tools

DOI: 10.4018/978-1-4666-1945-6.ch102

are not sensitive enough to cope with the multiple manufacturing variants. Some work has been reported in the literature (Munoz & Sheng, 1995; Dornkudwar, et al., 1998; Srinivasan & Sheng, 1999a, 1999b; Akbari, et al., 2001; Dahmus & Gutowski, 2004; Jayal & Balaji, 2007; Narita, et al., 2006; Zhigang, et al., 2008, etc.) considering green machining issues; however, in most cases the focus has been limited at the process and process planning level.

Munoz and Sheng developed a model with the three dimensions of material, energy, and time as a basis. The material inputs are the primary material and secondary catalyst material, with output of primary material, waste primary material, and waste catalyst. For the energy dimension, Munoz and Sheng identified thermal, electrical, and chemical as input energy with thermal, chemical, and radiative energy as possible outputs. For the time, there is the initiation time as input and the processing time as output. They found that the geometry of the part, the workpiece material and cutting fluid were the dominant factors affecting process energy.

Domkundwar et al. used features as a basis for analysis for environmental impact assessment. The features were treated on a global basis with additional process or process parameter constraints.

Srinivasan and Sheng worked on quantifying health hazards in wet and dry machining of a simple part with one drilling operation and two end-milling operations. No account was taken of solid particles released in completely dry machining.

Akbari et al. worked with energy consumption in the machining process. An interesting element introduced in this work was the notion of fixed energy consumption versus dynamic energy consumption. This energy is needed for production but is not connected with the production itself. In addition, there is the energy needed for the production itself which can be reduced by improving manufacturing strategies.

Dahmus and Gutowski also worked with energy analysis of the machining process. They categorised the energy consumed into three main types: "Constant start-up operations," "Run-time operations," and "Material removal operations." Based on a set of usage scenarios, which they defined, they compared the energy needs for machining both steel and aluminium on modern and conventional machines.

Jayal, Balaji et al. compared drilling of aluminium with both dry and wet cutting conditions. They concluded that flood application for drilling was needed for high accuracy.

Narita et al. developed a method for estimating the environmental burden of machining in terms of contribution to the global warming potential. They converted different elements, like the electrical consumption, the coolant, lubricants and so on, into equivalent CO_2 emissions and used the total as a measure of the environmental effects.

Zhi et al. investigated the environmental impacts of cutting fluids for cutting processes. They also studied some design aspects for machine tools and thermal deformations of both workpieces and machine tools during cutting.

Informatics is needed as a tool for industry, this can be thought of as 'green applied computing.' The work mentioned above needs to model manufacturing processes explicitly or implicitly and to calculate and present a multitude of diverse factors. This is an application of computing for improving environmental awareness, hence the term "green applied computing." Industry is doing a great deal to improve the environmental impact of manufacturing and computing tools are needed to understand and quantify the effects of manufacturing options. In addition, by exposing students to the topic, future engineers are made aware of their social responsibilities and how they can be managed. This research, on measurement and quantification, is important and needs to be extended so as to gain a better picture of environmental loading. The chapter will describe how green computing can be applied in an industrial sector, which is an important user of resources.

Machine Tool Systems

Machine tool systems are described as "mother machines" by Suh et al (2008, p. 3). in the sense that it is a machine that makes machines. There are, now, a great many types of machine tool, milling machines, turning machines, grinding machines, EDM machines as well as complex machines capable of performing multiple functions. Machine tools are complex systems with many elements to handle. In addition, the application area of machine tools involves many other variables concerning physical properties of materials, thermal and chemical effects. This chapter focuses on the use of machine tools for so-called "green machining." There are, too, many different manufacturing processes and machine tool types. The main manufacturing processes are milling and turning, but there are other processes, which are used as well, such as EDM, additive processes, laser cutting, stamping, pressing or welding. For the purposes of the research, the milling process was analysed in order to establish the principles for eco-evaluation. However, the analysis method is extensible.

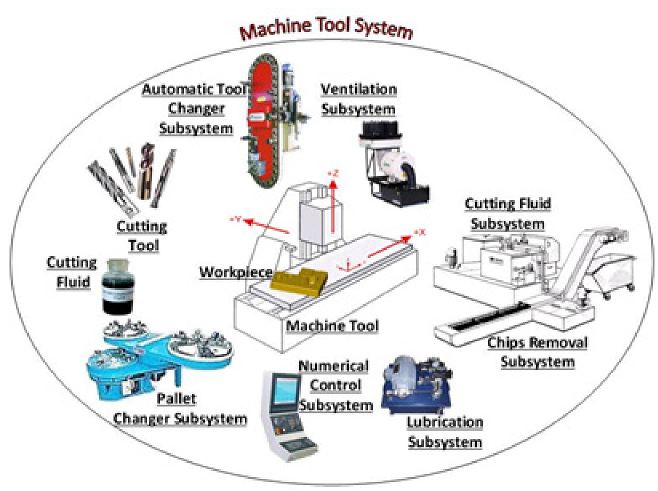
Figure 1 shows a stylised milling machine tool to illustrate the elements. There is a spindle, which holds a rotating cutting tool. The tool is moved in the Y- and Z-directions relative to the workpiece to be machined, which can be moved along X axis. Depending on the architecture of the machine the tool and the workpiece can be moved separetely or in combination.

In addition to the direct cutting processes, there are a number of subsystems for chip removal, lubrication of various components, pumps to supply cutting fluids or fans for cooling, which needed to be taken into account.

Life Cycle Costs of Machine Tools

To understand the ecological effects of any product, including machine tools, it is necessary to consider the life cycle of the product and divide it up into phases. In the design phase, it is possible to consider a number of product variants and optimise these according to different criteria. During manufacturing, the environmental effects of different manufacturing options can be evaluated for the part. The major environmental impact of many manufactured products, including machine tools, comes during the use phase. Finally, there is an End-Of-Life (EOL) phase when there are

Figure 1. The main subsystems of a machine tool system (MTS)



reuse, recycling, disposal options. The lifecycle cost of a machine tool is the sum of all these multiple effects.

As stated above, the most important environmental effects come during the use phase of the machine tool. This is also the most complicated phase, with an interaction between the ecological effects of the part and the environmental effects from the machine tool due to the way it is used for the manufacturing process. This is illustrated in Figure 2.

Use processes are performed by executing functions of the MTS, but the environmental impact does not result just from deliberated functions. Rather, they result from the behavior of the MTS subsystem responsible for that function. Therefore, it is important to describe the MTS's behavior not just its functions.

The evaluation of the use phase of the product can be simulated by determining settings of different activities within its utilisation such that the environmental impact can be reduced (i.e. finding the optimum combination of cutting parameters and their optimal sequencing among several possible combinations for the same process). The overall goal would be to propose the best-practice solution for each sub-function in order to improve the performance of the overall system.

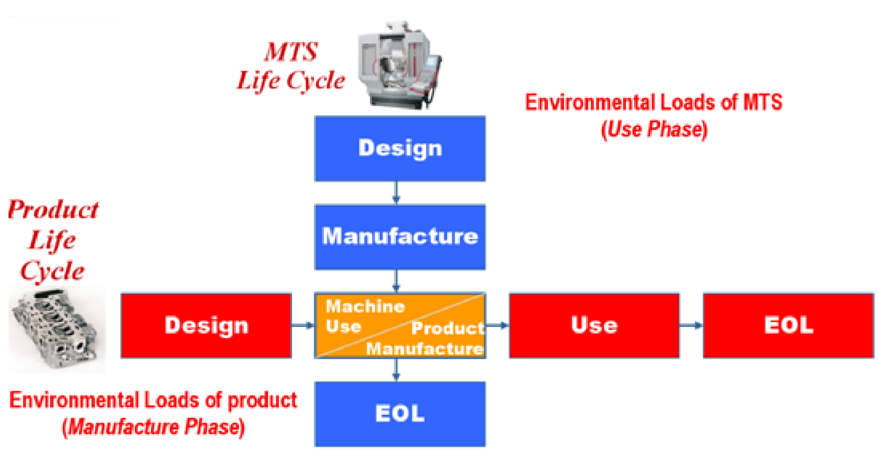
There are different environmental aspects, which need to be estimated. One important aspect is energy use. Another aspect is the resource use of potential noxious elements as waste, like cutting fluids, or in fumes, particles, etc. released into the air during machining.

EVALUATION OF THE USE PHASE

The methodology developed (Avram, et al., 2011) was based on extensive analysis and measurements of several machines. The experimental data was recorded in a structured relational database. The experiments were carried out to machine different manufacturing features under different conditions and on different machine tools. With the result data, it has been possible to evaluate and quantify the effects of manufacturing decisions. An experimental software tool was developed to show the research results.

The software tool, GREEM (Global Reasoning for Evaluation of Eco-Machining), worked on two levels. On the first level the user was asked to identify the manufacturing features to be machined, to identify the machining conditions and finally to identify the environmental aspects of interest. This data was then matched to experimental results from the database in order

Figure 2. Life cycle crossing point of a machine tool system



to retrieve relevant measurements. The user is also expected to provide weights for the different environmental aspects as a way of adapting the results to local conditions. For example, if a company uses renewable energy but has waste disposal concerns, then lubrication fluid might be set to have a higher priority than energy use. In this way the tool can be tailored to specific company needs. The results of the analysis are presented both in graphical form and as a textual form, which can be included in a manufacturing report.

While the first level is mainly concerned with aspects related to machining a specific part by an MTS, the second level assesses the machining capabilities of the MTS in terms of component specifications and activities, during its useful life when various shapes and materials have to be machined. Based on the specifications given by the MTS manufacturer for its various components and an energy consumption predictor module (Avram & Xirouchakis, 2011), the goal at the second level is to find the best performing machine tools system to complete a specific machining job.

In addition to the theoretical verification, this model has also been verified using experimental measurement of known machine performance under known conditions. The machines were run both with and without actual cutting so that the effects of the machine tool itself and the effects due to cutting could be measured. The experiments were run under different cutting conditions and with the machine tool moving at different speeds. As well as the main cutting, energy is also used by subsidiary systems and these, too, were measured for quantification. Using the machine tool model, it is possible, also, to estimate the future energy use of machines under development and to optimize the design at an early stage. For industrial users, energy minimization is important both in economic terms as well as for production optimisation.

GREEM Level 1

The first level consists of the assessment of the performance of a specific machining process with respect to a set of criteria. The machining process is defined at an elementary level, that is to say, with a unique tool class, a unique tool path, a set of cutting conditions and a cooling/lubrication alternative. The assessment can be extended at part level by gathering together under one score the performances of the machining process components carried out in order to complete the part.

The steps to be carried out for the analysis are:

- Input/Select the machine tool system
- Input/Select the machining features
- Input/Select the machining alternatives
- Input/Select the measured criteria
- Retrieve the experimental data

On this level, GREEM evaluates the effects of machining with particular options according to selected criteria. The machining description is given as a set of machining features. This method of giving machining instructions is termed "micro process planning" and derives from a new standard for machine tool control, ISO 14649 (2001). The standard allows direct use of Computer-Aided Design (CAD) data, another applied computing area, in machine tool control. The 'features' are elements like holes, pockets, face milling.

The user is first asked to define the workpiece size and material for mass property calculations for example. The user then defines the manufacturing operations in terms of manufacturing features, but only giving their gross geometric characteristics rather than the exact geometry. The user is also asked to define tool characteristics for more precise knowledge of the cutting conditions. The feature types identified for manufacturing are shown in Table 1.

An alternative, as a component of the machining strategy, refers to the choice between several possibilities all intended to accomplish a specific

Table 1. Feature types for manufacturing

Counterbore	Pattern (Rectangular)	Slot (full open)
Countersink	Spherical cap	Slot (loop)
Planar facing	Step	Slot (closed round
Hole (Round)	Thread	Slot (closed square)

Pocket (Closed)	Fillet	Slot (open round)
Pocket (Open)	Profile	Slot (open square)
Pattern (Circular)	Region	Slot (open Wood-ruff)

goal. Even though the focus of this research is on the alternatives for cooling/lubrication of the cutting area, the developed methodology is also able to accommodate other alternatives (i.e. HSM—High Speed Machining). The user is also offered a choice of criteria from which to evaluate the machining plan.

Once the machining plan, the alternatives, and the criteria have been selected, it is possible to evaluate the effects of machining a part. The input data are used to select measured data from a database of experimental results. The user then has to set weights for the different criteria indicative of their relative importance. The criteria belong to the three different categories: economical, technical, and environmental. The user can either give the relative importance of the criteria in a pairwise comparison, or set their relative importance on a global scale, depending on user preference.

The software calculates the best options for machining so that users can evaluate the consequences of their machining choices. Figure 3 shows the graphical presentation of the results which can also be presented for inclusion in a machining report. On the top left, there is a presentation of the global performances based on the weights defined by the user. This shows that the best global performance for manufacturing the features chosen is MQL, or minimum quantity lubrication. MQL means that only a small amount of lubrication is delivered to the contact point between the tool, often as a mist, and the workpiece instead of 'flooding' the working area with a continuous stream of lubrication. On the top right there is a presentation of the contribution factors for machining the round hole, with workpiece quality, force and lubrication evaluations. These were the criteria chosen by the user on which to evaluate the manufacturing steps. The chart shows that for the flood option, with a large amount of cutting lubrication, the main negative environmental effect is from the lubrication itself, with a small amount of force needed for cutting but giving the best workpiece quality. For the minimum quantity lubrication there is a small contribution from the lubrication, small force needed and good workpiece quality. For dry machining, more force is needed and the workpiece quality is poorest. On the bottom left of the figure, the equivalent effects for the planar facing operation are shown. This shows that the major negative effect for flood machining is again the lubricant and the workpiece quality is not too bad. For the MQL option, the main effect is the force needed. For dry machining, much more force is needed and the workpiece quality is lower than with MQL.

The computing tools for the first level of GREEM involve mainly database tools with user-friendly presentation tools. The computer tools are important to make sense of the wealth of information surrounding the manufacturing process.

GREEM Level 2

In addition, similarly to the first level, it is necessary for the user to set priorities. The second level has to address the performance of the machining system as a whole and not just certain aspects. The software makes it possible to compare different machine tool systems with respect to various criteria, e.g. productivity, precision, cost, safety, flexibility/adaptability, and energy. The user has to emphasise the relevant importance of these criteria by using the priority settings, which use

Figure 3. Graphical presentation

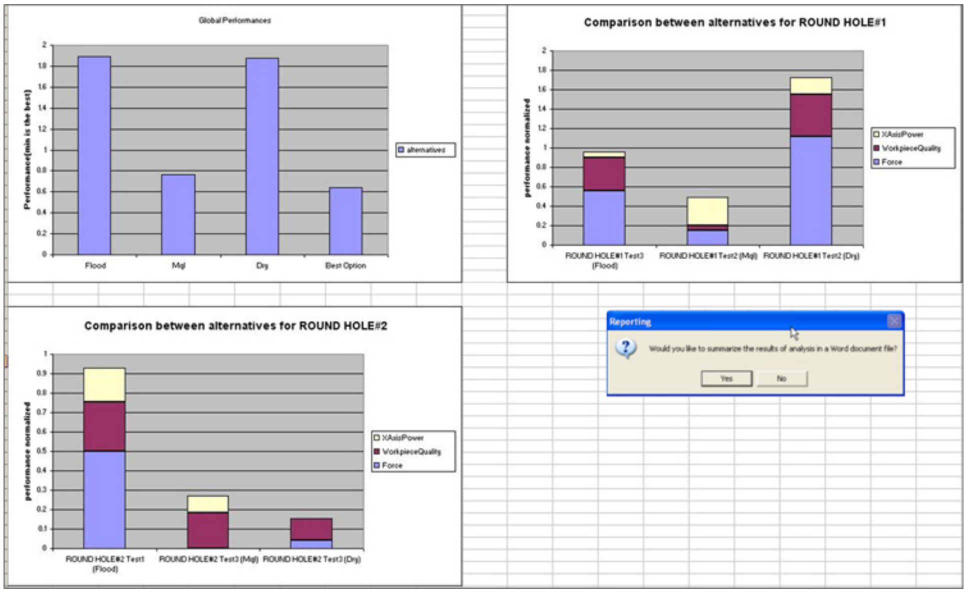

Figure 4. Priority setting

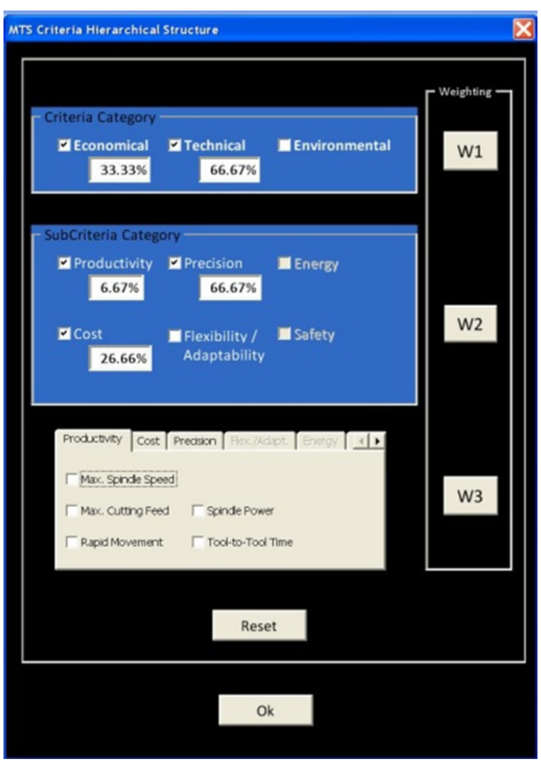
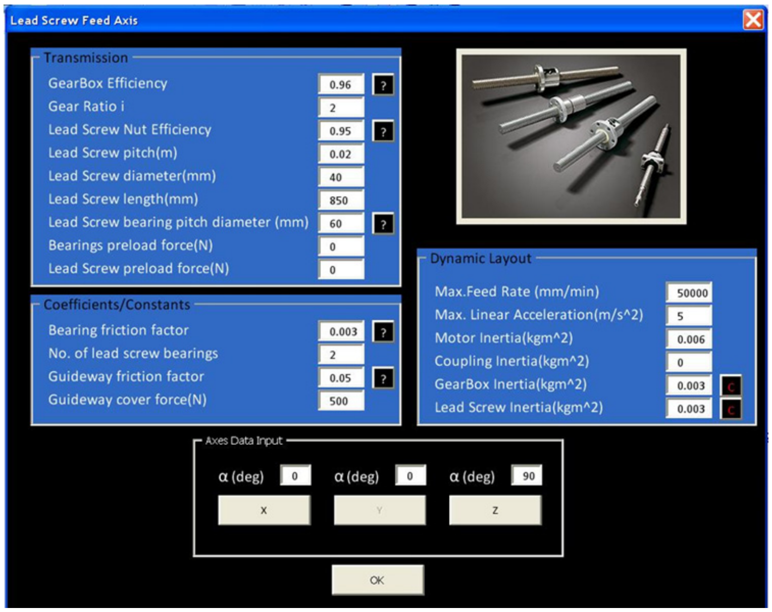


the same type of pair wise comparison technique as described earlier. Figure 4 shows the priority setting.

Energy use calculation is complicated and there are effects related to machining strategies. For the research done, a prismatic part was used. In order to calculate the expected energy use for machining a test part, it is necessary to have a model of the machine tool. Such a model has to include the masses of the machine tool elements, spindle and feed axes characteristics, kinematic structure, friction coefficients and so on. Figure 5 shows an example of input data required to estimate the energy used by one element, in this case the feed axis of the machine tool.

In order to calculate the movements of the machine it is also necessary to have the control data. For the purposes of the research, an APT (Automatically Programmed Tools) control data file was used. The APT file contains explicit movement data, which can be used to calculate the power requirements with respect to the chosen tool path. The same file was also used to mill the part while measuring the real power consumption so that the model could be verified.

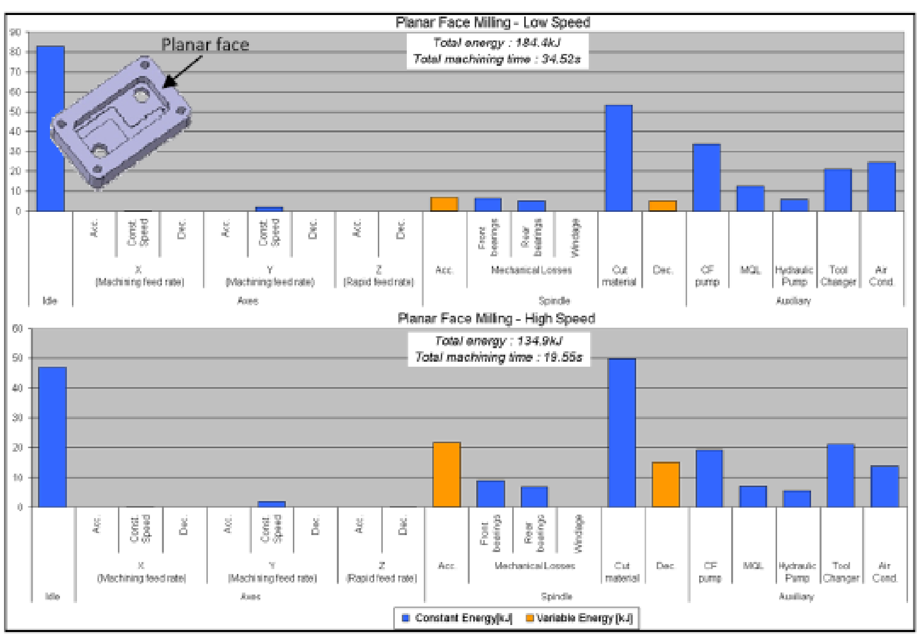
Figure 5. Feed-axis input for GREEM level 2



As with level 1 of GREEM, the analysis is divided into machining features. Figure 6 shows some results of the milling energy consumption for the planar face feature of the modelled part, machined under wet conditions and by removing the same amount of material at two different cutting speeds.

The scale on the left shows the number of kilojoules of energy consumed for different operations. On the bottom are the different elements

Figure 6. Machine tool system consumed energy (kJ) for planar face milling (low speed vs. high speed)



that were measured in the experiment. First there is the energy consumed while the machine is idling, that is, not cutting. Next, for each of the axes of the machine tool (which is a three-axis machine tool in this case), there is the energy measured while the axis was accelerating, moving at constant speed and decelerating. Then there is the contribution to energy consumption by the spindle. The acceleration and deceleration contributions are variable amounts of energy. Also shown is the energy loss due to mechanical effects of the spindle (front bearings, rear bearings, and windage). The energy consumed in actual cutting of material is also shown. The last five columns in the figure show the energy losses due to auxiliary equipment around the machine tool.

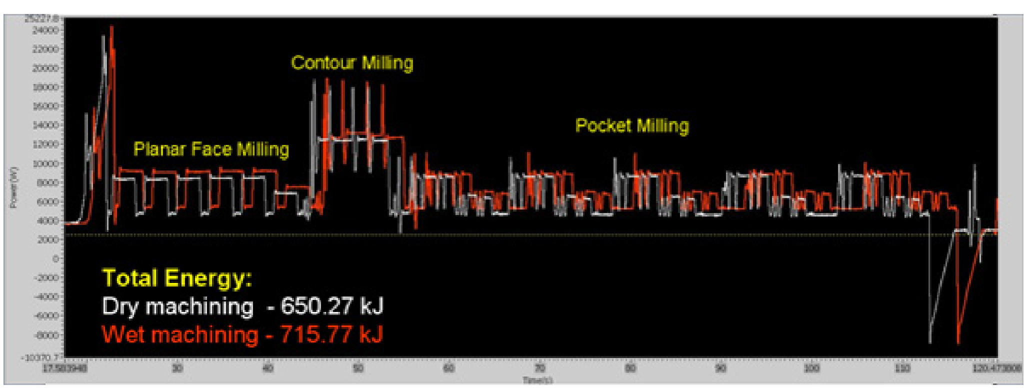
This kind of measurement provides a basis for accurate modelling of the machine tool and manufacturing processes. With this data, it is possible to help the user optimise machining parameters. It is also needed for accurate machine tool modelling for advanced machine tool control, to let the machine tool itself optimise its behaviour, which is a current research topic being actively worked on in many places.

The auxiliary equipment concerns other energy consuming subsystems on the machine tool, such as chip removal systems and pumps for providing cutting fluids. The energy consumed by the pump for the delivery of the cutting fluid (CF pump in the Figure 6) is notable because the pump cannot be switched off unless a part is to be machined 'dry.' The power drawn by the pump is highly influenced by the fact that a specific pressure should be maintained and frictions in pipes and fittings as well as elevation differences should be overcome across the length of the process. A more energy efficient alternative is the Minimum Quantity Lubrication (MQL).

Avram (2010) provides an extensive presentation of opportunities for improvement of the environmental impact of machine tools during their use phase. Due to space limitations, only a single example is illustrated here. Figure 7 shows the power profiles acquired during the machining of three milling features by employing identical cutting conditions but different cooling/lubrication strategies. Another interesting conclusion was that high-speed machining, a process where the tool spindle is rotated faster and the axis movement speed increased, can be more economical than conventional machining. Although high-speed machining needs more power, this is applied for shorter periods resulting in a net saving of energy.

Figure 7 shows the power consumption during milling of the example prismatic part used for the experiments. The scale on the left is the power consumption. Note that there is some negative consumption where power is generated in certain phases of the process as the motor becomes a generator under certain conditions. The figure shows two cutting profiles superimposed, in red

Figure 7. Machine tool system energy consumption (kJ) for part milling (wet vs. dry machining)



for wet machining and in white for dry machining. The scale at the bottom shows the time, in seconds, over which the machining took place.

For the test part, there were three machining phases: a planar face milling, a contour milling and pocket milling. The planar face milling removes a layer of material from the workpiece to make it the correct height. The profile milling cuts around the outside of the part to give it the right exterior shape. The pocket-milling phase removes material from the inside of the part.

The face-milling phase consists of a series of passes to cover the whole area of the part; the peaks in the diagram correspond to the different passes. In contour milling, the tool cuts material with the side. This is not done in one pass as cutting too deeply can lead to tool deformation and even breakage. Instead, the tool is passed round the material in a series of steps. For pocket milling, the tool is sunk into the material and then moved around to clear the material. As with profile-milling, this may not be possible in a single step and so the material clearance is done in a set of layers. The diagram shows the peak distributions of these different steps with different axes moving different amounts according to the operational characteristics. Here, only the total energy consumption is shown, not the individual contributions of the systems and subsystems of the machine tool. In order to get an accurate picture it is necessary to measure at high frequency, resulting in a huge amount of data to process.

For the second level of GREEM, database tools are also important as well as simulation, calculation and virtual instrumentation tools.

EXTENDING THE SCOPE OF THE SOFTWARE

The test plan for milling, which has been carried out on a number of machines, is shown as an example for comparison. The other test plans are suggestions for possible extensions to the database of experimental results. The milling tests were carried out, machining the same piece with three options: dry, MQL and flood machining, and with two types of tool: coated and uncoated. This means that six sets of experiments and six sets of tools were required for the tests for each set of machining parameters (feeds and speeds). The more experiments performed the more accurate the results. However, the experiments were performed with new tools for each set of measurements, making the experimental series expensive. The criteria measured were: power consumption of the main power-driven components of the machine, cutting forces and the quantity of cutting fluid applied.

It would certainly be possible to devise an extended set of tests to augment the existing database so that different process plans using different processes could be compared. Four cutting processes are considered here:

1. Milling
2. Turning
3. Wire EDM
4. Sink EDM

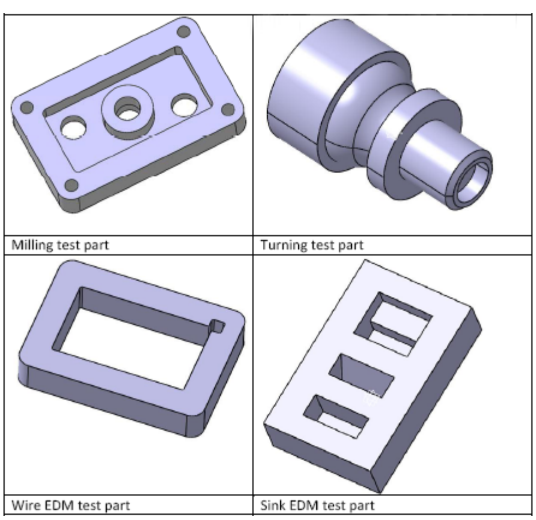
Milling is a much used process for creating general shapes using a rotating tool to remove material from a workpiece. Turning is also a conventional process in which the workpiece rotates and the tool is fixed to create rotationally symmetric parts. Wire EDM is a non-conventional process to produce accurate parts from material by cutting parts out from a block of material using a wire. Electric current is passed down the wire resulting in sparks between the wire and the workpiece. The sparks cause enough heat to be generated to vaporise, or erode, a small amount of material. As the wire is moved, it leaves a narrow cut behind it. Sink EDM is another non-conventional process used to create accurate shapes in metal for moulds and dies, for example. It works by slowly lowering a shape towards the block of material to be shape. As different parts of the shape approach the workpiece so sparks occur between the shape being lowered and the workpiece. These sparks erode away the workpiece to leave an accurately shaped cavity.

Figure 8 shows an extended set of test objects devised to provide information about a variety of manufacturing features in the different processes. These features derive from the ISO 14649 specification. For the turned part, there are profiles, chamfers and cut-ins, for example. For the wire EDM process there is a simple profile cutting feature as well as a 'pocket' feature where a complete volume of material is vaporised. For the sink EDM process, there are different types of pockets. Sink EDM is also interesting because it offers an alternative process for mould manufacture and could be compared with conventional and high-speed milling for particular examples.

RESEARCH VISION AND FUTURE RESEARCH

Figure 9 shows an image of the research vision, with an increased understanding of the interaction between different options in manufacturing. This obviously requires a far wider range of analysis than has yet been performed as well as more time and a greater investment. The milling machine tool analysis is complex enough, but the higher levels are even more complex and need more related research in order to be able to make the whole process more flexible.

Figure 8. Test parts for process extensions

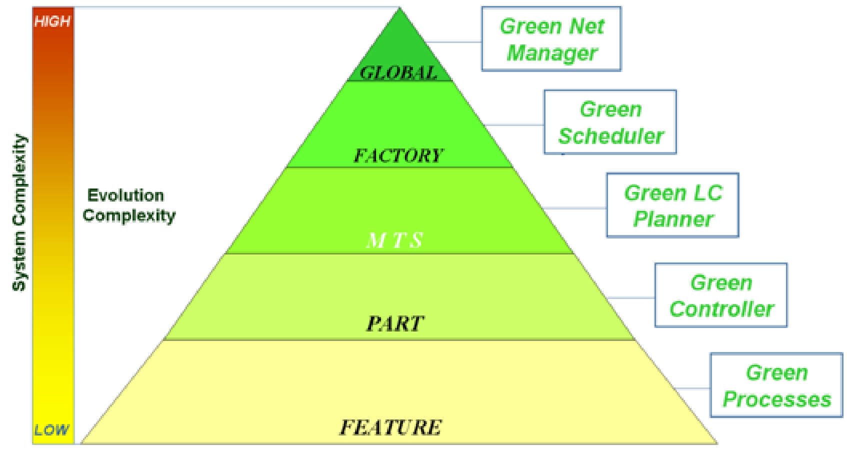


An example of the needs for change concerns the modern machine tool control standard, ISO 14649 or STEP-NC. The information provided for control by this new standard allows the machine tool to optimise its own behaviour for its architecture and the part to be machined. This is possible because of the increased computing power now available on the industrial computers used in controllers. Traditionally, movement planning had to be done off-line with neither details of the architecture of the target machine tool nor of workshop loading. An extension to this standard is to have a machine tool model to describe available manufacturing resources as well as to describe machining needs in the control file. Such an extension would allow workshop planners to make last-minute decisions about machine choice.

Another important aspect of improved level of information on the shop floor is the possibility to perform simulations and optimisation of plans. In some processes, such as EDM, the machine operators have extensive knowledge of the process and sometimes perform experiments to improve machining parameters before real production starts.

Concerning global levels, life-cycle analysis tools exist but sometimes need careful application in order to understand the results. An example of a tool, which is easier to use and can be used to compare alternatives is the EcoIndicators99 method. This method uses a scoring system to equate different environmental factors. Transport, machining, part treatments, recycling and so on are all assigned a unit score in a common basis which is then multiplied by part characteristics, such as weight, to arrive at a process score. These scores are then added together to give an idea of the relative environmental impact of the part production. The methods described above keep the different factors separate in order to understand from

Figure 9. Machine tool system hierarchy of modeling and optimization methods and tools



where the different environmental factors come, a so-called multi-criteria approach. The method presented also allows the user to understand the environmental effects in quantative terms rather than simply knowing which option may be better.

Further research is going on in other projects where advanced simulation and calculation are also being used. Data modelling based on computer science tools also plays a major part in the standardisation work.

CONCLUSION

Computing at the service of the environment has a wider application than simply improving the environmental aspects of computing itself. Green applied computing can be used to make sense of complex areas where the wealth of data is too great to be comprehensible without processing. In the manufacturing context there is a great deal of complexity already with machining but extending consideration to the factory level and the global supply chain then the complexity far exceeds the level which can be comprehended by users.

For the research presented, the main computing tools used were:

- Database tools
- Data collection and management tools
- Simulation tools
- Calculation

ACKNOWLEDGMENT

The authors would like to thank Vincent Capponi for all his work. We would also like to thank the European Union for financing the research presented during the NEXT project. Last but not least, we would like to thank the NEXT project partners for sharing their results and equipment for the experiments that were so necessary for the work.

Chapter 103
Improving Energy-Efficiency of Scientific Computing Clusters

Tapio Niemi
Helsinki Institute of Physics, Finland

Jukka Kommeri
Helsinki Institute of Physics, Finland

Ari-Pekka Hameri
University of Lausanne, Switzerland

ABSTRACT

The authors applied operations management principles on scheduling and allocation to scientific computing clusters to decrease energy consumption and to increase throughput. They challenged the traditional one job per one processor core scheduling method commonly used in scientific computing with parallel processing and bottleneck management. The authors tested the effect of increased parallelism by using different test applications related to high-energy physics computing. The test results showed that at best their methods both decreased energy consumption down to 40% and increased throughput up to 100%, compared to the standard one task per CPU core method. The trade-off is that processing times of individual tasks get longer, but in scientific computing, the overall throughput and energy-efficiency are often more important.

INTRODUCTION

Scientific computing clusters are widely used in many research fields, especially in experimental physics, astronomy, and bio-sciences. Computing intensive research easily deploys thousands, even hundreds of thousands, of CPUs to analyze various data sets and models. These clusters can be viewed as production resources processing jobs consisting of numerous tasks. The tasks can be processed by different resources, and finally the jobs are assembled together to be delivered back to the cluster customers. Operating such a cluster has its own cost structure related to capital invested, energy consumed, maintenance work, and facility related costs. In all, a computing cluster closely resembles an industrial production unit, thus the working hypothesis for this chapter is

DOI: 10.4018/978-1-4666-1945-6.ch103

to apply operations management principles used in manufacturing to improve computing cluster productivity and overall efficiency.

Green computing, as it is now often referred to, seeks to improve efficiency of computing centers. It is a wide topic incorporating issues like data centre locations near cheap energy sources (Brown & Reams, 2010), minimizing so called e-waste (Hanselman & Pegah, 2007), designing optimal cooling infrastructure and running the centre in an optimal way (Marwah, et al., 2009). Generally, energy and resource optimization in scientific computing has mostly focused on hardware and infrastructure issues, for example the development of more efficient hardware or optimizing cooling of computer centers, and has not focused as much on operational methods such as workload management and even less on operating systems and application software optimization for energy-efficiency.

The most well known method for comparing energy efficiency of data centers is Power Usage Effectiveness (PUE) metrics (Belacy, 2008). This is a ratio of the total facility power / IT equipment power. It indicates how much of the energy is lost in cooling, power distribution, and other infrastructures. However, it does not indicate how efficiently IT resources are operated. Limitations of PUE metrics have been recognized by the Green IT Promotion Council (2010), which proposes three additional metrics: ITEU (IT Equipment Utilization)—IT equipment usage in data center; ITEE (IT Equipment Energy Efficiency)—total rated capacity of IT equipment / total rated energy consumption of IT equipment; and GEC (Green Energy Coefficient)—Green (natural energy) energy / total energy consumption of data center. Based on these metrics it is possible to calculate Datacenter Performance Per Energy used (DPPE) metrics as follows: DPPE = (ITEU x ITEE x 1/PUE) / (1-GEC). Further, the report gives four methods for improving energy efficiency: 1) Operating the data center in an efficient way, i.e. reducing amount of hardware and increasing its utilization; 2) Installing energy efficient hardware; 3) Improving energy efficiency of non-IT infrastructure; and 4) Using renewable energy.

In this work, we focus on a typical computing problem in high-energy physics: How to process a large set of jobs efficiently. While most of the existing work on high performance computing focuses on optimizing processing time of individual computing jobs, we try to optimize energy consumption per computing job and the total processing time of the set of jobs by choosing an optimal scheduling policy.

We study this problem by using real experimental physics data, computing jobs, and dedicated computing clusters. CERN, the European Organization of Nuclear Research in Geneva, provided us with a unique possibility to experiment and test the hypothesis. The Large Hadron Collider (LHC) experiment at CERN produces about 15 petabytes of data in a year. The overall computing infrastructure comprises numerous computing clusters of alternative sizes, yet the total amount of CPUs is over 100,000 in over 140 computing centers. Efficient management of these computing resources is vital for the success of the project, which is foreseen to be active for the next 20 years.

Basically, the problem is similar to production management in any manufacturing facility. In manufacturing, this kind of optimization problem can lead to a trade-off situation: improving energy-efficiency can weaken throughput. However, within the context of the computing center our tests indicated that these two aims are not necessarily contradictory, meaning that optimizing system throughput also improves energy efficiency. Our approach is based on a conclusion that computers should run near full power or be turned off, since the fixed power consumption is around 50% of the full power of the server. This chapter is based on our earlier papers (Hameri & Niemi, 2010; Niemi, et al., 2009a, 2009b).

BACKGROUND

The theoretical background of our research comes from production optimisation research. Production engineers search ways to increase throughput of a facility with limited capacity. The principles of production, much like the law of capacity dictating that, in a steady state, all plants will release work at an average rate that is strictly less than average capacity, sets a challenge to get the best out of the facility by avoiding waste, unnecessary waiting times, shut downs and disrupting events. This means that the organization and allocation of work in production systems affects the performance of the system.

As a review of related research, we first present methods to improve efficiency at the whole data centre or at least pertaining to computing clusters. For example, Lefurgy et al. (2007) suggested a method to control peak server power consumption. The method is based on power measurement information on each computing server. Controlling peak power makes it possible to use smaller and more cost- and energy-effective power supplies. Moreover, Kappiah et al. (2005) developed a method to decrease power consumption of parallel computation in power-scalable clusters, while Conner et al. (2006) studied how energy can be saved by dynamically disabling network links in supercomputing clusters.

Another group of studies focuses on servers. Venkatachalam and Franz (2005) gave a detailed overview on techniques that can be used to reduce energy consumption of computer systems. Li et al. (2005) studied performance guaranteed control algorithms for energy management of the disk and main memory. Ge et al. (2005) studied methods based on the Dynamic Voltage Scaling technology of microprocessors and created a software framework to implement and evaluate these methods. Yuan and Nahrctedt (2002) studied the same issues in mobile devices. Essary and Amer (2008) optimized disk arm movements for saving energy, while Zhu et al. (2005) proposed a disk array energy management system. Finally, Zhang et al. (2004) gave compiler-based strategies to optimize cache energy consumption of microprocessors.

One relevant field of research for our study is scheduling methods on how the order and allocation of computing tasks to computing nodes affects the efficiency of the system. The way individual computers schedule their processes is beyond the scope of this chapter. Scheduling problems can be classified according to the following properties:

- on-line / offline
- knowledge on jobs
- knowledge on computing resources

More formally (e.g. following Pinedo [2008] or Brucker [2007]), the scheduling problem can be defined as follows: We have m machines (i.e. computing nodes in our case) and j jobs to be processed. A schedule S is an allocation of time intervals from machines for each job. The challenge is to find an optimal schedule for jobs when taking into account certain constraints. A schedule is optimal if it minimizes a given optimality criteria, for example time, cost, or usage of some resources. The optimality criteria can be defined in several ways, such as the completion time of the last job or the total completion time i.e. sum of all completion times, or in our case, energy efficiency. The overall objective can also be a (weighted) sum of the sub-objectives, which often leads to a Pareto-optimal schedule.

Scheduling is a widely studied topic but most of the work focuses on finding optimal schedules when jobs have proceeding constraints and/or strict time limitations. Optimizing total throughput or energy efficiency in high throughput computing has received less research interest. Instead, some works suggest clearly opposite approaches: For example, Koole, and Righter (2008) suggest a scheduling model in which tasks are replicated to several computers. However, the authors do not estimate how much more resources are needed when the same tasks (or at least parts of them) are computed several times. Fu et al. (2007) present a scheduling model capable to restart batch jobs. They give an efficient algorithm to solve the problem but they do not mention resource usage. Further, Da Silva et al. (2003) presented another model using replication.

Most of the research on scheduling focuses on theoretical aspects but some practical studies do exist. For example, Etsion and Tsafrir (2005) compared commercial workload management systems focusing on their scheduling systems and default settings. According to the authors, the default settings are often used by the administrators, or they are just slightly modified. Goes et al. (2005) studied scheduling of irregular I/O intensive parallel jobs. They noted that CPU load alone is not enough but all other system resources (memory, network, storage) must be taken into account in scheduling decisions.

More on the theoretical side, Prasanna and Musicus (1996) define a theoretical scheduling model in which the number of processors allocated to a task can be a continuous variable, which makes it possible to allocate all processors for one task if needed. Edmonds (2000) studied non-clairvoyant scheduling in multiprocessor environments. In his model, the jobs can have arbitrary arrival times and execution characteristics can change. Santos-Neto et al. (2004) studied scheduling in case of data-intensive data mining applications, while Wang et al. (2009) developed optimal scheduling methods in a case of identical jobs and different computers. Their on-line algorithm aims to maximize the throughput and to minimize the total load. Finally, self-learning scheduling models also exist, such as that of Shivam et al. (2006).

One group of scheduling research focuses on grid computing. Medernach (2005) studied workload in a grid-computing cluster in order to be able to compare different scheduling methods. The idea of the work was to find ways to group cluster users to characterize their usage. The scheduling was based on one job per CPU core idea. Kurowsk et al. (2008) studied two-level hierarchical grid scheduling taking into account all stakeholders of grid computing systems. The approach does not require time characteristics of jobs being known. Aziz and El-Rewini (2008) studied online scheduling algorithms based on evolutionary algorithms in the grid context. Ni et al. (2005) developed a heuristic scheduling algorithm for grid environments. The algorithm is based on the concept of changing tasks between computers. Some studies apply fuzzy logic and other novel optimization methods. For example, Cao et al. (2003) applied fuzzy time functions to a large-scale grid workflow management and Liouane et al. (2008) studied multi-objective scheduling with a fuzzy controller. Some evolutionary approaches, such as Moallem and Ludwig (2009) and Grosan et al. (2007) have also been studied. Finally, there are some studies on energy-aware scheduling. For example, Rajan and Yu (2008) and Mukherjee et al. (2009) studied this topic. Further, Bunde (2006) developed power aware scheduling methods for minimizing energy consumption and not reducing system performance by applying dynamic voltage scaling technologies.

Other related work (e.g. Mu'alem & Feitelson, 2001; Tsafrir, et al., 2005, 2007) investigates the accuracy of user time estimates and noticed that they are inaccurate. To solve the problem, Tsafrir et al. developed a model to simulate user run time estimates. Piro et al. (2009) studied a similar problem in the Grid context. Yom-Tov and Aridor (2008) presented a self-learning algorithm to estimate resource requirements of batch jobs. Moreover, Karlsson et al. (2005) introduced a method to control storage access in a data centre. The method is based on adaptive controllers and does not assume prior knowledge of the system.

Virtualization has also been studied as a novel method to improve energy efficiency of computing centers. Virtualization makes it possible to combine services from several physical machines on to one physical machine. This is helpful when the utilization of the machines is minimal and the services are running on dedicated hardware. With virtualization, it is possible to use excess resources and downsize the hardware pool. However, consolidation of jobs to fewer servers is not directly relevant to our problem since we assume that there are a large number of jobs to be processed. This is a realistic assumption in physics computing. Increased security provided by virtualization is not usually needed in scientific computing.

The allocation and management of virtualized resources is a widely studied area. Both dynamic and static solutions have been proposed. For example, Bobroff et al. (2007) developed a dynamic system that forecasts future load and in this way it can minimize the number of physical servers. Further, Viswanathan et al. (2011) studied energy efficiency of virtual servers with predefined loads. They succeeded in improving energy efficiency by scheduling predefined virtual machine loads to minimize resource contention and maximize resource usage. However, running several virtual machines on one physical computer does not come without penalties. Apparao et al. (2008) studied the effects of consolidation running several benchmarks in a virtualized environment. This study indicates that sharing physical resources and resource contention clearly reduces the performance of individual virtualized applications. Pradeep et al. (2007) carried out a performance study of two different virtualization technologies. They noticed that some overhead always exists and the size of it depends on the used virtualizing technology. Like Pradeep et al. (2007), Regola et al. (2010) evaluated different virtualization technologies and concluded that full virtualization technologies still pose heavy overheads and are not viable in high throughput computing that use I/O excessively. However, virtualization would allow scientists to use more heterogeneous environments and send their jobs to computing clusters in a form of a virtual machine.

As shown above, research on improving efficiency in computing systems focuses on hardware optimization, power management, various scheduling models etc. However, there is little research on how to apply production management principles to the management of computing resources, i.e. viewing a computing centre as a factory with limited capacity and bottleneck resources. According to the manufacturing and production management point of view, the key issues are related to the optimization of throughput and minimizing operating costs; these are also desirable objectives when computing resources are managed efficiently. Our aim is to increase the utilization rate of bottleneck components (usually I/O or CPU) and therefore increase throughput, which decreases average power consumed by a computing job.

PROBLEM AND METHODS

The main research question of our study is: How can computing centers improve throughput and energy-efficiency by scheduling jobs based on their estimated properties and load requirements of all components (CPU, memory, and network) in computing nodes. A computing system is much more flexible than a manufacturing system since, in a computer, it is possible to run several tasks in parallel, and since tasks are not dedicated to any specific resource, set-up times between different jobs are also practically non-existent. Another difference with manufacturing is that it is difficult to see what is happening inside the computer, thus all measures are based on the in- and output of the system, as actual work in progress takes place literally in a black box.

The motivation for our work comes from the CERN's LHC experiment. The Worldwide LHC Computing Grid (WLCG1) is used to analyze the data produced by the Large Hadron Collider at the CERN, and it consists of hundreds of terabytes of data storage and tens of thousands CPU cores. On this scale, even small system optimization can offer noticeable energy and cost savings and performance improvements. Since high-energy physics computing has many special characteristics, common industry practices are not always the best. The main characteristics of LHC computing are: jobs contain large sets of similar tasks, data-intensive computing, processing time of an individual task is not critical, no preceding conditions among tasks, and little intercommunication between tasks, i.e. high parallelisms.

We use the following basic terminology in this work: A task is the smallest elementary entity when work is processed. The task starts, retrieves/reads its possible input file, processes the data, and possibly writes its output file. A job is a collection of tasks. In our current work, we assume that the processing order of the tasks inside a job is irrelevant. By energy efficiency, we mean the number of similar tasks or jobs that can be processed by using the same amount of electricity while throughput means the number of similar tasks or jobs that can be processed in a time unit.

We started our study by collecting and analyzing log data for a physics-computing cluster. When analyzing the data we noticed that lead times of jobs are 15 to 50% longer than the actual CPU times. Since the cluster configuration was set to process one job per CPU core, this means that there is a bottleneck slowing down the computing process. The most obvious bottleneck is I/O access to the disk and network. When estimating memory utilization of jobs compared to their CPU utilization, the memory utilization rate was about half of the CPU utilization rate. One reason for this is an irregular memory utilization curve of physics jobs. We assume that the other reason is related to I/O waiting times. Based on this analysis we assumed that reasonable overloading and processing different kinds of tasks in parallel can improve throughput by keeping bottleneck resources busy. The following two hypotheses document this:

1. Throughput can be improved and electricity consumption reduced in data intensive High-Energy Physics (HEP) computing compared to the traditional single task per CPU core processing by multitasking, i.e. processing more than one task per CPU core in parallel.
2. The performance can further be increased by mixing heterogeneous tasks while multitasking.

The hypotheses above do not give any upper limit for the number of parallel tasks. In practice, the number is limited by physical resources, especially by memory. The practical challenge in multitasking is to find the optimum number of simultaneous tasks. We used the following criteria: 1) a task uses a minimal amount of energy, and 2) the total throughput is maximal. These goals could be contradictory, but in all our tests, we noticed that the maximal throughput also gives the minimal energy consumption per processed task. As far as the clusters are concerned, the problem can be divided into two independent steps assuming that cluster nodes are homogeneous:

1. Finding the optimal load combination for the computing node.
2. Scheduling jobs to the computing nodes in such a way that all computing nodes are as close as possible to the optimum state (i.e., Step 1).

In an important special case in which all tasks are identical, the problem becomes: How many tasks must be processed simultaneously in a computing node.

We tested the hypotheses by building a realistic test environment, and then developing, and finally testing different scheduling methods. In practice, we did this by processing a job, i.e., a large set of tasks and measuring the time and electricity consumed during the test run. As explained above, we assume having a large set of independent tasks, and we are interested in the total processing time and electricity consumption of this set. By the total processing time, we mean the total time from the submission of the first task in the set to the computing cluster to the end of processing the last task in the same set. Our aim is to minimize both the amount of electricity and time needed to process the set. Minimizing the processing time is equal to maximizing the throughput.

Our experimental system was comprised of one front-end computer running the workload management system and one computing node and 1 Gb local area network. To make sure that results are not valid for one particular computer, we used two different architectures: 1) a Dell PowerEdge SC1435 server with two 4-core ADM Opteron 2376 2.3GHz and 32 GB of memory, and 2) a Dell PowerEdge R410 server with two Intel Xeon E5520 quad core 2.27 GHz processors and 16 GB DDR3 memory. The first server was used in our first test and the second server in tests two and three. We used a Sun Grid Engine (SGE) (Sun, 2008) as a workload management system, as it is also commonly used in grid computing clusters. It has various features to control scheduling. The scheduling is based on the load of the computing nodes and resource requirements of the jobs. There are also various other batch scheduling systems such as Torque[1], OpenPBS[2], LSF[3], and Condor[4]. These systems have different features but their basic functionality is very similar.

Electricity consumption of the computing nodes was measured with the Watts Up Pro electricity meter. The accuracy of the meter is around +-1%. The operating system used with Xeon and Opteron was Rocks 5.0 with kernel version 2.6.18.

We used five different test applications. The first three were implemented to test usage of only one resource and the fourth and fifth were real physics applications:

- The I/O test application writes and reads 300 MB files multiple times. After generating a file, the content is copied to another file 20 times. Each time the file is a bit different (small shift in numerical values) to avoid buffering.
- The CPU test application contains a long loop calculating floating point multiplication. A reminder of the index variable is also used to make compiler optimization harder.
- The memory test application reserves memory (200 MB) and fills it with numbers. After that, it reads a part of the memory and writes it to another part. This is done multiple times.
- The physics data analysis application is based on the CMSSW framework. Input data for the test is from the CRAFT (CMS Running At Four Tesla) experiment that used cosmic ray data recorded with CMS detector at the LHC during 2008 (Acosta & Camporesi, 2008). This detector was used much like current LHC experiments and the data was very close to the final data analysis. The analysis software reads the input file (94 MB or 360 MB), performs the analysis, and writes a small summary file on the local disk. Input data is stored in ROOT data container files (Antcheva, et al., 2009). Physics data is stored in binary format to save space and one root file usually contains hundreds of events captured by the detectors. The disk I/O during the application processing is shown in Figure 1 and the memory usage in Figure 2.
- The CPU intensive physics application is also based on the CMSSW framework (Fabozzi, et al., 2008) including event generation with Pythia6 (Sjostrand, et al., 2006) and full detector simulation with Geant4 (Agostinelli, et al., 2003). The Pythia program is a standard tool for the generation of high-energy collisions using Monte Carlo methods.

Each of these test sets was run several times to get stable results. The input data were different for each run to eliminate the effect of the disk cache. Additionally, the disk cache was cleared

Figure 1. I/O usage of a single physics analysis job

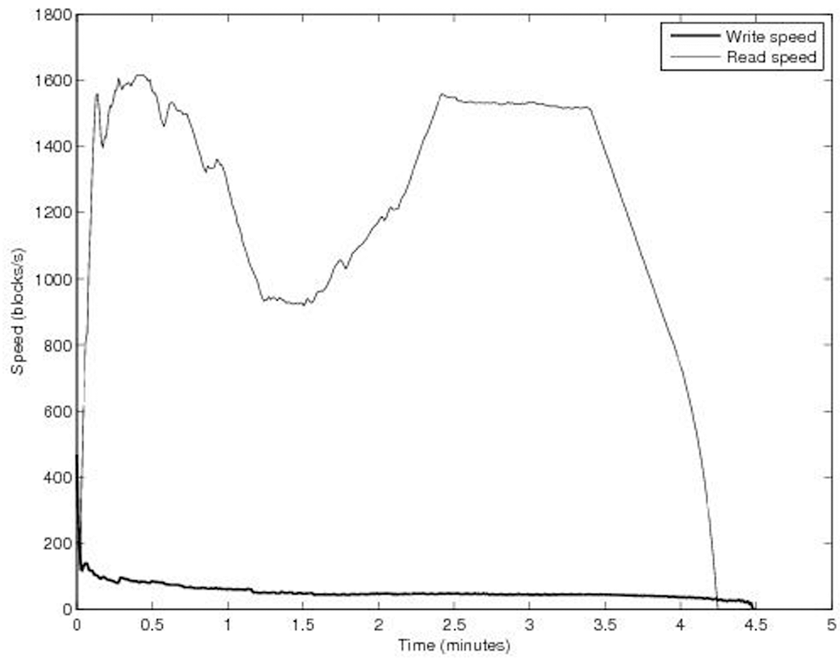

Figure 2. Memory usage of a single physics analysis job

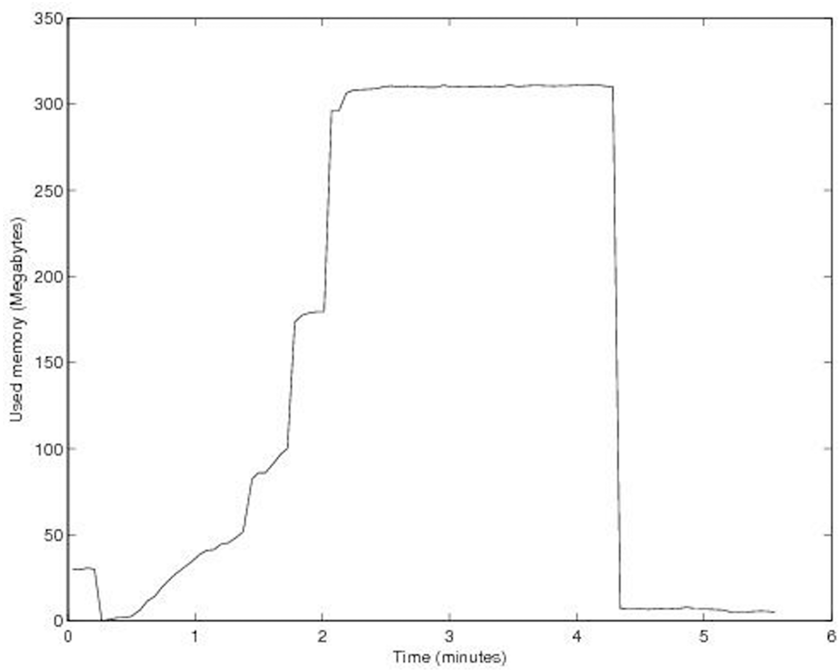


between the test sets to provide a similar environment for all the test sets. Since differences in averages among the different test sets were relatively high and standard deviation inside the sets low, this test setting gave us large enough sample size to look for statistically significant results.

TESTS AND RESULTS

We tested our hypotheses by using simplified test applications and high-energy physics applications. In the first test we compare the performance of different applications when changing the amount of parallelism. The second test shows how the performance of the I/O application varies when it is processed with a different amount of parallel tasks. The final test demonstrates that mixing different tasks (I/O and CPU oriented) can further increase performance.

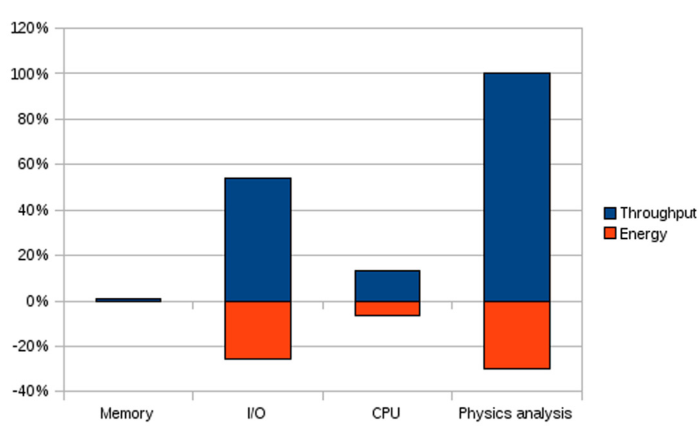
In the first test, running 3-4 tasks per CPU core yielded the best results, but the test also showed that benefit of multitasking heavily depends on the application used. If an application does almost only memory operations such as our memory test application, the benefit is almost zero. Luckily, few real applications are like this. For computing oriented CPU applications improvements are quite clear. Our first test case produced 13% more throughput, while 7% less energy was consumed. Much larger improvements are related to I/O, by processing our I/O test application using 4 tasks per CPU core setting instead of 1 task per core, improved throughput over 50% and decreased energy consumption around 25%. However, the biggest improvement gave our real physics analysis application 100% more throughput while 30% less energy was consumed. The test results are shown in Table 1 and percentile changes when comparing the best case to one task per CPU core case, are shown in Figure 3. These results validate Hypothesis 1.

The reason for the improvements is not straightforward. Intuitively one could assume that especially overloading I/O could decrease throughput.

Table 1. Test results of the first test

Test type	Jobs/core	Jobs/hour	Wh/job
Memory	1	90	2.9
	3	91	2.9
I/O	1	320	0.79
	4	493	0.59
CPU	1	407	0.6
	3	461	0.56
Physics analysis	1	188	1.1
	3	376	0.77

Figure 3. Improvements of running 3-4 tasks in parallel compared to 1 task/core



However, according to our tests, it seems to be that overloading I/O improves performance. We assume two possible reasons: 1) Overloading keeps the bottleneck busy and eliminates the total I/O waiting time in the system, and/or 2) overloading improves the efficiency of disk caches since it is more likely that some other task has already fetched the required data.

Figure 4 shows the variation of throughput and energy-consumption when processing 1 to 50 I/O tasks in a 8-core server. The difference is calculated comparing the result to 1 task per core, i.e. 8 tasks per server, setting. Each measurement was taken twice and the test application was standard physics data analysis. The figure shows that after reaching 1 task per core situation, the performance and energy-efficiency still improve almost linearly until the physical memory is full.

Our final test was related to mixing different applications in parallel processing. Since the physics analysis seemed to give the biggest benefit on multitasking, we tested the effect of mixing I/O and CPU intensive tasks by using two different physics applications: an I/O intensive data analysis and a CPU intensive simulation. We compared first processing CPU-oriented tasks and then I/O-oriented physics tasks to processing the same jobs mixed together. Figure 5 illustrates the improvements in energy consumption and throughput in these tests. The results indicated that mixing tasks using different resources clearly improved both throughput and energy-efficiency. This validates Hypothesis 2.

DISCUSSION

In scientific computing clusters, the single job (task) per core-scheduling method is mostly used. This simply means that each CPU core can run a maximum of one job. Usually the jobs are distributed equally to all computing nodes of the cluster. Instead of this common practice, we tested variations of different scheduling methods based on the idea that it is necessary to fully load computing nodes. Our tests showed that running multiple tasks simultaneously, or mixing tasks that utilize different resources, can decrease energy usage per computing task and improve throughput of the computing node when running High-Energy Physics (HEP) applications. The trade-off is that processing times of individual tasks are longer but in cases, such as HEP computing, in which the tasks are not time critical, usually only the total throughput is important. We assume that the reason for the improvement is that some component

Figure 4. Comparing performance and energy-efficiency when processing physics analysis jobs using different numbers of tasks per CPU core settings to 1 task per core setting

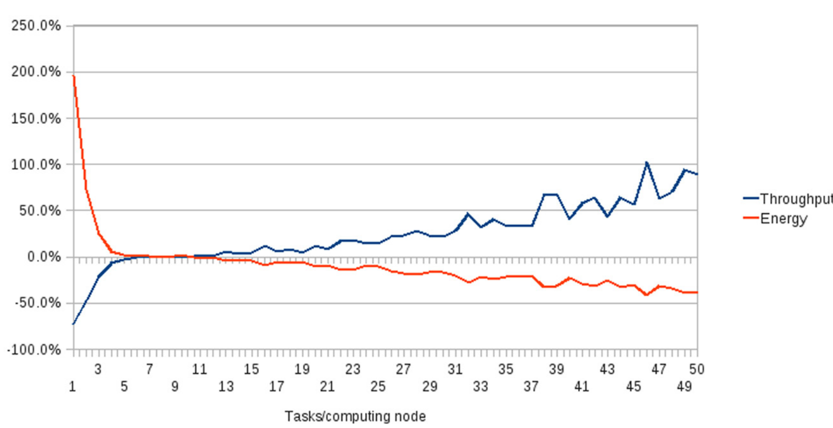


Figure 5. Comparing mixing CPU and I/O oriented physics tasks to processing first all CPU tasks

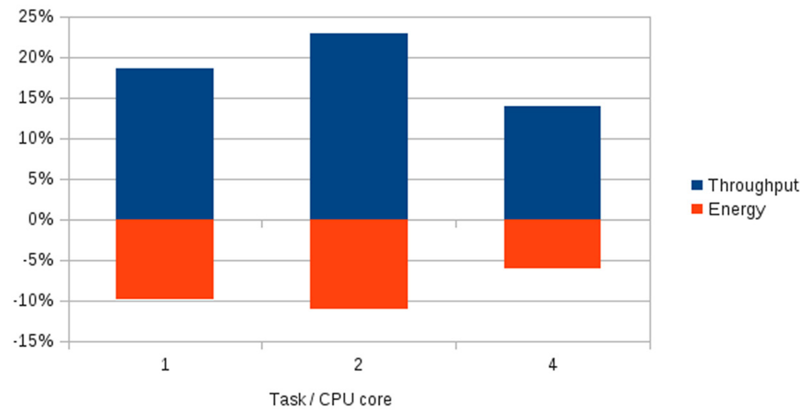

within the system becomes a bottleneck making the processor wait for some operations, causing CPU utilization to drop from the maximum 100%. Based on our tests, we can assume that I/O traffic is an obvious bottleneck.

The results are also in line with Schmenner (2010), who proposed that companies emphasizing swift even flow, i.e. they focus on speed and variability reduction, would outperform slower companies. This principle also implies that companies should focus on value adding tasks and removing of non-value adding tasks, while at the same time trying to eliminate bottlenecks in order to introduce even flow and short lead times.

Our work showed that multitasking improves efficiency in HEP data analysis but it also easily makes disk access a bottleneck. While the number of CPU cores continuously increases, I/O remains a bottleneck. Faster disks like Solid State Drives (SSD) can be used to partially remove this bottleneck, since SSD disks are clearly faster than hard disks. Our future research will also focus on this issue, and our preliminary results already confirmed this assumption (Niemi, et al., 2011). However, our results depended highly on the applications used.

Generally, value adding production systems with high throughput and short lead times have been proven to generate benefits other than pure output performance. Statistically these systems also produce better quality and less waste, and thus have a better overall environmental efficiency. Systems, which perform better operationally, also have more satisfied customers and tend to be more competitive in the market. Based on this, an optimized computing system should, in addition to reduced electricity consumption, also work more reliably and offer more computing power. When applying new optimizing methods to large scale computing resources, the results can bring remarkable savings, especially in large computing installations.

There are still several unsolved issues concerning the loading of computing resources. This chapter presented a method based on the processing of more than one task per CPU core. In this method an obvious challenge is to decide upon the number of tasks to run in parallel. Therefore, we have started to develop automated methods for dynamically finding the right settings. One method based on fuzzy control is introduced in Niemi and Hameri (2011). Another approach uses the simulation approach to test different scheduling strategies much faster than with contemporary test runs. We have developed simulator software for this purpose (Kommeri, et al., 2011).

CONCLUSION

We studied different scheduling settings with different hardware for high-energy physics computing to minimize electricity usage and maximize performance. Instead of the common practice of one task per CPU core scheduling used in many computing clusters, we tested variations of different scheduling methods based on the idea to process more tasks in parallel.

The results showed that optimizing the configuration of a workload management system by using our methods improved throughput and decreased electricity consumption. However, improvements heavily depended on the application. In a modern multicore environment running 3-4 tasks per CPU core gave the best results. The measured improvements of our methods increased throughput up to 100% and decreased energy consumption down to 40-50% compared to the standard one-task-per-core practice in scientific computing. The trade-off is that processing times of individual tasks become longer. Though in cases, such as HEP computing, in which the tasks are not time critical, the total throughput and energy-efficiency are more important. Instead, we did not find a trade-off between throughput and energy-efficiency, as in our tests the most efficient method also minimized energy consumption per processed task. As a general conclusion, our results show that information on all components of the computer, including memory usage, processor load, and I/O traffic, should be used when making scheduling decisions.

KEY TERMS AND DEFINITIONS

Computing Jobs and Tasks: A task is the smallest elementary entity when work is processed. The task starts, retrieves/reads its possible input file, processes the data, and possibly writes its output file. A job is a collection of tasks.

Energy Efficiency: Energy efficiency means how efficiently energy is used. For example how many of similar tasks or jobs that can be processed by using a fixed amount of electricity.

High-Energy Physics Computing: High Energy Physics is a discipline, which studies sub-atomic particles such as electrons, protons, and neutrons. The name "high-energy" comes from the fact that one needs very high energy in particle accelerators to separate these elementary particles apart. A lot of computing power is needed to analyze data collected by detectors in particle accelerators.

Load: Measurement of utilization of a computer. It indicates how many processes are waiting for CPU becoming available.

Scheduling: Scheduling means how to allocate computing tasks to computing nodes.

Scientific Computing Cluster: A group of computers that appears as one. They are connected via high a speed local area network. A cluster consists of at least one frontend and one too many computing nodes. The frontend is a machine that acts as a gateway and moderator for the cluster. Computing nodes are computers that do the actual computing.

Throughput: Throughput means the number of similar tasks or jobs that can be processed in a time unit.

Workload Management System: A system that keeps track of activity in a computing cluster and schedules tasks into computing nodes based on this knowledge.

ABSTRACT

Modelling and simulation of organic (polymer, dye sensitized, and nanotube) solar cells is discussed. High J-V theoretical curves, the calculation of key parameters, and also the relative influence of different parameters on the cell operation, are evidenced and analyzed. On this basis, the authors obtain information on the optimization of the solar cell design and manufacturing.

MODELING AND SIMULATION OF ORGANIC CELLS BASED ON POLYMERS

Introduction

The polymer-based photovoltaic devices present some important advantages, such as the low cost and the easy manufacturing from thin films by chemical/physical vapour deposition, screen-printing, or casting. The band gap of the films can be adjusted by chemical synthesis to convenient values and the carrier mobility can reach 10 $cm^2/V \cdot s$ (Dimitrakopoulos & Mascaro, 2001; Kwok, 2003). Therefore, the polymer-based photovoltaic cells are competitive with those based on amorphous silicon, so that the interest for both the properties of the polymer materials and the characteristics of the polymer-based cells increases.

The first structure was a Schottky diode type structure, which has a conversion efficiency under 1%. In 1986, Tang (1986) introduced the planar donor-acceptor heterojunction, which has a higher conversion efficiency. Hiramoto, Fujiwara, and Yokoyama (1991) developed this idea. Tang introduced the concept of Bulk Heterojunction—BH. Xue et al. (2005) introduced the concept of Hybrid Heterojunction (HH) with higher efficiency 5%.

DOI: 10.4018/978-1-4666-1945-6.ch104

Solar cells based on organic polymers used photoinduced transfer of electrons from semiconductor polymers, donor / acceptor polymers or acceptor molecules (such as C_{60}). Pairs of layers polymer / fullerene have a poor conversion efficiency of solar cell. Nanomorfological control at nanoscale of the separate regions in an interlaced network (BH) significantly increased the conversion efficiency of solar energy cells made of MDMO-PPV/C_{60}. Typical dimensions of the separate regions must be smaller than the exciton diffusion length. On the other hand, bicontinue percolation paths for the transport of charge carriers at the electrodes must be provided in order to increase the transport of charge carriers in organic and polymeric materials, and for mesoscopic order to improve crystallinity. So, an interlaced network at nanoscale with crystalline order of the both constituents is formed (these ones belong to individual sub-networks). Such a network is a convenient structure for the active layer of polymer PV devices. At the same time, forbidden bands of the photoactive layer materials should be chosen in order to absorb more light in solar radiation spectrum.

Using a mixture of MDMO-PPV soluble fullerene derivative (for example PCBM), it is possible to obtain solar cells with a 2.5% conversion efficiency.

It was shown (Shaheen, et al., 2001) that a conversion efficiency of 2.5% (for AM 1.5) can be obtained using chlorobenzenes as a solvent for the deposition by centrifuging in the mass ratio of 1:4 for the MDMO- PPV: PCBM. Using chlorobenzenes instead of toluene nanomorfology changes were remarked and the efficiency conversion increases 3 times. Such BH solar cells contain 80% PCBM. However, the MDMO-PPV polymer could be the main light absorber from these solar cells, because PCBM does not achieve almost no absorption in the visible and near infrared region. So an increase in volume concentration of MDMO-PPV was necessary for a better absorption of sunlight.

The electron mobility from pure PCBM is proved to be higher $(\sim 10^{-3}\ \mathrm{cm}^2/\mathrm{Vs})$ compared to the holes mobility from the MDMO-PPV $(\sim 10^{-4}\ \mathrm{cm}^2/\mathrm{Vs})$ and the holes mobility in the mixture increases with the increasing of fullerene mass, despite of the fact that the addition of fullerene introduces more defects (which would reduce the mobility).

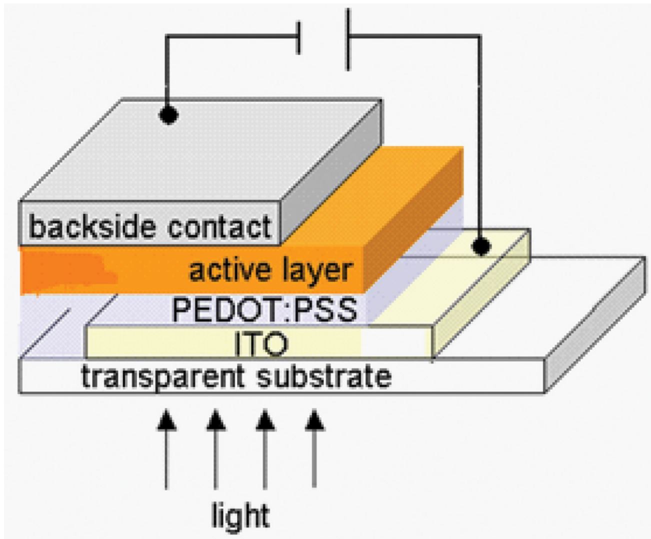
By replacing in PCBM the C_{60} fullerene with C_{70} one, the HOMO-LUMO transition would be easier and would increase the absorption of light. An improved efficiency of BH solar cells in isomeric mixture of MDMO-PPV and C_{70} derivatives was obtained (Wienk, et al., 2003). Mixtures of this kind are suitable when they are prepared from a solution of o-dichlorobenzene (ODCB) and solar cells have a conversion efficiency of $\eta = 3\ \%$ for PM 1.5.

Operating Principle of Polymer-Based Solar Cell

The process of conversion of light into electricity using a organic solar cell (Figure 1) can be plotted by the following steps: 1) absorption of a photon determining the formation of an excited state, that is, the creation of an exciton (electron-hole pair); 2) exciton diffusion to a region where dissociation occurs; 3) charge transport within the organic semiconductor to the respective electrodes.

The obtained photo-voltage is a direct result of the departure from thermodynamic equilibrium state after the movement of charge carriers, generated by solar radiation under the action of local fields, which in the case of organic semiconductors is due to the change in chemical composition. Because of the large band gap in organic materials, only a small portion of the incident solar light is absorbed. A band gap of 1.1 eV (1100 nm) is able of absorbing 77% of the solar irradiation on Earth (Nunzi, 2002). But, the majority of semiconducting polymers have band gaps higher than 2 eV (620 nm), which limits the possible harvest-

Figure 1. Schematic representation of standard bulk heterojunction solar cell



ing of solar photons to about 30% (Nunzi, 2002). On the other hand, because the absorption coefficients of organic materials are higher than 10^5 cm^{-1}, only 100 nm thickness is enough to absorb most of the photons when a reflective back contact is used.

The primary photoexcitations in organic materials do not influence directly the release of charge carriers, but determine to obtain the electron-hole pairs (it is estimated that only 10% of photoexcitations leads to the free charge carriers in conjugated polymers). For an efficient dissociation of excitons, strong electric fields are necessary.

At an interface, where sudden changes of the potential energy occur, strong local electrical fields are possible ($E = -grad\ U$). Photoinduced charge transfer can occur when the exciton has reached such an interface within its lifetime. Therefore, the exciton diffusion length limits the thicknesses of the double layers. Exciton diffusion length should be the same order of magnitude with the separation distance between donor and acceptor fields. Otherwise, the excitons recombine radiatively or non-radiatively before reaching the interface and their energy no longer contributes to solar energy conversion. Exciton diffusion length in organic polymers is usually around 10÷20 nm.

In the materials obtained by combining conjugated polymers with the acceptor materials, as fullerenes, the efficiency of converting the photogenerated excitons to free charge carriers increases. By the absorption of light in a donor an excited state from which the electron can be transferred to the LUMO unoccupied orbital of the acceptor arises. Following the transfer, the hole that appears remains in the donor material. Measurements showed that the photoinduced charge transfer in such a compound occurs in $45\ fs$, so in a much smaller time than other similar processes (e.g. photoluminescence transition lasts around 1 ns) (Brabec, et al., 2001).

Charge carriers are extracted from the device by two selective contacts. A contact of Indium and Tin Oxide (ITO) with a Fermi level of about 4.8eV matches with the HOMO levels of most conjugated polymers (contact holes), and a contact of aluminum with a Fermi level of roughly 4.3.eV matches with the LUMO of the PCBM acceptor (contact for electrons).

Theoretical Models

A number of models were developed aimed to the modeling and simulation of the organic solar cells based on polymers. Many of these models based on the diode-like equivalent circuit of a solar cell are analysing the $J-V$ characteristics; they can simulate the cell behaviour and/or evaluate their macroscopic parameters (Aernouts, 2006; Marlein & Burgelman, 2007; Marlein, Decock, & Burgelman, 2009; Greulich, et al., 2010; Chuan, et al., 2011).

In the absence of illumination typical current density-voltage characteristics of a solar cell is shown in Figure 2a; in the presence of illumination it is shown in Figure 2b.

In the following a modelling and simulation analyses is presented (Mitroi, Iancu, Fara, & Ciurea, 2010).

To represent a solar cell under illumination, an equivalent electronic circuit can be drawn as shown in Figure 3. It consists basically from a constant current source parallel to a diode. This current source is supposed to be bias independent and represents the current J_L, generated in the device due to the incoming light. Its value might thus vary according to the intensity of the illumination. A series and parallel resistance, R_s and R_p respectively, are additionally included to account for non-ideal behavior.

Under illumination the total current density is:

$$J = J_s \left\{ \exp\left[\frac{e\left(V - R_s J\right)}{\gamma k_B T} \right] - 1 \right\} + \frac{V - R_s J}{R_p} - eG\mu\tau \left(\frac{V_{bi} - V}{L} \right) \cdot \left[1 - \exp\left(\frac{L^2}{\mu\tau\left(V_{bi} - V\right)} \right) \right] \quad (1)$$

where J_s is the saturation current density, $e > 0$ is the elementary charge, V is the applied voltage, R_s and R_p are the linear series and derivation resistances, γ is the ideality factor, k_B is the Boltzmann constant, and T is the cell temperature, G is the pair generation rate, V_{bi} is the bias voltage, V is the voltage on a external resistance R_{ext}, L is the thickness of the active layer, and the product $\mu\tau$ is given by the relation:

$$\mu\tau = \mu_p\tau_p + \mu_n\tau_n, \quad (2)$$

where μ_p, μ_n, and τ_p, τ_n are the hole and electron mobilities and lifetimes, respectively. This product obviously depends on the recombination and carrier transport processes.

Figure 2. Current density-voltage characteristic in the absence of illumination

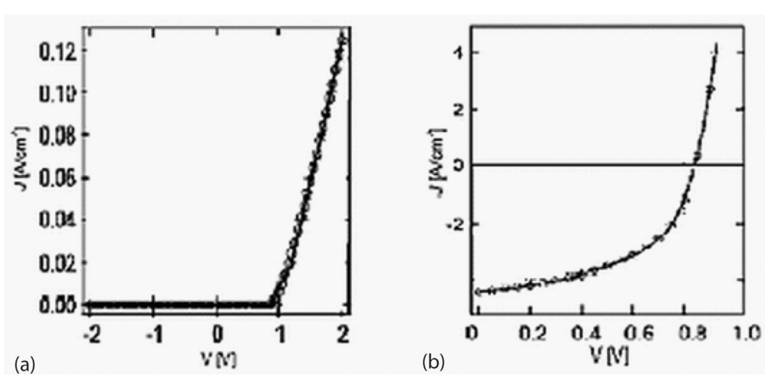


Figure 3. The diode-like equivalent circuit of a solar cell under illumination

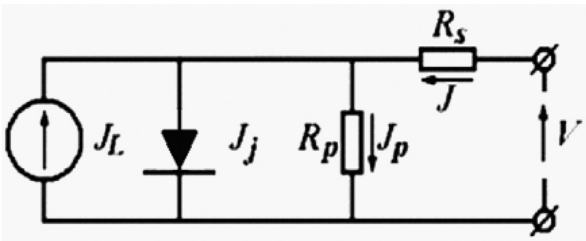


The effect of R_s and R_p on the illuminated *J-V* characteristics is shown in Figure 4.

This resistances act to reduce the fill factor, whereas very high values of R_s and very low values of R_p can also reduce J_{sc} and V_{oc}, respectively.

From the Formula (1) the following relationships results:

$$J_{sc} = J_s \left\{ \exp\left[\frac{e\left(-R_s J_{sc}\right)}{\gamma k_B T} \right] - 1 \right\} - \frac{R_s J_{sc}}{R_p} - eG\mu\tau \left(\frac{V_{bi}}{L} \right) \cdot \left[1 - \exp\left(\frac{L^2}{\mu\tau V_{bi}} \right) \right] \tag{3}$$

and

$$J_s \left\{ \exp\left[\frac{eV_{oc}}{\gamma k_B T} \right] - 1 \right\} + \frac{V_{oc}}{R_p} - eG\mu\tau \left(\frac{V_{bi} - V_{oc}}{L} \right) \cdot \left[1 - \exp\left(\frac{L^2}{\mu\tau \left(V_{bi} - V_{oc} \right)} \right) \right] = 0 \tag{4}$$

Equations (3) and (4) allow the calculation of the short-circuit current density J_{sc} and the open circuit voltage V_{oc}, respectively. Based on *J-V* theoretical curve, the Fill Factor (*FF*), and the energy conversion efficiency (η) are defined as:

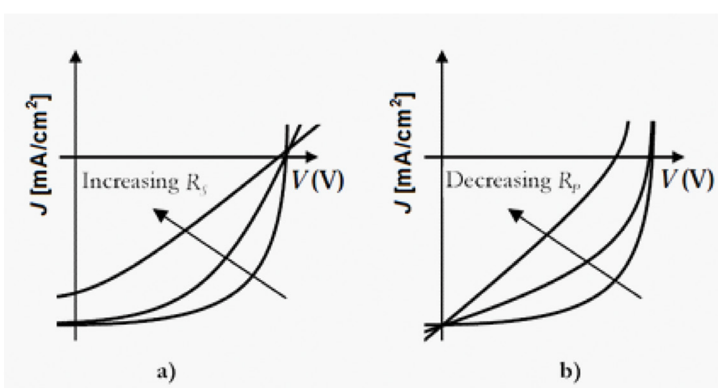
1. The Fill Factor (FF):

$$FF = \frac{V_M J_M}{V_{oc} J_{sc}} = \frac{P_M}{V_{oc} J_{sc}}, \tag{5}$$

where $P_M = V_M J_M$ is the maximum power density. V_M and J_M are the corresponding voltage and current density and they are determined from the $J-V$ curve.

2. The power conversion efficiency (□)

Figure 4. Parallel and series resistance influence on the J-V characteristic of the cell



$$\eta = \frac{P_M}{P_L} \cdot 100\ \% = \frac{V_M J_M}{P_L} \cdot 100\ \%, \qquad (6)$$

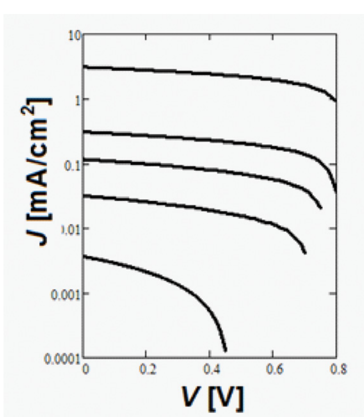
where P_L is the incident light flux power density.

Results and Discussion

The analyzed model allows the determination of the main parameters of the cell: the saturation current density J_s, the series and derivation (parallel) linear resistances R_s and R_p, the ideality factor γ, the product $\mu\tau$, the pair generation rate G, the built-in voltage V_{bi}, the short-circuit current density J_{sc}, the open-circuit voltage V_{oc}, the fill factor FF and the power conversion efficiency η. These parameters describe both the physical nature of the active layer and the technological characteristics of the cell.

From the Equation (3), one can see that J depends on seven parameters: J_s, R_s, R_p, μ, τ, γ, G, and V_{bi}. These parameters can be obtained by fitting the experimental data for the $J - V$ characteristics with this formula. These values were then introduced in the equation (8.1), and theoretical curves can be drawn (see Figure 5). Theoretical curves are obtained using the values of J_M and V_M. Then by solving the system of Equations (3) and (4), Jsc and Voc could be obtained, and by using the Equations (5) and (6) FF and η could be calculated.

Figure 5. J – V characteristics for the investigated cell



The dependences of the fill factor and the power conversion efficiency on the thickness of the active layer highlights the following results (Mitroi, Iancu, Fara, & Ciurea, 2010): the fill factor has a maximum at $L \approx 120\,\mathrm{nm}$, namely $FF_{max} \approx 44.5\ \%$, while the power conversion efficiency has a maximum of $\cdot_{max} \approx 1.22\ \%$ at $L \approx 230$ nm.

Conclusion

This model highlights the properties to be considered for improvement of photovoltaic cells based on organic polymers. Results obtained using this model are consistent with those reported in the literature (Nelson, 2003; Dennler, et al., 2006; Greulich, et al., 2010).

The model allows the determination of all the main parameters of the cell: the saturation current density J_s, the series and derivation (parallel) linear resistances R_s and R_p, the ideality factor γ, the product $\mu\tau$, the pair generation rate G, the bias voltage V_{bi}, the short-circuit current density J_{sc}, the open circuit voltage V_{oc}, the fill factor FF, and the conversion efficiency η. These parameters describe both the physical nature of the active layer and the technological characteristics of the cell. In addition, this model can determine the influence of various parameters on the total current density, fill factor and, importantly, the conversion efficiency.

The appearance of a maximum of the conversion efficiency leads to the optimization of such solar cells design and manufacturing.

MODELLING AND NUMERICAL SIMULATION OF DYE-SENSITIZED SOLAR CELLS

Introduction

Dye-Sensitized Solar Cells (DSSC) are based on sensitized nanostructures or mesoporous metal oxides. DSSC have attracted considerable attention starting from the work of O'Regan and Grätzel (1991; Grätzel, 2003).

Dye Sensitized Solar Cell (DSSC) is the only one that can offer both the flexibility and transparency.

Although, good results were obtained using DSSC both with nanostructures of TiO_2 and ZnO electrodes, ionic liquid electrolytes, carbon nanotubes, graphene and solid state DSSC (Cheng & Hsieh 2010**;** Nazeeruddin, et al., 2005; Gao, et al., 2008; Giannouli, et al., 2010; Meng, et al., 2003; Zhang & et al., 2004), maximum efficiency of such devices was only 11% (Chiba, et al., 2006), in comparison with other reported results (Zhao, et al., 1998; Contreras, et al., 1999; King, et al., 2007). These cells have potentially reduced fabrication costs in comparison with conventional silicon-based solar cells, due to the low costs of materials and the facility of the fabrication process. An optimization of DSSC requires a better insight into the interrelated processes of transport and accumulation of electrons in the mesoporous oxide phase and recombination of electrons with electron acceptors (Ferber & Luther, 2001; Knodler, et al., 1993; Smestad, Bignozzi, & Argazzi, 1994). Charge generation, transport, and recombination in DSSC are generally described by a continuity equation, in which transport is assumed to be purely diffusive, i.e. driven by concentration gradients only. However, time-dependent characterization techniques have later shown that charge transport through the TiO_2 film is impaired by multiple trapping/detrapping events (Bisquert & Vikhrenko, 2004).

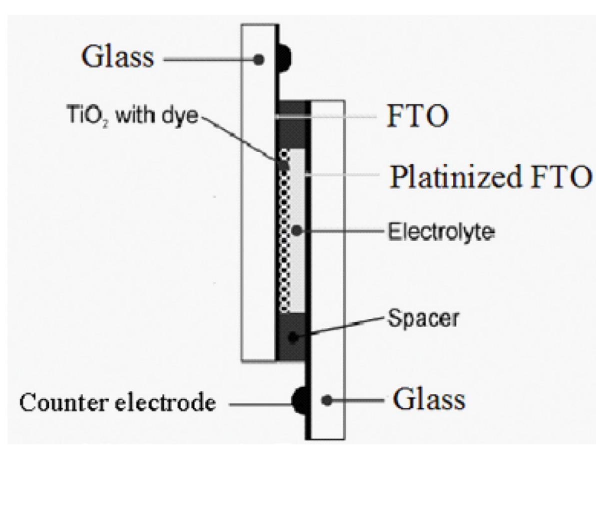
Theoretical Model

The device structure of the DSSC used in our model is presented in Figure 6. Sensitive dye solar cell is formed by a TiO_2 electrode nanopores; the pores are filled with an iodine redox electrolyte / triodura, coated with a dye that provides absorbing and transferring light task.

The two glass electrodes are made of transparent conducting electrode (fluorine-doped tin oxide, FTO). The front electrode is a transparent conductive oxide glass (FTO) coated with nanoporous TiO_2 covered with a monolayer of the Ruthenium-complex dye; the counter electrode is a FTO glass coated with a thin layer of platinum (~5 nm), where it regenerates the oxidized mediator. The gap between the two electrodes is filled by an electrolyte containing an iodide/tri-iodide (I^- / I_3^-) redox couple. Besides two different anions, the electrolyte also consists of cations being introduced by ionic liquid, usually by propylmethyl-imidazolium iodide. The cations provide electro-neutrality of the electrolyte; nevertheless they are not involved in the charge transport process in dye-sensitized solar cells.

Figure 7 shows the mechanism of a traditional wet-type DSSC containing redox couples in elec-

Figure 6. Device structure of the dye-sensitized solar cell



trolyte. Under illumination, the dye molecules become excited and initial charge separation occurs in a femtosecond time regime by injection of an electron from the dye into the conduction band of the TiO_2. This electron is transported to the external load via the nanostructured TiO_2 and TCO, while the positively charged photo-excited (S^+) dye is restored to its ground state (S) in a nanosecond time regime by receiving an electron from the iodide (I^-) (Wei, D., 2010).

Regeneration of iodide ions, which are oxidized in this reaction to tri-iodide, is achieved at a platinised counter electrode, according to Equations (7), (8), (9), (10), (11), and (12):

$$TiO_2\left|S + h\nu \rightarrow TiO_2\right|S^* \quad (7)$$

$$TiO_2\left|S^* \rightarrow TiO_2\right|S^+ + e \quad (8)$$

$$TiO_2\left|S^+ + e \rightarrow TiO_2\right|S \quad (9)$$

$$TiO_2\left|S^+ + \frac{3}{2}I^- \rightarrow TiO_2\right|S + \frac{1}{2}I_3^- \quad (10)$$

$$\frac{1}{2}I_3^- + e \rightarrow \frac{3}{2}I^- \quad (11)$$

$$I_3^- + 2e \rightarrow 3I^- \quad (12)$$

In these equations, *S* represents the dye sensitizer.

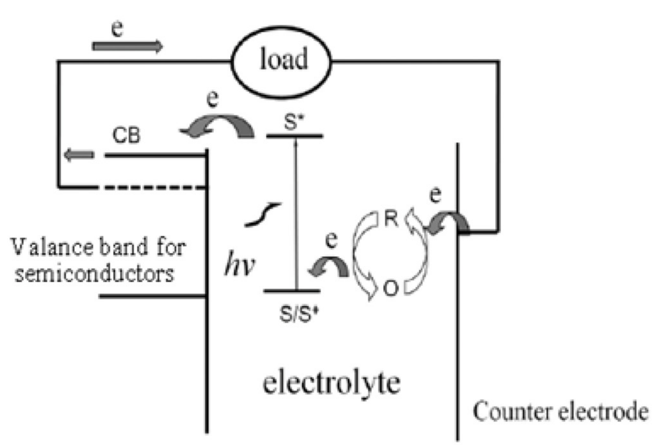
Iodide is subsequently regenerated by the reduction of tri-iodide (I_3–) at the counter electrode (Equation 12) to complete the circuit.

The Pt on the counter electrode acts as a catalyst for the reduction of tri-iodide. So far, the highest reported efficiency for a small area (< 0.2 cm^2) DSSC is 11.3%, using acetonitrile electrolytes (Grätzel, 2006) while great effort is still devoted to enhance the recorded efficiency.

Electrical Model

We will present a electric model of dye-sensitized solar cell where the active layer is modelled as a one dimensional pseudo-homogeneous layer. The electro active particles included in the model are generated by free electrons injected in nanoporous TiO_2; iodide and tri-iodide ions and cations are introduced into the cell together with electrolyte. The electrical model is based on continuity, transport, and Poisson's non-linear differential

Figure 7. The energy level scheme and the operating principle of a DSSC



equations and permits the steady-state calculation of the complete *J-V* characteristics, concentration of electro active species and their current densities in dye-sensitized solar cells (Oda, Tanaka, & Hayase, 2006; Ferber, Stangl, & Luther, 1998; Soedergren, Hagfeldt, Olsson, & Lindquist, 1994; Smestad, Bignozzi, & Argazzi, 1994).

The first important equation that connects generations and recombinations of dye-sensitized solar cell is a continuity equation for conduction band electrons:

$$-\frac{1}{e}\frac{dJ}{dx} = G(x) - R(x) \tag{13}$$

Here, *e* is the elementary charge, *x* represents the position inside the TiO_2 film thickness in interval [0, *d*], *G(x)* is the electron injection rate, determined from the optical model, *R(x)* is the recombination rate.

We assume that only electrons from the conduction band can recombine with tri-iodide in the electrolyte and that the recombination rate is linear in $n(x) - \bar{n}$:

$$R(x) = \frac{n(x) - \bar{n}}{\tau} \tag{14}$$

Here, τ is the lifetime of the conduction band electrons and $\bar{n}$ is the electron number density at equilibrium in the dark.

The movement of all four charged species in pseudo-homogeneous medium could be described by transport equations:

$$-\frac{1}{e}\frac{dJ_e(x)}{dx} = D_e\frac{d\,n_e(x)}{dx} + \mu_e\,n_e(x)E(x) \tag{15}$$

$$-\frac{1}{e}\frac{dJ_{I^-}(x)}{dx} = D_{I^-}\frac{d\,n_{I^-}(x)}{dx} + \mu_{I^-}\,n_{I^-}(x)E(x) \tag{16}$$

$$-\frac{1}{e}\frac{dJ_{I_3^-}(x)}{dx} = D_{I_3^-}\frac{d\,n_{I_3^-}(x)}{dx} + \mu_{I_3^-}\,n_{I_3^-}(x)E(x) \tag{17}$$

$$-\frac{1}{e}\frac{dJ_c}{dx} = -D_c\frac{d\,n_e(x)}{dx} + \mu_c\,n_c(x)E(x) \tag{18}$$

where D_e, D_{I^-}, $D_{I_3^-}$, and D_c are the diffusion coefficients, n_e, n_{I^-}, $n_{I_3^-}$, and n_c are electron, iodide, tri-iodide and cations concentrations, μ_e, μ_{I^-}, $\mu_{I_3^-}$, and μ_c are the mobilities of the individual charged spices, while $E(x)$ is the electrical field. Relation between diffusion coefficient and mobility of the same charged species could be described with the Einstein relation:

$$D = \frac{k_B T}{e}\mu \tag{19}$$

where k_B is the Boltzman constant and *T* is thermodynamic temperature.

Optical Model

The optical model is based on the Lambert-Beer law to determine the electron injection rate $G_e(x)$. The rate of incident photons flux is given by:

$$G_\lambda(x) = \int_{\lambda_1}^{\lambda_2} \alpha(\lambda)\,\varphi(\lambda)\exp\left(-\alpha(\lambda)\cdot x\right)d\lambda \tag{20}$$

Where λ is the wavelength of radiation, limits λ_1, λ_2 are imposed by the characteristics of absorptance α (λ) of dye used, ϕ (λ) is the incident photon flux density, and *x* is the distance from the illuminated surface of the cell to the point found inside the cell.

The incident photon flux density is reduced due to absorptance, reflectance and glass substrates

(Smestad, Bignozzi, & Argazzi, 1994), and relation (20) becomes:

$$G_{\lambda}(x) = \beta \cdot G_{\lambda}(x) \tag{21}$$

Here β is a factor that shapes the reflectance and absorptance.

The electron injection rate $G_e(x)$ is obtained multiplying the relation (21) with the injection efficiency η_{inj} :

$$G_e(x) = \eta_{inj} \cdot \beta \cdot G_{\lambda}(x) \tag{22}$$

If the quasi-equilibrium approximation is used (one single quasi-Fermi level for conduction band and trapped electrons), then, under steady-state conditions, the continuity equation does not include terms due to trapping/detrapping.

Boundary Conditions

Boundary conditions, in the integral form, are necessary to solve a coupled set of non-linear differential equations.

Conditions of preserving the total number of particles for each type of charge are:

$$\int_0^d n_c(x)dx = n_c^0 \cdot d \tag{23}$$

$$\int_0^d \left(\frac{1}{3} n_{I^-}(x) + n_{I_3^-}(x) \right) dx = \left(\frac{1}{3} n_{I^-}^0 + n_{I_3^-}^0 \right) \cdot d \tag{24}$$

$$\int_0^d \left(\frac{1}{3} n_{I^-}(x) + \frac{1}{2} n_e(x) \right) dx = \left(\frac{1}{3} n_{I^-}^0 + \frac{1}{2} n_e^0 \right) \cdot d \tag{25}$$

The boundary conditions which assure electroneutrality of solar cells are:

$$\int_0^d \left(n_e(x) + n_{I^-}(x) + n_{I_3^-}(x) \right) dx = \left(n_e^0 + n_{I^-}^0 + n_{I_3^-}^0 \right) \cdot d \tag{26}$$

$$\int_0^d \left(n_e(x) + n_{I^-}(x) + n_{I_3^-}(x) - n_c(x) \right) dx = 0 \tag{27}$$

The electric field at both boundaries equals zero, i.e.:

$$E(0) = E(d) = 0 \tag{28}$$

The electron current density at the front TCO $(x = 0)$ equals to external current density:

$$J_e(0) = J_{ext} \tag{29}$$

No electron transfer exists at $x = d$ since there is no TiO_2 layer and only a tiny bulk electrolyte layer exists:

$$J_e(d) = 0 \tag{30}$$

The opposite is true for iodide and tri-iodide ions where the iodide and tri-iodide current densities at $x = 0$ equals 0.

The cell's voltage, V, is calculated by the following relation:

$$V = \frac{1}{e}\left(E_F^n(0) - E_R(d) \right) \tag{31}$$

Here, $E_F^n(0)$ is the Fermi level of TiO_2 at the TCO-TiO_2 interface which is determined from the concentration of free electrons at TCO-TiO_2 interface $n_e(0)$:

$$E_F^n(0) = E_{CB} + k_B \cdot T \cdot \ln\left(\frac{n_e(0)}{N_{CB}}\right) \quad (32)$$

where N_{CB} is the effective density:

$$N_{CB} = 2 \cdot \left(\frac{2 \cdot \pi \cdot m_e^* \cdot k_B \cdot T}{h^2}\right)^{\frac{3}{2}} \quad (33)$$

and m_e^* is the effective electron mass, h is Planck's constant, and E_R (d) is the redox potential at counter electrode (the deviation of E_R from equilibrium value due to diffusion limitation is not taken into account).

Results and Discussion

For the numerical simulation, incident photon flux density was calculated using the global distribution of the solar spectrum type AM1.5, between the limits $\lambda_1 = 300\,nm$ and $\lambda_2 = 800\,nm$, because ruthenium was considered as dye. It was chosen because it is one of the dyes commonly used, and has values of $\alpha(\lambda)$ during the (λ_1, λ_1) range (Ferber, Stangl & Luther, 1998). The model permits the steady-state calculation of the complete *J-V* characteristic, electro active spices densities and their current densities in dye-sensitized solar cell. Such a current-voltage characteristic for illuminated DSSC is shown in Figure 8.

Using the simulated *J-V* characteristics could be determined the following parameters:

1. The fill factor:

$$FF = \frac{V_M\, J_M}{V_{oc}\, J_{sc}} = \frac{P_M}{V_{oc}\, J_{sc}}, \quad (34)$$

where $P_M = V_M\, J_M$ is the maximum power density; V_M and J_M are the corresponding voltage and current density and they are determined from the *J-V* curve.

2. The conversion efficiency:

$$\eta = \frac{P_M}{P_L} \cdot 100\ \% = \frac{V_M J_M}{P_L} \cdot 100\ \%, \quad (35)$$

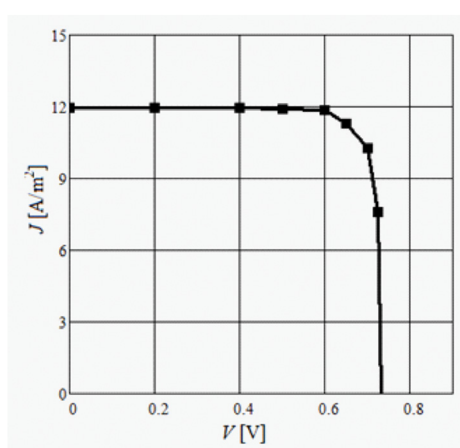
where P_L is the incident light flux power density.

Conclusion

The method allow simulated *J-V* characteristics of dye-sensitized solar cells and determination of all main parameters characterizing solar cells: the short-circuit current density J_{sc}, the open circuit voltage V_{oc}, the fill factor *FF* and the conversion efficiency η. These parameters describe both the physical nature of the active layer and the technological characteristics of the cell.

- The used method also enable to determine the influence of the different parameters of the cells on the total current density, the fill factor and, the most important, the conversion efficiency.

Figure 8. The typical simulated J-V characteristics for illuminated DSSC



- Internal electric field has low values, up to 1 mV / cm, confirming that transport tasks are carried out mainly by diffusion.
- The results based on such a model (Wenger, et al., 2009; Berginc, et al., 2009; Wenger, 2010) are consistent with theoretical results reported by different authors (Oda, Tanaka, & Hayase, 2006; Ferber, Stangl, & Luther, 1998; Oda, Tanaka, & Hayase, 2006; Ferber, Stangl, & Luther, 1998; Green, et al., 2011; Bowers, et al., 2010; Lai, et al., 2010; Agnaldo, et al., 2009; Hardin, et al., 2009; Deb, 2004; Yong, et al., 2008; Tian, et al., 2011).

NUMERICAL SIMULATION OF HIGH-ORDER TIO_2 NANOTUBE DYE-SENSITIZED SOLAR CELLS

Introduction

The electron-collecting layer in a DSSC is typically a 10 mm thick nanoparticle film, with a three-dimensional network of interconnected 15÷20 nm sized nanoparticles (Gratzel, 2004). The slow percolation of electrons (through the three-dimensional network) and low absorption of photons are two major factors which are limiting the conversion efficiency of DSSC cells using nanoparticles (Law, et al., 2005).

By using the nanotubes we could obtain a considerable increase in the photo- conversion of the DSSC. This is due to the improvement of the electrons transport in comparison to the nanoparticles one (Adachi, et al., 2010; Cummings, 2002).

In the last years, two different methods of obtaining Dye Sensitized Solar Cells have been studied (Mor, et al., 2006; Wang, et al., 2010; Flores, et al., 2007; Martinson, et al., 2007; Myahkostupov, et al., 2011), both aiming to develop new structures with improved properties in comparison with TiO_2 nanoparticles.

The arrangement of the highly ordered titania nanotube array perpendicular to the surface permits facile charge transfer along the length of the nanotube from the solution to the conductive substrate and simultaneously reduce the losses incurred by charge hopping across the nanoparticle grain boundaries (Gratzel, 2004; Law, et al., 2005; Tenne & Rao, 2004; Adachi, et al., 2003).

The enhancement in the electronic transport also allows the improved light harvesting as thicker films can be used to increase the optical density, thus improving the absorption of low-energy photons in the red and infrared without losing the additionally harvested charge carriers for recombination (Law, et al., 2005).

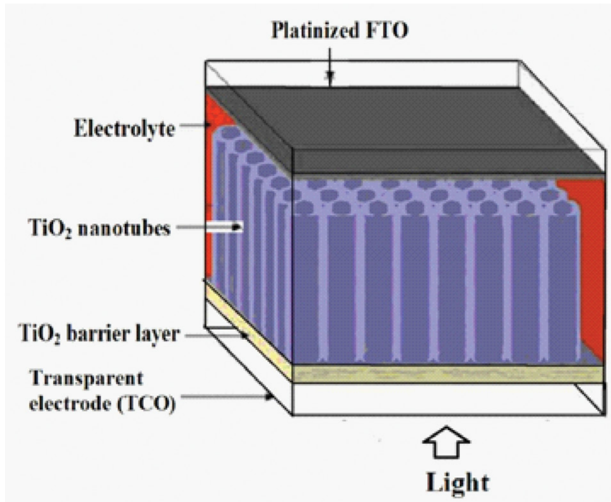
A highly-order TiO_2 nanotube dye-sensitized solar cell (Figure 9) consists of a TiO_2 nanotube electrode, coated with a suitable light-absorbing charge-transfer dye and wetted with an iodide/triiodide redox electrolyte. This compound is sandwiched between two Transparent and Conducting Oxide (TCO) glass. Usually fluorine doped SnO_2, exhibiting metallic conductivity, is used as the TCO. The TCO layer on the back glass substrate is covered with sputtered platinum, which acts as a catalyst for the redox reaction.

Theoretical Model

The simulation model (www.paper.edu.cn/index.php/default/feature/downCount/815) having a TiO_2 barrier layer, an electrolyte layer in TiO_2 nanotubes and a bulk electrolyte layer. This model introduces the TiO_2 barrier layer and the distinction between the electron transfer rate in the nanotube and in the nanoporous layer. The electrical model is based on that proposed by Ferber (Ferber, et al., 1998) and Oda (Oda, et al., 2006).

In the developed model (www.paper.edu.cn/index.php/default/feature/downCount/815), the electric field E has been ignored because of the negligible effect on charge carriers in the cell (Ferber, et al., 1998). A system of differential equations is obtained which is solved using the

Figure 9. Scheme of a cell structure with nanotube DSSC (Mor, et al., 2006)

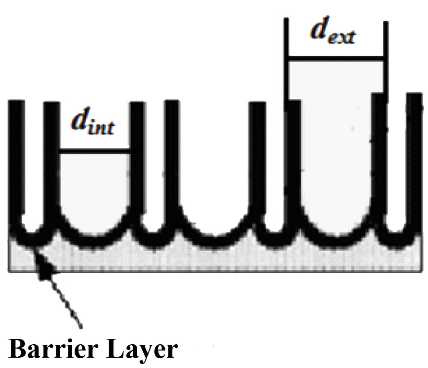


finite difference method (Ferber, et al., 1998). The equation system used in this model is very similar with the presented one. In this model, the ions n_{I^-}, $n_{I_3^-}$, and cations n_c depend on the porosity of TiO_2 nanotube layer. Figure 10 shows the view of nanotube arrays.

The porosity of nanotubes films is given by:

$$\rho_{nanotub} = 1 - \frac{V_e - V_i}{V} = 1 - \frac{\pi \left(r_{ext}^2 - r_{\text{int}}^2 \right) l}{3\sqrt{2}\ r_{ext}^2\ l} \tag{36}$$

Figure 10. Nanotube array with a corresponding top view



where

$r_{\text{int}} = \frac{d_{\text{int}}}{2}$, $r_{ext} = \frac{d_{\text{int}}}{2} + t_w$, dint = pore size, t_w = wall thickness, l = TiO_2 nanotube length

The incident photon flux density was calculated using the global distribution of the solar spectrum type AM 1.5 G, and has the value of $1000\ k\mathrm{W/m^2}$.

Material parameters are directly related to the performance parameters of the cell. The influence of the most important material parameters, such as electron mean lifetimes and mobilities, on the cell performance was investigated. The model permits the calculation of complete *J-V* curves, from which characteristical parameters of the solar cell are obtained: the short-circuit current (J_{sc}), the open-circuit voltage (V_{oc}), the fill factor (FF), and the energy conversion efficiency (η). Optimum parameters of Dye Sensitized Solar Cells based on TiO_2 nanotubes can be obtained.

Results and Discussion

The following values were obtained for characteristic parameters: $J_{sc} = 15.3\ \mathrm{mA/cm^2}$, $V_{oc} = 0.82$ V, $FF = 0.50$, and $\eta = 5.9\ \%$. These values are close to the experimental ones (Mor, et al., 2006; Wang, et al., 2010). In comparison with the present values obtained for nanocrystalline cells (Oda, et al., 2006): $J_{sc} = 16.1\ \mathrm{mA/cm^2}, V_{oc} = 0.81\ \mathrm{V}, FF = 0.72,$ and $\eta = 9.7\ \%$ the first ones are a little lower.

There are several reasons for the low efficiency of the nanotube DSSC cells:

- The used solar cells had the nanotubes of the negative electrode relatively short (of 6000 nm). This was reflected in a lower absorption than in the case of standard DSSC which have TiO_2 nanoparticles of 10 nm. It suggests the need of increasing the length of the nanotube array on the negative electrode as the amount of the absorbed dye appears to be the limiting factor.
- The low value of the form factor, $FF \sim 0.50,$ is caused by the serial resistance barrier introduced by the barrier layer thickness and poor contact between the barrier layer and FTO substrate. The annealing step used to crystallize the nanotube arrays can significantly increase the barrier layer thickness up to approximately 1 ¼m (Varghese, et al., 2003).
- The value of the conversion rate (power conversion efficiency) is influenced by the uniformity of the colorant absorbtion in the pores of the nanotube arrays. The nanotube has an array geometry which can absorb air and that is why the dye is not uniformly distributed.

CONCLUSION

Although the conversion rate of the nanotube solar cells is still low in this moment, a great potential can be foreseen.

Chapter 105
Programming Robots in Kindergarten to Express Identity: An Ethnographic Analysis

Marina Umaschi Bers
Tufts University, USA

Alyssa B. Ettinger
Tufts University, USA

ABSTRACT

This chapter presents a research program that uses robotics as a powerful tool to engage Kindergarten children in developing computational thinking and learning about the engineering design process. Using an ethnographic analysis of an experience in a Kindergarten classroom at the Jewish Community Day School (JCDS), a pluralistic school in Watertown, MA, in which children worked with robotics as a way to explore issues of identity, the chapter highlights both developmental and technological considerations that need to be addressed when engaging young children with robotic activities. This project used an innovative hybrid tangible programming system composed of interlocking wooden blocks, called CHERP, specifically designed to meet the developmental needs of young children. While many robotic programs highlight building aspects and their relationship to engineering education, the approach presented in this chapter complements this by focusing on programming by teaching powerful ideas from computer science at a very early age.

DOI: 10.4018/978-1-4666-1945-6.ch105

INTRODUCTION

Typically, "robotics" brings to mind metallic human-like contraptions wired with complex electronics. However, this chapter describes an experience in which simple Lego-based robotic cars were programmed by Kindergarten children with smart wooden blocks using CHERP (Creative Hybrid Environment for Robotic Programming), a developmentally appropriate tangible language (Horn, Crouser & Bers, 2011). This work was inspired by the realization that in the early grades, children learn very little about engineering and technology. Just as it is important to begin science instruction in the early years by building on children's curiosity about the natural world, it is as important to begin engineering instruction and the development of technological literacy by building on children's natural inclination to design and build things, and to take things apart to see how they work (Bers, 2008; Petroski, 2003). Robotics is a wonderful platform that taps into what is unique to today's human-made world: the fusion of electronics with mechanical structures.

With the growing popularity of robotics, the use of educational robotic kits and programming languages for controlling the robot's behaviors is becoming widespread in high schools, middle and elementary schools (Rogers, Wendell & Foster, 2010). In order to bring robots to "life" children must create computer programs—digital artifacts that allow robots to move, blink, sing, and respond to their environment. Previous research has shown that children as young as four years old can understand the basic concepts of computer programming and can build and program simple robotics projects (Bers, 2008; Cejka, Rogers, & Portsmore, 2006; Bers et al, 2006; Bers & Horn, 2010; Kazakoff & Bers, 2010; Bers, 2010a). However, young children need to work with interfaces that are developmentally appropriate. The robotics-based programming language we used, called CHERP, is such a tool and was developed by Bers and her DevTech research team at Tufts University (Horn et al., 2011). Rather than writing computer programs with a keyboard or mouse, the CHERP system allows children to instead *construct* physical computer programs by connecting interlocking wooden blocks. CHERP is described in the following section.

This chapter takes an ethnographic approach to analyze and describe the learning experience of 23 Kindergarten students who participated in a month long robotics curriculum called TangibleK, developed by the DevTech research group at Tufts University with funding from the National Science Foundation. The TangibleK curriculum, which utilizes CHERP to teach robotics and computer programming concepts to Kindergarten students, was adapted and extended to explore issues of identity at the pluralistic Jewish Community Day School (JCDS) in Watertown, MA. While the TangibleK curriculum encourages cognitive development in such areas as logical and sequential thinking (Kazakoff & Bers, 2010), the overarching project goal at JCDS was not only to engage children in learning about robotics, but also to provide them with robotics as a different medium, to express their explorations of identity in a creative way.

We collaborated with JCDS Kindergarten teachers to incorporate the TangibleK curriculum into the class' end-of-year project that encouraged the students' reflection of their accomplishments during the school year and their developing sense of self. This culminating project was called *Mi Ani* ("Who am I," in Hebrew). The extension to the TangibleK curriculum for the *Mi Ani* project focused on the creation of robotic artifacts and programmed behaviors to express the kindergartners' individual Jewish identities. Because the medium of robotics allows the display of actions, as opposed to static facts, children chose to create robots enacting behaviors that are related to their different ways of being Jewish. For example, one student programmed his robot to spin to represent lighting the Hanukkah menorah, while another programmed hers to roll back and forth, mimicking rolling out dough for Passover matzah. The robots created by the children represented a sense of dynamic identity, "chosen" by the children. The dynamic process that enhanced the conceptualization of identity involved engaging children in deciding how to make their robots, what aspects of their Jewish identities to convey through them, and how to program them to respond to certain events in the Jewish calendar (Libman, 2011; Bers & Urrea, 2000).

CONTEXT OF STUDY

Setting

At JCDS, 23 children in the *Gan Nitzan (Kindergarten)* class participated in the Mi Ani project using the TangibleK robotics curriculum developed by the DevTech team at Tufts University (Bers, 2010b). The philosophy of the school is one that supports progressive, child-centered learning styles, which provided a welcoming environment for the TangibleK curriculum. The school is philosophically committed to intentional pluralism, meaning that it actively embraces children and families with a wide range of Jewish expression, practice, and belief. Pluralism at the school extends beyond variations of Jewish religious affiliation. For example, the school's curriculum embraces differentiated instruction, celebrating the diversity of learners represented within the school's community.

Gan Nitzan is a combination of the Hebrew words *gan*, meaning 'Kindergarten' or 'preschool' and *nitzan,* meaning 'flower bud'. The Kindergarten has full days of school Monday through Thursday (8:00 am to 3:30 am) and a shorter day on Fridays (ending at 2:00 pm) in anticipation of *Shabbat*, the Jewish Sabbath. The Kindergarteners have two main teachers, and often an assistant teacher as well, to achieve a low student-teacher ratio. The *Gan Nitzan* classroom balances a developmentally sensitive academic structure with an emphasis on supporting the Kindergarteners' creativity and individual learning styles. The main curriculum integrates academic studies with Judaic studies, and fosters respect for multiple perspectives while promoting curiosity and a passion for learning. The main curriculum comprises English literacy studies, integrated Hebrew lessons, *Humash* (Bible) study, math, science, and social studies. Specialists also teach several additional subjects: physical education, art, music, Israeli dancing, and movement (a class that promotes body awareness). Of note, each grade at the JCDS has an overarching "central subject" that shapes all main areas of their curriculum. The Kindergarten's central subject is "Cycles", which is explored across multiple domains, such as the study of the cyclical Jewish holidays, the life cycle of plants and butterflies, and recognition of patterns in stories. *Gan Nitzan's* final project, *Mi Ani*, highlights the cyclical nature of time while celebrating the self-reflection of the Kindergarteners' experiences throughout the school year.

The *Mi Ani* project lasted for a period of one month and culminated in a final open house for family and friends where children presented their robots. One of the two main classroom teachers, who was trained in the technology by the DevTech Team, and two DevTech researchers, were in charge of classroom instruction. The curriculum that formed the foundation of the *Mi Ani* project was implemented in two stages. First, children were introduced to the robotic technology and the CHERP programming language by engaging with the TangibleK curriculum. This curriculum taught children computer programming and engineering concepts and provided a structured way for children to put those concepts to use by engaging in small-scale activities and challenges. Once children mastered the basics of programming and building robots, the second part of the curriculum focused more specifically on the *Mi Ani* project. Together with their teachers, children reflected on their experiences and learning during the year, coming up with a timeline consisting of the differ-

Figure 1. A section of the timeline of the Kindergarten year

ent activities, during each academic month, that were meaningful to them (see Figure 1).

Each child chose three moments in the year as "stations" at which his or her robot would stop and perform a program to represent the child at that given moment. For example, one child programmed his robot to stop along the timeline at November, spinning to represent eating turkey on Thanksgiving, while another programmed her robot to sing at December to show singing Hanukkah songs. The children decorated the robots to represent their self-identities, using art materials to depict them, their interests, and their characteristics. For example, one child decorated her robot with drawings of all her favorite sports, while another molded a clay image of herself that she attached to the top of her robot. Finally, children combined their three robot programs from individual moments in the year into one comprehensive program, which represented their journey throughout the year. Each child programmed his or her robot to travel alongside the timeline, demonstrating the children's own understanding of significant moments of their experience throughout the year.

CHERP in the Classroom

The teachers created an environment that emphasized an engineering mindset, with a focus on teaching the Engineering Design Process and with the impetus to engage Kindergarteners to consciously take on the identity of engineers. Students were immersed in a community of engineers that shared a set of core values, knowledge, skills, and identities. At the introduction of the TangibleK curriculum, the Kindergarteners were explicitly introduced to the Engineer Design Process, which was presented to the class as a visual web that cycled through the five steps: *ask, imagine, plan, create, improve*. The teachers discussed and provided examples for each step, emphasizing that the students would become engineers when they engaged in the process of designing and programming their own robots.

After about one week of lessons on sturdy building with Lego blocks and understanding what a robot is, the children were actively taught the robotics technology. The TangibleK program uses CHERP in combination with different robotic kits. For this project we used the Lego MINDSTORMS® RCX brick, an embedded micro-computer or the "robot brain". The programs children created with the CHERP tangible blocks were downloaded to the Lego RCX brick using infrared. The CHERP programming language draws on work from the field of human computer interaction (HCI) on tangible interfaces that shows that we can overcome the inherent limitations of writing computer programs with a keyboard or mouse, by offering tangible systems (Blikstein, Buechley, Horn & Raffle, 2010). Tangible languages, instead of relying on pictures and words on a computer screen, use physical objects to represent the various aspects of computer programming. Users arrange and connect these physical elements to construct programs. Tangible languages exploit the physical properties of objects such as size, shape, and materials to express and enforce syntax. This is crucial when working with Kindergarten age children who might not have developed the motor skills to work with a mouse interface or who might need physical objects to manipulate in order to

Figure 2. The CHERP language developed at Tufts University. Children construct programs for their robots using interlocking wooden blocks.

understand abstract concepts (Horn et al, 2011; Bers & Horn, 2010).

With the CHERP system, young children can transition back and forth between using interlocking tangible wooden blocks, or onscreen programs using the same icons that represent actions for their robots to perform (see Figure 2). This hybrid approach allows children to work with multiple representations (Horn et al, 2011).

CHERP uses a collection of image processing techniques to convert physical programs into digital instructions. A standard webcam connected to a desktop or laptop computer takes a picture of the program. A compiler converts the picture into digital code that gets downloaded to the robot in a few seconds.

Children worked in eleven pairs, while one child worked alone. This set-up fostered the potential for collaboration and social development along with cognitive gains. Each group shared an RCX brick to build a car, onto which they connected two Lego motors and wheels and a "leg" in the front to keep the base upright. Each pair also had a mini laptop station set up with the CHERP software, a webcam to scan in the wooden block, and a Lego tower to upload the programs to the RCX brick. Large bins of Legos and CHERP wooden blocks were available on the rug to be shared by all of the students.

TangibleK Curriculum: Introduction to Programming

The overarching goal of the TangibleK curriculum is to introduce young children to computational thinking. Computational thinking is a type of analytical thinking that shares many similarities with mathematical thinking (e.g., problem solving), engineering thinking (designing and evaluating processes), and scientific thinking (systematic analysis). The foundation for computational thinking is abstraction – abstracting concepts from cases and evaluating and selecting the "right" abstraction. It relies on selection of inputs (manipulation of variables and computational instructions), observation of outputs (outcome data), and decomposition of what happens in between. Computational thinking is about the ability to abstract from computational instructions (programming languages) to computational behaviors, to identify potential "bugs" and places for errors, to decide what details among the input-computation-output algorithm to highlight and retain and what details to discard (Wing, 2006).

The term computational thinking grew out of the pioneer work of Seymour Papert and colleagues on design-based constructionist programming environments, to refer to ways to algorithmically solve problems and to the acquisition of technological fluency (Papert, 1980; Papert, 1993). Previous work on young elementary school-aged children and computational thinking can be found in the research literature on constructionist programming environments (Repenning, Webb, & Ioannidou, 2010; Resnick, Maloney, Monroy-Hernandez, Rusk, Eastmond, Brennan, et al., 2009, 2009). Wing (2006) describes computational thinking as a fundamental skill for everyone, not just for computer scientists.

In order to engage children in computational thinking, the TangibleK curriculum focuses on the

Table 1. The six powerful ideas of the TangibleK program

Powerful idea	*Definition*	*Activity*	*Discipline connections*
Robotics	The engineering discipline that focuses on the creation and programming of robots, machines that can follow instructions and move on their own to perform tasks.	*What Is a Robot?* After an introduction to robotics by looking at different robots and talking about the functions they serve, children build their own robotic vehicles and explore their parts and the instructions they can use to program them.	• Engineering • Computer Science
Engineering design process	A process used to develop products to solve a need or problem. It has several iterative steps: identifying a need or defining the problem, doing research, analyzing possible solutions, developing the product, communicating and presenting the product.	*Sturdy building:* Children build a non-robotic vehicle to take small toy people from home to school. The vehicle needs to be sturdy as well as perform its intended functions.	• Engineering • Computer science
Sequencing / control flow	A sequence of instructions can be described in a program and acted out in order by a robot. Each block has a specific meaning. The order of the blocks is important.	*The Hokey-Pokey:* Choose the appropriate commands and put them in order to program a robot to dance the Hokey-Pokey.	• Creative storytelling • Organization of ideas • Mathematical proofs • Procedural thinking
Loops and Parameters	A sequence of instructions can be modified to occur over and over again. Control flow commands can be qualified with additional information. For example, loops can be modified to repeat forever or a concrete number of times.	*Again and Again until I Say When:* Students use a pair of loop blocks ("repeat" / "end repeat") to make the robot go forward again and again, infinitely and then just the right number of times to arrive at a fixed location.	• Cyclical events in nature • Scheduling • Timing and control • Feedback loops • Number sense
Sensors	A robot can use sensors, akin to human sense organs, to gather information from its environment. Sensor information can be used to control when the robot follows given commands.	*Through the Tunnel:* Children use light sensors and commands to program a robot to turn its lights on when its surroundings are dark and vice versa.	• Scientific observations • Cause and effect • Sensors (both human-made and natural)
Branches	At a branch in the program, a robot can follow one set of commands or another depending on the state of a given condition.	*The Robot Decides:* Students program their robot to travel to one of two destinations based on light or touch sensor information.	• Cause and effect • Sensors (both human-made and natural)

following powerful ideas: robotics, engineering design process, sequencing and control flow, loops and parameters, sensors and branches. See Table 1 for descriptions of these.

The TangibleK curriculum is designed for a minimum of 20 hours of classroom work, divided into the following structured sessions based on the six powerful ideas identified above:

1) Sturdy building (the engineering design process);
2) What is a robot? (robots have special parts to follow instruction);
3) Hokey-Pokey: sequence of commands (the sequence or order of commands matters);
4) Again & Again Until I Say When (loops and number parameters);
5) Through the tunnel (sensors and loops) ; and
6) The robot decides (sensors and branches).

In the first phase of the curriculum, the teachers taught the CHERP system one lesson at a time, with directed challenges following the teaching of each new type of block representing an action. One of the first lessons challenged the children to make their robots dance the "Hokey Pokey". This required mastery of the CHERP syntax and the sequential nature of computer programming. For example, the "Hokey Pokey" program used the following sequence of commands:

"BEGIN/FORWARD/BACKWARD/FORWARD/SHAKE/SPIN/END".

The robotics terms were taught by comparing electronic parts to human body parts, such as the "ear" of the robot that receives the signals of the program from the computer tower. During one morning meeting, a teacher led a very successful game where a student acted out his own program and the class had to guess what the program blocks were. Bodrova and Leong (2007) emphasize play as the time when most learning takes place, in particular during cooperative dramatic play, which involves taking on different roles. Activities in which the children and robots took on each other's roles likely allowed the Kindergarteners to better learn how the robots work through a sort of dramatic play.

ETHNOGRAPHIC ANALYSIS OF ROBOTICS EXPERIENCE

Our methodology for this ethnographic study involved the full immersion of the ethnographer into the *Gan Nitzan* classroom during the month of the TangibleK curriculum. The ethnographer was introduced to the class as an assisting member of the DevTech research team, and was familiar with the TangibleK technology and software so that she could actively participate in the curriculum. She worked with the students throughout the curriculum and conducted face-to-face interviews with the children as they developed their robotics skills and projects. Observation notes were compiled each day along with frequent audiovisual documentation, and the ethnographer helped administer the post-curriculum assessments of the students at the

Figure 3. The CHERP program for performing the "Hokey Pokey" dance, as it would appear on the graphical computer interface

end of the curriculum. During robotics lessons, the ethnographer was free to navigate the classroom to observe, interview, and offer help to those students who needed it. The role of the ethnographer as an active participant in the classroom allowed her to form positive relationships with the children and to experience each phase of the curriculum from their perspectives.

Programming Challenges and Learning to Fail

As the children were introduced to complex blocks, the programming challenges became more difficult and children faced confusion and frustration as they began to deal with many more failures than successes. For example, one of the later lessons exposed the children to light sensors and light bulbs that can connect to the robot brain. One of the head JCDS teachers began the lesson asking the children to think about how we would tell whether it is day (light) or night (dark), highlighting the comparison between the robots' light sensors and our eyes. This attribution of human characteristics to the robot parts again allowed the children to easily grasp the concept of the light sensors. Utilizing this new material and building upon the repeat loops from the previous lesson, the challenge of the day was to create a program that took their robot down a straight "street" and through a dark tunnel, turning on its light when it was inside the tunnel, and then back off when it reached the other side. This challenge was certainly more complex than previous ones because it necessitated repeat loops with light sensors as the parameter, a novel combination that was not explicitly modeled for the children.

Perhaps because of the steady pace at which the curriculum was moving, most children were not yet comfortable enough with the repeat loops to manipulate them for such an abstract challenge. Without being able to work from a model, many children began the challenge with little direction and were easily distracted by their classmates. Subsequent prompting from the teachers did provide some scaffolding for a few students to come close to solving the challenge, but for the first time the majority of students were not successful. Many children were still unsure of how exactly to use the repeat loops, especially with qualitative rather than quantitative parameters.

As a result, the class did not necessarily master the conceptual content, but the lesson was crucial in establishing the mindset that initial failure is acceptable. The students were always encouraged to continuously test out their robot and modify their program, following the Engineer Design Process, but this was one of the first challenges in which there were multiple solutions and many more opportunities for trial and error. A compounding difficulty was that the light sensors themselves proved finicky and resulted in a false negative feedback for most of the students when they tested their robot's performance of the programs.

During the last few minutes of the robotics period, the teachers led "Technology Circles" for the students to share their programs and talk about their successes and difficulties. The teachers made sure to emphasize that it was okay to have to keep on trying and that even our robots did not work perfectly with the light sensors. Remarkably, a few pairs did create working programs by the end of the day, and the rest at least learned a valuable lesson in emotional regulation and perseverance.

Mastering Concepts of Computer Programming: Earning "License"

Once the children had learned the robotics content, the second phase of the curriculum was a final project for children to explore how to express, through their robots, a sense of Jewish identity. The Mi Ani (Who am I?) project allowed the children to use their knowledge of robotics creatively to design and program personalized robots representing their own journeys through the school year. Each individual robot would traverse a linear timeline of large "month" posters filled with photographs of the students from each month of the year and would stop at three months of the child's choice. At each point, the robot would perform a series of actions that corresponded to the child's interpretation of a memorable school event that month. Here the students were given an open-ended opportunity to express their identities and experiences, and were encouraged to be creative, playful, and imaginative. In some ways, the thought process shifted here from the traditional Engineer Design Process to the Creative Thinking Spiral (imagine, create, play, share, reflect), which emphasizes imagination and reflection over solving a problem (Resnick, 2007).

Before the Kindergarteners began their final projects, they were required to demonstrate essential robotics and programming tasks to a teacher in order to earn their "licenses". Since we had observed that many students still had not grasped some of the robotics and programming concepts or relied on their partner for programming their robot, the teachers decided to use the license as an individual assessment method and right of passage to being able to progress to the Mi Ani projects. The students received stickers on notecards for successfully completing such tasks as building a sturdy robot, connecting wires correctly, creating a working program, and uploading the program to the robot. Having concrete tasks presented step-by-step and with immediate gratification dramatically improved the Kindergarteners' motivation and performance. In contrast to most other lessons, almost every student remained on task until she had completed her license, and most partners were able to negotiate taking turns with the robot, even when they had not worked well together in the past.

The licenses proved to be a wonderful assessment tool to ensure that everyone was at least at a baseline understanding of the robotics and to boost the students' confidence and motivation with a sense of personal achievement and mastery. It is worth noting that at the beginning of the curriculum, most students were drawn to the blocks as their choice of interface, but by the time they arrived at the license phase, every student had switched over to the graphical interface to complete the tasks. Perhaps the tangible blocks was the appropriate interface to initially transition the Kindergarteners to robotics because the coded blocks closely resembled familiar toys they were used to playing with. However, once the students were comfortable enough with the abstract concepts of programming, they likely favored the graphical interface because of its convenience. This switch is significant because it suggests that the Kindergarteners had achieved a sense of symbolic representation – they could view the 2-dimensional squares on the computer screen as abstract representations of their 3-dimensional tangible blocks.

Mi Ani?: Personalization and Mindful Planning

Once the children were cleared to start their Mi Ani projects, they were shown how to change the "channel", or program number, on the RCX so that each partner could create and upload his separate program onto different memory slots in the same robot. To further provide the students with a sense of identity and ownership for their robots, each child created her own platform reflecting her identity, which she would secure to the robot when running her program. The students were provided with a wide range of arts and crafts materials, including Plasticine modeling clay, paper, markers, colored wires, and Lego with which to design their platforms. The platforms provided an opportunity to combine robotics with traditional arts and crafts materials and were also key to the children's sense of ownership and personal investment in their projects. The children utilized diverse designs and materials, with images ranging from favorite foods, animals and colors to symbols of their religious identity, such as Jewish stars. Many students also drew JCDS signs, demonstrating a strong sense of community and close identification with their school.

The children brainstormed significant events and activities from each month of the school year with their head teachers, looking at photographs that the teachers had taken to document their experiences. Each child eventually chose three favorite events from different months and filled out her own design journal to plan out their robot's program by gluing down paper cut-outs of the blocks. The design journals also contained the child's explanation of the chosen event and the meaning behind the robot's actions. Although most of the students' programs inevitably changed from the original plan, the design journals were extremely helpful in making the programming stage more efficient because students had already formulated ideas before sitting down at the computer. The guiding questions in the journal also emphasized the reflective nature of the project, helping the students remember that their programs needed to be thoughtfully and meaningfully planned.

For the week leading up to the Mi Ani final presentation, students moved between several stations: choosing photos to decorate posters for the months, working on design journals, and programming their latest event. As the children began programming their robots, most of them opted for simplicity until they were urged to revise or modify their programs by a teacher. For example, students would put a series of five forwards in a row instead of using only three blocks in a repeat loop to achieve the same motion (REPEAT/5/FORWARD). Once prompted by a teacher or researcher, most of the children demonstrated sufficient knowledge of how to utilize the repeat blocks.

The personal investment that children had in their Mi Ani projects motivated each student to put more effort into her own robot and program than they had for previous lessons with their partners. Although many students noticeably developed more self-regulation and patience in the face of obstacles over the course of the curriculum, their personal interest in their project's success sometimes made failures more devastating.

Student Achievements in Expressing Their Identity through Robotics

Overall, the students came up with thoughtful programs and indicated that they had sufficiently internalized the robotics concepts to create meaningful robotic avatars of themselves. The children were able to narrate and explain the programs they had created to make their robots stop and perform actions that represented experiences they remembered from the school year. For example, one girl explained that "In September, on the first day of gym, [my robot] shakes…It's not letting anyone tag it." Through her narrative, this child demonstrated her understanding that her robot's programmed actions represent a memorable event in one of her favorite classes, and that this event can be narrated like a story.

Another student demonstrated her conceptual integration of the robotic program and her self-representation by personally acting out some of her robot's actions as she watched it move, such as shaking her head with the robot's shaking motion. Her creative narration also indicated a thoughtful intentionality in the program she created ("So in September, I was looking for my name [tag] so I turned. I put my light on and off because I was like, 'Bingo'"). Her use of the first person for her robotic avatar emphasized her internalization of its representational function.

The programs represented a creative combination of actions and emotions (Libman, 2011). In addition to the concrete use of actions, such as "sing" to represent singing a favorite Hebrew song, one student used "spin" to show her excitement at meeting a favorite teacher, while another student's robot moved forward and backward to represent her rolling pin flattening dough for matzah. A few exceptional programs were even more abstract, representing students' emotions using symbolism and imagery. For example, one boy's robot shook and then spun to represent the overwhelming experience of tasting a bitter lemon during Citrus Fruits Explorations. Another child created a program to turn the robot's lights on and off at the stop for her birthday celebration to represent the metaphoric idea of her eyes "lighting up" in excitement.

Overall, one of the most challenging aspects of the project emerged after all three stops were programmed separately: the children had to compile their three programs into one long journey, arrange their events chronologically and get their robots to travel the correct distance (and in a straight line) between each event so that it stopped at exactly the right months. This required extensive trial-and-error, with the children programming a certain number of forwards, testing out their robot with the line of posters representing the months of the year, and modifying the programs accordingly.

This task proved quite challenging for many of the Kindergarteners, because they did not yet possess the estimation skills to guess how many forwards would correspond to a certain distance for the robot to travel. An unrelated complication was that the robots themselves did not travel exactly in a straight line, and required the children to closely follow them, nudging them in the right direction every few seconds. Between hitting the wall or being nudged too forcefully, robot wheels and platforms would often fall off in the testing phase, which caused significant delays in the program revision process.

On the final presentation day, parents and relatives of each child were given a handout of the child's explanations of each event and program. The handout considerably helped to orient family members, as many of the Kindergarteners were not yet able to coherently verbalize their projects. The parents were amazed to see their child's robot travel the poster time line "by itself" and the students showed a clear sense of pride and confidence in demonstrating and explaining their robot's behaviors to their families. Interestingly, some students narrated their robot's journey in the third person ("My robot is doing…") while others used the first person ("Now I am going…"). This difference suggested a developmental divide between those Kindergarteners who had grasped the representational concept of the Mi Ani project and fully identified with their robot, as opposed to those who considered their robot a third party that was simply duplicating their past actions.

Post-Curriculum Assessment

Children were assessed on the thoroughness of their understanding and application of core concepts and skills using the TangibleK assessment form, a 6-point Likert scale. See Table 2 for the interpretation of each point of the scale.

This assessment tool evaluates concepts and skills derived from programming the robots as part of the TangibleK curriculum. For each of the curriculum's six activities (defined in Table 1), the children were presented with a series of tasks involving either verbal explanation or physical manipulation of the robots or the programming blocks. Their responses were systematically coded using the above Likert scale for demonstrated understanding and implementation of a set of core concepts relevant to each particular curriculum unit. For example, for the "Loops and

Table 2. Definition of the six points of the Likert scale used in the TangibleK assessment form

5	4	3	2	1	0
Complete Achievement of goal/task/understanding	Mostly Complete Achievement of goal/task/understanding	Partially Complete Achievement of goal/task/understanding	Very Incomplete Achievement of goal/task/understanding	Did Not Complete goal/task/understanding	Did not attempt/Other

Parameters" unit, a student might be asked to arrange a set of programming icons to tell the robot to turn four times. To code the student's response, a Likert score would be determined for each of several core concepts, including "Knows when and how to use Repeats," "Selects the right instructions," and "Arranges instructions in the correct order." If applicable, the student's debugging skills for each set of tasks would be evaluated by generating Likert scores for core concepts such as "Recognizes incorrect instructions" and "Attempts to solve the problem."

Many children in the class achieved a high level of comprehension in the application of the powerful ideas related to robotics and programming over the course of the curriculum's six activities and culminating in the Mi Ani project. Regardless of how completely they understood the more abstract concepts of the project, the Kindergarteners showed confidence in their programming skills during post-assessments ("This is so easy"; "I already know I did it right"), even if they actually made a few mistakes in terms of programming syntax. Nonetheless, it was clear that by the completion of the curriculum all of the children understood the logic of the program blocks they were taught.

In the first three curriculum activities, which introduced the engineering design process, robotics, and control flow by sequencing instructions, children's levels of achievement on most skills were particularly high (77% on average achieving "complete" or "mostly complete" understandings). One notable exception was the connection of robotic parts (i.e. connecting tiny wires) which was more difficult for small hands (achievement level was 44% on this task). In the last three activities, which introduced the more sophisticated programming concepts of loops and parameters, sensors, and branches, fewer children (41%, on average) attained the same high level of understanding.

For instance, more children achieved the highest scores on properly sequencing instructions when the programming activities involved only action instructions (71%) as compared to activities which necessarily involved the conceptually and functionally more complicated control flow instructions, or sensors (44%). Programs that use special control flow instructions look linear, but the robot does not carry out one action per programming block, as it does with a program containing only action instructions. This introduces a conceptual complexity to programming with control flow instructions that does not exist with action instructions alone. These differences in achievement reflect the relative theoretical difficulty of each programming structure, with conceptually simpler structures being more conducive to understanding than more complex ones.

The fact that fewer children achieved the highest levels of understanding on more complex topics than on the introductory concepts might indicate that more time is necessary for children to explore the harder material in order to fully understand it. Exposure to concepts makes a difference. For example, after initial introduction to "repeat" instructions, 38% of children achieved a high level of understanding, compared to after their final Mi Ani projects where 86% of children achieved a high level of understanding. Scores on correspondence (matching a programming instruction to intended robot actions) increased from 60% at the curriculum's introduction to 94% after completing the Mi Ani project. Scores on both correspondence and sequencing decreased as activities introduced increasingly complex programming concepts – correspondence decreased to 36% and sequencing decreased to 39%. However, sequencing scores in the Mi Ani project saw a similar jump to that of correspondence scores, with 100% of children achieving a high level of understanding. During the open ended Mi Ani projects, children were able to choose a level of challenge that matched their abilities, leading to a program that was comfortable for each child and led to maximum success.

Analyzing the Experience through the PTD Theoretical Framework

The use of technology in the classroom should be guided by a particular pedagogical stance or theoretical framework. In the Mi Ani project, the PTD (Positive Technological Development) framework guided the design of the educational experience. PTD is a natural extension of the computer literacy and the technological fluency movements that have influenced the world of educational technology in the last thirty years by adding psychosocial and ethical components to the cognitive ones (Bers, 2008; Bers, 2006; Bers, 2010a). PTD provides a model for developing and evaluating technology-rich programs.

From a theoretical perspective, PTD is an interdisciplinary approach that integrates ideas from the fields of computer-mediated communication, computer-supported collaborative learning, and constructionist learning and views them in light of research in applied development science and positive youth development. Informed by both Constructionism (Papert, 1993) and Positive Youth Development (Phelps et al., 2009), PTD is a multi-dimensional framework that proposes six C's of positive behaviors supported by new technologies: content creation, creativity, communication, collaboration, community building and choices of conduct (Bers, 2010b). As a framework to guide the design and implementation of educational interventions, PTD takes into consideration the learning environment and the pedagogical practices, as well as cultural values and rituals, that mediate teaching and learning (Rogoff, 2003; Rogoff, Turkanis & Bartlett, 2001). The following paragraphs summarize the Mi Ani experience in light of the 6 C's of PTD.

Content creation is strongly supported by the CHERP software, with which children were able to program robots through either a graphical or tangible user interface. With directed challenges in the early phase of the curriculum and then in dealing with their own goals for their Mi Ani projects, the children developed competence in the technological domain and learned valuable problem-solving skills, logical thinking, and how to debug and revise their programs, while engaging in developing computational thinking.

The open-ended nature of the Mi Ani project was successful in fostering *creativity* in the ways the children used the technology. Although explicit lessons and challenges were initially helpful in teaching and demonstrating uses of robotics, they offered limited outlets for creativity in the solutions. However, children found extremely creative ways to express their identities and experiences when given the freedom to do so. As they had time to creatively explore and gain competence in navigating CHERP, the Kindergarteners also gained a strong sense of confidence in their programming abilities, which was extremely evident in their pride as they demonstrated their projects to their families. The students' growing confidence also bolstered their ability to overcome technological frustrations when their robots malfunctioned or when CHERP froze, either by trying to fix the problem themselves or soliciting help.

The TangibleK curriculum did support *communication* in several ways. First, the culminating Mi Ani project communicated to parents and family a sense of identity. Kindergarteners programmed their robots as personal avatars to communicate their views of themselves as members of the Jewish people and their particular classroom. Second, children communicated with each other to overcome frustrations and share possible solutions. The Kindergarteners also engaged in *collaboration* by working with their peer partners to solve the robotics challenges posed to them at the beginning of the curriculum. With a wide spectrum of developmental levels and social skills children not only learned about robotics but also about team work. The final projects were shared in an open house. This served a *community building* purpose.

Finally, many aspects of the robotics curriculum at JCDS allowed the Kindergarteners to make *choices of conduct*, which offer opportunities to build character. During the creation of their platforms for the Mi Ani project, children were encouraged to examine and reflect upon their defining character traits. In addition, the limited supply of materials created social challenges in which the students had the freedom to choose whether or not to act responsibly and share materials. During the first phase of the curriculum, children had to navigate sharing of responsibilities and resources with their partners, and negotiate turn-taking. In the rug area, children at the Lego bins could choose to take an excessive amount of Lego, or to take only what they needed so they could share the Lego with their peers.

CONCLUSION

This chapter describes an innovative approach, the TangibleK robotics program, to bring ideas of computer science and engineering into the early childhood classroom in a developmentally appropriate way. Furthermore, the experience described in this chapter focuses on how robotics can be used as a tool for identity exploration. By creating robotic representations of themselves, young children underwent a process of examining their beliefs and practices as members of the Jewish community in a pluralistic school. The dynamic nature of the technology allowed for expressions of actions and experiences, as opposed to only static symbols or facts.

We believe that robotics could be beneficially integrated into any receptive Kindergarten curriculum, if accomplished in a manner that is sensitive to the needs and abilities of young children. There exists some controversy as to how suitable such programs are for this grade level, and we stress that the appropriate design of the robotics technology and the integration with other areas of the curriculum is crucial to its success in the classroom. According to our data, the majority of the *Gan Nitzan* Kindergarteners did achieve high understanding on average for basic programming skills (control flow by sequencing intructions), although most had not fully grasped the more sophisticated skills of loops and parameters, sensors, and branches by the end of the curriculum. The data suggests that greater time exposure to the more complex concepts may have improved the Kindergarteners' level of understanding in these areas.

An ethnographic approach proved particularly useful in holistically evaluating the TangibleK curriculum in this context. While quantitative data demonstrates the effects of the robotics technology within the cognitive domain, the ethnographic study elucidated the potential value of the technology across less quantifiable domains such as creativity and identity exploration. Our ethnographic perspective also acknowledges the role of culture and student population on the implementation of the project. We anticipate the importance of shaping future robotics curricula around the unique culture and population group in each classroom. We recognize that the current project was carried out within a relatively homogenous group of predominantly white, middle-class, Jewish children from the greater Boston area. It is likely that these children had received significant exposure to computer technology at home and it was observed that they were all at least beginning readers by the time the program began. We imagine that these are significant factors that contribute to successful navigation of the graphical TangibleK interface and understanding of syntax and sequential nature of the programs. Such technological fluency and literacy cannot be expected of all populations of kindergarteners, such as those coming from families of lower socio-economic status, and this must be taken into account when designing the curricula. One focus of future research is the development of more affordable robotic hardware that is developmentally appropriate and that can be used with the CHERP programming environment.

In our multicultural world, projects such as this one, that offer children opportunities to explore and represent their own dynamic notion of identity, present educators and researchers with a lens into young children's conceptualization of their identity. While the experience described in this chapter was carried out with a specifically Jewish population, it is our hope that this project will be replicated with a wide range of cultural, religious, or ethnic groups.

ACKNOWLEDGMENT

The authors would like to extend many thanks to the wonderful and creative teachers who used our curriculum in their classroom for this study: Jared Matas and Miriam Newman; to their principal Ruth Gass for embracing a new venture into JCDS; to Nehama Libman for her thesis work on the Mi Ani project, and to all the students in the DevTech group, specially Louise Flannery, Elizabeth Kazakoff and Jordan Crouser for making this project possible. This research was funded by the National Science Foundation (NSF Grant DRL-0735657). Any opinions, findings, and conclusions or recommendations expressed in this article are those of the authors and do not necessarily reflect the views of the National Science Foundation.

KEY TERMS AND DEFINITIONS

CHERP: Creative Hybrid Environment for Robotic Programming – A hybrid tangible programming system composed of interlocking wooden blocks specifically designed to meet the developmental needs of young children.

Ethnographic: The scientific description of the customs of individual peoples as observed from within the culture.

Graphical Interface: A representation displayed on a computer screen for communicating instructions and feedback.

Identity: The salient characteristics defining an individual's sense of self.

Positive Technological Development (PTD): An interdisciplinary educational approach that integrates ideas from the fields of computer-mediated communication, computer-supported collaborative learning, and constructionist learning and views them in light of research in applied development science and positive youth development.

Tangible Interface: A physical modality for communicating instructions and feedback.

TangibleK: A curriculum created by the Tufts University DevTech Team using developmentally appropriate methodology to teach robotics and computer programming concepts to kindergarten students.

Chapter 106

Prototyping of Robotic Systems in Surgical Procedures and Automated Manufacturing Processes

Zheng (Jeremy) Li
University of Bridgeport, USA

ABSTRACT

The prototyping and implementation of robotic system is a scientific and technological integrating of robotic system design, development, testing, and application. This chapter describes the recent development and applications of robotic systems to surgery procedures in biomedical engineering and automated manufacturing processes in industry. It includes the design and development, computer-aided modeling and simulation, prototype analysis, and testing of robotic systems in these two different applications.

1. INTRODUCTION

Robotic system is constructed mechanically of kinematic chains and actuators which function as muscles that transfer potential energy to body motion (Dylan, 2005, p.797 & Schreuder, 2010, p.253). The robotic mechanisms can be controlled to perform different tasks. The applications of programmable logic control to the industry bring revolution for the manufacturing techniques. It allows more sophisticated, flexible, reliable, and cost-effective manufacturing process controls (Feil-Seifer, 2007, p.425 & Kim, 2007, p.13 & Yang, 2008, p.79). Robotic system is to use control system to reduce human labor intervention during manufacturing processes and productions. It plays very important role and puts strong impact in today's industries (McComb, 2003, p.435 & Pott, 2005, p.101). Computer-aided engineering design can quickly model the robotic systems and speed the design and development cycles (Kumar, 2011, p.994 & Menzel, 2000, p.180 & Tsagarakis,

DOI: 10.4018/978-1-4666-1945-6.ch106

2003, p.21). Computer aided manufacturing can improve the engineering integral processes of robotic design, development, engineering analysis, and production (Schiff, 2005, p.122 & Tapus, 2007, p.15 & Tholey, 2003, p.158). The current economic globalization requires significant labor cost reduction through industrial automation, applied robotic system, improved machine tools, and efficient production process (Ahmed, 2009, p.431 & Siebert, 2004, p.127). This chapter aims at the introduction of some robotic systems applied in surgical procedure and automated manufacturing processes. Two new research projects of robotic systems are introduced in this chapter through design analysis, computer modeling, computational engineering simulation, and prototype testing.

2. BACKGROUND

Robotic surgery has many advantages including minimally invasive surgical process, narrow incisions, decreased infection, reduced pains, and less hospital stays (Cadierre, 2001, p.1467 & Eirik, 2009, p.77 & Taylor, 2003). The development of surgical robots can improve the situation limited by current laparoscopic surgery and technologies (Backes, 2008, p.97 & Camarillo, 2004, p.188 & Hu, 2002 & Kazanzides, 2008). Also the robotic surgical system can be set up whereby the patients could be loaded into a vehicle by robotic surgical equipment and surgery can be performed by a surgeon remotely at a nearby mobile advanced surgical hospital (Brown, 2007, p.253 & Estey, 2009, p.488 & Ghomi, 2010, p.87 & Mataric, 2007, p.1). The robotic arms can be manipulated through surgeon's voice instructions to control the endoscopic cameras (Bargar, 2007, p.31 & Carigan, 2007, p.179 & Gerhardus, 2003, p.242 & Tapus, 2008, p.169). Figure 1 shows one robotic surgical application in gallbladder surgery. The gallbladder removal by robotic surgery is minimally invasive by way of robot technology permitting optimal viewing of the surgical field through small incisions with less pain and faster recovery time for patients (Gockley, 2006, p.150 & Hanna, 2011, p.761 & Harja, 2007, p.365 & Rosen, 2011). It closely mimics the surgery that is used in traditional 'open' procedures, but allows surgeon to perform the operation by da Vinci™ Surgical Systems through small incisions that are associated with minimally invasive and laparoscopic surgeries (Gortchev, 2010, p.153 & Kaouk, 2009, p.181 & Koh, 2011, p.1945 & Puntambekar, 2009, p.259).

Figure 2 shows the da Vinci robotics surgical system for gynecology, urogynecology, urology and cardiology procedures. It has flexible, safe, précised features that allows surgeon to operate the surgery with reduced trauma to the patients and a faster recovery time (Kwartowitz, 2006, p.157 & Li, 2002, p.90 & Melvin, 2003, p.33 & Passerotti, 2006, p.193 & Peters, 2007, p.179).

Figure 3 displays another robotic-assisted surgical system to help surgeon in surgery. It allows the surgeon to perform surgery with enhanced precision that reduces post-operative complications, less pain and discomfort after surgery, less scarring and a shorter hospital stay (Kypson, 2004, p.87 & Melvin, 2003, p.11 & Passerotti, 2006, p.193 & Patel, 2011, p.423).

Figure 1. Robotic surgery for gallbladder removal (Gockley, 2006)

Figure 2. da Vinci robotics surgical system (Passerotti, 2006)

The common robotic systems in manufacturing processes include robotics systems for picking and placing work pieces, assembling operations, and handling machine tools (DeLaurentis, 2002, p.91). The common type of robotic unit is the mechanical arms being used in industry and manufacturing processes (Desforges, 2011, p.963). This mechanism, like human arm, can perform many different motions, including left-and-right, up-and-down, and angular motions. Robotic arms can be either controlled through computer program or human interference. Industrial robots have a multi-linked manipulating arm and end effecter such as a gripper mechanism. It can be applied to industrial packaging, welding, painting, printed circuit boards, hazard environment, and many other manufacturing processes (Torbjorn, 2009, p.87). Figure 4 shows one robotic system for picking and placing parts in automobile production. It can increase the efficiency at multiple working cells by automatically picking and placing product components in production (Ullman, 2002, p.178).

Figure 3. da Robotic-assisted surgical system (Melvin, 2003)

Figure 5 shows one heavy duty robot applied in product lifting operation. It has a payload capacity of 2200 lbs and a reach of 10 feet for extremely heavy lifting and manipulation applications in industries of automotive, foundry and building materials (Yang, 2011, p.1010).

Figure 6 displays one robotic system in material removal operations. It assists to process the material removal processes including drilling, milling, polishing, grinding, buffing and deflashing (Yun, 2011, p.977). The robot-assisted manufacturing can boost manufacturing efficiency throughout industrial applications.

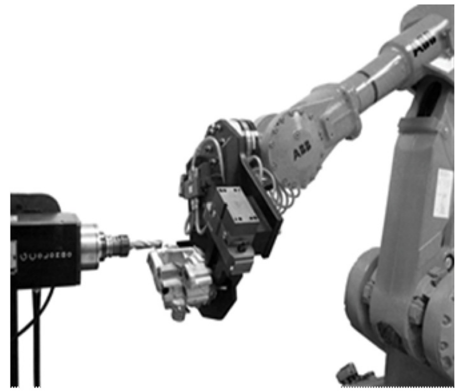
Figure 4. Robotic system for picking and placing parts in automobile production (Torbjorn, 2009)

Figure 5. One heavy duty robot in product lifting and manipulation operation (Yang, 2011)

3. MECHANISM AND CONTROL OF ROBOTIC SYSTEMS

The robotic systems convert the energy into motion. It may include electric motors, linear actuators, piezo motors, air wires, and electroactive polymers (Howard, 2006, p.1360). Electric motor is the most popular type of actuator (Shakernia, 2002, p.2793). Linear actuator is used in applications where the large forces are required in linear motion (Dagalakis, 2007, p.180, Mellinger, 2010). Piezo motor uses the vibration of the piezo elements to drive the motor. Air wire is a special tube and its length can be adjusted as internal air is exerted (Matsui, 2005, p.47). Electroactive polymer, functions as the arm of robotic system, is a special plastic material that can change its length significantly by electricity. Current robotic systems receive tactile signals with sensors simulating the mechanical properties and touch receptors of human fingertips (Gurdan, 2007, p.288). The sensor can consist of a rigid core with conductive fluid surrounded (Kazerooni, 2005, p.3459 & Kennedy, 2003, p.2106). The conductive fluid is enclosed by the elastomeric materials. Electrode is installed at the surface of the rigid core and connected to an impedance-measuring device inside the core.

Figure 6. Robotic system for material removal processes (Yun, 2011)



When the elastomeric material touches an object, the fluid volume surrounded electrode is changed, causing the impedance changes that simulate the loads received from the object. Computer-aided vision is the technology of mechanism that gets data information from images with different format including video sequences or cameras (Lerman, 2006, p.225). It uses the image sensor to detect electromagnetic radiation of visible or infra-red light.

Robots can manipulate objects by “end effectors” (hands) and “manipulators” (arms) (Eljamel, 2007, p.372 & Frutiger, 2002, p.619 & Hong, 2006, p.81). Some robotic arms equipped in exchangeable effectors with which it can perform different tasks. Mechanical grippers are the most common effectors with two fingers that can open and close to pick up and place the objects. Vacuum grippers are simple and common effectors to pick and place large objects through suction. Robotic system control process is complex and dynamic related (Frisoli, 2005, p.195). Some technical methodologies include: (1). zero moment point technology—it is the algorithm used by robotic systems to keep the total forces balanced with combination of gravity, acceleration and deceleration of object body; (2). Hopping—it is the technology that keeps robotic system functioning properly and the algorithm in the control program is generated to maintain the system balance if robotic system is unbalanced; (3). dynamic balance—it is a more advanced methodology to control robotic system by dynamic balancing algorithm and more robust than zero moment point technology; (4). passive dynamics—it is applied with high efficiency in momentum of robotic system and the robotic system only requires less motor power if compared with other conventional robotic systems.

The control of robotic systems consists of three different phases: (1). Perception—sensors are applied to detect the external signal information for actuators; (2). Processing—it translates sensor information into commands to drive actuators; (3). Action—object pattern verification and computer vision can be used to track objects (Gerkey, 2004, p.939). The study of motion in robotic systems includes both kinematics and dynamics. The position, orientation, velocity, and acceleration of end effectors can be calculated through direct kinematics. The kinematics can be used to analyze the same robotic motion in different possibilities to avoid the collision and singularity in robotic systems. With all results from kinematics analysis, dynamics can be applied to study the effect of forces on motion of robotic systems. The dynamic technique is a powerful tool in computer-aided modeling and simulation of robotic systems to improve the control algorithms of a robotic system (Tinelli, 2011, p.2654).

4. NEW RESEARCHES IN SURGICAL AND INDUSTRIAL ROBOTIC SYSTEMS

Based on author's current researches, two new robotic systems have been introduced and analyzed in this chapter including robotic system design and development in surgical procedures and automated manufacturing processes. These two robotic systems are designed in such way that they can be made cheaper and simple without losing the reliability. These robotic systems have been designed and analyzed by computer-assisted modeling, simulation and analysis. The simple prototypes were being built and tested to verify its performance. The preliminary results indicated that these robotic systems function properly during the prototype testing.

4.1 New Robotic System for Surgical Procedures

The surgical operations can be performed through robotic systems with more accuracy. Robotic surgery applies the surgical robots that lead direct or indirect involvement of surgeon in surgical operation. The robotic systems are computerized mechanical systems with motorized mechanisms. The basic robotic systems may consist of sensors, programmable systems, and actuators (Carigan, 2007, p.185). The important advantages of robotic surgery over conventional surgery include the accuracy of surgery, capability of repeating identical motions, and options of remote surgery (Finkelstein, 2010, p. 42). There are three categories in robotic surgery based on different surgeon involvement (Hanna, 2011, p.780): (1). supervisory—before surgical procedure, surgeon inputs the computer program into robotic system so that the surgical operation can be solely performed without surgeon direct interaction, but It requires complex program for the surgery and more advanced technologies to get images and data of patient body; (2). Telesurgery—it is a remote surgery in which surgeon directly manipulates the robotic systems during the surgical process without pre-programming the robotic system and surgeon can perform surgical operation from other locations by using real-time data information obtained from sensors in robotic system; (3). share-control—this procedure needs the most involvement of surgeon who performs the surgical operation by using robotic system that provides more accurate and stable manipulations of surgical instruments. A new surgical robotic system, shown in Figure 7, is designed and de-

Figure 7. New robotic system for surgical application

veloped based on computer modeling, analysis and prototype testing.

Computer tomography scans can get cross-section images that are important to the diagnosis and surgeons can use these images to decide surgical pathways to precisely guide operation instruments with less surgical injury during procedures. The robotic arms in this robotic system can precisely access the patient's body through tiny and narrow incisions. Surgeons can use remote manipulation device to perform complex surgical operation with accuracy and less fatigue because of proper geometrical design, wide angular motion, and 3-dimensional clear visualization. The wide view of surgical operations using this surgical robot provides surgeons with great capability to perform many surgical tasks including robotic prostate cancer surgeries for cancel removal, damage control, sexual and urinary function recovery with minimal side effects. This robotic surgery can benefit patients by quick recovery, less postoperative pain, short hospital stays, small tissue trauma, and better cosmetics. This surgical robot provides surgeons with more precise, flexible and accurate procedures than traditional surgical techniques. It also permits highly efficient suturing because of accurate placement and well controlled motion of surgical instrument in this robotic system. In summary, this surgical robot has the following features:

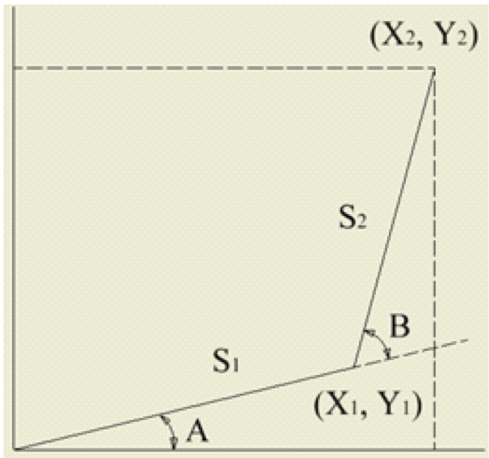
1. The simpler system design allows loose manufacturing tolerance control on major components in this robotic system so that it can be made cheap and maintained easily in the future;
2. The moving components in this robotic system are designed to keep its proper geometry and light weight to benefit surgeon in surgical operation with less moving vibration and higher energy efficiency.
3. Manipulated by surgeons, the robotic arms can have wider angular degrees of motion freedom with more flexible function;
4. Larger visual magnification for better surgical function;
5. Less post-operative length of stay due to the capability of performing minute surgical incisions more precisely.

4.1.1 Mathematics and Computer-Aided Simulation of Robot Arms

The robotic systems are programmed with mathematics that controls the motion of robot arms accurately and reliably. The double-link robot arm is simple, shown in Figure 8, if compared with more complicated triple-link robot arm which involves more difficult mathematics. In the double-link arm system, the first link (assistant arm) turns around the origin of an XY Cartesian coordinate system and the second link (arm to hold the surgical tools) turns around the pivot point which connects link 1 and 2. The angle between link 1 and horizontal axis is defined as A, and angle between link 1 and 2 is assumed as B. The robot arm is at the end positions (X_1, Y_1) of link 1 and (X_2, Y_2) of link 2.

There are three solution methodologies in this robotic system analysis (Carlone, 2010, p.283): (1).kinematics—determine robot arm location (X_1, Y_1) if the angles A and B are given; (2).inverse kinematics—determine angles A and B if robot

Figure 8. Double-link robot arm



arm location (X_1, Y_1) is given; (3).trajectory generation—determine robot arm new location (X_2, Y_2) by adjusting the angle A and B if current location (X_1, Y_1) is given.

4.1.2 Methodology of Kinematics (McComb, 2003)

Based on Figure 8, we can find the end location:

$$X_2 = S_1 \cdot \cos(A) + S_2 \cdot \cos(A+B) \qquad (1)$$

$$Y_2 = S_1 \cdot \sin(A) + S_2 \cdot \sin(A+B) \qquad (2)$$

Here,

$$X_1 = S_1 \cdot \cos(A)$$

$$Y_1 = S_1 \cdot \sin(A)$$

$$X_2 = X_1 = S_2 \cdot \cos(A+B)$$

$$Y_2 = Y_1 + S_2 \cdot \sin(A+B)$$

4.1.3 Methodology of Inverse Kinematics (McComb, 2003)

Referring kinematics Equations (1) and (2), the problem is nonlinear to determine angles A and B if end location (X_2, Y_2) is given. The algebraic methodology can be applied to solve this nonlinear problem and Equations (1) and (2) are combined to get following equations:

$$\cos(A+B) = \cos(A) \cdot \cos(B) - \sin(A) \cdot \sin(B) \qquad (3)$$

$$\sin(A+B) = \cos(A) \cdot \sin(B) + \sin(A) \cdot \cos(B) \qquad (4)$$

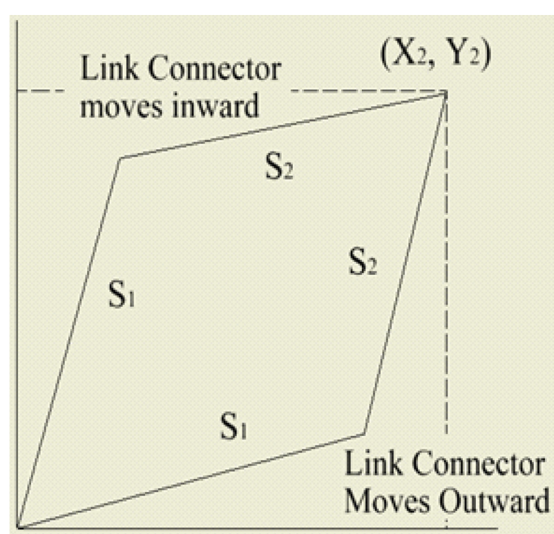
Solving these two equations can derive the new equation of finding angle B:

$$B = \arccos\left(\frac{X_2^2 + Y_2^2 - S_1^2 - S_2^2}{2S_1 \cdot S_2}\right) \qquad (5)$$

Since cos (B) = cos (-B), the inverse kinematics problem has two solutions (link 2 clockwise and counter-clockwise turning), shown in Figure 9.

Angle A can be found based on solution of angle B in inverse kinematics methodology.

Figure 9. Inverse kinematics for robotic arm



$$X_2 = [S_1 + S_2 \cos(B)]\cos(A) - S_2 \cdot \sin(B) \cdot \sin(A) \quad (6)$$

$$Y_2 = S_2 \cdot \sin(B) \cdot \cos(A) + [S_1 + S_2 \cdot \cos(B)] \cdot \sin(A) \quad (7)$$

The angle A can be determined by solving Equations (6) and (7).

4.1.4 Methodology of Trajectory Generation (McComb, 2003)

In case of double-link robot arm, the arm location (X_1, Y_1) is associated to link angles A_1 and B_1. When rotate the arm to a new location (X_2, Y_2), the angles of A_2 and B_2 can be determined through inverse kinematics analysis. There are several ways to control robotic arm moving from old location to a new location: (1). adjust angle A before changing B; (2). adjust angle B before changing A; (3). adjust angles A and B at the same time; (4). robot arm turns clockwise; (5). robot arm turns counterclockwise. A good robot arm design can reduce the energy needed to rotate the robot arm and decrease the time needed to change arm mechanism. Figure 10 shows a robot arm rotating in trajectory generation with angle A changing in a clockwise direction.

Two moving trajectories of robot arm, shown in Figure 10, indicated the desired condition. In straight line trajectory generation methodology, a line or curve can be divided into many small segments and corresponding (X, Y) coordinates at the end of each segment are calculated through computational simulation. For each (X, Y) coordinate pair, the required angles A and B are computed. The robot arm mechanisms are adjusted as each new A and B are calculated. The computer-aided solutions of angles A and B continue, along the line or curve, until the target arm location is reached.

The more complex situation for robotic arm motion could be analyzed through computer-aided modeling and simulation. Figure 11 shows the trajectory curve of robot arm using multiple data points along the moving path. If the angles of A and B change simultaneously, the moving path is much smoother.

Figure 10. Robotic arm rotates clockwise in trajectory generation

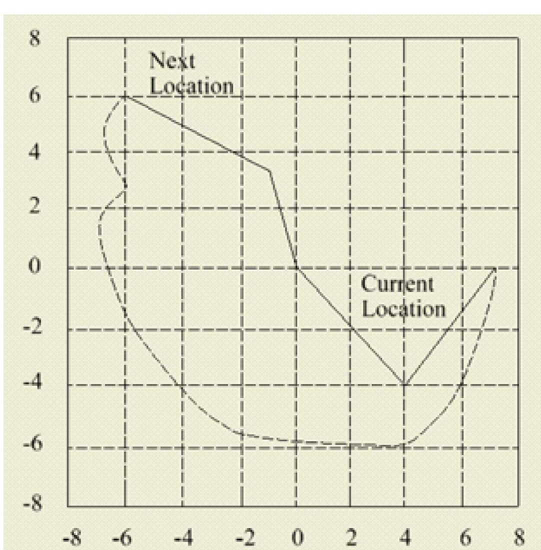


Figure 11. Simulation of robotic arm moving path with multiple data points

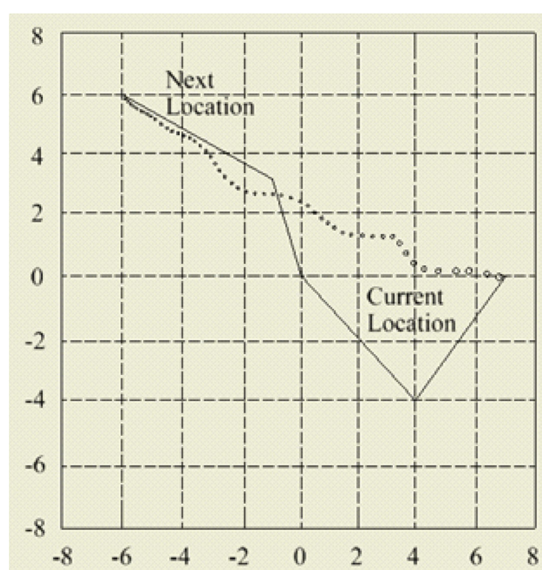

Figure 12 shows the robot arm moving in an alternate path with smoother curve when angles A and B are changed at the same time.

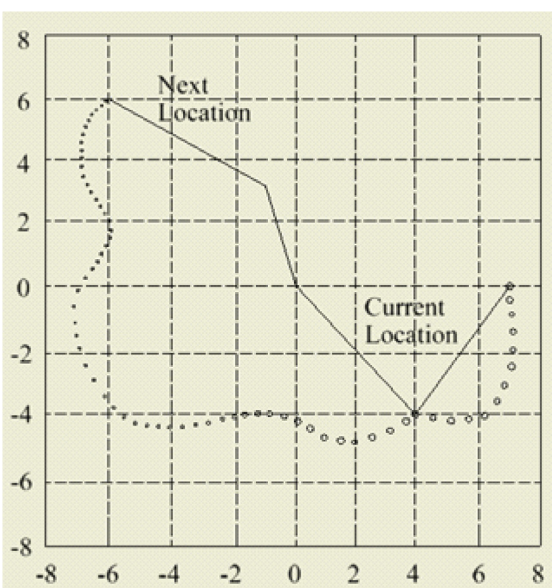
The robot arm system is a nonlinear functioning system which requires the complex mathematical analysis, computer-aided modeling, and computational simulation to analyze and solve the arm motion problems. The variable length links could be used to define the potential coverage regions of robotic arms. Modifying the inverse kinematics methodology can implement the solution for trajectory generation methodology. The computational modeling and simulation are required in the analysis of robotic arm movement.

4.1.5 Prototype Testing

The kinematic motion of this robot is measured by pulse-width modulation (PWM) methodology in preliminary prototype testing. The PWM register's values are used to drive the motors of robotic system in different directions. The curves in Figures 13 (a), (b), (c), (d), (e) and (f) show the power required to drive the movement of this surgical robot arm towards the front, back, left, right, higher and lower directions. All PWM resultant pictures corresponding to the motions of robotic arm in different directions were recorded when robotic system was manipulated by the operator. The average voltage or current values fed to the load is manipulated by controlling the switch connected between the supply and load. The switch quickly changes between on and off status. If switch stays longer in status of "on" than "off", more power will be supplied to the load which can manipulate the robotic system motions. The PWM values in these plots are related to the power that drives the robotic system in different directions.

Figure 12. Simulation of robotic arm moving in an alternate path



The preliminary prototype testing indicated the maximum movement of 16 inches towards the front and back directions, 20 inches towards the left and right directions, and 24 inches towards the higher and lower directions. These preliminary results are in good agreement with design expectation since this surgical robot is expected the motion of 15 × 20 × 24 inches in 3-D design function. More tests have been planned to verify the functionality and reliability of this surgical robot. Further modification on this surgical robot will be made to determine if large moving range can be achieved.

4.2 New Robotic System for Automated and High Speed Viscous Fluid Filling

Figure 14 shows this new robotic system used in automated manufacturing processes. One of the industrial applications is to pick and place the empty cartridges from floor container to the working station in automated viscous liquids filling production line shown in Figure 15.

The precision indexing conveyor controls indexing tolerance to keep part movement within tolerance range. The empty cartridges are picked up and placed to the cartridge holders by this robotic system and securely held in indexing

Figure 13. (a) movement of robot arm towards the front; (b) movement of robot arm towards the back; (c) movement of robot arm towards the left; (d) movement of robot arm towards the right; (e) movement of robot arm towards higher direction; (f) movement of robot arm towards lower direction

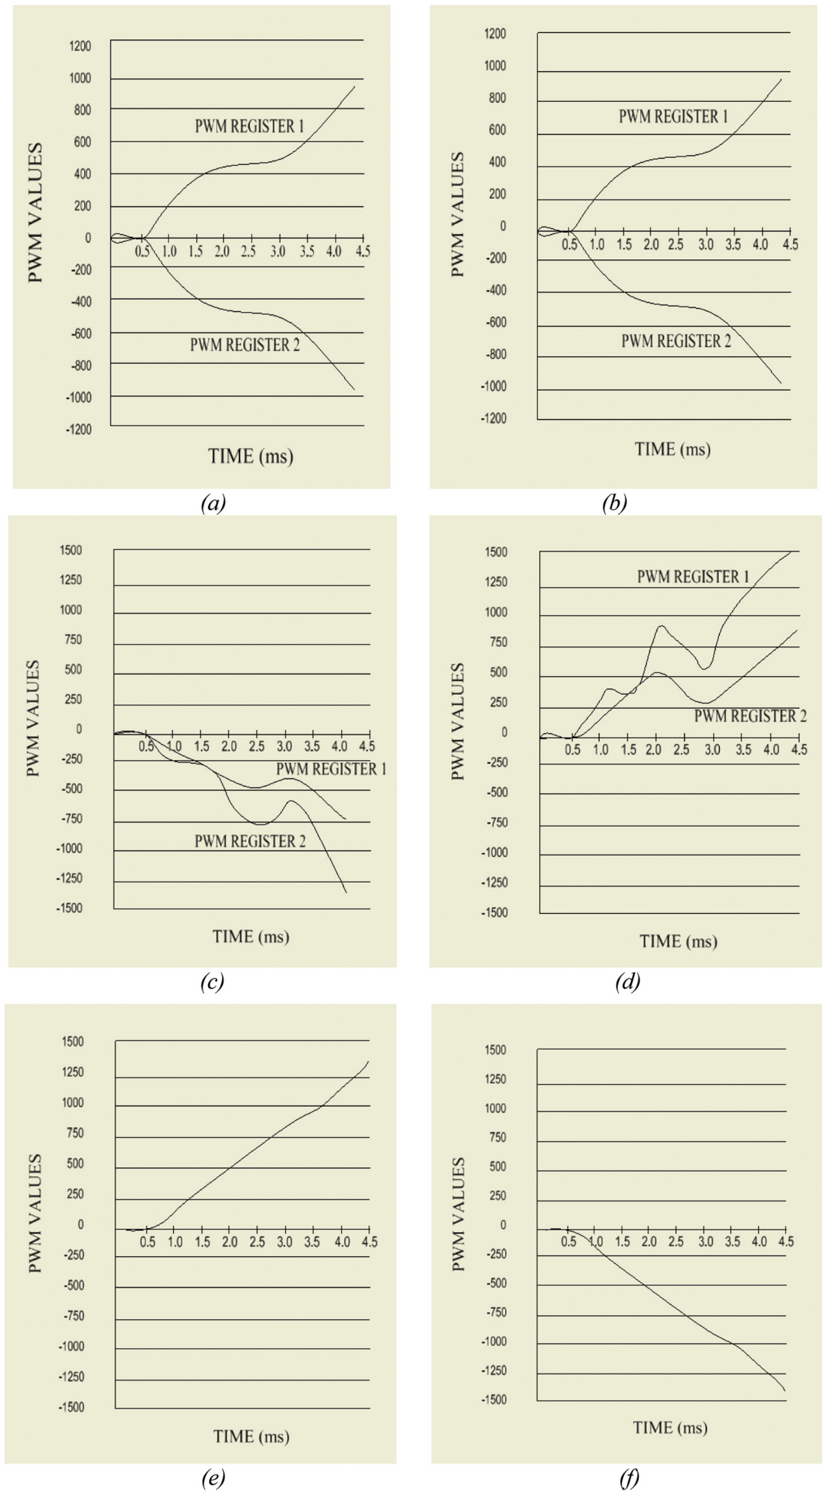


Figure 14. New robotic system for manufacturing applications

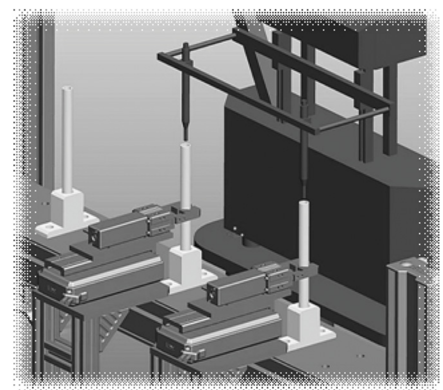
Figure 15. Robot-assisted automated and high speed viscous liquids filling production line



conveyor. The liquids filling holders are controlled to keep good dimensional and location tolerances between holders and cartridges to secure the product in automated and high speed filling process. When empty cartridges are delivered to the location below filling nozzles, the indexing conveyors stop through sequential control of PLC system that receives filling holder location signal from opposed mode sensor. Horizontal sliders mounted in gripper system drive gripper pair forward to secure cartridges in filling process. The nozzles are driven downward by vertical sliders and inserted into cartridges to begin filling process. As soon as filling process is completed, the vertical air slide drives nozzles upward. Then grippers release cartridges and move away from filling holder location for next filling cycle. The control system in this prototype can detect each filling pump to precisely determine the amount of liquids being filled. When target filling volume is reached, all pumps and nozzles shut off instantly, resulting in accurate filling process of high viscous liquid products. The control system stores all filling parameters in memory for fast changeovers.

This robot-assisted automated and high speed liquid filling system is accurately and reliably controlled in filling of different high viscous liquids. It can be applied to many industries including pharmaceutical, cosmetic, dairy, chemical, food, etc. For example, some thick liquids, cosmetic creams, and chunky sauces with pasteurized temperatures can all be filled in this new robot-assisted automated filling system. The positive displacement pump will be required in high viscosity and high temperature environment. Double driving rotors are designed in this pump to make this filling system more durable in delivery of high viscosity liquids.

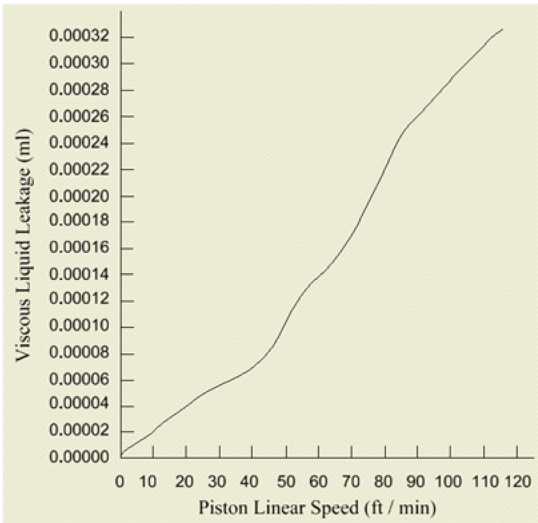
4.2.1 Computer Aided Modeling and Simulation

The computer-aided simulation of liquid leaking rate L during high speed liquid filling process can be determined as follow (Klopcar, 2007, p.86):

$$L = Q \cdot C \cdot \left(\frac{T_b}{P_b}\right) \cdot E^{2.5} \cdot H \cdot \left(\frac{P_1^2 - P_2^2}{I \cdot G \cdot T_a \cdot N_a \cdot J}\right)^{0.5} \quad (8)$$

The computer-aided simulation result, shown in Figure 16, indicated that the liquid leakage in this high speed filling process can be ignored. The computer-aided simulation shows that this new robotic-assisted automated and high speed filling system has reliable function, good sealing capability and high production rates. Also the manufacturing cost for this system is low due to

Figure 16. Viscous liquid leakages vs. piston linear speed



less requirement of tolerance control for assembled robotic components in this new robotic-assisted manufacturing system design.

4.2.2 Prototype Testing

The prototype of this new robotic-assisted automated and high speed liquid filling system has been tested with preliminary results shown in Table 1.

Both prototype testing and computational simulation show the similar results that verify the creditability and feasibility of this new robot-assisted automated and high speed liquid filling system.

Table 1. Liquid leakage vs. piston linear speed

Piston Linear Speed (Ft/in)	Estimated Liquid Leakage (ml)	Piston Linear Speed (Ft/ Min)	Estimated Liquid Leakage (ml)
10	0.000015	70	0.000145
20	0.000035	80	0.000185
30	0.000055	90	0.000205
40	0.000088	100	0.000235
50	0.000102	110	0.000265
60	0.000125	120	0.000305

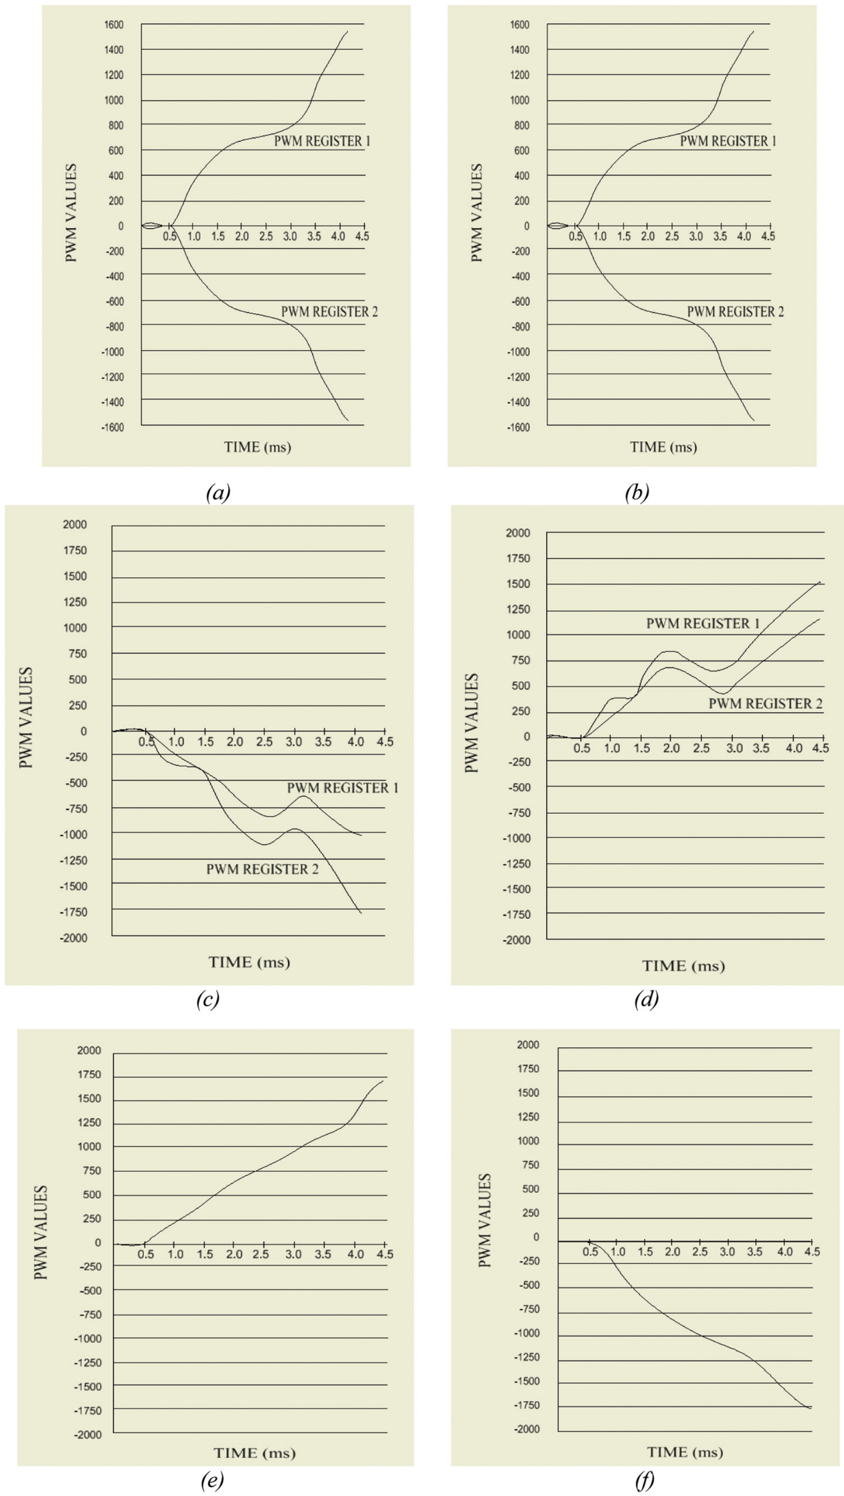
The curves in Figure 17 (a), (b), (c), (d), (e) and (f) represent the power related movement of manufacturing robot arm towards the front, back, left, right, higher and lower directions. The kinematic motion of this robot is measured by pulse-width modulation (PWM) methodology in preliminary prototype testing. The PWM register's values are used to drive the motors of robotic system in different directions. All PWM resultant pictures corresponding to the motions of robotic arm in different directions were recorded when robotic system was manipulated by the operator. The average voltage or current values fed to the load is manipulated by controlling the switch connected between the supply and load. The switch quickly changes between on and off status. If switch stays longer in status of "on" than "off", more power will be supplied to the load which can manipulate the robotic system motions. All these PWM plots represent the power needed to drive the robot arm moving in different directions.

The preliminary testing of this manufacturing robot indicated the maximum movement of 40 inches towards the front and back directions, 48 inches towards the left and right directions, and 52 inches toward the higher and lower directions. The above preliminary results are in good agreement with design expectation because this manufacturing robot is expected to move 3-D dimension in 40 × 49 × 52 inches to meet design target. To verify the functionality and reliability of this surgical robot, more prototype tests will be performed and further modifications of mechanism in this manufacturing robot will be carried out to increase moving range in different directions.

5. FUTURE IMPROVEMENT

The future improvement on these two new robotic systems include: (1). Simplify the robotic systems for easy maintenance and cost-effectiveness, in-

Figure 17. (a) movement of robot arm towards the front; (b) movement of robot arm towards the back; (c) movement of robot arm towards the left; (d) movement of robot arm towards the right; (e) movement of robot arm towards higher direction; (f) movement of robot arm towards lower direction



cluding making arm opening more accessible; (2). Investigate using lighter and durable materials; (3). Modify the robotic mechanism to increase its moving range in different directions; (4). Improve system design for better function including mechanical joint connections to keep more accurate and smooth robotic motion; (5). Optimize the robotic mechanism through computer-aided simulation to verify and guide further design modification; (6). Implement the prototype and prepare to send for field evaluations.

6. CONCLUSION

Robotic system is not only significantly increasing the production speed but also more accurately controlling product quality. It can maintain consistent quality, shorten lead time, simplify material handling, optimize work flow, meet product demand for flexibility and convertibility in production, and perform some specific, precise, and dangerous tasks in industry that are very difficult using human work forces. Robotic surgery has greater levels of accuracy and precision than traditional open surgery. The robotic systems have also been widely used in many industrial fields including automated and high speed production, automobile manufacturing, hazardous duty service, and heavy facility maintenance. Two new research projects of robotic system introduced in this chapter are illustrated mathematically with verifications from computer-aided analysis and preliminary prototype testing. These new research projects can be applied to robotic surgery and automated manufacturing process. Further modifications will keep these robot-assisted systems with more reliable function, flexible features, reduced cost, and enlarged moving range.

Chapter 107
Software Process Lines:
A Step towards Software Industrialization

Mahmood Niazi
Keele University, UK & King Fahd University of Petroleum and Minerals, Saudi Arabia

Sami Zahran
Process Improvement Consultant, UK

ABSTRACT

The industrial revolution transformed the cottage industry into mass production. In this chapter, the authors trace the recent advancement of the software industry and establish that it is following a similar route followed by the manufacturing industry towards industrialization. The chapter positions the concept of Software Product Lines (http://www.sei.cmu.edu/productlines/), as a possible foundation for software industrialization, and the authors introduce the concept of Software Process Lines as complimentary foundation for software industrialization. The chapter discusses a number of questions: What are the Software Process Lines? What are the justifications and benefits of Software Process Lines? What are the steps for implementing Software Process Lines? How can Software Process Lines enable and facilitate the establishment of a continuous Software Process Improvement environment?

INTRODUCTION AND JUSTIFICATION

Mega Waves in the Software Industry

The software industry has moved a long way since the early times of it being a cottage industry. In its short history it has passed through a number of mega changes and waves of changes moving firmly towards a discipline similar to what happened to manufacturing through the industrial revolution. The authors believe that the era of software industrialization is coming, in spite of some difficulties facing software development efforts. The first wave of the software industry started with the structured methods in the 1970's, which were developed to cater for the increasing demands and complexity of software. The efforts to adopt structured methods were assisted by automated

DOI: 10.4018/978-1-4666-1945-6.ch107

tools, and this was the beginning of transforming the software industry from a 'cottage industry' towards a disciplined production culture. The second wave of the software industry came with the rise of the object-oriented technology and its associated reuse, combined with the emergence of the focus of the software process maturity and improvement started by Watts Humphrey (Humphrey, 1989) and championed by the Software Engineering Institute (SEI). The software process movement had great promises towards injecting discipline and continuous improvement into the software industry. However this was not enough to move the software industry into the state of industrialization.

Research and industry survey show that the effort put into Software Process Improvement (SPI) models and frameworks can assist in producing high quality software, reducing cost and time, and increasing productivity and employee satisfaction (Ashrafi, 2003; Butler, 1995; Jiang, Klein, Hwang, Huang, & Hung, 2004; Niazi, Wilson, & Zowghi, 2006b; Pitterman, 2000; Yamamura, 1999; Zahran, 1998). However, only a small proportion of the software developing organisations' population has adopted SPI models and framework. This is depicted in the SEI CMMI appraisal report in which only 3113 CMMI appraisals were reported to the SEI (SEI, 2008). Research also shows that a large majority of software development organisations appear to be unwilling to follow SPI initiatives based on process capability maturity models like CMMI (Staples et al., 2007). This may be due to the fact that an SPI programme is quite an expensive undertaking as organisations need to commit significant resources over a long time period (Coleman & O'Connor, 2008). Even organisations who are willing to commit the resources and time do not always achieve their desired results from their SPI initiatives (Florence, 2001; Kautz & Nielsen, 2000). Hence, the significant investment required and limited success are considered two of the main reasons why many organisations are reluctant to embark on a long path of systematic process improvement (Staples et al., 2007). In the case of small and medium size organisations, there are more concerns about the relevance and applicability of SPI models like CMM or CMMI (Brodman & Johnson, 1994; Staples et al., 2007).

Due to complex nature of SPI initiatives it has been proven to be hard for companies to successfully design and implement software process improvement. A typical approach to SPI in general has three stages: process appraisal, process definition/redesign and process implementation and deployment. The process appraisal phase consumes a larger percent of the budget and resources; process definition requires model knowledge, process design knowledge and skills and knowledge of the organisation/company; and often process implementation and deployment is not only across multi-project, but also across multi-site and multi-customer type. The whole SPI initiative is a long-term approach and it takes time to fully implement a SPI initiative. This is one of the reasons that many organisations are reluctant to embark on a long path of systematic process improvement.

Extensive literature review revealed that many standards and models exist for SPI but little attention has been paid to their effective adoption and implementation of these models. The chaotic implementation process is the most common cause of SPI implementation failure (Zahran, 1998). Attention to a defined SPI implementation process is essential for the success of any SPI initiative. In order to address the SPI implementation issues a Software Process Lines approach has been proposed in this chapter. The objective of the Software Process Lines is to reuse the artefacts in SPI initiatives which are costly to develop from scratch. This will not only help organisations to save their time for process definition/ deployment but will also assist them in quickly moving from lower maturity level to higher maturity levels. We believe that the concept of Software Process Lines, introduced in this chapter, in association with the concept of Software Product Line, championed by the SEI (http://www.softwareproductlines.com/), has the potential to instil process discipline and continuous improvement into software development. We believe that are witnessing the early stage of moving towards an era of software industrialization.

Need to Address both the Software Product and the Software Process

In our view, the move towards Software Industrialization requires parallel progress on two fronts: the first is the software product development and the second is the software process maturity and improvement. There are some serious progress and promising results on the front of software product development as reported by the Software Engineering Institute's (SEI) program on Software Product Lines (http://www.sei.cmu.edu/productlines/index.cfm). There should be a similar progress on the front of software development process.

For the last decade there have been many advances in standards and models to improve the software development process. Research shows that the effort put into these SPI models and standards can assist in producing high quality software, reducing cost and time, and increasing productivity (Ashrafi, 2003; Butler, 1995; Pitterman, 2000; Yamamura, 1999). However, these advances have not been matched by equal advances in the adoption of these standards and models in software development (Leung, 1999) which has resulted in limited success for many SPI efforts. Studies show that 67% of SPI managers want guidance on 'how' to implement SPI activities, rather than 'what' SPI activities to actually implement (Herbsleb & Goldenson, 1996). Despite the importance of the SPI implementation process, little empirical research has been carried out on developing ways in which to effectively implement SPI programmes. This suggests that the current problem with SPI is not due to a lack of a standard or model, but rather a lack of effective strategies to successfully implement these standards or models.

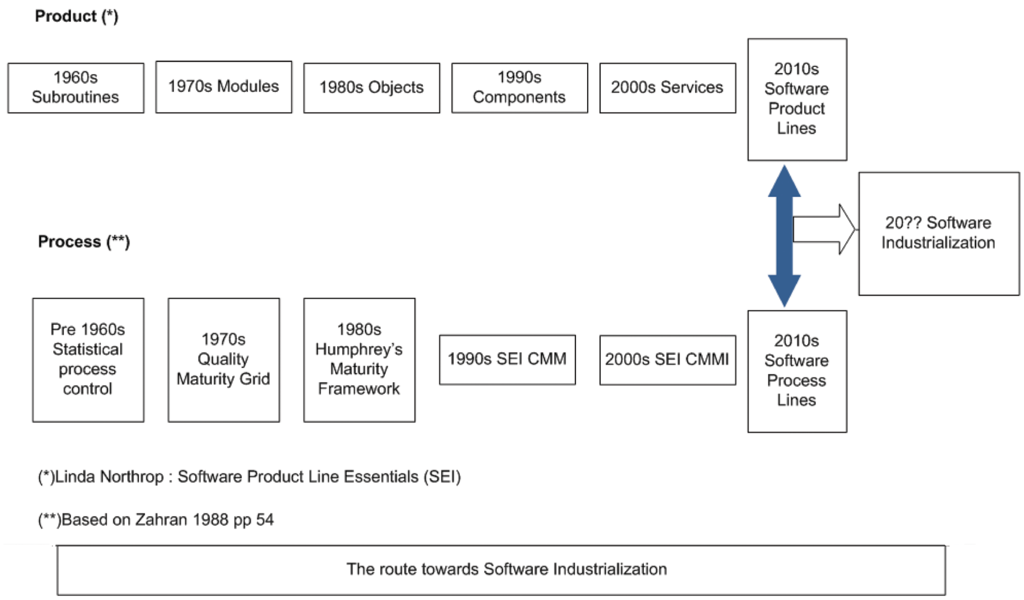
Software quality has received much attention in both academia and industry. This is due to the role software plays in modern-day business and, to some extent, modern-day living. Attempts to improve software quality have been going on for several decades. Software organisations have been struggling with a questionable quality image for their products for a long time (Zahran, 1998). Customer satisfaction has also become the motto of many software organisations in order to survive with quality software (Paulk, Weber, Curtis, & Chrissis, 1994). Software quality has become more critical as software pervades our day-to-day lives (Pitterman, 2000; Yamamura, 1999). We believe that Software Industrialization will provide a way to deliver quality software within budget and schedule, something that currently eludes most software organisations (Ashrafi, 2003; Jiang et al., 2004; Paulk et al., 1994; Standish-Group, 2003). In order to effectively address the software quality issues different approaches have been developed, of which software process improvement (SPI) is the one most widely used (SEI, 2004).

TOWARDS SOFTWARE INDUSTRIALIZATION

We believe that the Software Industry has made big steps over the past five decades towards achieving moving the software industry away from being a "cottage industry" towards achieving a level of process discipline, automation and mass production similar to those achieved in the manufacturing industry as a result of the industrial revolution.

Achieving the status of Industrialization, there is a need to make progress at two parallel fronts: one on the Product Development front, and the other on the Process and Tools front. Figure 1 highlights a number of major milestones of the software industry's progress along the route to-

Figure 1. The route towards software industrialization (Northrop, 2008; Zahran, 2008)



wards Software Industrialization on the two fronts of Product and Process.

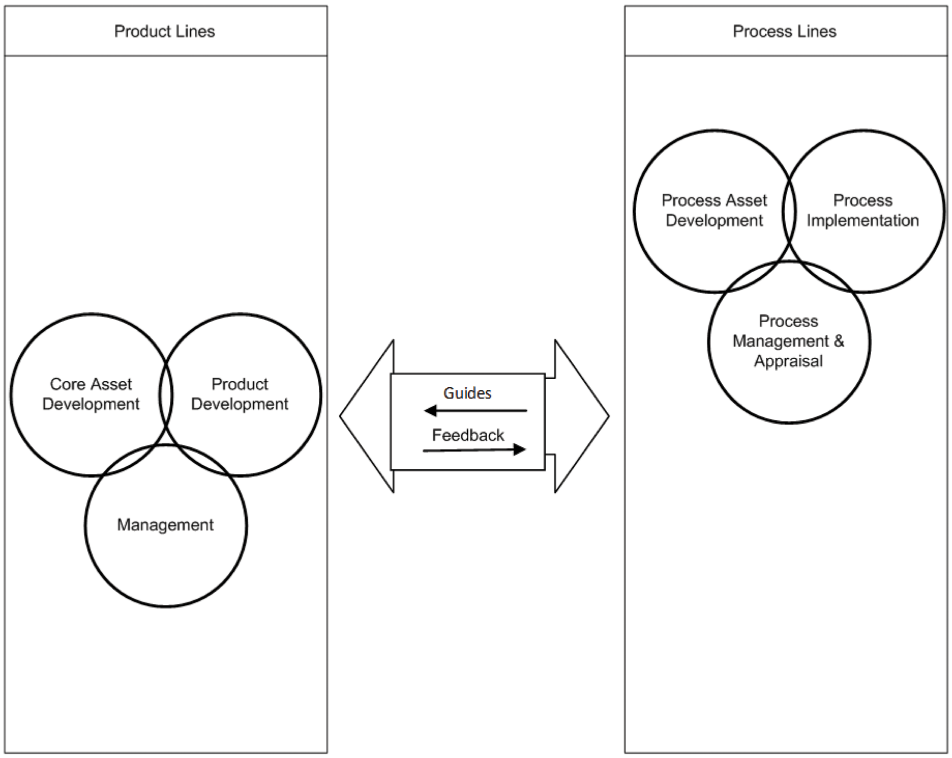
Software Product Lines need to be supported by corresponding Software Process Lines in order to achieve the qualitative shift towards the industrialization of software product development. Successful implementation of Software Product Lines will not be possible in the absence of mature disciplined processes that are continuously optimised and improving. In the case of the manufacturing industry, there was no way for it to achieve its current advanced status without well defined and mostly automated processes. The concept of Software Product Lines is well developed and is now pioneered by a number of product domains in diverse areas including: mobile phones, satellite ground station systems, command and control ship systems, mass storage systems, billing systems, printers and medical devices). Leading organisations who piloted the Software Product Lines and achieved gains and benefits include: Boeing, ERICSSON, NOKIA, HP, ABB, and GM. (Northrop, 2008).

The concept of Software Process Lines, which we developed and describe in this chapter, is still in the early stages of development. Figure 2 illustrates how Product Lines and Process Lines may interact with each other. As illustrated, the Software Process Lines are used to tailor generic processes to generate specific processes to be followed to develop specific products using the generic assets in the Software Product Lines. That means that the Process Lines provide guidance on how to customise and use the core component assets in the Product Lines to develop specific products. In the other direction, there should be feedback from the Product Lines to the Process Lines on the process performance and any need to upgrade or modify the processes in the Process Lines. That feedback should include all the lessons learned resulting from the tailoring of the product lines and any additions to the product lines.

OVERVIEW OF SOFTWARE PRODUCT LINES

Software product lines are emerging as a new and important software development paradigm. A software product line is "a set of software-intensive

Figure 2. Interaction between process lines and product line



systems sharing a common set of features that satisfy the specific needs of a particular market segment or mission" (Clements & Northrop, 1999)

The rationale behind software product lines is that "the practice of building sets of related systems from common assets can yield remarkable quantitative improvements in productivity, time to market, product quality, and customer satisfaction" (Clements & Northrop, 1999) in contrast to being developed one at a time in separate efforts. Using common sets, a new product is formed by taking applicable components from the asset base, tailoring them as necessary through pre-planned variation mechanisms such as parameterisation, adding new components that may be necessary, and assembling the collection under the umbrella of a common, product line-wide architecture (Clements & Northrop, 1999). Building a new product becomes more a matter of generation than creation; the predominant activity is integration rather than programming.

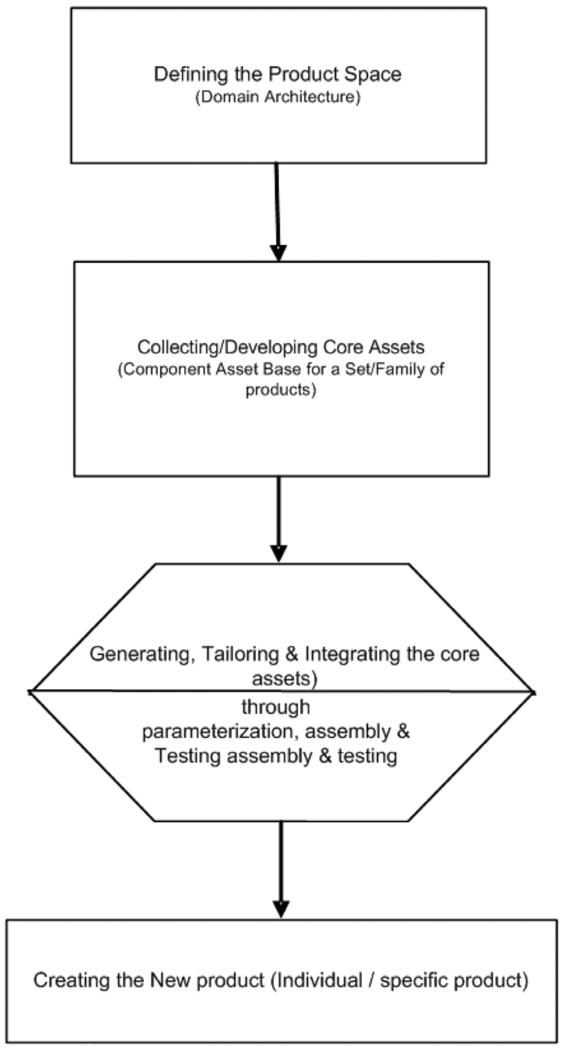
According to the SEI (http://www.sei.cmu.edu/productlines/), organisations of all types and sizes have discovered that a product line strategy, when skilfully implemented, can produce many benefits—and ultimately give the organisations a competitive edge. Example organisational benefits include:

- Improved productivity by as much as 10x
- Increased quality by as much as 10x
- Decreased cost by as much as 60%
- Decreased labour needs by as much as 87%
- Decreased time to market (to field, to launch) by as much as 98%
- Ability to move into new markets in months, not years

Figure 3 below illustrates the main activity flow in a software product line environment.

Generally, adopting a software product line approach involves two classes of activities: Core

Figure 3. Main activity flow in Software Product Lines environment



asset development or acquisition, and Product development or acquisition using core assets. The activities involved are:

- Defining the product space
- Producing the core assets
- Requirements for the specific product
- Developing the production plan

A number of practice areas relevant to each of these activities are suggested by the SEI Product Lines Program in a framework for software product line practice (www.sei.cmu.edu/productlines/frame_report/PL.essential.act.htm)

SOFTWARE PROCESS LINES

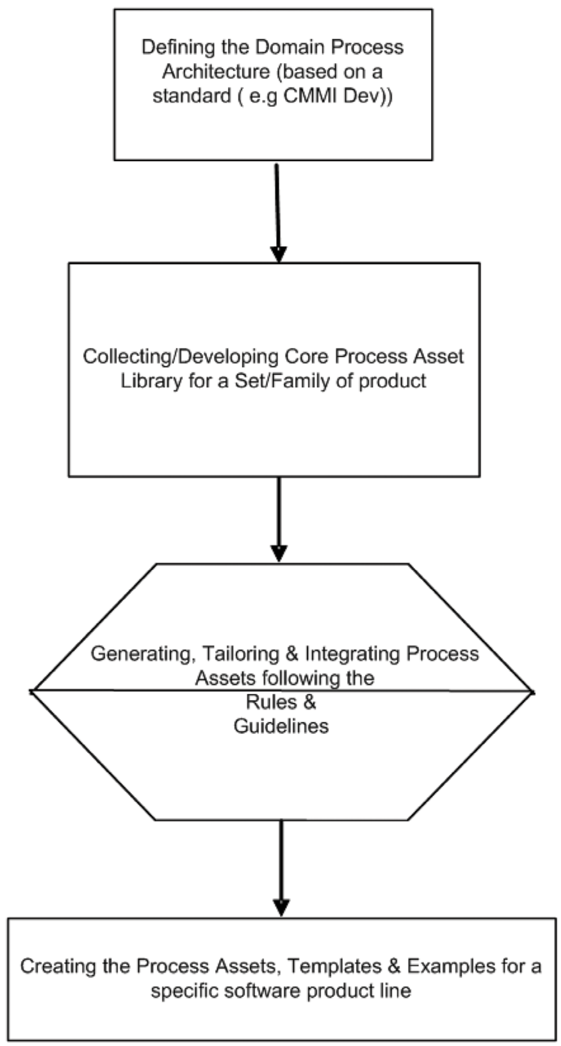
Our suggested Software Process lines approach is based on the concept of software product line approach (Northrop, 2002). As mentioned above, "A software product line is a set of software-intensive systems that share a common, managed feature set satisfying a particular market segment's specific needs or mission and that are developed from a common set of core assets in a prescribed way" (Northrop, 2002). One of the important characteristics of a software product line is Strategic Reuse of a set of reusable product components which has a significant impact on cost of the product.

We have noticed through our experience and working in academia and industry that a similar approach can be adapted for a software process lines which encourages the reuse of generic process assets, thus avoiding the costly effort of developing the process artefacts from scratch. Software Process Line can be defined as "a set of core processes that share a common feature set to satisfy the needs and requirements for process implementation strategies". These core processes form the basis for the software process lines (Figure 4).

Like the essential product line activities described in (Northrop, 2002), we have proposed three essential activities in software process line as shown in Figure 5. Software Process line involves "core process development", "process implementation" and "process management and appraisal".

In the "core process development" activity, generic process patterns will be developed, using process definitions, process patterns, styles and frameworks, which can be adapted by the product development team to their process needs and requirements. Several examples of process pat-

Figure 4. Main activity flow in software process lines environment



terns are already available (Forster, 2006; Telesko & Ferber, 2007; Zahran, 2008). Reuse of these patterns in the process development should save the organisation effort and time in the core process development.

In the "core process implementation" activity, generic process implementation strategies will be developed, using change management methods and process improvement implementation theories, practices and frameworks, which can be adapted by organisations in their SPI implementation initiatives in order to save organisations time for designing new SPI implementation strategies.

The objective of "process management and appraisal" activity is to provide technical and organisational support to other two activities of the software process line in order to successfully implement the software process line initiative.

Core Process Development

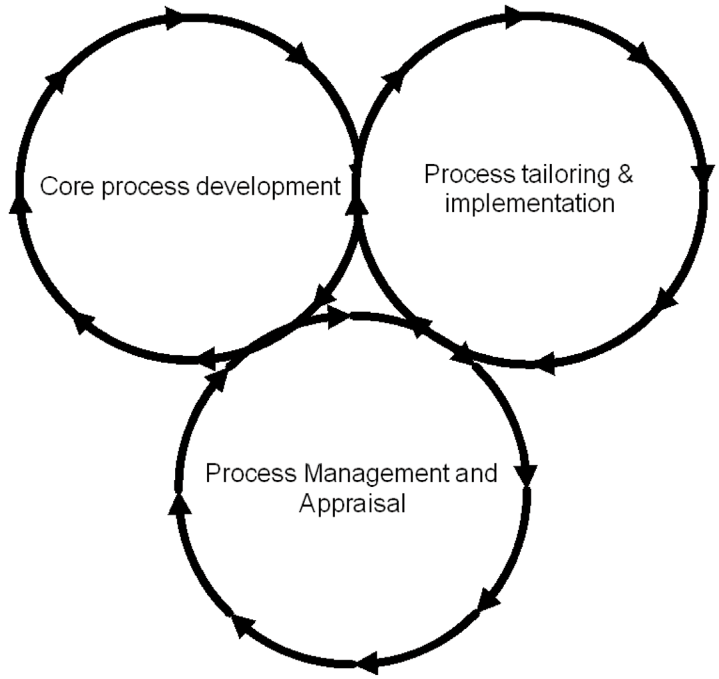
The objective of core process development is to develop core generic process patterns which can easily be adapted by organisations to their SPI needs and requirements as shown in Figure 6. This will not only help organisations to save their time for process definition and development but will also assist them in quickly moving from lower maturity level to higher maturity levels. Research shows that organisations are spending a lot of time in moving from lower maturity level to higher maturity levels which is depicted in the Software Engineering Institute report (SEI, 2004):

- Maturity level 1 to 2 is 22 months
- Maturity level 2 to 3 is 19 months
- Maturity level 3 to 4 is 25 months
- Maturity level 4 to 5 is 13 months

The basic reason for this delay is that in any SPI initiative organisations develop processes from scratch because there are little benchmark processes and process patterns available which might be used to develop these new processes quickly. Despite the importance of this issue, little research has been carried out on software process implementation strategies in general and designing of benchmark process or process patterns in particular. As mentioned earlier only recently some pioneering work on software process patterns has taken place (Forster, 2006; Telesko & Ferber, 2007; Zahran, 2008).

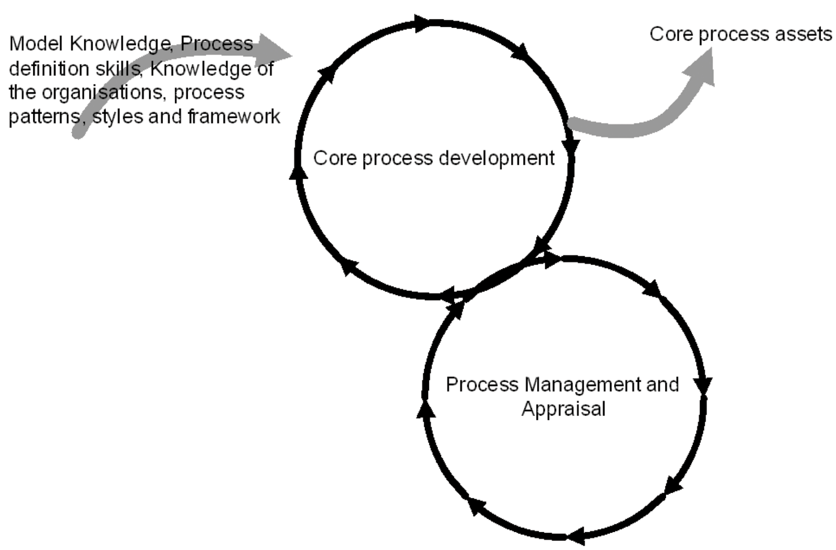
In our previous research (Niazi, Hickman, Ahmad, & Babar, 2008) we have taken initiatives to start work in this missing area of SPI.

Figure 5. Software process lines activities



The objective was, as a pilot project, to design a process pattern for CMMI Level 2 specific practice–"manage requirements changes" as shown in Figure 7. We have proposed a pattern in the form of a model for requirements change management and also discussed initial validation of that model in (Niazi et al., 2008). That model was based on both an empirical study that

Figure 6. Core process line development



we have carried out and our extensive literature review of SPI and requirements engineering. For data collection we have interviewed SPI experts from reputed organisations. Further work included analysing research articles, published experience reports and case studies. Our model is based on five core elements: request, validate, implement, verify and update. Within each of these elements we have identified specific activities that need to take place during requirements change management process.

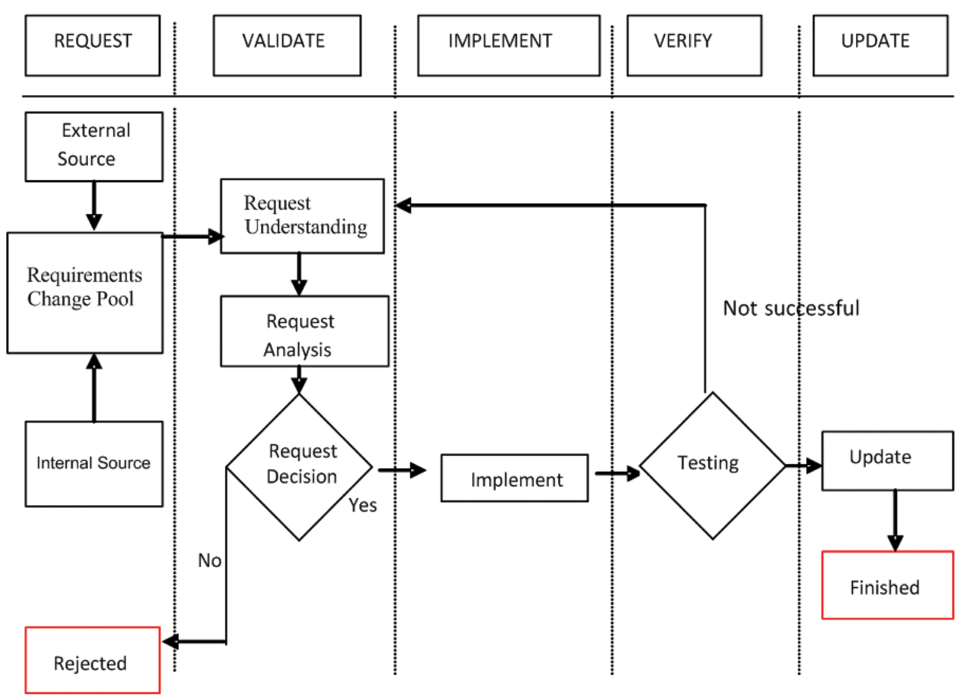
The initial stage is the change "Request". The main sources of requests may be either internal or external. The internal requests come from the project management or software maintenance teams within the company. The external requests come from the customers. These internal and external requests are then fed to a requirements change pool. The requirements change pool contains a description of the change, the reasons behind the changes and who has requested the change.

The next stage is to "Validate" the change request. The first activity in the validate stage is to understand the change request (i.e. what needs to be done–fix, an enhancement or removal). Request analysis is the activity to look at the different ways in which the request can be met, i.e. how much effort is needed to make this change, how much effort is needed to implement this change, the impact of the change, the risk of change and the priority of each change request.

The final activity of the validation process is to make decision if the change request should be accepted, rejected or reanalysed with new evidence. The third stage is to "Implement" the changes. In this stage all the accepted changes are consolidated and are implemented in the form of end product or software.

The fourth stage is to "Verify" changes where it is ascertained that the software conforms to its specification. In this stage the new product/software is tested in the form of regression testing, field trials or user acceptance. The testing method

Figure 7. An example of a process pattern for core process line



will depend on the characteristics of the request and the environment of the product/software. If the verification stage is not successful the change request is sent back to the "Validate" stage for further understanding and analysis of the change request.

The final stage is "Update". Documentation on the software is updated with the changes made. The customers and the project team are all informed about these update so that everyone is working on the current up to date version. The finished step is when the product/software is released with the new requirements included.

The initial evaluation of the model was performed via an expert review process. The initial evaluation of the model showed that the requirements change management model is clear, easy to use and can effectively manage the requirements change process. However, more case studies are needed to evaluate this model in order to further evaluate its effectiveness in the domain of the requirements process.

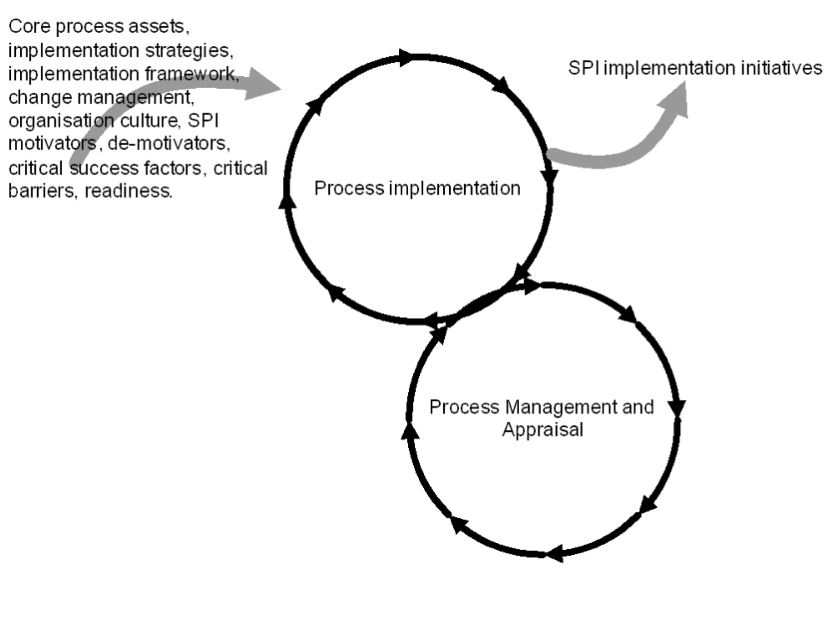
After successfully developing the pattern for one specific practice we are now planning to develop patterns for all of the specific practices of CMMI. However, we encourage other people to conduct more studies to develop new process patterns which can satisfy CMMI specific and generic practices.

Process Implementation

The objective of process implementation activity is to develop process implementation strategies which can easily be adapted by organisations in their software process implementation and process implementation initiatives as shown in Figure 8 This will also help organisations to save time and effort in designing new process implementation and process improvement strategies.

A number of researchers have tried to address some of the issues of SPI implementation by exploring SPI implementation success factors, barriers, motivators and de-motivators (Baddoo & Hall, 2002, 2003; El-Emam, Fusaro, & Smith, 1999; Goldenson & Herbsleb, 1995; Niazi & Babar, 2008, 2007a, 2007b; Niazi & Staples, 2005; Niazi, Wilson, & Zowghi, 2004, 2006a). These studies indeed contribute towards SPI implementation where SPI managers can use their lessons

Figure 8. Process implementation



and concepts as motivators in their SPI implementation strategies. In addition the SPI managers can also design some strategies to cope with and overcome any barriers and or de-motivators to software process improvements in their organisations. However, more work is needed to assist SPI managers in the form of models and frameworks that could help in successfully implementing SPI initiatives. More work is also needed to develop generic implementation strategies which can easily be adapted by organisations in their SPI implementation initiatives to save their time for designing new SPI implementation strategies.

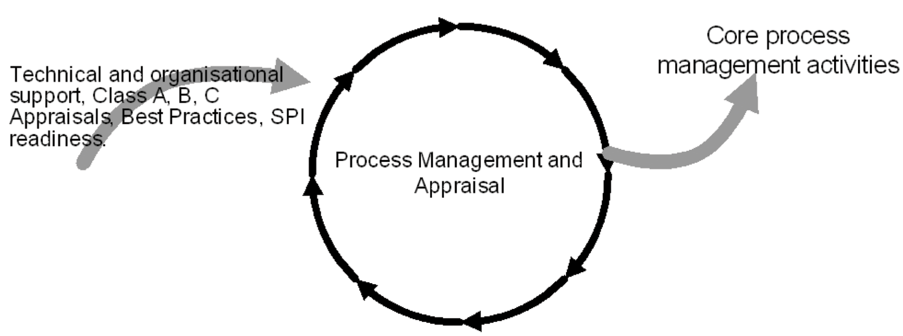
Process Management and Appraisal

The objective of process management and appraisal activity is to provide technical and organisational support to other two activities of process line SPI in order to successfully develop the whole process line SPI initiative as shown in Figure 9. In addition, different appraisals are performed to assess the core process development and process implementation activities. The technical management oversees the core process development and process implementation, ensuring that the stakeholders involved in building processes and patterns engage in the right activities and collect sufficient data to perform these activities. The organisational support ensures that the SPI teams receive the right and enough resources (i.e. experienced people, training, and budget) for SPI activities. In the organisational support the management assist SPI teams to address any barriers or risks that threaten Software Process Line activities. Finally, someone should be designated as the process line manager to lead all the Software Process Line activities.

In order to perform process appraisals, there are three classes available of CMMI SCAMPI appraisals Class A, B, and C (Ahern et al., 2005; CMMI-Product-Team, 2001). Class A appraisals are very costly, time-consuming, and resource-intensive, but provide the highest levels of assurance about their findings. Class B appraisals are less costly, time-consuming and resource-intensive as they use fewer appraisers, appraise fewer projects, and rely on fewer forms of evidence. Class C appraisals are the cheapest and easiest to perform, and can approach the simplicity of a structured questionnaire. All appraisals result in a report of findings about an organisation's capability, but only Class A appraisals can result in a publicly-reportable "rating" of the organisation's CMMI level.

Conducting research on SPI implementation has convinced us to conduct some research on appraisal of organisations readiness for SPI implementation. It is very important to measure organisations readiness for SPI implementation as the failure rate for SPI programmes has been reported up to 70% in a report from the Software Engineering Institute (SEI) (Ngwenyama

Figure 9. Process management and appraisal



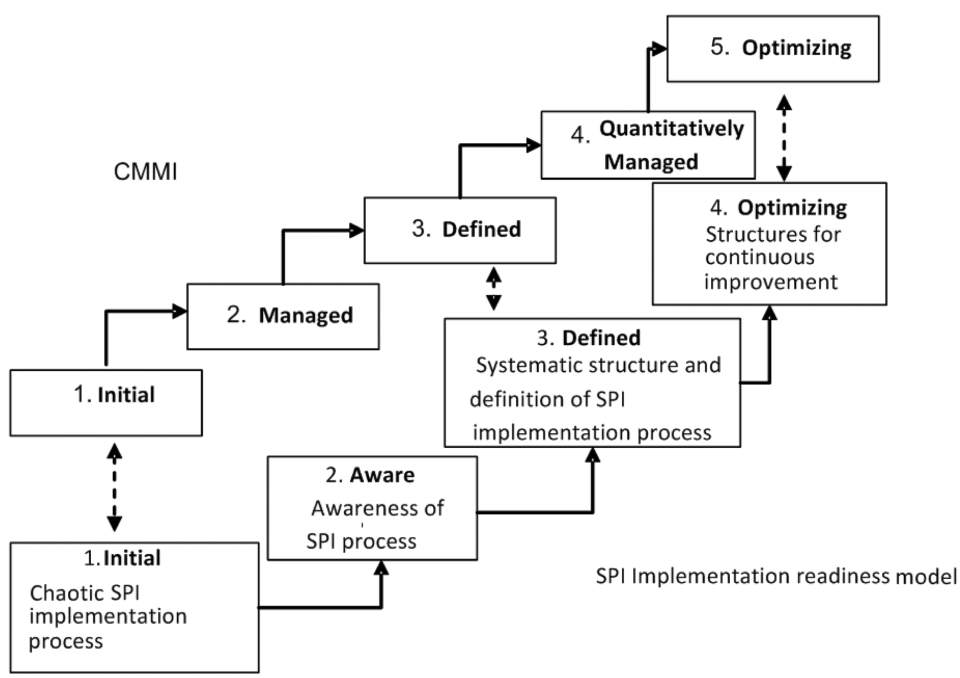
& Nielsen, 2003; SEI, 2002). This shows that many organisations go for SPI implementation prior to testing their readiness for SPI activities. We have focused on these issues and developed a SPI readiness model (as shown in Figure 10) in order to assess the SPI implementation readiness of the organisations (Niazi et al., 2005). The CMMI perspective (Chrissis, Konrad, & Shrum, 2006) and the findings from our previous empirical study (Niazi, Wilson, & Zowghi, 2003; Niazi et al., 2004) were used in the design of the SPI readiness model. The SPI readiness model has four SPI implementation readiness levels abstracted from CMMI. These readiness levels contain different critical success factors (Niazi et al., 2006a) and critical barriers (Niazi et al., 2004) identified through the literature and interviews. Under each factor, different practices have been designed that guide how to assess and implement each factor. We have evaluated this model with three large sized and two medium sized organisations. The evaluation results showed that this model can be used effectively to identify SPI implementation issues with a goal of increasing SPI implementation readiness. All the case study participants agreed that this model is clear, easy to use and specifically geared to assess the organisations' SPI implementation readiness.

CONCLUSION AND FUTURE WORK

In conclusion, here is a summary of the main points in this chapter:

- Software process improvement is still a costly and complex endeavour for many organisations.
- There is a lack of re-use of software process patterns to create core software processes and instil software process improvement practices in the organisation's fabric.
- The SEI Software Product Lines initiative is achieving success and resulting in

Figure 10. SPI implementation readiness model (Niazi, Wilson, & Zowghi, 2005)



benefits for organisations that adopted this approach.

- We believe that an effort to develop Software Process Lines is necessary to complement, support and enhance the value of adopting the Software Product Lines approach.
- In this chapter we have introduced our approach to Software Process Lines, which we believe together with the Software Product Lines can provide a good springboard to moving towards the Software Industrialization

We suggest that further work is still needed in progressing our concepts forward, especially in the following areas which we recommend them for students and researchers:

- Prototyping our approach to Software Process Lines in order to prove the concepts viability in commercial and business environment
- Piloting the combined implementation of the Software Product Lines and the Software Process Lines (in a software factory-like environment) to order to prove the concept of Software Industrialization
- Elaborating of the definitions and descriptions of the basic concepts described in this chapter and formulating them in coherent methodology for developing and using Software Process Lines
- Practicing and piloting the Software Process Lines activity flow shown in Figure 3, and elaborating the activities and the flow based on the lessons learned resulting from the pilots.
- Suggesting more details of the possible interface and interaction between Process Lines and Products Lines as outlined in Figure 2.

The authors welcome any initiative in the above direction and are willing to provide advice and support to any effort in this direction.

Chapter 108
Super High Efficiency Multi-Junction Solar Cells and Concentrator Solar Cells

Masafumi Yamaguchi
Toyota Technological Institute, Japan

ABSTRACT

While single-junction solar cells may be capable of attaining AM1.5 efficiencies of up to 29%, Multi-Junction (MJ, Tandem) III-V compound solar cells appear capable of realistic efficiencies of up to 50% and are promising for space and terrestrial applications. In fact, the InGaP/GaAs/Ge triple-junction solar cells have been widely used in space since 1997. In addition, industrialization of concentrator solar cell modules using III-V compound MJ solar cells have been announced by some companies. This chapter presents principles and key issues for realizing high-efficiency MJ solar cells, issues relating to development and manufacturing, and applications for space and terrestrial uses.

INTRODUCTION

Multi-Junction (MJ, Tandem) solar cells are composed of multi-layers with different bandgap energies are shown in Figure 1 and have the potential for achieving high conversion efficiencies of over 50% and are promising for space and terrestrial applications due to wide photo response. Figure 2 shows theoretical conversion efficiencies of single-junction and Multi-Junction (MJ) solar cells in comparison with experimentally realized efficiencies.

Tandem solar cells were proposed by Jackson (1955) and Wolf (1960). Table 1 shows progress of the III-V compound multi-junction solar cell technologies. MIT group (Fan, Tsaur, & Palm, 1982) encouraged R&D of tandem cells based on their computer analysis. Although AlGaAs/GaAs tandem cells, including tunnel junctions and metal interconnectors, were developed in the early years, a high efficiency close to 20% was not obtained (Hutchby, Markunas, & Bedair,

DOI: 10.4018/978-1-4666-1945-6.ch108

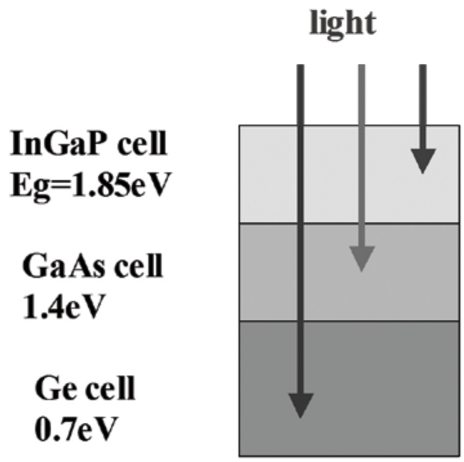

Figure 2. Theoretical conversion efficiencies of single-junction and multi-junction solar cells in comparison with experimentally realized efficiencies

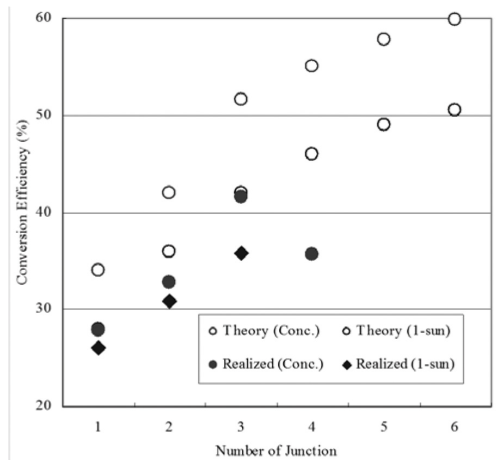

1985). This is because of difficulties in making high performance and stable tunnel junctions, and the defects related to the oxygen in the AlGaAs materials (Ando, Amano, Sugiura, et al., 1987). A Double Hetero (DH) structure tunnel junction was found to be useful for preventing diffusion from the tunnel junction and improving the tunnel junction performance by the authors (Sugiura, Amano, Yamamoto, & Yamaguchi, 1988). The authors demonstrated 20.2% efficiency AlGaAs/GaAs 2-junction cells (Amano, Sugiura, Yamamoto, & Yamaguchi, 1987). An InGaP material for the top cell was proposed by NREL group (Olson, Kurtz, & Kibbler, 1990). As a result of performance improvements in tunnel junction and top cell, over 30% efficiency has been obtained with InGaP/GaAs 2-junction cells by the authors (Takamoto, Ikeda, Kurita, et al., 1997).

InGaP/GaAs-based MJ solar cells have drawn increased attention for space applications because superior radiation-resistance of InGaP top cells and materials have been discovered by the authors (Yamaguchi, Okuda, Taylor, et al., 1997). and those have the possibility of high conversion efficiency of over 30%. In fact, the commercial satellite (HS 601HP) with 2-junction GaInP/GaAs-on Ge solar arrays was launched in 1997 (Brown, Goldhammer, Goodelle, et al., 1997).

More recently, InGaP/GaAs-based MJ solar cells have drawn increased attention for terrestrial applications because concentrator operation of MJ cells have great potential of providing high performance and low-cost solar cell modules. For concentrator applications, grid structure has been designed in order to reduce the energy loss due to series resistance, and 38.9% (AM1.5G, 489-suns) efficiency has been demonstrated by Sharp (Takamoto, Kaneiwa, Imaizumi, & Yamaguchi, 2005). Most recently, 41.6% efficiency has been reported with InGaP/GaAs/Ge 3-junction concentrator cells by Spectrolab (King, Boca, Hong, et al., 2009). In addition, the authors have realized high-efficiency and large-area (5,445cm^2) concentrator InGaP/InGaAs/Ge 3-junction solar cell modules of an outdoor efficiency of 31.5% (Araki, Uozumi, Egami, et al., 2005). as a result of developing high-efficiency InGaP/InGaAs/Ge 3-junction cells, low optical loss Fresnel lens and homogenisers, and designing low thermal conductivity modules. Some companies including Sharp (Tomita, 2006) have announced to commercialise

KEY ISSUES FOR REALIZING HIGH-EFFICIENCY MJ SOLAR CELLS

Key issues for realizing high-efficiency MJ tandem cells are discussed based on our results.

Selection of Cell Materials and Improving the Quality

MJ cells with different band gaps are stacked in tandem so that the cells cover wide wavelength region from 300 nm to 1800 nm. Cell materials are selected by considering band gap energies close to the optimal band gap energy combination based on theoretical efficiency calculation, and by considering lattice matching to substrates and less impurity problems. Figure 3 shows minority-carrier diffusion length dependence of GaAs single-junction solar cell efficiency. It is clear that the higher minority-carrier diffusion length L (minority-carrier lifetime $\tau = L^2 / D$, where D is minority-carrier diffusion coefficient) is substantially necessary to realize the higher efficiency solar cells. Figure 4 shows carrier concentration dependence of minority-carrier lifetime in p-type and n-type GaAs (Ahrenkiel, Keyes,

Figure 3. Minority-carrier diffusion length dependence of GaAs single-junction solar cell efficiency

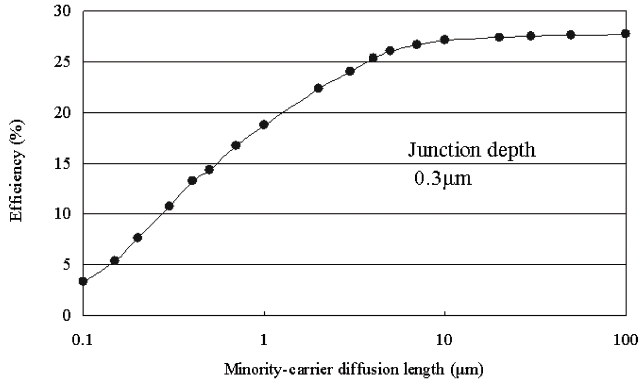

Figure 4. Carrier concentration dependence of minority-carrier lifetime in p-type and n-type GaAs (Ahrenkiel, Keyes, Durbin, & Gray, 1993)

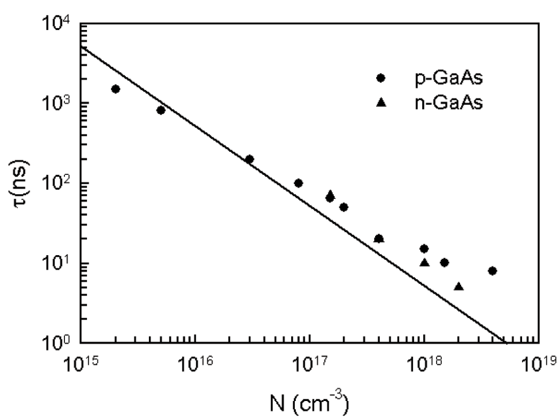


Durbin, & Gray, 1993). Minority-carrier lifetime τ is dependent on carrier concentration N of solar cell layers as expressed by:

$$\tau = 1 / BN \tag{1}$$

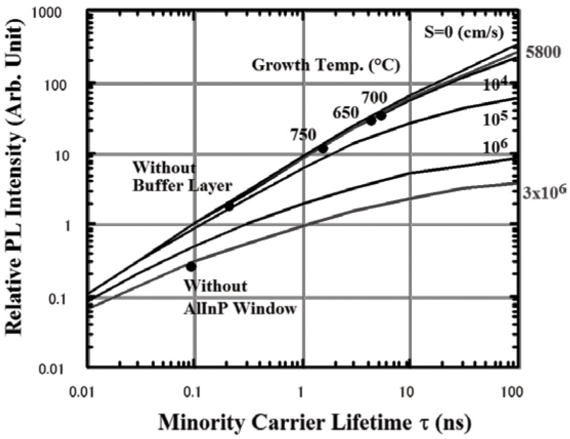
where, B is radiative recombination coefficient. Therefore, carrier concentration of cell layers must be optimised by considering minority-carrier lifetime, build-in potential, and series resistance of p-n junction diodes.

Selection of cell materials, especially selection of top cell materials is also important for high-efficiency tandem cells. It has been found by the authors (Hutchby, Markunas, &. Bedair, 1985) that oxygen-related defect in the AlGaAs top cell materials acts as the recombination centre. As a top cell material latticed matched to GaAs or Ge substrates, InGaP has some advantages (Olson, Kurtz, & Kibbler, 1990) such as lower interface recombination velocity, less oxygen problem and good window layer material compared to AlGaAs. The top cell characteristics depend on the minority carrier lifetime in the top cell layers. Figure 5 shows changes in Photoluminescence (PL) intensity of the solar cell active layer as a function of the minority carrier lifetime τ of the p-InGaP base layer grown by MOCVD (metal-organic chemical vapour deposition) and surface recombination velocity (S). The lowest S was obtained by introducing the AlInP window layer and the highest τ was obtained by introducing buffer layer and optimising the growth temperature. The best conversion efficiency of the InGaP single-junction cell was 18.5% (Yang, Yamaguchi, Takamoto, et al., 1997).

Lattice Matching between Cell Materials and Substrates

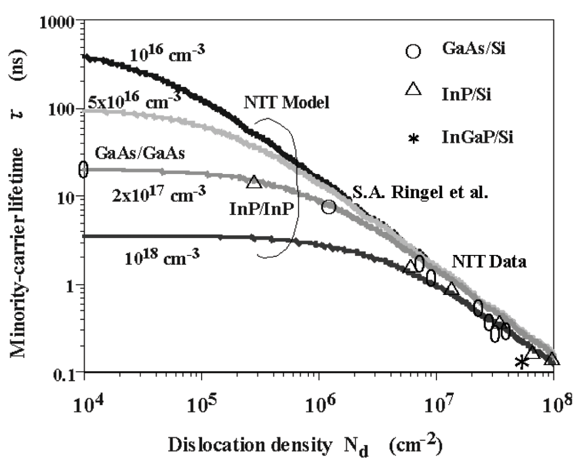
Lattice mismatching of cell materials to substrates should be decreased because miss-fit dislocations must be generated in the upper cell layers and deteriorate cell efficiency. Figure 6 shows calculated and experimental dislocation density depen-

Figure 5. Changes in photoluminescence (PL) intensity of the solar cell active layer as a function of the minority carrier lifetime in GaAs, grown by MOCVD and surface recombination velocity (S)



dence of minority-carrier lifetime in GaAs (Yamaguchi & Amano, 1985). Dislocation density N_d dependence of minority-carrier lifetime τ is expressed by the following equation (Yamaguchi & Amano, 1985):

Figure 6. Calculated and experimental dislocation density dependence of minority-carrier lifetime in GaAs, InP, and InGa



$$1/\tau = 1/\tau_r + 1/\tau_0 + \pi^3 D N_d / 4 \qquad (2)$$

where τ_r is radiative recombination lifetime and τ_0 is minority-carrier lifetime associated with recombination at other unknown defects.

Application of InGaAs middle cell (Yamaguchi & Amano, 1985) lattice-matching to Ge substrates has demonstrated to increase open-circuit voltage (V_{oc}) due to lattice-matching and short-circuit current density (J_{sc}) due to decrease in bandgap energy of middle cell.

Effectiveness of Wide Bandgap Back Surface Field (BSF) Layer

Figure 7 shows surface recombination effect on short-circuit current density J_{sc} of $In_{0.14}Ga_{0.86}As$ homo-junction solar cells as a function of junction depth. Therefore, in order to improve efficiency drop attributed from front and rear surface recombination as shown in Figure 8, formation of heteroface or double-hetero structure is necessary.

Figure 8 shows changes in V_{oc} and J_{sc} of InGaP single-junction cells as a function of potential barrier ΔE. Wide bandgap Back-Surface Field (BSF) layer (Yamaguchi & Amano, 1985) is found

Figure 7. Surface recombination effect on short-circuit current density Jsc of $In_{0.14}Ga_{0.86}As$ homo-junction solar cells as a function of junction depth

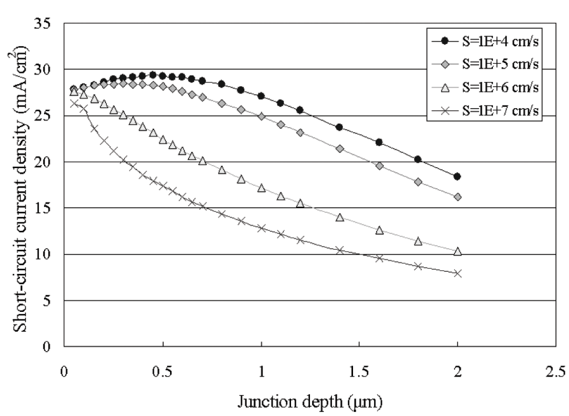


Figure 8. Changes in Voc and Jsc of InGaP single-junction cells as a function of potential barrier ΔE

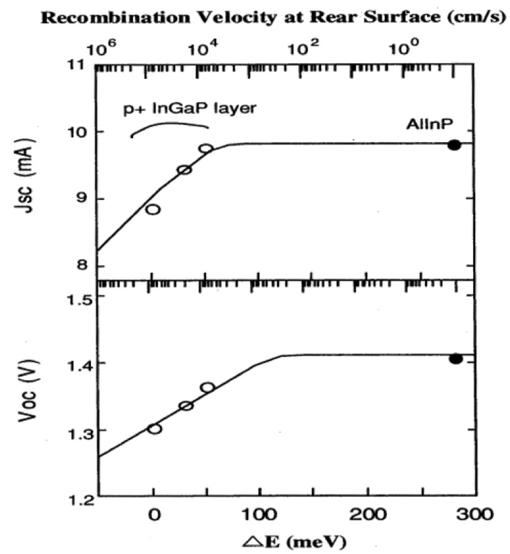

to more effective for confinement of minority carriers compared to highly doped BSF layers.

Low Loss Tunnel Junction for Intercell Connection and Preventing Impurity Diffusion from Tunnel Junction

Another important issue for realizing high-efficiency monolithic-cascade type tandem cells is the achievement of optically and electrically low-loss interconnection of two or more cells. A degenerately doped tunnel junction is attractive because it only involves one extra step in the growth process. To minimize optical absorption, formation of thin and wide-bandgap tunnel junctions is necessary as shown in Figure 9. However, the formation of a wide-bandgap tunnel junction is very difficult because the tunnelling current decreases exponentially with increase in bandgap energy.

In addition, impurity diffusion from a highly doped tunnel junction during overgrowth of the top cell increases the resistivity of the tunnel junction. As shown in Figure 10, a Double Hetero (DH) structure was found to be useful for preventing diffusion by the authors (Sugiura, Amano, Yamamoto, & Yamaguchi, 1988). An InGaP tunnel junction has been for the first time tried for an InGaP/GaAs tandem cell in our work (Takamoto, Ikeda, Kurita, et al., 1997). As p-type and n-type dopants, Zn and Si were used, respectively. Peak tunnelling current of the InGaP tunnel junction is found to increase from 5mA/cm^2 up to 2A/cm^2 by making a DH structure with AlInP barriers. Therefore, the InGaP tunnel junction has been observed to be very effective for obtaining high tunnelling current, and DH structure has also been confirmed to be useful for preventing diffusion.

DH structure effect on suppression of impurity diffusion from the tunnel junction has been examined. Effective suppression of the Zn diffusion from tunnel junction by the InGaP tunnel junction with the AlInP-DH structure is thought to be attributed to the lower diffusion coefficient (Takamoto, Yamaguchi, Ikeda, et al., 1999) for Zn in the wider bandgap energy materials such as the AlInP barrier layer and InGaP tunnel junction layer.

Table 2 summarizes key issues of realizing super-high-efficiency MJ solar cells

Figure 9. Calculated tunnel peak current density and short-circuit current density Jsc of GaAs bottom cell as a function of bandgap energy of tunnel junction

HIGH-EFFICIENCY INGAP/GAAS/GE 3-JUNCTION SOLAR CELLS AND THEIR SPACE APPLICATIONS

Development of High-Efficiency InGaP/GaAs/Ge 3-Junction Solar Cells

As one of the Sunshine Program in Japan, an R&D project for super high-efficiency MJ solar cells was started in 1990. Conversion efficiency of InGaP/GaAs based multijunction solar cells has been improved by the following technologies. A schematic illustration of the InGaP/(In)GaAs/Ge triple junction solar cell and key technologies for improving conversion efficiency are shown in Figure 11.

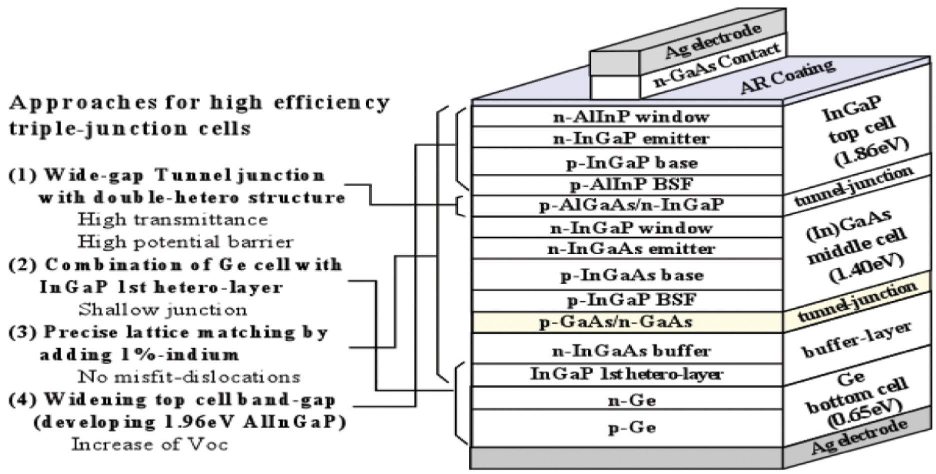
Wide Band-Gap Tunnel Junction

A wide band-gap tunnel junction which consists of double-hetero structure p-Al(Ga)InP/p-AlGaAs/n-(Al)InGaP/n-Al(Ga)InP increases incident light into the (In)GaAs middle cell and produces effective potential barriers for both minority-carriers generated in the top and middle cells. Both Voc and Isc of the cells are improved by the wide band-gap tunnel junction without absorption and recombination losses (Takamoto, Ikeda, Kurita, et al., 1997).. It is difficult to obtain high tunnelling peak current with wide gap tunnel junction, so thinning depletion layer width by formation of highly doped junction is quite necessary. Since impurity diffusion is occurred during growth of the top cell (Sugiura, Amano, Yamamoto, & Yamaguchi, 1988), carbon and silicon which have low diffusion coefficient are used for p-type AlGaAs and n-type (Al)InGaP, respectively. Furthermore,

Table 2. Key issues for realizing super high-efficiency multi-junction solar cells

Key Issue	Past	Present	Future
Top cell materials	AlGaAs	InGaP	AlInGaP
3rd layer materials	None	Ge	InGaAsN etc.
Substrate	GaAs	Ge	Si
Tunnel junction	DH-structure GaAs Tunnel Junction (TJ)	DH-structure InGaP TJ.	DH-structure InGaP or GaAs TJ
Lattice matching	GaAs middle cell	InGaAs middle cell	(In)GaAs middle cell
Carrier confinement	InGaP-BSF	AlInP-BSF	Widegap-BSF Quantum Dots (QDs)
Photon confinement	None	None	Bragg reflector, QDs, etc.
others	None	Inverted Epi.	Inverted Epi. Epitaxial Lift Off

Figure 11. Schematic illustration of a triple-junction cell and approaches for improving efficiency of the cell

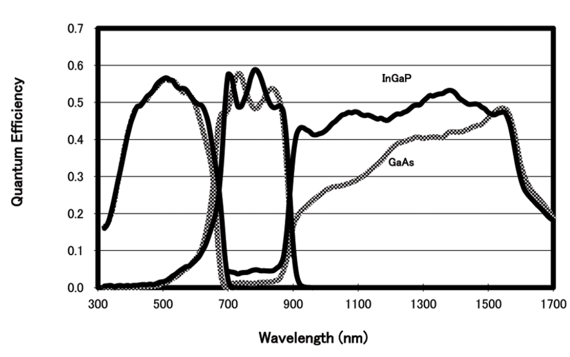


the double-hetero structure supposes to suppress impurity diffusion from the highly doped tunnel junction (Takamoto, et al., 1999). The second tunnel junction between middle and bottom cells consists of p-InGaP/p-(In)GaAs/ n-(In)GaAs/n-InGaP which have wider band-gap than middle cell materials.

Heteroface Structure Ge Bottom Cell

InGaP/GaAs cell layers are grown on a p-type Ge substrate. PN junction is formed automatically during MOCVD growth by diffusion of V-group atom from the first layer grown on the Ge substrate. So, the material of the first hetero layer is important for the performance of Ge bottom cell. An InGaP layer is thought to be suitable material for the first hetero layer, because phosphor has lower diffusion coefficient in Ge than arsenic and indium has lower solubility in Ge than gallium. Figure 12 shows the change in spectral response of the triple-junction cell by changing the first hetero growth layer on Ge from GaAs to InGaP. Quantum efficiency of the Ge bottom cell was improved by the InGaP hetero-growth layer. In the case of GaAs hetero-growth layer, junction depth was measured to be around 1μm. On the other hand, thickness of n-type layer produced by

Figure 12. Change in the spectral response due to modification of the 1st hetero-layer from GaAs to InGaP (without anti-reflection coating)



phosphor from the InGaP layer was 0.1µm. An increase in Ge quantum efficiency was confirmed to be due to a reduction in junction depth.

Precise Lattice-Matching to Ge Substrate

Although 0.08% lattice-mismatch between GaAs and Ge was thought to be negligibly small, misfit-dislocations were generated in thick GaAs layers and deteriorated cell performance. By adding about 1% indium into the InGaP/GaAs cell layers, all cell layers are lattice-matched precisely to the Ge substrate. As a result, crosshatch pattern caused by misfit-dislocations due to lattice-mismatch was disappeared in the surface morphology of the cell with 1% indium, as shown in Figure 13. The misfit-dislocations were found to influence not to Isc but to Voc of the cell. Voc was improved by eliminating misfit-dislocations for the cell with 1% indium. In addition, wavelength of the absorption edge became longer and Isc of both top and middle cells increased, by adding 1% indium.

As one of the Sunshine Program in Japan, an R&D project for super high-efficiency MJ solar cells was started based on our results in 1990. Conversion efficiency of InGaP-based 3-junction solar cells has been improved by the following technologies:

1. Selection and high quality growth of InGaP as a top cell material
2. Proposal of double-hetero structure and wide-band gap tunnel junction for cell interconnection.
3. Precise lattice matching of InGaP top cell and InGaAs middle cell with Ge substrate
4. Proposal of AlInP as a back surface field layer for the InGaP top cell
5. Proposal of InGaP-Ge heteroface structure bottom cell

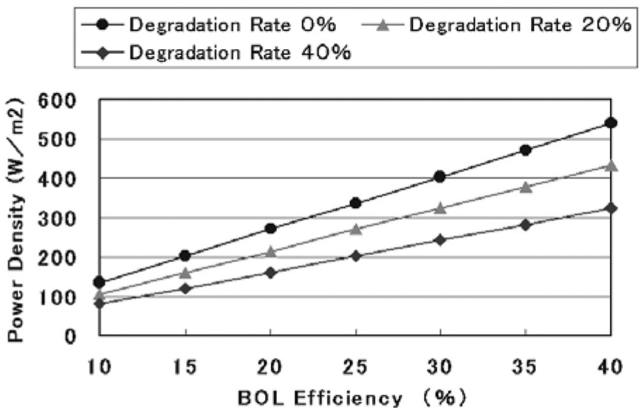
As a result of the above proposals and performance improvements, we have demonstrated a world-record efficiency (33.3% at 1-sun AM1.5G) InGaP/GaAs/InGaAs 3-junction solar cell in 1997 (Takamoto, Ikeda, Agui, et al., 1997). The conversion efficiency of InGaP/(In)GaAs/Ge 3-junction solar cells has been improved to 31.7% (AM1.5G) (Takamoto, et al., 2000).

Radiation-Resistance of InGaP-Based MJ Solar Cells

Figure 14 shows effectiveness of radiation-resistance and high conversion efficiency of space cells from the point view of power density. Since radiation in space is severe, particularly in the Van Allen radiation belt, lattice defects are induced in semiconductors due to high-energy electron and proton irradiations, and the defects cause a decrease in the output power of solar cells. Further improvements in conversion efficiency and radiation-resistance of space cells are necessary for widespread applications of space missions. Recently, InGaP/GaAs-based MJ solar cells have drawn increased attention because of the possibility of high conversion efficiency of over 40% and radiation-resistance. An AM0 efficiency of 29.2%

Figure 13. Surface morphology of InGaAs with various indium compositions grown on Ge

Figure 14. Effectiveness of radiation-resistance and high conversion efficiency of space cells from the point view of power density



has been demonstrated for an InGaP/InGaAs/Ge 3-junction cell ($4cm^2$) (Takamoto, et al., 1997).

Figure 15 shows the maximum power recovery due to light illumination of 100 mW/cm^2 at various temperatures for 1-MeV electron-irradiated InGaP/GaAs tandem cells (Yamaguchi, et al., 1997). The ratios of maximum power after injection, P_I, to maximum power before irradiation, P_0, are shown as a function of injection time. Even at room temperature, photo injection-enhanced annealing of radiation damage to InGaP/GaAs tandem cells was observed. The recovery ratio increases with an increase in ambient temperature within the operating range for space use. Such a recovery is found to be attributed from damage recovery in InGaP top cell layer (Yamaguchi, et al., 1997). Therefore, the results show that InGaP/GaAs tandem cells under device operation conditions have superior radiation-resistant properties.

Figure 15. The maximum power recovery of the InGaP/GaAs tandem cell due to light illumination at various temperatures

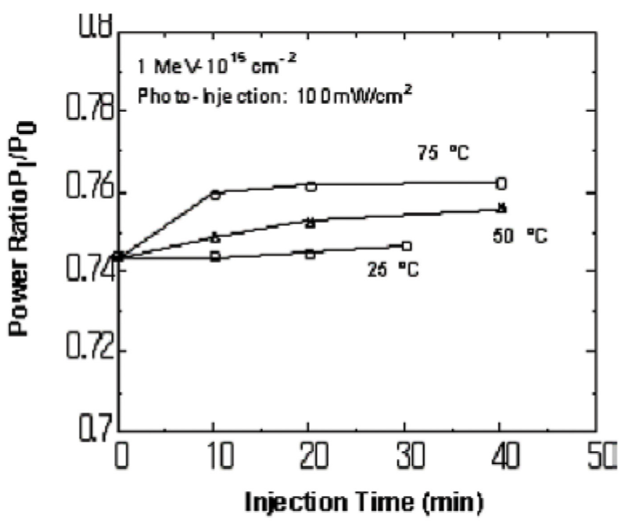


Figure 16 shows DLTS (Deep Level Transient Spectroscopy) spectrum of Trap H2 (Ev+0.55eV) for various injection times at 25^{0}C with an AM1.5 light intensity of 100mA/cm^2. It is also found (Kahn et al., 2000) by DLTS measurements that a major defect level H2 (Ev+0.55eV) recovers by forward bias or light illumination. Moreover, the H2 center is confirmed to act as a recombination center by using the double carrier pulse DLTS method. The enhancement of defect annealing in InGaP top cell layer under minority-carrier injection conditions is thought to occur as a result of the nonradiative electron-hole recombination process (Lang & Leung, 1976) whose energy E_R enhances the defect motion. The thermal activation energy E_A (1.1eV) of the defect is reduced to E_I (0.48~0.54eV) by an amount E_R (0.56~0.62eV). Thus electronic energy from a recombination event can be channeled into the lattice vibration mode which drives the defect motion: $E_I = E_A - E_R$.

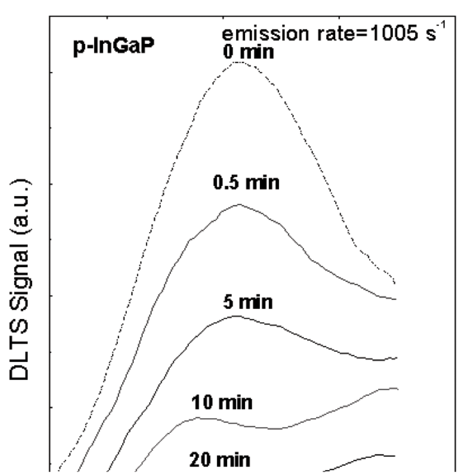
Space Applications of InGaP/GaAs/Ge 3-Junction Solar Cells

Advanced technologies for high efficiency cells and discovery of superior radiation-resistance of InGaP based materials are thought to contribute to industrialization of InGaP-based multijunction space solar cells in Japan. Figure 17 shows Sharp space solar cell conversion efficiency heritage. Since 2002, InGaP/GaAs/Ge 3-junction solar cells have been commercialized for space use in Japan.

Figure 16. DLTS spectrum of trap H2 (Ev+0.55eV) for various injection timesat 25^{0}C with an injection density of 100mA/cm^2



LOW COST POTENTIAL OF CONCENTRATOR MJ SOLAR CELL MODULES AND HIGH EFFICIENCY CONCENTRATOR INGAP/GAAS/GE 3-JUNCTION SOLAR CELL MODULES AND TERRESTRIAL APPLICATIONS

Concentrator operation is very effective for cost reduction of solar cell modules and thus that of PV systems. Figure 18 shows configuration of PV system composed of solar cell, optics and tracker. Concentrator operation of the MJ cells is essential for their terrestrial applications. Since the concentrator PV systems using MJ solar cells have great potential of cost reduction as shown in Figure 19 (Yamaguchi, et al., 2003), R&D on concentrator technologies including MJ cells is started in Japan.

In order to apply a high efficiency MJ cell developed for 1 sun condition to a concentrator cell operating under ~500suns condition, reduction in energy loss due to series resistance is the most important issue. Cell size was determined to be 7mm x 7mm with considering total current flow. Grid electrode pitching, height and width were designed in order to reduce series resistance. Figure 20 shows fill factor (FF) of the cell with various grid pitching under 250 suns. Grid electrode with 5μm height and 5μm width was made of Ag. Grid pitching influences lateral resistance between two grids (RL) and total electrodes resistance (RE). Series resistance of the cell (RS), RE and RL are also shown in Figure 20. RE was measured directly after removing electrode from the cell by chemical etching. RL was calculated

Figure 17. Sharp space solar cell conversion efficiency heritage

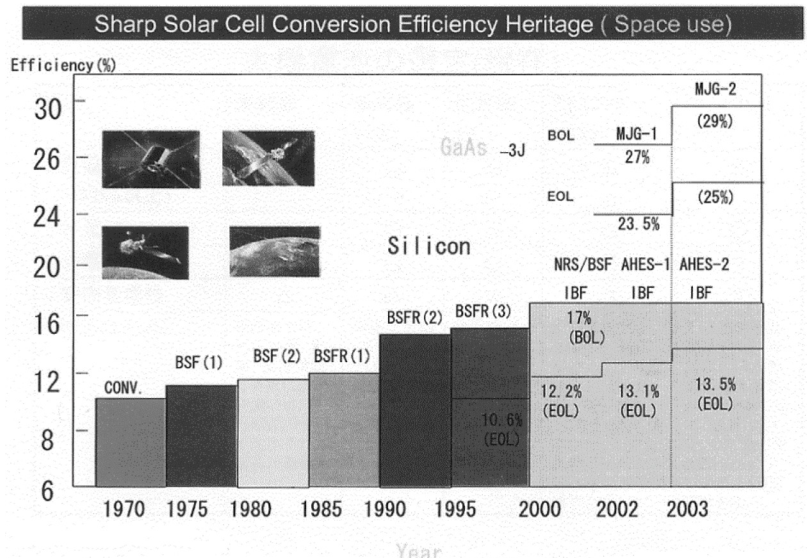


Figure 18. Configuration of PV system composed of solar cell, optics, and tracker

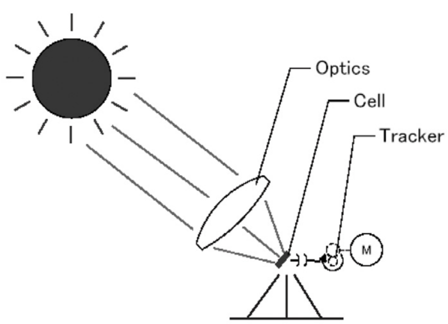

Figure 19. Summary of estimated cost for the concentrator PV systems vs. concentration ratio (Yamaguchi, et al., 2003)

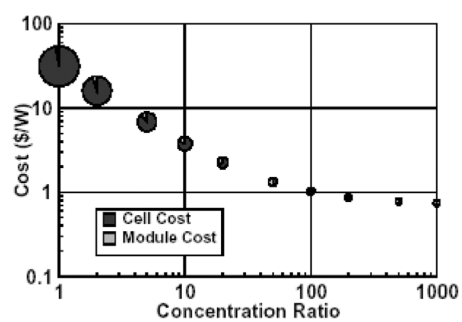

by using sheet resistance of window and emitter layers. Based on the data in Figure 20, the grid pitching is determined to be 0.12 mm at this time. In order to reduce series resistance down to 0.01Ω and obtain high FF under 500 suns, grid height should be increased to be twice. High efficiency under <500 suns is thought to be obtained by the optimal grid design without modification of the cell layer.

For concentrator applications, the grid structure has been designed in order to reduce the energy loss due to series resistance as shown in Figure 20. The authors have successfully fabricated high efficiency concentrator InGaP/InGaAs/Ge 3-junction solar cells designed for 500-sun application. The efficiencies by in-house measurement are 39.2% at 200-suns and 38.9% at 489-suns as shown in Figure 21 (Takamoto, et al., 1997). The solar simulator was equipped with both Xe lamp and halogen lamp and adjusted AM1.5G spectrum. Most recently, 41.6% efficiency has been reported with InGaP/GaAs/Ge 3-junction concentrator cells by Spectrolab (King, et al., 2009).

Figure 20. FF of the concentrator cells with various grids pitching under 250-suns light. Series resistance (Rs), lateral resistance (RL) and total electrodes resistance (RE) are also shown.

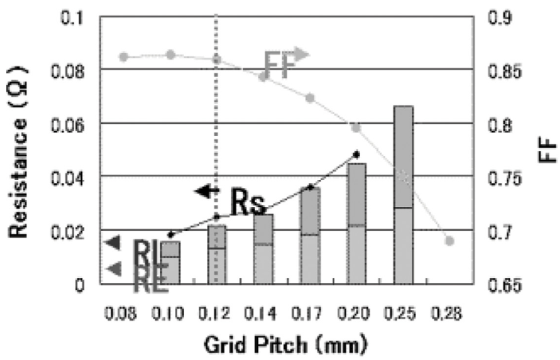

Figure 21. Efficiency of a high-efficiency InGaP/InGaAs/Ge 3-junction cell vs. number of suns

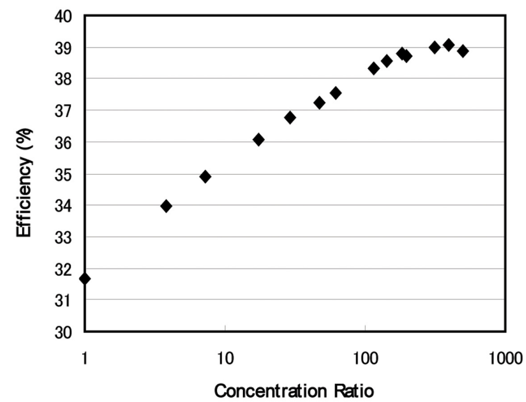


Concentrator InGaP/GaAs/Ge 3-junction solar cell modules have also been developed for terrestrial use (Araki, et al., 2005). A new concentrator optics is introduced, consist of a non-imaging dome-shaped Fresnel lens, and a kaleidoscope homogenizer. The non-imaging Fresnel lens allows wide acceptance half angle with keeping the same optical efficiency with minimum chromatic aberration. The homogenizer reshapes the concentrated into square solar cell aperture, mixed rays to uniform flux. Injection molding is capable of manufacturing thousands of lenses in a single day and by a single machine. The drawback of this method is difficulty of creating precise prism angles and flat facets. The maximum efficiency was a little above 80% and overall efficiency was 73%. After improvement of the process conditions, the averaged efficiency raised to 85.4%.

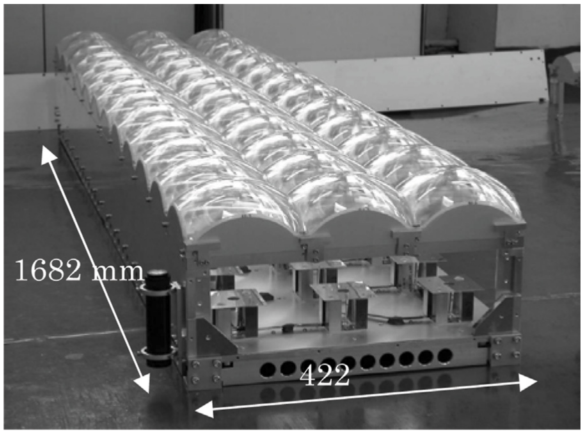
A new packaging structure for III-V concentrator solar cells is developed, applicable mainly to Fresnel lens concentrator modules but may also be used in dish concentrator systems. The solar cell used in the new receiver package is III-V 3-junction concentrator solar cell developed. It is grown on a fragile Ge substrate with thickness of only 150 um. The overall size was 7 mm X 9 mm with 7 mm square aperture area.

In addition, the following technologies have been developed:

1. Super-high pressure and vacuum-free lamination of the solar cell that suppresses the temperature rise to 20 degrees under 550 X geometrical concentration illumination of sunbeam.
2. Direct and voids-free soldering technologies of the fat metal ribbon to the solar cell, suppressing hot-spots and reducing the resistance, thereby allowing a current 400 times higher than normal non-concentration operation to be passed with negligible voltage loss.
3. A new encapsulating polymer that survives exposure to high concentration UV and heat cycles.
4. Beam-shaping technologies that illuminate the square aperture of the solar cell, from a round concentration spot.
5. Homogeniser technologies that give a uniform flux and prevent the conversion losses that stem from chromatic aberration and flux intensity distribution.

The concentrator module is designed with ease of assembly in mind. All the technologically complex components are packaged into a

Figure 22. Inside of the 400 X concentrator module with 36 receivers connected in series



receiver so that a series of receivers and lenses can be assembled with standard tools, using local materials and workforce. The concept is similar to the computer and automobile assembly industries, where key components are imported but the product assembled locally. It is anticipated that this approach will reduce the manufacturing cost of the module as shown in Figure 22.

The peak uncorrected efficiency for the 7,056 cm^2 400 X module with 36 solar cells connected in series was 26.6%, measured in house. The peak uncorrected efficiencies for the same type of module with 6 solar cells connected in series and 1,176 cm^2 area measured by Fraunhofer ISE and NREL were 27.4% and 24.9%. The 5,445 cm^2 550 X modules have also demonstrated 27-28.9%, measured in house. Table 3 summarizes the measured efficiency in three different sites.

A new 400X and 550X (geometrical concentration ratio) are developed and show the highest efficiency in any types of PV as well as more than 20 years of accelerated lifetime. This achievement is blessed with new innovative concentrator technologies. The new concentrator system is expected to open a door to a new age of high efficiency PV.

MOST RECENT RESULTS OF MJ CELLS

Recently, more than 40% efficiency cells were reported by Fraunhofer ISE (Bett, et al., 2009) and Spectrolab (King, et al., 2009). Concentrator 4-junction or 5-junction solar cells have great potential for realizing super high efficiency of over 50%. We have been studying concentrator multi-junction solar cells under Japanese Innovative Photovoltaic R&D program started since FY2008 (King, et al., 2009). Figure 23 shows overview of NEDO's PV R&D Program. Japanese Innovative

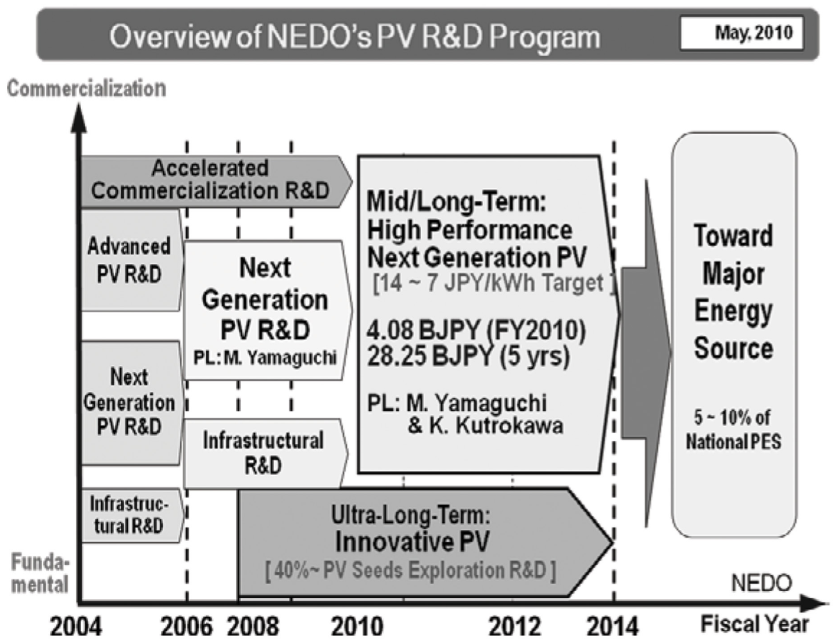
550 X	5,445	Inuyama, Japan Manufacturer	33 C	28.9%	741
550 X	5,445	Toyohashi, Japan Independent	28 C	27%	777

Figure 23. Overview of NEDO's PV R&D program



Photovoltaics R&D Program has been started from fiscal year 2008 and the target in this program is to develop high efficiency solar cells with conversion efficiency of more than 40% and low electricity cost of less than 7 JPY/kWh until 2050.

Most recently, world-record efficiency (36.9%) at 1-sunAM1.5G has been realized with inverted epitaxial grown InGaP/GaAs/InGaAs 3-junction cells by Sharp (Takamoto, et al., 2010). Figure 24 fabrication process of InGaP/GaAs/InGaAs 3-J solar cell inverted epitaxial grown. Figure 24 shows I-V curve of world-record efficiency InGaP/GaAs/InGaAs solar cell. Figure 25 shows chronological improvements in conversion efficiencies of III-V compound MJ solar cells under 1-sun and concentrator conditions (see Figure 26).

Figure 24. Fabrication process of InGaP/GaAs/InGaAs 3-J solar cell inverted epitaxial grown

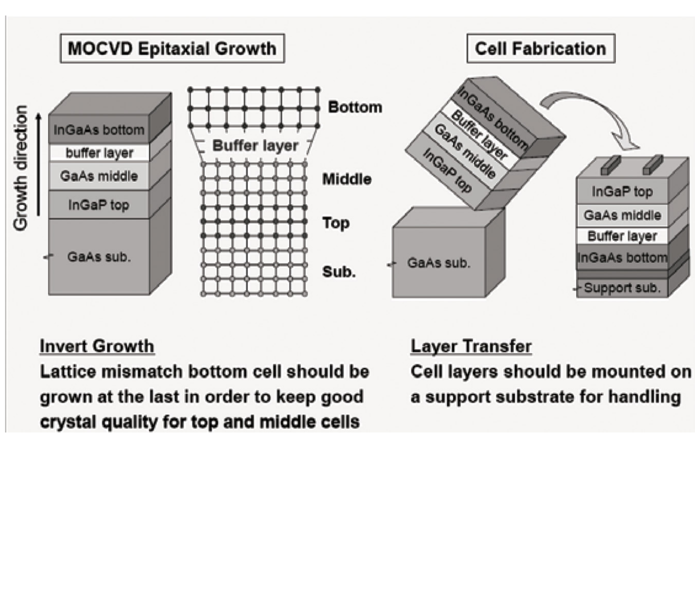


Figure 25. Current(I)–voltage(V) curve of world-record efficiency InGaP/GaAs/InGaAs measured by the AIST

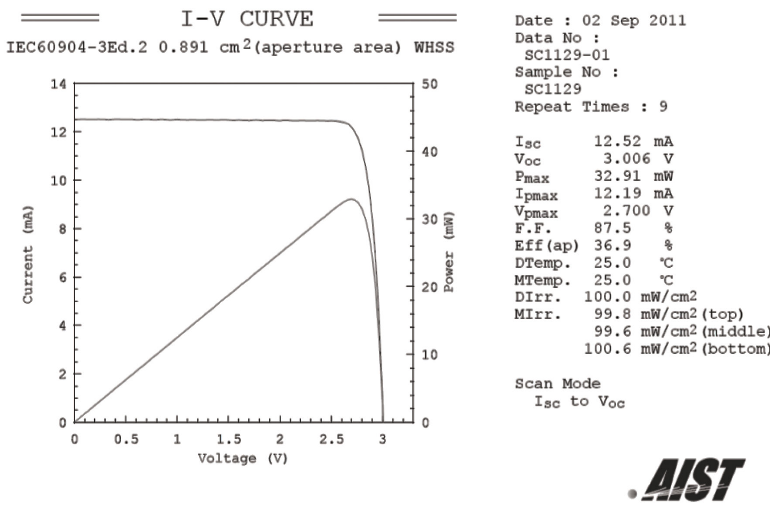

Most recently, 42.1% efficiency under 230-suns has been obtained with InGaP/GaAs/InGaAs cell as shown in Figure 27 (Takamoto, et al., 2010).

FUTURE DIRECTION

Multi-junction solar cells will be widely used in space because of their high conversion efficiency and better radiation-resistance. In order to apply super high-efficiency cells widely, it is necessary to improve their conversion efficiency and reduce their cost. The new Concentrator PV system with two times more annual power generation than the conventional crystalline silicon flat-plate system will open a new market for apartment or building rooftop applications. Another interesting appli-

Figure 26. Chronological improvements in conversion efficiencies of III-V compound multi-junction solar cells under 1-sun and concentrator conditions

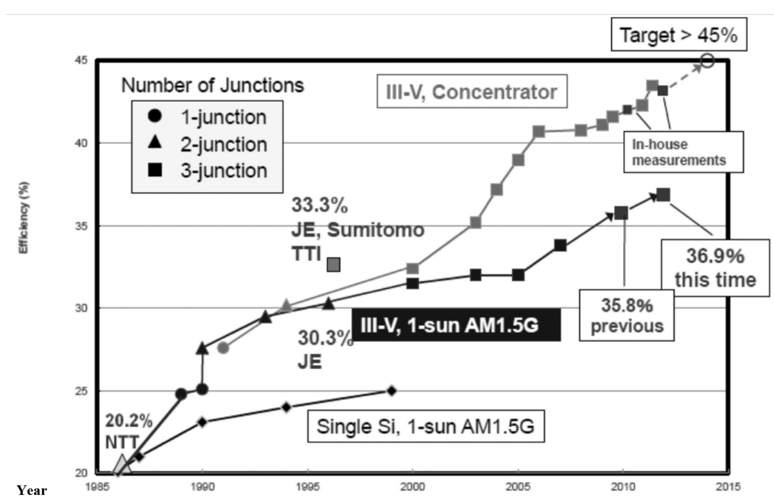

Figure 27. Concentration ration dependence of efficiency of a high-efficiency InGaP/GaAs/InGaAs 3-junction cell

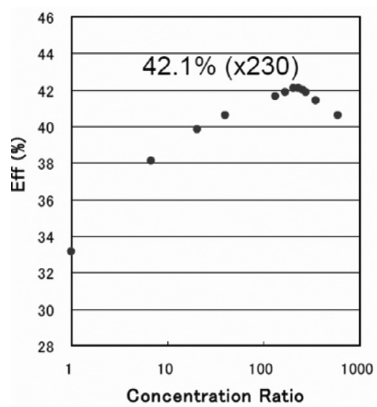

cation is what we call the tree planting PV and large-scale PV power plant applications

Now, we are approaching 40% efficiency by developing concentrator MJ solar cells as shown in Figure 28. Concentrator 4-junction or 5-junction solar cells have great potential for realizing super high-efficiency of over 50% [29,30]. Therefore, concentrator 3-junction and 4-junction solar cells have great potential for realizing super high-efficiency of over 40%. As a 3-junction combination, InGaP/InGaAs/Ge cell on a Ge substrate will be widely used because this system has already been developed. The 4-junction combination of an Eg=2.0eV top cell, a GaAs second-layer cell, a material third-layer cell with an Eg of 1.05eV, and a Ge bottom cell is lattice-matched to Ge substrates and has a theoretical efficiency of about 42% under 1-sun AM0. This system has a potential efficiency of over 47% under 500-suns AM1.5 condition.

The new Concentrator PV (CPV) system with two times more annual power generation than the conventional crystalline silicon flat-plate system will open a new market for apartment or building rooftop applications. Another interesting application is what we call the tree planting PV and large-scale PV power plant applications. Since concentrator MJ and crystalline Si solar cells are expected to contribute to electricity cost reduction for widespread PV applications as shown in Figure 29, we would like to contribute to commercialization of CPV technologies as the 3rd PV technologies in addition to the first crystalline Si PV and the 2nd thin-film PV technologies. The scale of the CPV industry lags that of flat-plate PV by about one or two decades. It is expected, however, to make up this delay to the point where, in, 2013 the cumulative installed capacity will lie in the region of several hundred MWp. R&D work has to be undertaken particularly in the area of large-scale production, i.e. high-throughput, to realise this ambition. Material consumption must

Figure 28. Future predictions of solar cell efficiencies

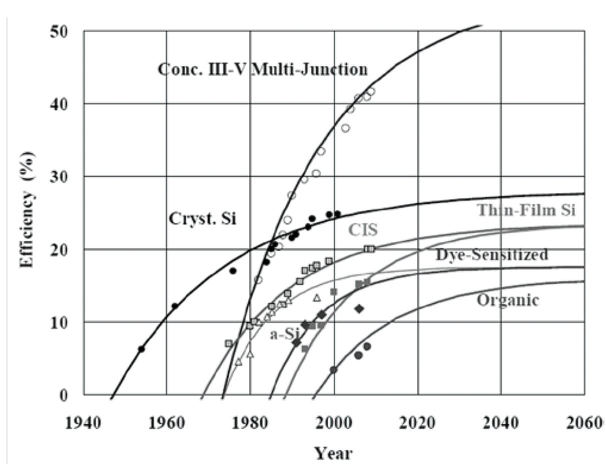

Figure 29. Scenario of electricity cost reduction by developing concentrator solar cells

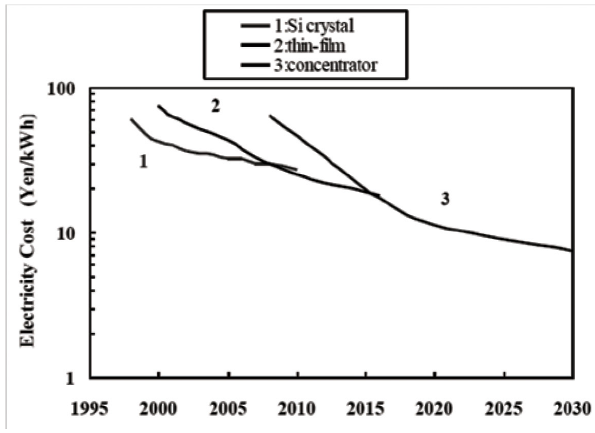

also be reduced. A projection for future turnkey CPV system prices extrapolated from current prices are shown in Figure 30. Figure 30 shows the expected yearly production of Concentrator PV (CPV) systems (red) and the price of turn-key installed CPV systems in Euro/W_p (black) (EC, 2007).

The most important R&D in CPV manufacturing will aim at (EC, 2007):

1. Improving the efficiency of mass-produced cells to the levels currently seen in the laboratory (over 26%) and to 35 to 45% efficiency in the longer term
2. Improving optical elements (optical efficiency, lifetime and product engineering)
3. Automated industrial module assembly (adjustment of elements, packaging and sealing), high-throughput manufacturing with high yield, resulting in products with long lifetimes
4. Construction of light, robust, and precise trackers for all outdoor climate conditions
5. Set-up and monitoring of demonstration systems and large plants, in the range several hundred kWp (short term) to multi-MWp (medium term)
6. Techniques for guaranteeing the quality of products with intended lifetimes of over 20 years, development of standards, in-line testing, and recycling methods for the modules.

Figure 30. The expected yearly production of concentrator PV (CPV) systems (red) and the price of turn-key installed CPV systems in euro/ W_p (black)

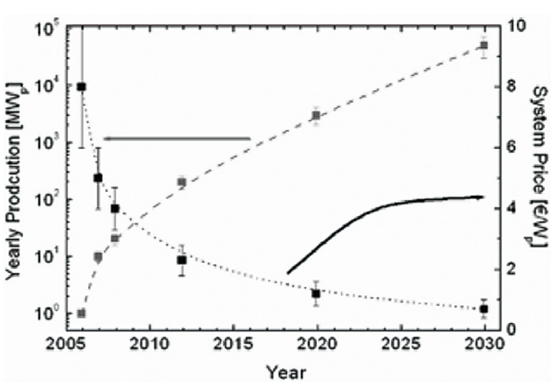

Figure 31 shows World Energy Vision 2100 recommended by the German Council on Global Change (WBGU, 2003). As a result of further development of higher efficiency, lower cost and highly reliable solar cells, larger contribution to world energy by PV is expected.

Chapter 109
Zero-Downtime Reconfiguration of Distributed Control Logic in Industrial Automation and Control

Thomas Strasser
AIT Austrian Institute of Technology, Austria

Alois Zoitl
Vienna University of Technology, Austria

Martijn Rooker
PROFACTOR GmbH, Austria

ABSTRACT

Future manufacturing is envisioned to be highly flexible and adaptable. New technologies for efficient engineering of reconfigurable systems and their adaptations are preconditions for this vision. Without such solutions, engineering adaptations of Industrial Process Measurement and Control Systems (IPMCS) will exceed the costs of engineered systems by far and the reuse of equipment will become inefficient. Especially the reconfiguration of control applications is not sufficiently solved by state-of-the-art technology. This chapter gives an overview of the use of reconfiguration applications for zero-downtime system reconfiguration of control applications on basis of the standard IEC 61499 which provides a reference model for distributed and reconfigurable control systems. A new approach for the reconfiguration of IEC 61499 based control application and the corresponding modeling is discussed. This new method significantly increases engineering efficiency and reuse in component-based IPMCS.

INTRODUCTION

The decisive factor for the market success of the manufacturing industry (e.g. auto manufacturers and part makers, process industry etc.) is a fast and flexible reaction to changing customer demands—companies must show a high degree of changeability. New paradigms like "Flexible production up to small lot-sizes", "Mass Customization" or "Zero-Downtime Production" will achieve these requirements but demand completely new technologies for its realization (European Commission, 2004). Changeability, which describes the ability

DOI: 10.4018/978-1-4666-1945-6.ch109

of companies being flexible concerning customer demands, impacts all levels of product manufacturing. In particular these are the agility at a strategic level, the transformability at a factory level and the reconfigurability at the manufacturing system and machine level (Koren, 1999).

The state-of-the-art in manufacturing systems is inadequate to meet the above mentioned requirements. Current manufacturing systems are either tailored towards a specific product at high volume production and thus they can hardly be adapted to new products or they are flexible and programmable but technology specific and only for single item or small batch production. Another relatively new approach which is flexible and programmable but less technology specific but also hardly adoptable concerning the above mentioned requirements is the usage of “Multi Machining Technology Integration Production Systems” (Abele, 2005) which are characterized by the static implementation and combination of different technologies within one production system. The major drawback of this approach is that it is very resource consuming and therefore it can hardly be ported to small and resource constrained embedded controllers which are often used in modern industrial automation and control systems.

To reach the above mentioned changeability at the manufacturing systems and machine level it can be postulated that a change from product and technology rigid manufacturing systems towards product and technology flexible, modular, easy to setup component-based production systems is necessary. Following consequently this trend means that future plants will produce their products on manufacturing systems and machines which will be designed and setup just prior to production of goods since they are constructed on basic building blocks. Such building blocks are in general smart mechatronic components with embedded intelligence. These building blocks are designed in a way that they provide a specific manufacturing and/or automation functionality and they are not reconfigurable in general. Machining, assembly and transport systems of such production systems are also designed and set up by the utilization of various flexible autonomous and intelligent mechatronic components just before usage within the production line.

The consequences of the above mentioned attempt are extensive and many technological breakthroughs will be necessary. Beside others the development of an adequate automation system for heavily interacting distributed real-time systems can be seen as a major task. Current architectures of IPMCS do not conceptually support reconfiguration and distribution which are necessary to fulfill the requirements for the above mentioned systems (Sünder, 2006). Distributed embedded real–time systems for industrial automation and control of plants that evolve towards zero-downtime adaptable systems will play a key role to realize the roadmaps towards adaptive manufacturing (Koren, 1999) of products, goods and services in 2020. Most value will then be added in engineering and performing a system transition or reconfiguration (the change from one system state to another) rather than in engineering and performing “normal operation”.

The challenge and aim of this chapter is to present an approach for modeling of reconfiguration control applications based on the IEC 61499 standard which provide an adequate engineering methodology for programmed system reconfiguration (i.e. system reconfiguration executed by a special control application). The first section discusses general reconfiguration issues. The next section gives an overview of state-of-the-art in reconfiguration of control applications. After that a summary of the main features and characteristics of IEC 61499 as the reference model for distributed automation and control systems with special focus of the management capabilities for reconfiguration is given. Furthermore an enhanced IEC 61499 Device Management is introduced which is used for the proposed approach for the controlled reconfiguration of control applications as the main topic of this chapter. Especially the modeling of reconfiguration control applications based on the IEC 61499 reference model is topic of this chapter. Tests at the Odo Struger Laboratory at Vienna University of Technology (Automation and Control Institute) and at PROFACTOR are also presented. The summary of this work concludes this chapter.

BACKGROUND: GENERAL CONSIDERATIONS ABOUT RECONFIGURATION

In industrial informatics, reconfiguration of software modules and components has been discussed many times, for instance (Brennan, 2002; Bussmann, 1999; Burmester, 2004). Agile software processes like the extreme programming method recognize change as an essential part of the software life–cycle (Mens, 2005).

Basic vs. Dynamic Reconfiguration

Within the scope of this chapter reconfiguration is described best as altering a system's operation in order to meet changes in requirements. Quite a simple reconfiguration method—hence further denoted as basic reconfiguration—is to stop current operation, apply all necessary changes to the system and restart the desired operation again (coldstart). But this approach is not sufficient to meet the constraints mentioned in the introduction.

Brinkschulte et al. (2005) define dynamic reconfiguration as reconfiguration of an application while it is running. What therefore further distinguishes dynamic from basic reconfiguration is provision for timeliness constraints (Brennan, 2002). Dynamic reconfiguration considers timeliness as a crucial facet of correctness. With respect to control applications this means that timeliness requirements put on the whole application must be preserved while parts of it are modified.

Classification of Dynamic Reconfiguration

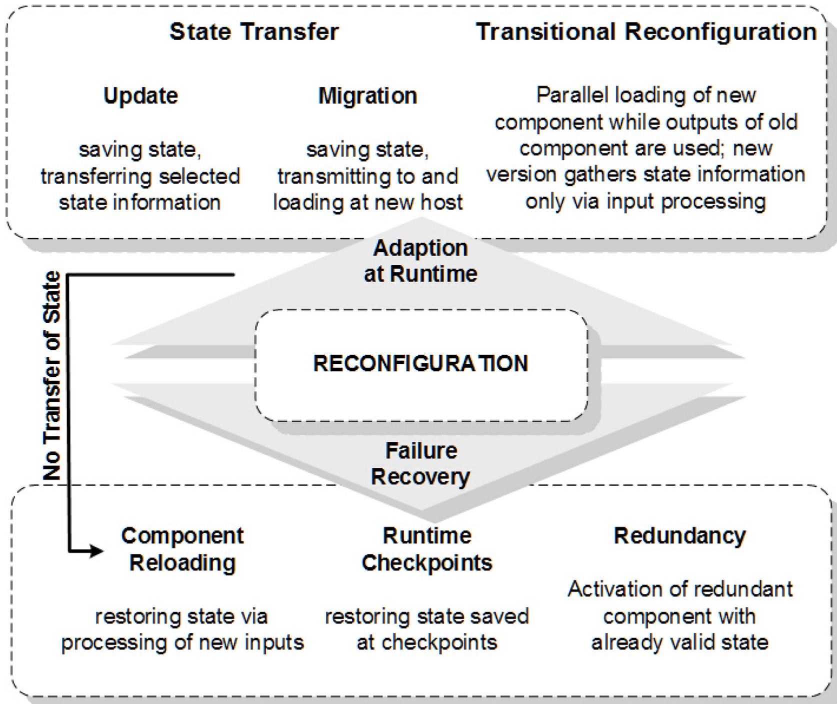
Within the topic of dynamic reconfiguration a big variety of opportunities arises. This especially demands means of classification for the different approaches within this field. Wermelinger (1997) has formulated 3 essential questions that have to be answered for dynamic reconfiguration:

1) What kind of modifications can be done?
2) How are they performed?
3) When may the changes be performed?

The first two questions concern the reconfiguration model (model of system architecture and modification process) as well as the features of the underlying operating system and/or the runtime environment. Question 3 is of special interest. The answer to this question is that those parts of an automation system that will undergo changes have to be in a consistent state before. But consistency is not only is a prerequisite for reconfiguration. Quite on the contrary, consistency is an important attribute of systems that must be preserved over reconfiguration in order to avoid unnecessary disruption to the system environment. This requires transfer of state information from the current system state to the desired state after reconfiguration.

Rasche and Polze (2005) give an idea of how consistent state information can be ensured in the context of different use cases of reconfiguration, illustrated in Figure 1. Adaptation at runtime (upper part of the figure) either requires transfer (save/transmit/load) of state information (update, migration) or gathering state information via input processing (transitional reconfiguration). On the other hand failure recovery (lower part of figure) must be able to restore a consistent state either by loading saved state information (runtime checkpoints) or input processing (component reloading) or by activating redundant components (which already have gathered valid state information).

Figure 1. State consistency and reconfiguration



State-of-the-Art Reconfiguration Approaches

This section briefly outlines current reconfiguration approaches relevant for industrial automation. Today common automation systems predominantly rely on the programming paradigms of the standard IEC 61131–3 (IEC, 2003) dedicated to systems based on programmable logic controllers (PLCs). The common paradigm within IEC 61131 is a device centered engineering methodology. Aspects of distribution (cooperation of several devices within an overall application) have to be considered from the beginning of the engineering phase.

Current IEC 61131–3 based engineering tools such as (kirchner SOFT, 2009) already enable online code exchange—called instant-reload—for single devices at task level, including transfer of variable values. Their product logi,CAD already provides some basic support for reconfiguration of applications (i.e. of programs, resources and configurations; this keywords are used in terms of IEC 61131) in the programming system logi.CAD as well as in kirchner SOFT's target system implementations (i.e. Soft-PLCs). Their reconfiguration approach is centered on managing changes for a single IEC 61131-3 resource at a time. Changing applications at runtime without stopping them is fully supported for the user. Unfortunately using such a resource-centered approach has some disadvantages when changes for too many different applications running in different resources have to be applied simultaneously. In addition there exist also some other drawbacks of this approach like undeterministic switching points in time (due to cyclic execution policy), lack of fine granularity (reconfiguration at task level), jitter effects (task reconfiguration influences other tasks) or the possibility of inconsistent states (e.g. leading to deadlocks) (Sünder, 2006).

The International Electrotechnical Commission (IEC) addresses these issues by the standard IEC 61499 (IEC, 2005), which extend the Function

Block (FB) model of IEC 61131–3 in order to meet the requirements of engineering distributed automation systems. The most important concepts of IEC 61499 are an event–driven execution model; a management interface capable of basic reconfiguration support and the application centered engineering methodology. The major benefit of this approach is a separation of concerns: first the whole application is programmed as a function block network like in centralized systems; afterwards the components of this network (the function blocks) are mapped to the devices of the real system where they shall be executed. Doing so e.g. facilitates the movement of functionality from one controller to another as mentioned in section I, since only the mapping is concerned while the original application remains unchanged. A more detailed description of IEC 61499 and its aptitude for reconfiguration purposes can be found in (Strasser, 2005).

Various researchers have developed reconfiguration methodologies based on IEC 61499: the research project TORERO (Lorentz, 2006) focuses on plug–and–play and self–(re)configuration of field devices in a so–called total lifecycle approach utilizing IEC 61499 for modeling control logic. The main objective of this project was on the creation of a total lifecycle web-integrated control design architecture and methodology for distributed control systems for industrial and factory automation. The major focus and research was on the development of a self-configuring and maintaining control infrastructure with automated distribution support. One of the major drawbacks of the TORERO approach is the fact that a device hast to be stopped for the deployment of code and afterwards it has to be restarted.

Thramboulidis et al. (2004) use Realtime–UML (Unified Modeling Language) as a meta model between the design models of IEC 61499 and their implementation models to support dynamic reconfiguration of control applications. Brennan et al. (2002) propose an agent–based reconfiguration approach, extending the IEC 61499 function block model: they introduce a second state–machine within the basic function block together with a reconfiguration agent and a second event and data flow for reconfiguration purposes. All these reconfiguration approaches rely on technology that is outside the scope of IEC 61499 (e.g. Universal Plug and Play, agents or Realtime–UML), they do not consider utilizing the basic reconfiguration functionality provided by the IEC 61499 management model outlined in the next section.

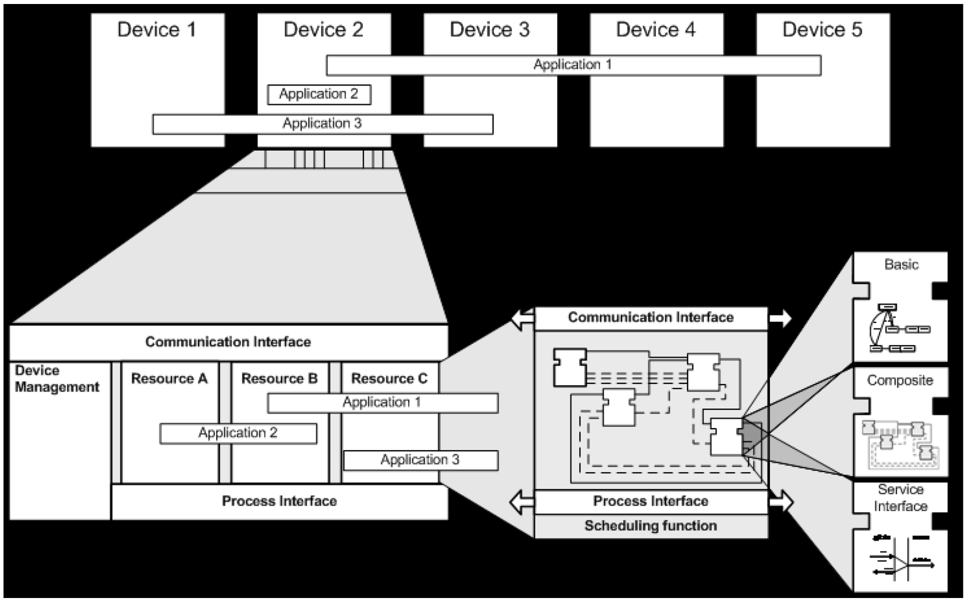
IEC 61499 as Reference Model for Reconfigurable Distributed Control

The new standard IEC 61499 (IEC, 2005) serves as a reference architecture that has been developed for distributed, modular, and flexible control systems. It specifies an architectural model for distributed applications in IPMCS in a very generic way and extends the function block model of its predecessor IEC 61131-3 (Function Block Diagram - FBD) with additional event handling mechanisms and concepts for distributed systems.

The standard builds a good basis to overcome the above mentioned problems according to reconfiguration processes in current IPMCS. The following sections describe some fundamental issues of IEC 61499 that make this standard suitable as a reference architecture for building zero-downtime IPMCS by using the concept of reconfiguration applications. More detailed information is available from (Christensen, 2009; Lastra, 2004; Lewis, 2001).

Figure 2 provides a brief overview of the most important concepts and models of the IEC 61499 standard. In the following we briefly explain important aspects of the reference model in order to better understand this standard. For more details about definitions, concepts and models we refer to the IEC standard (IEC, 2005).

Figure 2. The IEC 61499 reference model for distributed automation and control



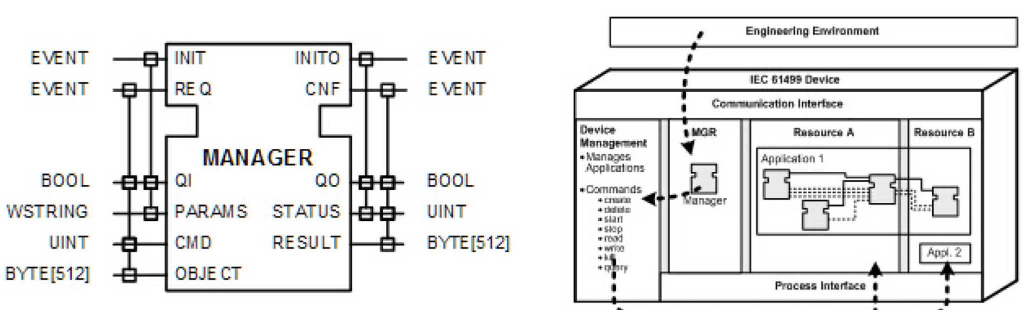
Execution Control by Events

The function block model of IEC 61499 defines function blocks that are characterized by the occurrence of two Input/Output (I/O) types: events and data. The execution is triggered by events, needed data have to be valid at the inputs of the FB before an event arrives (denoted as the WITH construct in IEC 61499, i.e. the vertical lines between event and data inputs or outputs as shown in Figure 3a). Only if an event occurs at a FB input, the runtime environment has to process the execution of this FB. Therefore it is obvious and clearly understandable whether an application is active or not and even exactly which part is currently processed. Compared to PLC-based approaches like IEC 61131-3 the IEC 61499 approach doesn't define any time base nor has a cyclic-based execution approach

Distribution Model

One of the main intentions of IEC 61499 is enabling distributed applications. The system model

Figure 3. Generic management function block type



(a) (b)

consists of devices connected by a communication network and applications. These applications may be distributed within devices. Moreover the IEC 61499 standard allows in addition the separation of devices into independent resources which are execution containers for function block networks. This concept allows a local distribution of an application part of a specific device into several resources of this device. The engineering process starts with the top-level functionality that has to be realized without reference to the concrete hardware structure. By use of libraries of software components, the user models the needed applications. The last step within the engineering cycle is the mapping of the applications to concrete hardware components; independent of whether the application is executed by one device or distributed to several devices.

Management Interface of IEC 61499 Devices

The configuration of a distributed automation and control system based on IEC 61499 can be enabled by the use of management functions which can be included in each device. For this purpose the standard defines a management application, represented by a management FB (the generic interface is depicted in Figure 3a). By using this FB combined with a remote application, mutual access between different IEC 61499 compliant devices is possible. The IEC 61499 Compliance Profile for Feasibility Demonstrations (available from Christensen (2009)) describes a concrete interface of a management FB and an appropriate remote application. The following standardized management functions can be used to interact with a device (IEC, 2005, Part 1-Table 6, 8). For illustration examples of possible actions are added.

- **CREATE:** FB instance, data or event connection
- **DELETE:** FB instance, data or event connection
- **START:** FB instance, application
- **STOP:** FB instance, application
- **READ:** FB instance data outputs
- **WRITE:** FB instance data inputs
- **KILL:** FB instance
- **QUERY:** FB types, FB instance, data or event connection

Especially the management of software components (i.e. FBs) regarding to their execution is a very important issue in reconfiguration processes. A FB instance operates according to a state machine (IEC 2005, Part 1-Figure 24) that includes an initialization and operation state controlled by management commands: Create, Start, Stop/Kill and Delete.

Verification and Validation

A very important feature of a control modeling language is the possibility to proof correctness. The basic function block of IEC 61499 includes an event-triggered state machine (Execution Control Chart, ECC) that provides the connection between an incoming event and the execution of algorithms and outgoing events. This basic model enables the conversion of IEC 61499 applications to mathematical models like Petri Nets to provide verification and validation. Different approaches to this topic are already available, for instance Net Condition/Event Systems (Vyatkin, 1999), timed automata (Stanica, 2004) or Signal/Net Systems (Schnakenbourg, 2002).

ENHANCED IEC 61499 DEVICE MANAGEMENT FOR DOWNTIMELESS RECONFIGURATION

In the case of dynamic reconfiguration of control applications or application parts it is necessary to define several (re-)configuration services, which provide enough functionality to vary FB parameters, to change the behavior of FBs or Function Block Networks (FBN) and to create or delete instances of FBs and Resources. This section describes the necessity of an enhanced set of (re-) configuration services based on the IEC 61499 standard. As mentioned in the previous section the IEC 61499 standard already provides a basis set of (re-)configuration services but it lacks a method and an implementation how these services can be efficiently applied for the reconfiguration of control applications. Therefore the aim of this approach is to make extensions to the IEC 61499 standard to simplify the reconfiguration process. This will be explained in the next sub-sections.

Considerations on Enhanced (Re-)Configuration Services

The following list displays possible reconfiguration scenarios for IEC 61499 based FBNs:

- **Instance reconfiguration:** regards to the exchange, adding or removal of a certain instance of IEC 61499 types (FB, Data, Resource, and Device). In case of an exchange of FB instances there exists the possibility with and without the adoption of internal FB variable values.
- **Type reconfiguration / runtime set-up:** the supported IEC 61499 types (Function Block, Data, Resource and Device) have to be exchanged; added or removed from a runtime system (i.e. this issue is mainly related to the change in the structure and elements of the type library of the runtime system).
- **Parameter reconfiguration:** the parameterization of Function Blocks, Resource or Device instances has to be adapted.
- **Application structure reconfiguration:** the logical configuration of the control applications has to be adapted. This is mainly related to the change of event and data connections or the type instances in IEC 61499 based control applications.
- **System reconfiguration:** the structure of the IEC 61499 system (i.e. the device and communication structure) is adapted to new requirements. This issue means that the IEC 61499 system configuration (i.e. the system model as represented in Figure 2) will be changed. Such changes can be the addition or deletion of devices and/or resources or even the exchange of existing devices with other once. Moreover it is also possible to (ex-)change the communication system similar to the (ex-)change of the device configuration.

Categorization of Basic Reconfiguration Services

Based on the device management commands introduced by IEC 61499 and the analysis of general reconfiguration tasks the following set of basic reconfiguration services are identified and categorized:

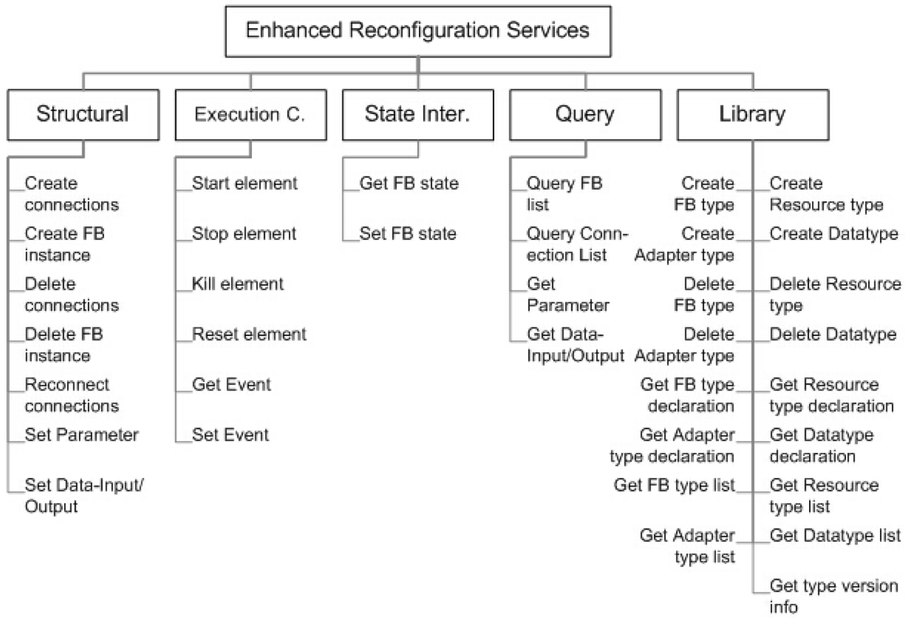
- **Structural services:** These services are mainly related to the modification/change of the logical configuration/structure of control applications and their behavior. IEC 61499 already provides a very rudimentary set of services that allow to create and delete FBs, resources and connections and to write parameters of FBs and resources. This rudimentary set of IEC 61499 configuration services is extended with additional features to form a more comprehensive set of basic structural reconfiguration services.
- **Execution control services:** These services allow interaction with the currently executing control application. In this case IEC 61499 provides a start, stop and kill mechanism for FBs. By extending these mechanisms with an additional restart ser-

vice and also using these services for event and data connections the reconfiguration process provides more possibilities to manage and change the execution of Function Block Networks (i.e. IEC 61499 applications). This especially enables a more efficient rewiring of FBs without use of extra computational power compared to the standard execution control services (i.e. start, stop and kill) provides by the IEC 61499 standard. The execution of only one management service (i.e. restart) is necessary compared to the execution of the service sequence stop FB and start FB. The restart service can be implemented more efficiently in a runtime environment. Fulfilling this requirement is essential if running control applications are reconfigured. In the case of reconfiguration of running control applications high effort has to be put into keeping the interruption of the running system as short as possible.

- **State interaction services:** These services retrieve and set internal states of FBs. The IEC 61499 standard does not clearly define these services. Such services are mainly needed for providing transition management, which takes care that the process is also under stable control during the reconfiguration phase (i.e. instabilities during the reconfiguration phase have to be avoided). The FBs are just components without access to anything outside their interface. In the case of reconfiguration full access to internal FB states and data is necessary to force the FB to a defined state avoiding reinitializing the FB.
- **Query services:** These services are necessary to acquire the current state of the distributed control application running on several devices. Especially during dynamic reconfiguration the system state will change several times. Because of that, query services are necessary in order to obtain the actual systems state and moreover also consistency checks are necessary to during dynamic reconfiguration. A consistent state after a reconfiguration is very important in industrial automation and control systems because inconsistent system states can lead to catastrophic faults. Another fact is that the execution of reconfiguration applications is characterized by a time span between engineering and execution. Within a multi user system, the reconfiguration has to ensure that the considered system part has not changed between this time span. The query mechanisms provided by IEC 61499 can serve as basis for this service.
- **Library services:** These services allow adding or removing IEC 61499 types such as Function Blocks, Event, Data or Resources to or from the runtime library of the control device respectively. They are also not clearly defined within IEC 61499. The main description of FBs is defined by the use of the Extended Mark-up Language (XML), but e.g. the description language for algorithms within FBs is still not defined. The capability of device independent type libraries needs a full new specification.

In addition to the above mentioned basic reconfiguration services it is often necessary to define further services that will be used in many reconfiguration applications (e.g. rewire a connection). To simplify reconfiguration applications and to reduce their size, it is envisaged to provide also more sophisticated reconfiguration services in addition to the basic services whereby a trade-off between reconfiguration application size and runtime environment complexity has to be found. Figure 4 gives an overview of the set of identified basic reconfiguration services based on the above categorization.

Figure 4. Enhanced Reconfiguration Service of IEC61499 Device Management



The above-presented enhanced services are either implemented as IEC 61499 XML commands or as special management FBs.

Reconfiguration of Control Applications

The reconfiguration can be initiated from a user via configuration tools (see Figure 5) or as a special control application—herein referred as Reconfiguration Control Application (RCA)—as depicted in Figure 6.

Therefore in both cases an underlying runtime system has to provide the necessary (enhanced) services for reconfiguration which are presented above. The reconfiguration steps can also be directly implemented into the control application but the RCA is especially used to encapsulate

Figure 5. Reconfiguration via configuration tool

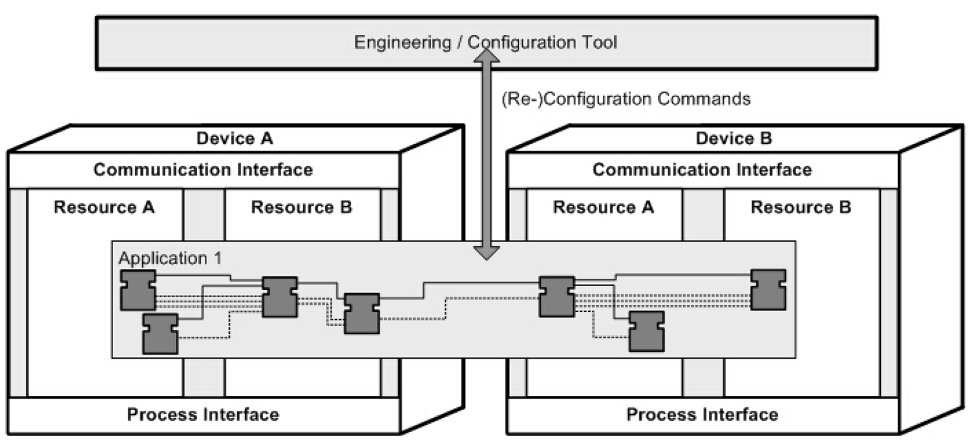


Figure 6. Reconfiguration Control Application

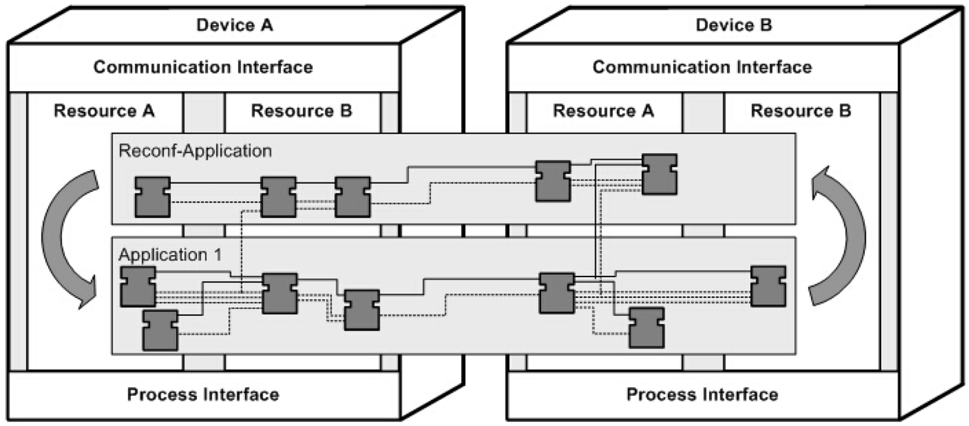


these reconfiguration steps into a separate application. This makes the presented approach for a control engineer more useable otherwise the control application will be overloaded with reconfiguration parts. The RCA is built of special IEC 61499 compliant management FB types that encapsulate the above mention reconfiguration services for dynamic reconfiguration of control application in a distributed system. The trigger to execute the RCA can either be initiated by the user, the control application or by the underlying controlled process.

AN ENGINEERING METHOD FOR RECONFIGURATION OF IPMCS APPLICATIONS

To overcome the limitations of current embedded industrial automation and control engineering methods, we propose an application centered engineering method for efficient component-based modeling of applications for controlled reconfiguration of IPMCS. The execution of a reconfiguration will become a normal operational state of such systems, while dependability and Quality of Service (QoS) of the reconfigured system are not endangered and migration is cost–efficient. Thus important steps towards Adaptive Manufacturing will be realized.

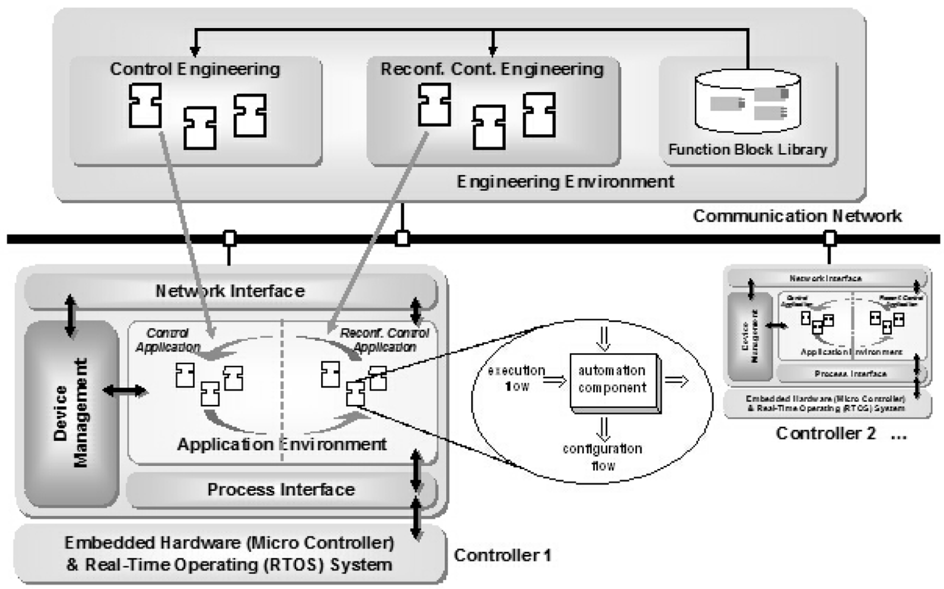
An Approach for Controlled Reconfiguration

The top–level approach focuses on replacing state–of–the–art “ramp down—stop—download—restart—ramp up” methods with a zero-downtime system reconfiguration, which is controlled by a reconfiguration control application that is modeled with components in the same way as control applications are. Zero-downtime means in this context to perform the controlled reconfiguration during runtime without the need to stop the execution of a runtime system. Reconfiguration control can be either executed from an engineering environment or it can be distributed to different controllers (as shown in Figure 7).

Modeling Cycle for Control and Reconfiguration Control Applications

The following engineering process provides a method for handling system reconfiguration of IPMCS by an efficient support for engineering of control applications and reconfiguration control applications. This engineering method consists of the following four major parts as depicted in Figure 8.

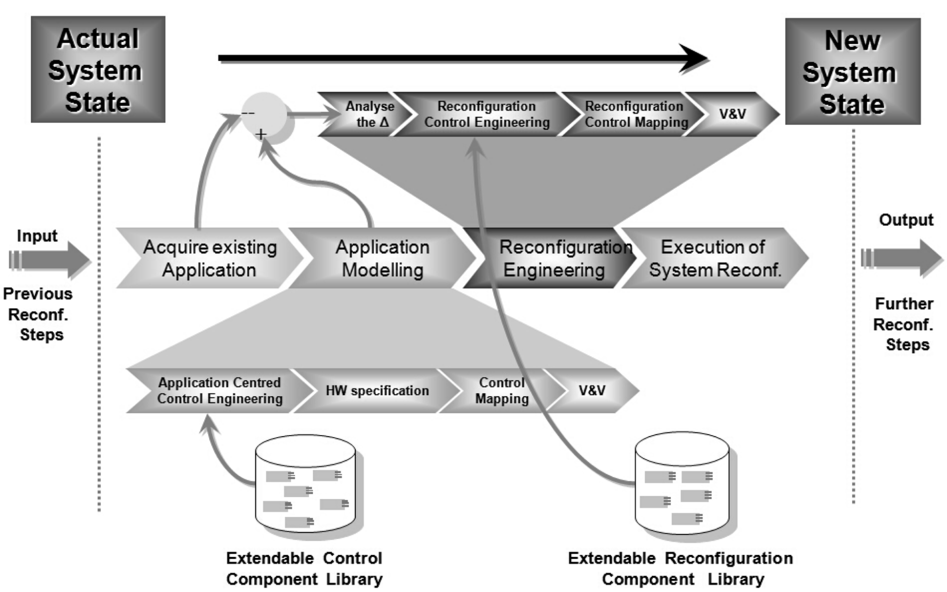
Figure 7. Controlled reconfiguration of control applications



1. Acquire Current System State (Acquire existing application)

Collect all data necessary for describing the current system state and deliver it as input to the application modeling. The data consists of the system model including applications currently running in the system, the hardware configuration of the system (used devices and network structure), the mapping of the applications to the different devices and the hardware capability descriptions.

Figure 8. Modeling cycle for control and reconfiguration control applications



2. Model New Control Application (Application Modeling)

Modeling of the new control application based on the existing ones by adding/removing components, their interconnections and specification of application properties (e.g. real–time constraints). The next step is the configuration of the system configuration (i.e. the IEC 61499 system model) with Devices, Resources and Network connections. After this the modeled application parts are mapped to the according devices they should be executed on. The final step is a formal verification and validation of the control application n order to determine if the specified application constraints will be met or not. For this verification and validation step approaches like Net Condition/Event Systems (Vyatkin, 1999), timed automata (Stanica, 2004) or Signal/Net Systems (Schnakenbourg, 2002) can be applied.

3. Model Reconfiguration Control Application (Reconfiguration Engineering)

Differences between the current running control application and the newly modeled control application are determined with the Delta Analysis. These differences serve as input and starting point for the modeling of the reconfiguration control application that will change the existing application to the new one. The reconfiguration control properties and parameters are specified in the same way as control application properties (according to step 2). Similar to the mapping of the control application the reconfiguration application parts are mapped to the devices. The final step is the verification of the reconfiguration control application together with device capabilities in order to determine if reconfiguration constraints (e.g. the timeframe in which a reconfiguration can take place or how long a reconfiguration can take place, etc.) will be met and the running application is disturbed as little as possible.

4. Execute Reconfiguration Control Application (Execution of System Reconfiguration)

To execute reconfiguration control applications the utilization of basic reconfiguration services at runtime platforms based on IEC 61499 management commands is necessary. The first step is to instantiate the reconfiguration control application on the according devices. Next the execution of the reconfiguration control application is done, i.e. the currently running control application is transformed into the new control application. This is achieved through basic reconfiguration services proving real–time constraint execution of reconfiguration processes at device level. The main services are:

- Control application component load/remove
- Connect/disconnect
- Query parameters
- Write parameters
- Query component state
- Write component state

To finish the reconfiguration procedure the reconfiguration control application will be removed after it has successfully executed all commands and all changes are finished.

Reconfiguration Methodology

The process of reconfiguring an automation system without downtimes sets high demands on the underlying concepts and methodologies: Applications within the automation system have to work without disturbances; the reconfiguration process has to be adapted to the special environmental conditions of the affected application part. Any fault during the reconfiguration process has to be managed at least to such a degree, that the system is left in a defined state. As described in the introduction the standard IEC 61499 already includes basic management commands for configuration and reconfiguration of applications. This section now proposes useful extensions to the management model of IEC 61499 enhancing the reconfiguration abilities of IEC 61499 with special regard to remaining compliant to the ideas of the standard.

The main idea of this new methodology is to control the reconfiguration of control logic (part of the control application) by an application, the so called reconfiguration application. The reconfiguration application does not differ from any other application and can therefore be modeled in the same manner. But it will have an impact on the control application, which means that it will include management commands that influence FBs and their interconnections in a defined manner. The basic idea of reconfiguration applications is described by Sünder et al. (2006). The presented engineering methodology builds on these results, particularly with regard to the setup and characteristics of reconfiguration applications.

Reconfiguration Control Terminology and Definitions

At this point it is suitable to define a few terms used later on for the development of an appropriate engineering methodology for dynamic reconfiguration processes:

- **Region of Interest (ROI):** this is a specific part of an IEC 61499 application that will be target for a specific reconfiguration. A reconfiguration application is assigned to this specific part. The definition of this region is given by the following cases of system changes:
- **Creating/Deleting a function block:** the suggested ROI is the function block itself plus the connected event as well as data inputs and outputs, since there is a significant temporal order of operations (a function block cannot be deleted unless all of its connections have been deleted).
- **Creating/Deleting a connection:** the suggested ROI consists of the corresponding halves of source and target function blocks of the connection along with their interconnections.
- **Creating/Deleting a parameter (i.e. a parameter in the context of IEC 61499 is a fixed value on a data input of a Function Block):** quite similar to connections, but without a source function block. So the suggested ROI only consists of the left half of the target FB and the parameter itself.
- **System reconfiguration:** the whole process of transforming the current control application in an IPMCS into the desired control application (instead of the state–of–the–art method "ramp down—stop—download—restart—ramp up"). Usually such a process is carried out by a number of reconfiguration applications on a number of ROIs. Reconfiguration takes place in four phases as depicted above (see Figure 8).
- **Reconfiguration Execution Control Function Blocks (RECFB):** special function blocks encapsulating reconfiguration functionality (e.g. a whole reconfiguration application). Within the execution of *RECFB* 3 reconfiguration control execution phases can be distinguished (see Figure 9; the vertical connections of the event as well as data inputs and outputs denote that only such data inputs and outputs are sampled which are connected to a specific event; this is a general concept of the IEC 61499 Function Block model; more details are explained in the IEC 61499 standard (IEC, 2005)):
- **INIT Sequence:** is needed in order to start-up and to configure the RECFB and the underlying runtime environment.
- **RINIT Sequence:** contains all preparation work that is needed to enable a controlled change of applications (for in-

stance new FBs will be instantiated and interconnected).

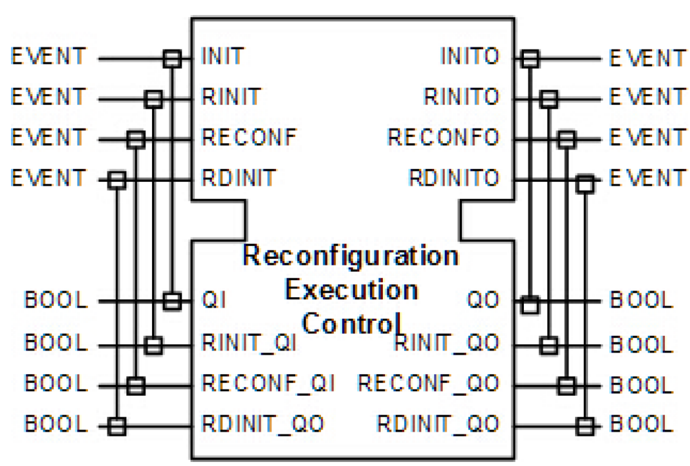
- **RECONF Sequence:** encapsulates all operations necessary to change from the old state to the new one. This for instance includes reading of internal states, calculation of the new internal states and writing the internal state to the new FB in case of a simple FB exchange with awareness to consistency. The final step of this sequence is the switch to the new FB.
- **RDINIT Sequence:** responsible for cleaning up after reconfiguration (e.g. deleting connections and function blocks not needed anymore). One *RECFB* belongs to one ROI, there is a one to one relation between them.
- **Reconfiguration Control Application:** application (i.e. a special IEC 61499 based function block network) built of *RECFBs*, that carries out the whole system reconfiguration process on an ordinary IEC 61499 system.

Reconfiguration Engineering Method

Reconfiguration applications define and describe the controlled reconfiguration within a ROI during runtime. The main intentions for the introduction of a reconfiguration engineering method handling these reconfiguration applications are:

- **Complexity:** The use of reconfiguration applications includes a reasonable amount of engineering complexity. The bigger the ROI is the more complex the whole reconfiguration application will be. This can lead to hardly understandable reconfiguration control applications which make the development and maintenance of them more complex. By using small or smaller ROIs, the engineering complexity keeps quite low.
- **Scalability:** There has to be a way to compose larger reconfiguration scenarios from several smaller reconfiguration steps. The RECFBs give the possibility to build composite RECFBs in the same way as in “normal” control applications using the same means (i.e. the models and concepts of the IEC 61499 standard).
- **Reusability:** As scaling is possible, the use of libraries for often used scenarios within typical application scopes will be useful. The concept enables such standardized RECFBs and their simple usage within composite RECFBs, again in the same way as in “normal” applications.

Figure 9. Reconfiguration Execution Control Function Block (RECFB)

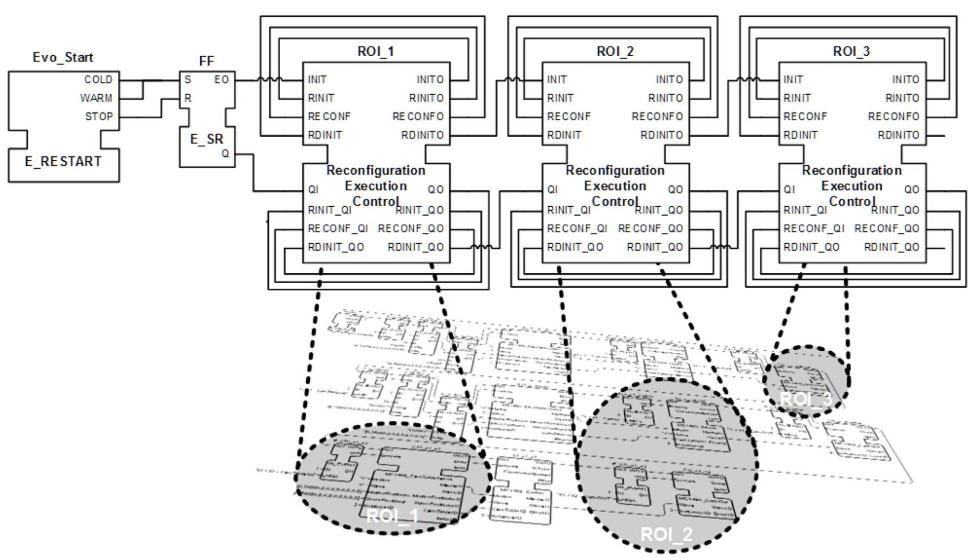


The main idea of the proposed approach is to maintain the fundamental principles of IEC 61499 (application centered engineering, component-based architecture, event–driven execution and the management model) for reconfiguration engineering. Figure 10 illustrates a reconfiguration control application containing 3 RECFBs. Each of these RECFBs contains a reconfiguration application performing reconfiguration on the associated ROI in the IEC 61499 application shown in the lower part of the figure. The interconnection of the RECFBs defines the way of executing the three steps. In the shown example only one RECFB is active at the same time (serial execution). In detail, each RECFB runs through the three phases of Initialization, Reconfiguration and Deinitialization before the next RECFB is triggered. By using the QI and QO data variables of the RECFBs, the internal sequences of the RECFBs communicate in a very simple manner. If one sequence fails, the next step will not be executed. Of course this communication can be enhanced according to the reconfiguration purpose. For instance, the coupling of two or more RECFBs is also possible.

The presented engineering methodology handles the two main tasks of reconfiguration applications according to Figure 1 in the following way:

- It performs runtime adaptations on the control application of a distributed automation system, corresponding to the upper half of Figure 1. This includes transfer of state information from one system state to another, if necessary to avoid disruption to the system.
- It performs runtime–checks during execution to ensure correct operation. In case of failures at least the system must be left in a tolerable state, this may include undo functionality for abortive reconfiguration steps. Such failure recovery strategies also require backup and restore mechanisms for state information, corresponding to the lower half of Figure 1. In our approach these topics are handled on different lev-

Figure 10. Regions of interest during the reconfiguration process



els. First of all within one reconfiguration application (an ROI represented by an RECFB) the issues of recovery or undo have to be handled internally of a RECFB. Second also within reconfiguration control applications this issue has to be modeled explicitly. The example in Figure 10 only provides a very simple failure handling. If an error occurs in one of the RECFB instances (i.e. instance names ROI_1, ROI_2 and ROI_3) then the QO data outputs (i.e. RINT_QO, RECONF_QO and RDINIT_QO) are set to false. This is an indication that a failure has occurred and the reconfiguration of a ROI will not take place. But of course more sophisticated error handling procedure can be defined as this simple once.

Another important aspect for reconfiguration is real-time constrained execution. IEC 61499 leaves issues such as timeliness open and delegate's appropriate specifications to compliance profiles and runtime implementations respectively. There exists no barrier to apply such a capability of the runtime environment to the presented engineering methodology. So if the underlying runtime system features timeliness (i.e. deterministic behavior), it can also be applied to the reconfiguration process (doing so certainly the complexity is further increasing).

Reconfiguration Patterns

Based on the above presented reconfiguration method enhanced system reconfiguration the following reconfiguration patterns have been defined in order to provide design rules for reconfiguration processes to the control engineer. These patterns cover the following scenarios:

- Moving of function block instances between IEC 61499 Resources at one device,
- Moving of function blocks instances between different IEC 64199 Devices,
- Moving of resource configurations between IEC 61499 Devices,
- Exchange of Function Block types (same and different interface), and
- Exchange of Resource types.

All of these patterns have in common that they are using RECFBs to describe the reconfiguration process.

Fault Handling During the Reconfiguration Process

In order to manage possible errors or faults during the reconfiguration process the following error scenarios for the zero-downtime system reconfiguration have been covered:

- **Creation of the reconfiguration control application fails:** This situation can be caused by download errors and initialization errors during the deployment phase of the reconfiguration control application. Download errors comprise connection faults, i.e. loss of connection from the engineering environment to the device management (possible reasons might be network or device failure), and device management exceptions.
- **RINIT phase of a reconfiguration step fails:** This situation again comprises connection faults, device management exceptions and initialization errors. Possible reasons are for creating the reconfiguration control application, except network failure, since the reconfiguration application or parts of it are executed locally on the Device.
- **RECONF phase of a reconfiguration step fails:** This category consists of reconfiguration errors and application faults. Reconfiguration errors again comprise

connections faults and device management exceptions. Application faults can be characterized as follows: all reconfiguration tasks terminated successfully, but the overall behavior of the new application is faulty.

- **RDINIT phase of a reconfiguration step fails:** The reasons why the RDINIT phase can fail are quite similar to those of the RINIT phase in. The only differences are that device management exceptions can occur upon deleting FBs or connections (reasons remain the same) and that initialization errors are replaced by de-initialization errors possible for all FBs requiring an INIT-event.

In order to handle these error scenarios the following error handling and fallback strategies have been developed:

- **Error handling during download of the reconfiguration application (RINIT phase):** The error scenarios and therefore the possible handling strategies are the same for these two phases. Connection faults might be recoverable by a simple RETRY; since these errors are time-uncritical it could also prove useful to wait for a short time before retry as a busy network might recover meanwhile. Unrecoverable connection faults terminate the whole reconfiguration process, cleanup is thereby impossible for devices with unreachable manager. Initialization errors can be handled likewise, except that upon failed RETRY of INIT+ the targets should be cleaned up. Device management errors will not be automatically recoverable in general. Already a single unrecoverable error terminates the whole reconfiguration process. Two approaches seem feasible: (i) Terminate upon the first error, which is primitive but rather safe; (ii) Let the user interact (e.g. let him download missing FB types or delete instances already present) and continue if the error could be resolved that way, which is advanced, but dangerous. Upon any termination the targets should be cleaned up.
- **Error handling during RECONF phase:** First of all, error handling during RECONF is time-critical. Upon connection faults two cases must be distinguished: (i) No structural change has been made to the application (only transfer of internal states has occurred so far). If the device is still operational no damage has been caused, otherwise within modern plants emergency measures will be activated if the failed device is a critical one. RETRY, although possible, is a dangerous option to handle connection faults during RECONF, since a faulted connection indicates problems; (ii) At least one structural change has been made already. The system is in an inconsistent state, RETRY is imperative (try to reach a consistent state by all means). If RETRY fails this is the worst case, all that can be done is give alarm and let emergency measures take control.

Also application faults can be divided in two categories: (i) Uncritical faults, e.g. the process are under control in desired manner, but a display is not updated. In this situation it is possible to keep the new application, perform RDINIT as scheduled and resolve the remaining problem by means of another reconfiguration. Certainly error handling strategies below might also be applied here, in doubt the user should be notified to decide how to continue; (ii) Critical faults → the new application is unusable, control over the process might be lost. Several possibilities exist to cope with this situation: UNDO of all changes until a tolerable state is reached; pre-modeled scenarios in the reconfiguration control application could enable reaching a "failsafe" state by further reconfiguration steps or the new application already contains alternative branches along with appropriate switching logic. If the favored branch fails, the second-best solution is tried and so on. Note: this is not real error handling anymore; such a fallback strategy rather belongs to the domain of fault tolerance of the (new) application.

Device management exceptions during RECONF can be treated like critical application faults. In general the RDINIT phase cannot be executed as scheduled if critical errors have occurred during RECONF. Hence the RDINIT phase must either be blocked or adjusted properly (e.g. FB instances planned for removal must not be deleted if still active due to UNDO).

- **Error handling during RDINIT:** Error handling in this phase is quite similar to the RINIT phase, with a few exceptions: errors do not terminate the whole process anymore (e.g. continue with cleanup measures, even if a certain FB could not be deleted, as long as it is safe). De-initializing errors are also candidates for RETRY; caution is advised if de-initializing of an FB fails. In this case it might cause the system to become unstable if such a FB is deleted.

TESTS AND CONCEPT VALIDATION

Engineering Prototype

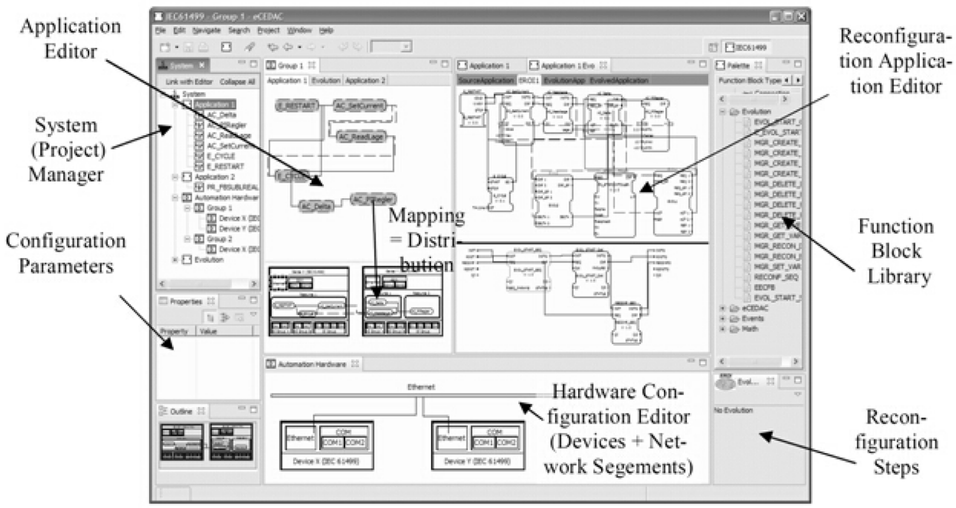
The following section gives an overview of a prototypic implementation of the proposed reconfiguration engineering method. Based on Eclipse SDK and the Graphical Editing Framework (GEF) (Gamma, 2003) the engineering environment supporting the definition of RECFBs is realized as a set of different plug-in for Eclipse. Eclipse is an open source community whose projects are focused on providing an extensible development platform and application frameworks for building software which is very suitable for the engineering of the proposed reconfiguration approach. Figure 11 shows the prototypic implementation.

The main parts of the tool are the Application, the Hardware Configuration Editor, the System (Project) Manager, the Reconfiguration Application Editor and the Function Block and Device Libraries. The Application Editor is used to specify and define function block networks (i.e. IEC61499 applications). Usability and aid for the user are main goals of the editor. Functions like copy/paste or undo/redo are supported by the tool. Checks during drawing of connections are performed in order to avoid programming errors in a very early stage. Functions like zooming helps the user developing larger function block networks. The Outline View provides an overview of the developed control application. Furthermore connections are drawn by a dotted line if connected function blocks are mapped to different devices. This shows the user that communication links have to be configured (see Figure 11).

The Hardware Configuration Editor is responsible for the modeling of the automation hardware (incl. communication network and devices as defined by the IEC 61499 standard). The network can be split into more parts for structuring. Each of these parts can be opened with the editor. Within this editor a function block can be mapped to a device. Mapping means that a function block gets assigned to a device or to a resource if the device has more resources (execution environments for function blocks according to IEC 61499). The system manager gives an overview of different automation projects and can be use to navigate through these projects.

Within the Reconfiguration Application Editor the reconfiguration control applications are modeled based on existing control applications according to the approach presented in this chapter. The tool supports the control engineer in the definition of the reconfiguration control application. It shows the old and the new application and provides also a Delta Analysis as shown in Figure 8. In addition the tool provides also a support to partly generate

Figure 11. Engineering Prototype



a RECFB based on some user interaction. For example if a control engineer wants to exchange a function block of a control application he has to drop the new function block over the old one in the Reconfiguration Application Editor. The tool replaces the function block and generates a RECFB and makes also some configurations of this block based on the reconfiguration templates as explained in the previous section.

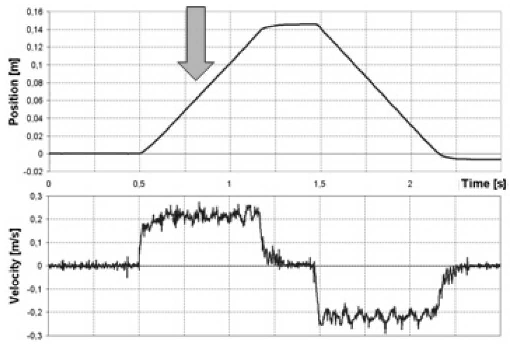
Servo Drive Controller Configuration

First tests in the "Testbed for Highly Distributed Control" for the proposed reconfiguration concept have been performed at the Odo Struger Laboratory of the Automation and Control Institute (ACIN), Vienna University of Technology. These tests gave us the possibility of validating our reconfiguration concepts. In detail, reconfiguration of a prototypic implementation of an execution environment with enhanced (re-)configuration services as explained above, a linear servo drive, has been performed during operation, in this example the movement of the axis according to a position profile.

The control program for the linear servo drive consists of the velocity closed-loop control and the position closed-loop control. The tests have been provided for both of these two parts of the control program. For instance a proportional control algorithm has been exchanged by a new one including also an integral part or in addition a derivative part. The scenario for the velocity closed-loop control was the exchange of the control algorithm without changes in the control hardware. So the ROI for this scenario was restricted to the FB including the control algorithm and its surrounding. During the RECONF sequence an appropriate algorithm has to be applied to avoid disturbances, in this example the output fitting method has been used (Guler, 2003). In the second scenario the position closed-loop control has been exchanged and also the hardware configuration has been changed. An additional controller has been introduced and the new position controller has been applied to the new controller. The results of the second scenario are presented in Figure 12.

The linear axis performs a ramp. During the ramp up sequence the reconfiguration takes place, depicted by the arrow in Figure 12. In the lower part of Figure 12 the corresponding velocity of

Figure 12. Reconfiguration with output-fitting at time 0.75 s



the linear axis gives an impression of the performance of the reconfiguration. There is no influence visible in the velocity graph (of course also in the position graph), although the control algorithm of the position controller has been changed and the position controller itself has been moved to another device within the network. This first result provides first evidence that the proposed reconfiguration approach is sufficient for providing dynamic reconfiguration of lower level control applications in distributed IPMCS. In the provided example the reconfiguration took place only in a few microseconds which is normally fast enough for control tasks in IPMCS.

Communication Reconfiguration

Additional tests for the proposed reconfiguration concept have been also performed by PROFACTOR. To show how a controlled reconfiguration, as explained above, works an example has been created that uses two embedded control boards (DIGI ConnectME development boards, DIGI, 2009) called DIGI1 and DIGI2. Both embedded boards are equipped with the Net+OS 6.3 real-time operating systems (which is based on the ThreadX open source project) and an IEC 61499 compliant runtime environment with enhanced reconfiguration services. The initial control application performs the following steps:

1) A HMI device (e.g. PC) sends a user input (a number) to the DIGI1 device over Ethernet.
2) DIGI1 device sends data to DIGI2 device over Ethernet.
3) The DIGI2 device sends the data to the HMI device over Ethernet and this device displays the result to the user

All communication in this application is over Ethernet, but this can be changed online by a reconfiguration application. This application has been designed such that it changes Step 2 from a communication over Ethernet to a communication over a serial link (for hardware layout see Figure 13).

Figure 14 shows the part of the application that is mapped to the DIGI1 device. The simplified reconfiguration application has to change the PUBLISH_1 FB instance to a SERCOMM_1_0 FB instance and performs the following steps:

Figure 13. Two DIGI ConnectME embedded controller connected via serial link

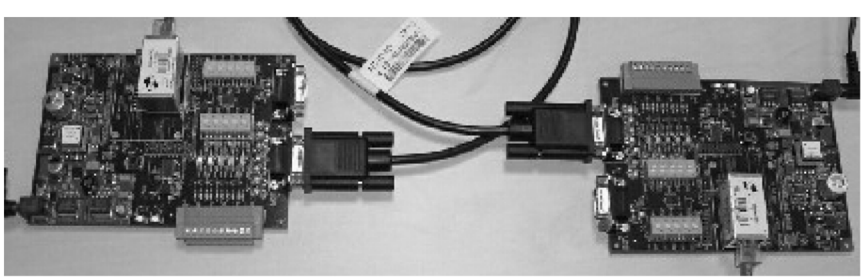


Figure 14. Part of the application in the DIGI1 device

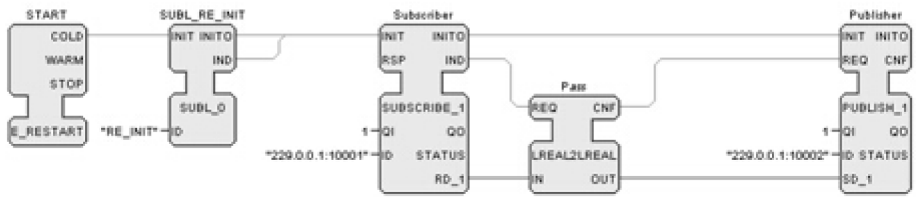
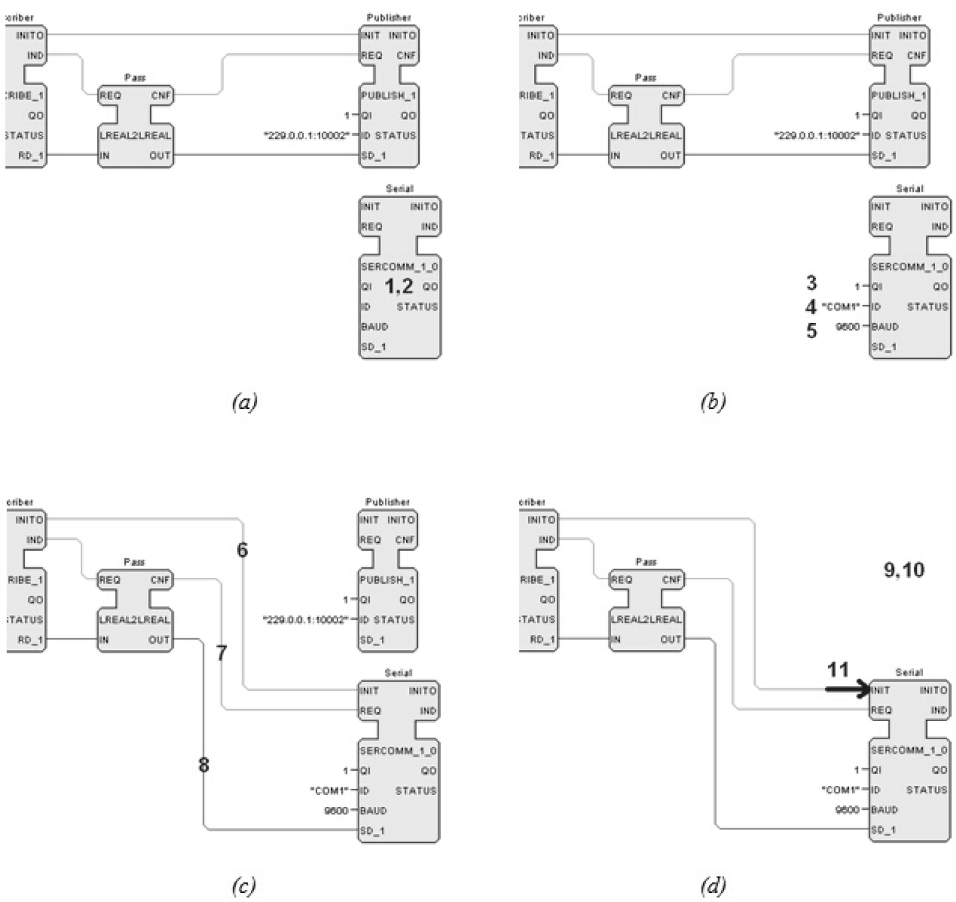


1) Create SERCOMM_1_0 FB with name "Serial"
2) Start "Serial"
3) Set parameter "Serial.QI" to value "1"
4) Set parameter "Serial.ID" to value "COM1"
5) Set parameter "Serial.BAUD" to value "1200"
6) Reconnect[1] "Publisher.INIT" to "Serial. INIT"
7) Reconnect "Publisher.REQ" to "Serial. REQ"
8) Reconnect "Publisher.SD_1" to "Serial. SD_1"
9) Stop "Publisher"

Figure 15. Reconfiguration steps in the DIGI1 device



10) Delete “Publisher”
11) Send INIT event to “Serial”

All these steps can be mapped to the above mentioned special management FBs that are available. Figure 15 shows these steps graphically. Similar steps have to be taken to change the part of the application in device DIGI2.

FUTURE RESEARCH DIRECTIONS

The next steps in our research work are to implement reconfiguration services in an advanced IEC 61499 based runtime environment which is capable of executing reconfiguration control applications. Furthermore a validation of the above described approach will be carried out over a wide range of different control scenarios and applications in the future. Moreover we will also focus our work on an enhanced engineering environment supporting the design and implementation of reconfiguration control applications.

CONCLUSION

This chapter presents an approach for structured modeling of reconfiguration control applications of IPMCS based on the IEC 61499 standard. It has been shown that the concept and elements of the IEC 61499 standard's management model, with little extensions, are sufficient for dynamic reconfiguration of distributed applications.

KEY TERMS AND DEFINITIONS

ACIN: Automation and Control Institute.
EC: Embedded Controller.
ECC: Execution Control Chart.
FB: Function Block.
FBN: Function Block Network.
GEF: Graphical Editing Framework.
IPC: Industrial PC.

IEC: International Electrotechnical Commission.

I/O: Input/Output.

IEC 61131: Standard for PLCs.

IEC 61499: Reference model for distributed and reconfigurable automation and control systems.

IPMCS: Industrial Process Measurement and Control Systems.

PC: Personal Computer.

PLC: Programmable Logic Controller.

QoS: Quality of Service.

RCA: Reconfiguration Control Application.

RECFB: Reconfiguration Execution Control Function Blocks.

Reconfiguration: Arrange into a new PLC/EC configuration.

ROI: Region of Interest.

SDK: Software Development Kit

UML: Unified Modeling Language.

XML: Extended Mark-up Language.

ENDNOTE

[1] Reconnect in this context means disconnect the event connection from "Publisher.INIT" and connect it to "Serial.INIT"
