Precautions in use. Not suitable for use in oxidizing acids

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 550 MPa (80 ksi); yield strength, 185 MPa (27 ksi); elongation, 35% in 50 mm (2 in.). See also Fig. 44.

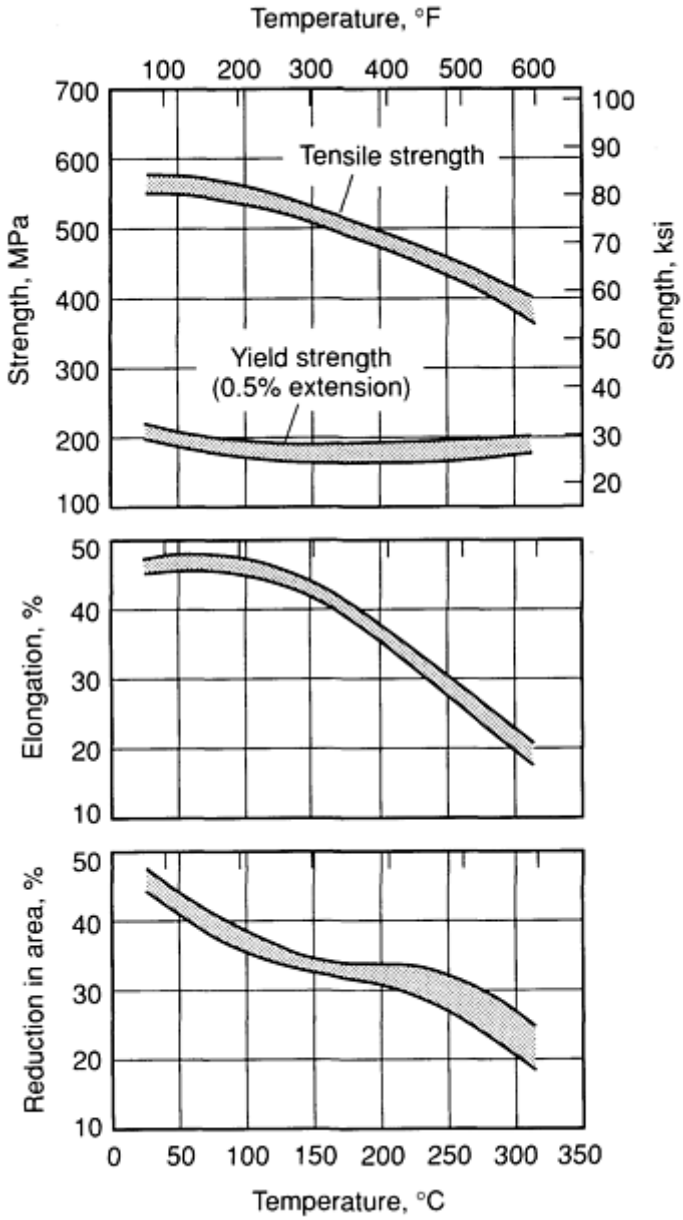

Fig. 44 Typical short-time tensile properties of C95200, as-cast

Hardness. 64 HRB; 125 HB (3000 kg load)

Poisson's ratio. 0.31

Elastic modulus. Tension, 105 GPa (15×10^6 psi); shear, 39 GPa (5.7×10^6 psi)

Impact strength. Charpy keyhole, 27 J (20 ft · lbf) at -18 to 38 °C (0 to 100 °F); Izod, 40 J (30 ft · lbf) at -18 to 38 °C (0 to 100 °F)

Fatigue strength. Rotating beam, 150 MPa (22 ksi) at 10^8 cycles

Creep-rupture characteristics. Limiting creep stress for 10^{-5}%/h: 145 MPa (21 ksi) at 230 °C (450 °F); 54 MPa (7.9 ksi) at 315 °C (600 °F). See also Fig. 45.

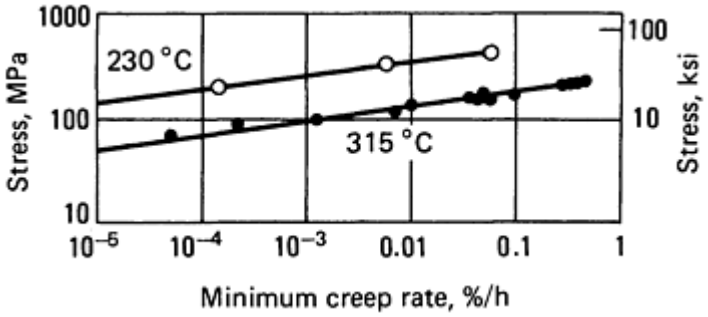

Fig. 45 Typical creep properties of C95200, as-cast

Structure

Microstructure. As cast, the microstructure is primarily fcc alpha, with precipitates of iron-rich alpha in the form of rosettes and spheres. Depending on the cooling rate, small amounts of metastable cph beta or alpha-gamma eutectoid decomposition products may be present. Annealing followed by rapid cooling reduces the amount of residual beta to about 5% of the apparent volume.

Metallographic etchant. Acid ferric chloride (10% HCl, 5% $FeCl_3$)

Mass Characteristics

Density. 7.64 g/cm^3 (0.276 lb/in.^{3}) at 20 °C (68 °F)

Volume change on freezing. Approximately 1.7% contraction

Patternmaker's shrinkage. 2%

Thermal Properties

Liquidus temperature. 1045 °C (1915 °F)

Solidus temperature. 1040 °C (1905 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 380 J/kg · K (0.091 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 50 W/m · K (29.1 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 12% IACS at 20 °C (68 °F)

Electrical resistivity. 144 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. 1.20 at 16,000 A/m (200 oersteds)

Chemical Properties

General corrosion behavior. C95200 has generally fair resistance to attack in nonoxidizing mineral acids such as sulfuric, hydrochloric, and phosphoric, and in alkalies such as sodium and potassium hydroxide. Cast components are used successfully in systems for seawater, brackish water, and potable water. The alloy resists many organic acids, including acetic and lactic, plus all esters and ethers. Moist ammonia atmospheres can cause stress-corrosion cracking.

Fabrication Characteristics

Machinability. 20% of C36000 (free-cutting brass). Carbide or tool steel cutters may be used. Good surface finish and precision attainable with all conventional methods. Typical conditions using tool steel cutters: roughing speed, 105 m/min (350 ft/min) with a feed of 0.3 mm/rev (0.011 in./rev); finishing speed, 350 m/min (1150 ft/min) with a feed of 0.15 mm/rev (0.006 in./rev)

Annealing temperature. 650 to 745 °C (1200 to 1375 °F)

C95300
89Cu-1Fe-10A1

Commercial Names

Trade name. Ampco B2

Common names. Aluminum bronze 9B; 89-1-10

Specifications

ASTM. Sand castings: B 148; centrifugal castings: B 271; continuous castings: B 505; ingots: B 30

SAE. J462

Government. Centrifugal and sand castings: QQ-C-390; precision castings: MIL-C-11866, composition 22

Ingot identification number. 415

Chemical Composition

Composition limits. 86 Cu min, 9.0 to 11.0 Al, 0.8 to 1.5 Fe, 1.0 max other (total)

Consequence of exceeding impurity limits. Possible hot shortness, loss of casting soundness, embrittlement, reduced response to heat treatment

Applications

Typical uses. Pickling baskets, nuts, gears, steel mill slippers, marine equipment, welding jaws, nonsparking hardware

Precautions in use. Not suitable for exposure to oxidizing acids. Prolonged heating in the 320 to 565 °C (610 to 1050 °F) range can result in a loss of ductility and notch toughness.

Mechanical Properties

Tensile properties. Minimum values. As cast: tensile strength, 450 MPa (65 ksi); yield strength, 170 MPa (25 ksi); elongation, 20% in 50 mm (2 in.); reduction in area, 25%. TQ50 temper: tensile strength, 550 MPa (80 ksi); yield strength, 275 MPa (40 ksi); elongation, 12% in 50 mm (2 in.); reduction in area, 14%

Compressive properties. Compressive ultimate strength: as-cast, 760 MPa (110 ksi); TQ50 temper, 825 MPa (120 ksi). Elastic limit: as-cast, 125 MPa (18 ksi); TQ50 temper, 205 MPa (30 ksi).

Hardness. As-cast, 67 HRB; TQ50 temper, 81 HRB

Poisson's ratio. 0.314

Elastic modulus. Tension, 110 GPa (16×10^6 psi); shear, 42 GPa (6.1×10^6 psi)

Impact strength. Cast and annealed: Charpy keyhole, 31 J (23 ft · lbf); Izod, 38 J (28 ft · lbf) at -20 to 100 °C (-5 to 212 °F). TQ50 temper: Charpy keyhole, 37 J (27 ft · lbf) at -20 to 100 °C (-5 to 212 °F)

Structure

Crystal structure. Alpha phase, face-centered cubic; beta phase, close-packed hexagonal

Microstructure. As-cast and properly cooled or annealed, the structure is approximately 70% alpha and 30% metastable beta. Quenched and tempered (TQ50 temper), the structure is largely tempered metastable beta martensite, but also contains both primary alpha and reprecipitated acicular alpha.

Mass Characteristics

Density. 7.53 g/cm^3 (0.272 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 1045 °C (1915 °F)

Solidus temperature. 1040 °C (1905 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 375 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 63 W/m · K (36 Btu/ft · h · °F) at 20 °C (68 °F); temperature coefficient, 0.12 W/m · K per K at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 13% IACS at 20 °C (68 °F)

Electrical resistivity. 133 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. 1.07 at field strength of 8 kA/m

Chemical Properties

General corrosion behavior. Corrosion characteristics of C95300 are slightly inferior to those of C95200, primarily because C95300 has more and larger beta areas. Heat treatment enhances corrosion resistance, particularly in mediums that promote dealloying. The alloy shows characteristic resistance to nonoxidizing mineral acids, neutral salt solutions, seawater, brackish water, and some organic acids.

Fabrication Characteristics

Machinability. 55% of C36000 (fire-cutting brass). Tool steel or carbide cutters may be used. Good surface and precision finish may be obtained in the as-cast, cast and annealed, and TQ50 tempers. Typical conditions using tool steel cutters: roughing speed, 90 m/min (300 ft/min) at a feed of 0.2 mm/rev (0.009 in./rev); finishing speed, 290 m/min (950 ft/min) at a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 595 to 650 °C (1100 to 1200 °F)

C95400 (85Cu-4Fe-11Al) and C95410

Commercial Names

Trade name. Ampco C3

Common names. Aluminum bronze 9C; G5; 85-4-11

Specifications

ASME. Sand castings: SB148

ASTM. Sand castings: B 148; centrifugal castings: B 271; continuous castings: B 505; ingots; B 30

Government. QQ-C-390. Sand castings, MIL-C-22229 (composition 6); investment castings, MIL-C-15345 (Alloy 13); centrifugal castings, MIL-C-22087 (composition 8)

Ingot identification number 415

Chemical Composition

Composition limits of C95400. 83 min Cu, 10.0 to 11.5 Al, 3.0 to 5.0 Fe, 0.50 Mn max, 2.5 Ni max (+ Co), 0.5 max other (total)

Composition limits of C95410. 83.0 Cu min, 3.0 to 5.0 Fe, 1.5 to 2.5 Ni (including Co), 10.0 to 11.5 Al, 0.50 Mn max

Cu + sum of named elements. 99.5 min

Consequence of exceeding impurity limits. Possible hot shortness, reduced casting soundness, embrittlement and loss of heat treating response

Applications

Typical uses. Pump impellers, bearings, gears, worms, bushings, valve seats and guides, rolling mill slippers, slides, nonsparking hardware

Precautions in use. Not suitable for use in oxidizing acids. Prolonged heating in the 320 to 565 °C (610 to 1050 °F) range can result in loss of ductility and notch toughness.

Mechanical Properties

Tensile properties. Minimum values. As cast: tensile strength, 515 MPa (75 ksi); yield strength, 205 MPa (30 ksi); elongation, 12% in 50 mm (2 in.); reduction in area, 12%. TQ50 temper: tensile strength, 620 MPa (90 ksi); yield strength, 310 MPa (45 ksi); elongation, 6% in 50 mm (2 in.), reduction in area, 6%. See also Fig. 46.

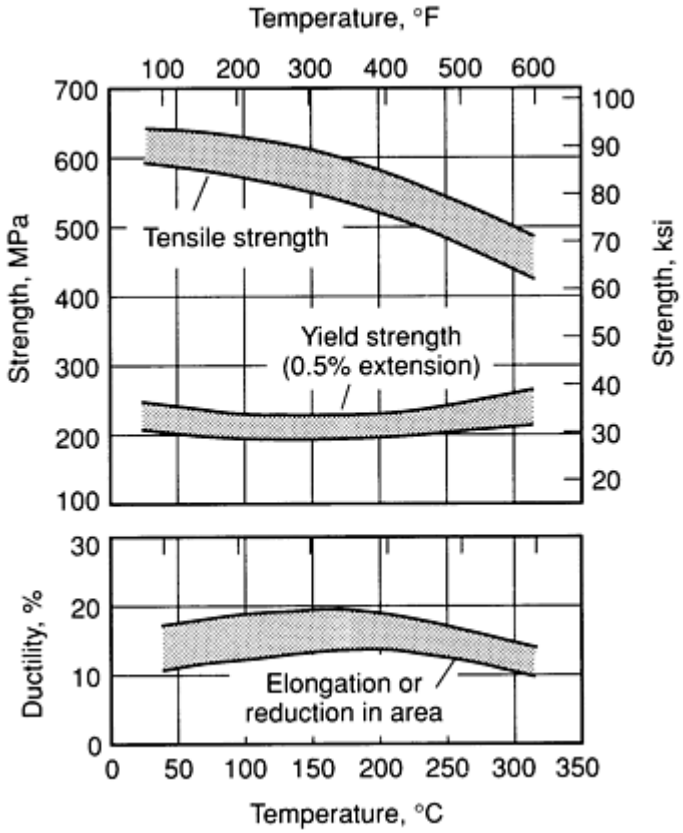

Fig. 46 Typical short-time tensile properties of C95400, as-cast

Compressive properties. Compressive strength, ultimate: as-cast, 940 MPa (136 ksi); TQ50 temper, 1070 MPa (155)

Hardness. As-cast, 83 HRB; TQ50 temper; 94 HRB

Poisson's ratio. 0.316

Elastic modulus. Tension, 110 GPa (16×10^6 psi); shear, 41 GPa (6.1×10^6 psi)

Impact strength. As-cast: Charpy keyhole, 15 J (11 ft · lbf); Izod, 22 J (16 ft · lbf) at 20 °C (68 °F). TQ50 temper: Charpy keyhole, 9 J (7 ft · lbf); Izod, 15 J (11 ft · lbf) at 20 °C (68 °F)

Fatigue strength. Reverse bending, 240 MPa (35 ksi) at 10^8 cycles (TQ50 temper)

Creep-rupture characteristics. Limiting creep stress at a strain rate of 10^{-5}%/h: 115 MPa (17 ksi) at 230 °C (450 °F); 51 MPa (7.4 ksi) at 315 °C (600 °F); 30 MPa (4.4 ksi) at 370 °C (700 °F); 20 MPa (2.9 ksi) at 425 °C (800 °F). See also Fig. 47.

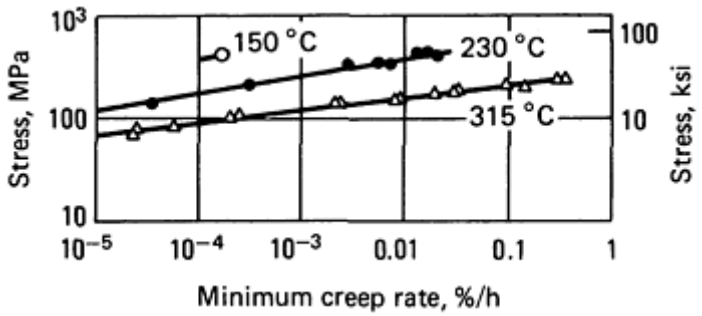

Fig. 47 Typical creep properties of C95400, as-cast

Structure

Crystal structure. Alpha, face-centered cubic; beta, close-packed hexagonal

Microstructure. As-cast and annealed material normally consists of approximately 50% alpha and 50% metastable beta. Under some conditions, eutectoid decomposition may produce an alpha-gamma-2 structure instead of the beta phase. Quenched-and-tempered structures consist of fine acicular alpha crystals in a tempered beta matrix.

Mass Characteristics

Density. 7.45 g/cm^3 (0.269 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 1040 °C (1900 °F)

Solidus temperature. 1025 °C (1880 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 420 J/kg · K (0.10 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 59 W/m · K (34 Btu/ft · h · °F) at 20 °C (68 °F); temperature coefficient, 0.117 W/m · K per K at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 13% IACS at 20 °C (68 °F)

Electrical resistivity. 133 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. As-cast, 1.27 at field strength of 16 kA/m; TQ50 temper, 1.20 at field strength of 16 kA/m

Chemical Properties

General corrosion behavior. C95400 has fair resistance to attack by nonoxidizing solutions of mineral acids such as sulfuric and phosphoric, as well as to neutral salts such as sodium chloride. The alloy also resists acetic; lactic, and oxalic acids; organic solvents such as esters and ethers; and seawater, brackish water, and potable waters. In some environments, C95400 can undergo dealloying caused by corrosive attack on the beta phase. Heat treatment improves resistance to dealloying. Moist ammonia environments may cause stress-corrosion cracking under high levels of applied stress.

Fabrication Characteristics

Machinability. 60% of C36000 (free-cutting brass.) C95400, in either as-cast or TQ50 temper, is easily machined by all standard operations using high-strength tool steel or carbide cutters. Typical conditions using tool steel cutters: roughening speed, 90 m/min (300 ft/min) at a feed of 0.34 mm/rev (0.011 in./rev); finishing speed, 290 m/min (950 ft/min) at a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 620 °C (1150 °F)

C95500
81Cu-4Fe-4Ni-11Al

Commercial Names

Previous trade name. Ampco D4

Common names. Aluminum bronze 9D; 415; 81-4-4-11

Specifications

AMS. 4880

ASTM. Sand castings: B 148; centrifugal castings: B 271; continuous castings: B 505: ingots: B 30

SAE. J462

Government. QQ-C-390; centrifugal castings, MIL-C-15345 (Alloy 14); sand castings, MIL-C-22229 (composition 6); investment castings, MIL-C-22087 (composition 8)

Ingot identification number. 415

Chemical Composition

Composition limits. 78 Cu min, 10.0 to 11.5 Al, 3.0 to 5.0 Fe, 3.5 Mn max, 3.0 to 5.5 Ni (+ Co), 0.5 max other (total)

Consequence of exceeding impurity limits. Possible hot shortness in welding, embrittlement, increased quench-cracking susceptibility, possible loss of heat-treating response. Excessive Si can cause machining difficulties.

Applications

Typical uses. Valve guides and seats in aircraft engines, corrosion-resistant parts, bushings, gears, worms, pickling hooks and baskets, agitators

Precautions in use. Not suitable for use in strong oxidizing acids

Mechanical Properties

Tensile properties. Typical. As-cast: tensile strength, 620 MPa (90 ksi); yield strength, 275 MPa (40 ksi); elongation, 6% in 50 mm (2 in.); reduction area, 7%. TQ50 temper: tensile strength, 760 MPa (110 ksi); yield strength, 415 MPa (60 ksi); elongation, 5% in 50 mm (2 in.); reduction in area, 5%

Compressive properties. As-cast: compressive strength, 895 MPa (130 ksi); compressive yield strength, 825 MPa (120 ksi) at a permanent set of 10%; elastic limit, 310 MPa (45 ksi). TQ50 temper; compressive strength, 1140 MPa (165 ksi); compressive yield strength, 1030 MPa (150 ksi) at a permanent set of 10%; elastic limit, 415 Mpa (60 ksi)

Hardness. As-cast, 87 HRB; TQ50 temper, 96 HRB

Poisson's ratio. 0.32

Elastic modulus. Tension: as-cast, 110 GPa (16×10^6 psi); TQ50 temper, 115 GPa (17×10^6 psi). Shear as-cast, 42 GPa (6.1×10^6 psi); TQ50 temper, 44 GPa (6.4×10^6 psi)

Impact strength. Charpy keyhole, 14 J (10 ft · lbf); Izod, 18 J (13 ft · lbf) at 20 °C (68 °F)

Fatigue strength. Rotating beam, as-cast, 215 MPa (31 ksi) at 10^8 cycles; TQ50 temper, 260 MPa (38 ksi) at 10^8 cycles

Creep-rupture characteristics. Limiting creep stress at a strain rate of 10^{-5}%/h: 72 MPa (10.5 ksi) at 315 °C (600 °F); 38 MPa (5.5 ksi) at 370 °C (700 °F); 17 MPa (2.5 ksi) at 425 °C (800 °F)

Structure

Crystal structure. Alpha, face-centered cubic; beta, close-packed hexagonal; kappa, ordered face-centered cubic

Microstructure. As-cast or annealed structures consist of alpha crystals plus kappa precipitates, forming a pearlitic appearance. Small areas of metastable beta may exist. Heat-treated structures consist of tempered beta martensite with very fine reprecipitated alpha needles. Some undissolved equiaxed alpha crystals may be evident, depending on the actual composition and quenching temperature.

Mass Characteristics

Density. 7.53 g/cm^3 (0.272 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 1055 °C (1930 °F)

Solidus temperature. 1040 °C (1900 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 418 J/kg · K (0.10 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 42 W/m · K (24 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 8.5% IACS at 20 °C (68 °F)

Electrical resistivity. 203 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. As-cast, 1.30 at field strength of 16 kA/m; TQ50 temper, 1.20 at field strength of 16 kA/m

Chemical Properties

General corrosion behavior. Good cavitation resistance in salt water and fresh tap water. Avoid nitric acid and strong aeration when using other acids.

Fabrication Characteristics

Machinability. 50% of C36000 (free-cutting brass). Heat treating reduces machinability in drilling and tapping operations. Tool steel or carbide cutters may be used. Typical conditions using tool steel cutters follow.

Roughing speed: as-cast, 76 m/min (250 ft/min) at a feed of 0.3 mm/rev (0.011 in./rev); TQ50 temper, 90 m/min (300 ft/min) at a feed of 0.2 mm/rev (0.009 in./rev).

Finishing speed: as-cast and TQ50 temper, 290 m/min (950 ft/min) at a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 620 to 705 °C (1150 to 1300 °F)

C95600
91Cu-2Si-7Al

Commercial Names

Common name. Aluminum-silicon bronze

Specifications

ASTM. Ingot: B 30; sand castings; B 148, B 763

Government. QQ-B-675, MIL-V-11 87

Ingot identification number. 415E

Chemical Composition

Composition limits. 88.0 Cu min, 0.25 Ni (including Co) max, 6.0 to 8.0 Al, 1.8 to 3.3 Si.

Cu + sum of named elements. 99.0% min

Applications

Typical uses. Cable connectors, terminals, valve stems, marine hardware, gears, worms, pole-line hardware

Mechanical Properties

Tensile properties. Typical data for as-sand-cast separately cast test bars (M01 temper): tensile strength, 515 MPa (75 ksi); yield strength, 235 MPa (34 ksi) at 0.5% extension under load; elongation, 18% in 50 mm (2 in.)

Hardness. Typically, 140 HB (3000 kg)

Elastic modulus. Tension, 105 GPa (15×10^6 psi) at 20 °C (68 °F)

Mass Characteristics

Density. 7.69 g/cm^3 (0.278 lb/in.^{3}) at 20 °C (68 °F)

Volume change on freezing. Patternmaker's shrinkage, 16 mm/m ($\frac{3}{16}$ in./ft)

Thermal Properties

Liquidus temperature. 1005 °C (1840 °F)

Solidus temperature. 982 °C (1800 °F)

Specific heat. 376 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 8.5% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. M01 temper; 60% at C36000 (free-machining brass)

Stress-relieving temperature. 260 °C (500 °F)

C95700
75Cu-3Fe-8Al-2Ni-12Mn

Commercial Names

Previous trade name. Superstone 40, Novoston, Ampcoloy 495

Common name. Manganese-aluminum bronze; 75-3-8-2-12

Specifications

ASTM. Sand castings: B 148; ingot: B 30

Government. Sand castings: MIL-B-24480

Chemical Composition

Composition limits. 71.0 Cu min, 11.0 to 14.0 Mn, 7.0 to 8.5 Al, 2.0 to 4.0 Fe, 1.5 to 3.0 Ni, 0.10 Si max, 0.03 Pb max, 0.5 max others (total)

Consequence of exceeding impurity limits. Possible hot shortness and reduced cast strength

Applications

Typical uses. Propellers, impellers, stator clamp segments, safety tools, welding rods, valves, pump casings, marine fittings

Precautions in use. Slow cooling or prolonged heating in the 350 to 565 °C (660 to 1050 °F) range may cause embrittlement. Not suitable for use in oxidizing acids

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 620 MPa (90 ksi); yield strength, 275 MPa (40 ksi); elongation, 20% in 50 mm (2 in.); reduction in area, 24%

Compressive properties. Compressive strength, as-cast: 1035 MPa (150 ksi) at a permanent set of 0.1%

Hardness. As-cast, or cast and annealed: 85 to 90 HRB

Poisson's ratio. 0.326

Elastic modulus. Tension, 125 GPa (18×10^6 psi); shear, 44 GPa (6.4×10^6 psi)

Impact strength. Izod, 27 J (20 ft · lbf) at 20 °C (68 °F)

Fatigue strength. Reverse bending, 231 MPa (33.5 ksi) at 10^8 cycles

Creep-rupture characteristics. Limiting creep stress for 10^{-5}%/h: 66 MPa (9.6 ksi) at 205 °C (400 °F); 31 MPa (4.5 ksi) at 290 °C (550 °F). Rupture stress for 10^5 h life: 470 MPa (68 ksi) at 205 °C (400 °F); 232 MPa (33.6 ksi) at 260 °C (500 °F); 39 MPa (5.7 ksi) at 370 °C (700 °F)

Structure

Microstructure. As-cast and annealed tempers: fcc alpha crystals with cph beta phase in various amounts, typically, 25% by volume

Mass Characteristics

Density. 7.53 g/cm^3 (0.272 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 990 °C (1815 °F)

Solidus temperature. 950 °C (1740 °F)

Coefficient of linear thermal expansion. 17.6 μm/m · K (9.8 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 400 J/kg · K (0.105 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 12.1 W/m · K (7.0 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 3.1% IACS at 20 °C (68 °F)

Electrical resistivity. 556 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. Magnetic condition (as-cast, slow cooled): 2.2 to 15.0 Demagnetized (annealed, fast cooled): 1.03

Chemical Properties

General corrosion behavior. Generally comparable to that of the aluminum bronzes and nickel-aluminum bronzes. See C95200.

Fabrication Characteristics

Machinability. 50% of C36000 (free-cutting brass). Tool steel or carbide cutters may be used. Good surface finishes and tolerance are possible in all conventional machining operations. Typical conditions using tool steel cutters: roughing speed, 75 m/min (250 ft/min) with a feed of 0.3 mm/rev (0.011 in./rev); finishing speed, 290 m/min (950 ft/min) with a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 620 °C (1150 °F)

Poisson's ratio. 0.326

Elastic modulus. Tension, 125 GPa (18×10^6 psi); shear, 44 GPa (6.4×10^6 psi)

Impact strength. Izod, 27 J (20 ft · lbf) at 20 °C (68 °F)

Fatigue strength. Reverse bending, 231 MPa (33.5 ksi) at 10^8 cycles

Creep-rupture characteristics. Limiting creep stress for 10^{-5}%/h: 66 MPa (9.6 ksi) at 205 °C (400 °F); 31 MPa (4.5 ksi) at 290 °C (550 °F). Rupture stress for 10^5 h life: 470 MPa (68 ksi) at 205 °C (400 °F); 232 MPa (33.6 ksi) at 260 °C (500 °F); 39 MPa (5.7 ksi) at 370 °C (700 °F)

Structure

Microstructure. As-cast and annealed tempers: fcc alpha crystals with cph beta phase in various amounts, typically, 25% by volume

Mass Characteristics

Density. 7.53 g/cm^3 (0.272 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 990 °C (1815 °F)

Solidus temperature. 950 °C (1740 °F)

Coefficient of linear thermal expansion. 17.6 μm/m · K (9.8 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 400 J/kg · K (0.105 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 12.1 W/m · K (7.0 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 3.1% IACS at 20 °C (68 °F)

Electrical resistivity. 556 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. Magnetic condition (as-cast, slow cooled): 2.2 to 15.0 Demagnetized (annealed, fast cooled): 1.03

Chemical Properties

General corrosion behavior. Generally comparable to that of the aluminum bronzes and nickel-aluminum bronzes. See C95200.

Fabrication Characteristics

Machinability. 50% of C36000 (free-cutting brass). Tool steel or carbide cutters may be used. Good surface finishes and tolerance are possible in all conventional machining operations. Typical conditions using tool steel cutters: roughing speed, 75 m/min (250 ft/min) with a feed of 0.3 mm/rev (0.011 in./rev); finishing speed, 290 m/min (950 ft/min) with a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 620 °C (1150 °F)

C95800
82Cu-4Fe-9Al-4Ni-1Mn

Commercial Names

Common names. Alpha nickel-aluminum bronze; propeller bronze

Specifications

ASTM. Sand castings: B 148; centrifugal castings: B 271; continuous castings: B 505; ingots, B 30

SAE. J462

Government. Sand and centrifugal castings: QQ-C-390; MIL-B-24480; centrifugal castings only: MIL-C 15345, Alloy 28

Ingot identification number. 415

Chemical Composition

Composition limits. 79.0 Cu min, 0.03 Pb max, 3.5 to 4.5 Fe, 4.0 to 5.0 Ni (+ Co), 0.8 to 1.5 Mn, 8.5 to 9.5 Al, 0.10 Si max

Consequence of exceeding impurity limits. Hard spots, embrittlement, possible hot shortness, possible weld cracking

Applications

Typical uses. Propeller blades and hubs for fresh-and salt-water service, fittings, gears, worm wheels, valve guides and seals, structural applications.

Precautions in use. Not suitable for use in oxidizing acids or strong alkalies

Mechanical Properties

Tensile properties. Typical. Cas and annealed: tensile strength, 585 MPa (85 ksi); yield strength, 240 MPa (35 ksi); elongations, 15% in 50 mm (2 in.); reduction in area, 16%

Compressive properties. Compressive strength, cast and annealed: 240 MPa (35 ksi) at a permanent set of 0.1%; 330 MPa (48 ksi) at a permanent set of 1%; 690 MPa (100 ksi) at a permanent set of 10%

Hardness. Cast and annealed, 84 to 89 HRB

Poisson's ratio. 0.32

Elastic modulus. Tension, 110 GPa (16×10^6 psi); shear, 42 GPa (6.1×10^6 psi)

Impact strength. Charpy keyhole, 13 J (10 ft · lbf) at -23 to 66 °C (-10 to 150 °F); Charpy V-notch, 22 J (16 ft · lbf) at -23 to 66 °C (-10 to 150 °F)

Fatigue strength. Rotating beam, 230 MPa (33 ksi) at 10^8 cycles

Structure

Crystal structure. Alpha, face-centered cubic; beta, close-packed hexagonal; kappa, ordered face-centered cubic

Microstructure. As-cast or annealed structures are generally continuous equiaxed alpha crystals with small areas of metastable beta phase. Kappa phase precipitates are found in the alpha phase, in grain boundaries, and in beta areas. Quench-and-temper treatments results in refinement and redistribution of the kappa phase throughout a matrix of tempered beta martensite and alpha-kappa eutectoid decomposition product. Some undissolved primary alpha crystal may also be present.

Mass Characteristics

Density. 7.64 g/cm^3 (0.276 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.6%

Thermal Properties

Liquidus temperature. 1060 °C (1940 °F)

Solidus temperature. 1045 °C (1910 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 440 J/kg · K (0.105 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 36 W/m · K (21 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 7.1% IACS at 20 °C (68 °F)

Electrical resistivity. 243 nΩ · m at 20 °C (68 °F)

Magnetic Properties

Magnetic permeability. 1.05 at field strength of 16 kA/m

Chemical Properties

General corrosion behavior. Corrosion properties of C95800 are similar to those of other nickel-aluminum bronzes, except that C95800 has better resistance to cavitation and seawater fouling attack. Resists dealloying in most mediums

Fabrication Characteristics

Machinability. 50% of C36000 (free-cutting brass). Excellent surface finish and tolerances possible in all standard machining operations. Carbide or tool steel cutters may be used. Typical conditions using tool steel cutters: roughing speed, 76 m/min (250 ft/min) at a feed of 0.3 mm/rev (0.011 in./rev); finishing speed, 290 m/min (950 ft/min) at a feed of 0.1 mm/rev (0.004 in./rev)

Annealing temperature. 650 to 705 °C (1200 to 1300 °F)

C96200
90Cu-10Ni

Commercial Names

Common name. 90 Cu-10 Ni

Specifications

ASTM. Centrifugal, B 369; sand, B 369; ingot, B 30

Government. Centrifugal: QQ-C-390; MIL-C-15345, alloy 25; MIL-C-20159, type II. Sand: QQ-C-390; MIL-C-20159, type II; MIL-V-18436

SAE. Centrifugal and sand: J461, J462

Chemical Composition

Composition limits. 84.5 to 87.0 Cu, 1.0 to 1.8 Fe, 9 to 11.0 Ni, 0.15 C max, 0.03 Pb max (0.01 Pb max for welding grades), 1.5 Mn max, 1.0 Nb max, 0.30 Si max

Applications

Typical uses. Component parts of items being used for seawater corrosion resistance

Mechanical Properties

Tensile properties. Properties for as-sand-cast separately cast (M01 temper) test bars: Tensile strength, 310 MPa min (45 ksi min); yield strength, 172 MPa min (25 ksi min); elongation, 20% min in 50 mm (2 in.)

Compressive strength. Typically, 255 MPa (37 ksi) at 0.1 mm/mm (0.1 in./in.) set

Impact strength. Charpy V-notch, 135 J (100 ft · lbf)

Elastic modulus. Tension, 124 GPa (18×10^6 ksi) at 20 °C (68 °F)

Mass Characteristics

Density. 8.94 g/cm^3 (0.323 lb/in.^{3})

Patternmaker's shrinkage. 16 mm/m ($\frac{3}{16}$ in./ft)

Thermal Properties

Liquidus temperature. 1150 °C (2100 °F)

Solidus temperature. 1100 °C (2010 °F)

Specific heat. 376 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 45 W/m · K (26 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 11% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. M01 temper; 10% of C36000 (free-cutting brass)

Weldability. Soldering and brazing: excellent. Gas shielded arc welding: poor. Metal arc welding: good, using R, Cu, Ni, or E, Cu, Ni filler metal. Oxyacethylene and carbon arc welding are not recommended.

C96400
70Cu-30Ni

Commercial Names

Previous trade name. 70-30 copper-nickel

Specifications

ASTM. Centrifugal castings: B 369; continuous castings: B 505; sand castings, ingot, B 30

Government. Centrifugal castings: MIL-C-15345, (Alloy 24); sand castings: QQ-C-390, MIL-C-20159 (type 1)

Chemical Composition

Composition limits. 65.0 to 69.0 Cu, 28.0 to 32.0 Ni, 0.50 to 1.5 Nb, 0.25 to 1.5 Fe, 1.5 Mn max, 0.50 Si max, 0.15 C max, 0.03 Pb max (0.01 Pb max for welding applications)

Applications

Typical uses. Centrifugal, continuous, and sand castings for valves, pump bodies, flanges, and elbows for applications requiring resistance to seawater corrosion

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 470 MPa (68 ksi); yield strength, 255 MPa (37 ksi) at 0.5% extension under load; elongation, 28% in 50 mm (2 in.)

Hardness. Typical, 140 HB using 3000 kg load

Elastic modulus. Tension, 145 GPa (21×10^6 psi)

Impact strength. Charpy V-notch, 106 J (78 ft · lbf)

Fatigue strength. Reverse bending, 125 MPa (18 ksi) at 10^8 cycles

Mass Characteristics

Density. 8.94 g/cm^3 (0.323 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 19 mm/m ($\frac{7}{32}$ in./ft)

Thermal Properties

Liquidus temperature. 1240 °C (2260 °F)

Solidus temperature. 1170 °C (2140 °F)

Coefficient of linear thermal expansion. 16 μm/m · K (9.0 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 375 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 29 W/m · K (17 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, as-cast tempers: 5% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 20% of C36000 (free-cutting brass)

Weldability. Soldering and brazing: excellent. Gas-shielded arc and shielded metal-arc welding: good, using RCuNi or ECuNi filler metal. Oxyfuel gas and carbon arc welding are not recommended.

C96600
69.5Cu-30Ni-0.5Be

Commercial Names

Previous trade name. Beryllium cupro-nickel alloy 71C; CA966

Common name. Beryllium cupro-nickel

Specifications

Government. Sand castings: MIL-C-81519

Chemical Composition

Composition limits. 0.40 to 0.7 Be, 29.0 to 33.0 Ni, 0.8 to 1.1 Fe, 1.0 Mn max, 0.15 Si max, 0.01 Pb max, bal Cu

Consequence of exceeding impurity limits. An excessive amount of Si will increase as-cast hardness and lower ductility. High Pb will cause hot shortness.

Applications

Typical uses. C96600 is a high-strength version of the well-known cupro-nickel alloy C96400, possessing twice the strength. Like C96400, C96600 exhibits excellent corrosion resistance to seawater. Typical uses are high-strength constructional parts for marine service; pressure housings for long, unattended submergence; pump bodies; valve bodies; seawater line fittings; marine low-tide hardware; gimbal assemblies; and release mechanisms.

Precautions in use. See C82500.

Mechanical Properties

Tensile properties. Typical data for separately cast test bars. TB00 temper: tensile strength, 515 MPa (75 ksi); yield strength, 260 MPa (38 ksi); elongation in 50 mm (2 in.), 12%. TF00 temper: tensile strength, 825 MPa (120 ksi); yield strength, 515 MPa (75 ksi); elongation, 12%

Hardness. TB00 temper: 74 HRB. TF00 temper: 24 HRC

Poisson's ratio. 0.33

Elastic modulus. Tension, 150 GPa (22×10^6 psi); shear, 57 GPa (8.3×10^6 psi)

Mass Characteristics

Density. 8.80 g/cm^3 (0.320 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 1.8%

Thermal Properties

Liquidus temperature. 1180 °C (2160 °F)

Solidus temperature. 1100 °C (2010 °F)

Coefficient of linear thermal expansion. 16 μm/m · K (9 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 377 J/kg · K (0.091 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 30 W/m · K (17.3 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 4.3% IACS at 20 °C (68 °F)

Electrical resistivity. 4 nΩ · m at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. Essentially identical to that of C96400

Fabrication Characteristics

Machinability. TF00 temper, 40% of C36000 (free-cutting brass)

Melting temperature. 1100 to 1180 °C (2010 to 2160 °F)

Casting temperature. 1260 to 1370 °C (2300 to 2500 °F)

Solution temperature. 995 °C (1825 °F)

Aging temperature. 510 °C (950 °F). Typical aging time, 3 h

C97300
56Cu-2Sn-10Pb-20Zn-12Ni

Commercial Names

Previous trade name. 12% nickel silver

Common name. Leaded nickel brass; 56-2-10-20-12

Specifications

ASTM. Centrifugal castings: B 271; sand castings: B 584; ingot: B 30

Chemical Composition

Composition limits. 53.0 to 58.0 Cu, 1.5 to 3.0 Sn, 8.0 to 11.0 Pb, 17.0 to 25.0 Zn, 11.0 to 14.0 Ni, 1.5 Fe max, 0.50 Mn max, 0.35 Sb max, 0.15 Si max, 0.08 S max, 0.05 P max, 0.005 Al max

Applications

Typical uses. Investment, centrifugal, permanent mold, and sand castings for hardware fittings; valves and valve trim; statuary, and ornamental castings

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 240 MPa (35 ksi); yield strength, 115 MPa (17 ksi) at 0.5% extension under load; elongation, 20% in 50 mm (2 in.)

Hardness. Typical, 55 HB using 500 kg load

Elastic modulus. Tension, 110 GPa (16×10^6 psi)

Mass Characteristics

Density. 8.95 g/cm^3 (0.321 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 16 mm/m ($\frac{3}{16}$ in./ft)

Thermal Properties

Liquidus temperature. 1040 °C (1904 °F)

Solidus temperature. 1010 °C (1850 °F)

Coefficient of linear thermal expansion. 16.2 μm/m · K (9.0 μin./in. · °F) at 20 to 260 °C (68 to 500 °F)

Specific heat. 375 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 28.5 W/m · K (16.5 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, as-cast tempers: 5.7% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 70% of C36000 (free-cutting brass)

Weldability. Soldering, brazing: excellent. Welding: not recommended

Stress-relieving temperature. 260 °C (500 °F), 1 h for each 25 mm (1 in.) of section thickness

Casting temperature. Light castings, 1200 to 1315 °C (2200 to 2400 °F); heavy castings, 1090 to 1200 °C (2000 to 2200 °F). Melt rapidly at no more than 55 to 85 °C (100 to 150 °F) above maximum casting temperature.

C97600
64Cu-4Sn-4Pb-8Zn-20Ni

Commercial Names

Previous trade name. 20% nickel silver

Common name. Dairy metal, leaded nickel bronze, 64-4-4-8-20

Specifications

ASME. Sand castings: SB584

ASTM. Centrifugal castings: B 271; sand castings: B 584; ingot: B 30

Government. Sand castings: MIL-C-17112

Other. Ingot code number 412

Chemical Composition

Composition limits. 63.0 to 67.0 Cu, 3.5 to 4.5 Sn, 3.0 to 5.0 Pb, 3.0 to 9.0 Zn, 19.0 to 21.5 Ni, 1.5 Fe max, 1.0 Mn max, 0.25 Sb max, 0.15 Si max, 0.08 S max, 0.05 P max, 0.005 Al max

Applications

Typical uses. Centrifugal, investment, and sand castings for marine castings; sanitary fittings; ornamental hardware; valves, and pumps

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 310 MPa (45 ksi); yield strength, 165 MPa (24 ksi) at 0.5% extension under load; elongation, 20% in 50 mm (2 in.)

Compressive properties. Compressive strength, 205 MPa (30 ksi) at a permanent set of 1%; 395 MPa (57 ksi) at a permanent set of 10%

Hardness. Typical, 80 HB using 500 kg load

Elastic modulus. Tension, 130 GPa (19×10^6 psi)

Impact strength. Charpy V-notch, 15 J (11 ft · lbf)

Fatigue strength. Reverse bending, 107 MPa (15.5 ksi) at 10^8 cycles

Creep-rupture characteristics. Limiting stress for creep of 10^{-5}%/h: 224 MPa (32.5 ksi) at 230 °C (450 °F); 153 MPa (22.2 ksi) at 290 °C (550 °F)

Mass Characteristics

Density. 8.90 g/cm^3 (0.321 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 11 mm/m ($\frac{1}{8}$ in./ft)

Thermal Properties

Liquidus temperature. 1143 °C (2089 °F)

Solidus temperature. 1108 °C (2027 °F)

Coefficient of linear thermal expansion. 17 μm/m · K (9.3 μin./in. · °F) at 20 to 300 °C (68 to 572 °F)

Specific heat. 375 J/kg · K (0.90 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 22 W/m · K (13 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, as-cast tempers: 5% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 70% of C36000 (free-cutting brass)

Weldability. Soldering, brazing: excellent. Welding: not recommended

Stress-relieving temperature. 260 °C (500 °F), 1 h for each 25 mm (1 in.) of section thickness

Casting temperature. Light castings, 1260 to 1430 °C (2300 to 2600 °F); heavy castings, 1230 to 1320 °C (2250 to 2400 °F). Melt rapidly at no more than 55 to 85 °C (100 to 150 °F)above casting temperature range.

C97800
66.5Cu-5Sn-1.5Pb-2Zn-25Ni

Commercial Names

Previous trade name. 25% nickel silver

Common name. Leaded nickel bronze; 66-5-2-2-25

Specifications

ASTM. Centrifugal castings: B 271; sand castings: B 584; ingot, B 30

Chemical Composition

Composition limits. 64.0 to 67.0 Cu, 4.0 to 5.5 Sn, 1.0 to 2.5 Pb, 1.0 to 4.0 Zn, 24.0 to 27.0 Ni, 1.5 Fe max, 1.0 Mn max, 0.20 Sb max, 0.15 Si max, 0.08 S max, 0.05 P max, 0.005 Al max

Applications

Typical uses. Investment, permanent mold, and sand castings for ornamental castings; sanitary fittings; valve bodies; valve seats; and musical instrument components

Mechanical Properties

Tensile properties. Typical data for sand-cast test bars: tensile strength, 380 MPa (55 ksi); yield strength, 205 MPa (30 ksi) at 0.5% extension under load; elongation, 15% in 50 mm (2 in.)

Hardness. Typical, 130 HB using 3000 kg load

Elastic modulus. Tension, 130 GPa (19×10^6 psi)

Mass Characteristics

Density. 8.86 g/cm^3 (0.320 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 16 mm/m ($\frac{3}{16}$ in./ft)

Thermal Properties

Liquidus temperature. 1180 °C (2156 °F)

Solidus temperature. 1140 °C (2084 °F)

Coefficient of linear thermal expansion. 17.5 μm/m · K (9.7 μin./in. · °F) at 20 to 260 °C (68 to 500 °F)

Specific heat. 375 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 25.4 W/m · K (14.7 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, as-cast tempers: 4.5% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 60% of C36000 (free-cutting brass)

Weldability. Soldering, brazing: excellent. Welding: not recommended

Stress-relieving temperature. 260 °C (500 °F)

C99400
90.4Cu-2.2Ni-2.0Fe-1.2Al-1.2Si-3.0Zn

Commercial Names

Common name. Nondezincification alloy, NDZ

Chemical Composition

Composition limits. 0.25 Pb max, 1.0 to 3.5 Ni, 1.0 to 3.0 Fe, 0.50 to 2.0 Al, 0.50 to 2.0 Si, 0.50 to 5.0 Zn, 0.50 Mn max, bal Cu

Applications

Typical uses. Centrifugal, continuous investment, and sand castings for valve stems; propeller wheels; electrical parts; gears for mining equipment; outboard motor parts; marine hardware; and other environmental uses where resistance to dezincification and dealuminification is required

Mechanical Properties

Tensile properties. Typical. M01 temper: tensile strength, 455 MPa (66 ksi); yield strength, 235 MPa (34 ksi) at 0.5% extension under load; elongation, 25% in 50 mm (2 in.). TF00 temper: tensile strength, 545 MPa (79 ksi); yield strength, 370 MPa (54 ksi) at 0.5% extension under load

Shear strength. M01 temper, 330 MPa (48 ksi)

Hardness. M01 temper, 125 HB; TF00 temper, 170 HB. Determined using 3000 kg load

Elastic modulus. Tension, 133 GPa (19.3×10^6 psi)

Mass Characteristics

Density. 8.30 g/cm^3 (0.30 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 16 mm/m ($\frac{3}{16}$ in./ft)

Electrical Properties

Electrical conductivity. Volumetric, TF00 temper: 16% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 50% of C36000 (free-cutting brass)

Weldability. Shielded metal-arc welding: poor

Solution temperature. 885 °C (1625 °F), 1 h for each 25 mm (1 in.) of section thickness

Aging temperature. 480 °C (900 °F), 1 h at temperature

Stress-relieving temperature. 315 °C (600 °F), 1 h for each 25 mm (1 in.) of section thickness

C99500

Commercial Name

Trade name. NDZ-S

Specifications

ASTM. Sand castings: B 763

Chemical Composition

Composition limits. 0.25 Pb max, 3.5 to 5.5 Ni, 3.0 to 5.0 Fe, 0.50 to 2.0 Al, 0.50 to 2.0 Si, 0.50 Mn max, 0.50 to 2.0 Zn, bal Cu

Applications

Typical uses. Valve stems, marine, and other environmental uses where resistance to dezincification and dealuminification is required, propeller wheels, electrical parts, gears for mining equipment and outboard marine industry; same as C99400 but used where higher yield strength is required

Mechanical Properties

Tensile properties. Properties for as-sand-cast separately cast (M01 temper) test bars: tensile strength, 483 MPa min (70 ksi min); yield strength, 275 MPa min (40 ksi min); elongation, 12% min in 50 mm (2 in.)

Hardness. Typically, 145 HB (500 Kg); 50 HB (3000 kg)

Proportional limit. Typically, 145 MPa (21 ksi)

Mass Characteristics

Density. 8.3 g/cm^3 (0.30 lb/in.^{3})

Volume change on freezing. Patternmaker's shrinkage, 16 mm/m ($\frac{3}{16}$ in./ft)

Electrical Properties

Electrical conductivity. Volumetric, 13.7% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. M01 temper; 50% of C36000 (free-cutting brass)

Stress-relieving temperature. 315 °C (600 °F)

C99700
56.5Cu-5Ni-1Al-1.5Pb-12Mn-24Zn

Commercial Names

Common name. White manganese brass

Trade name. White Tombasil

Chemical Composition

Composition limits. 54.0 Cu min, 19.0 to 25.0 Zn, 11.0 to 15.0 Mn, 4.0 to 6.0 Ni, 2.0 Pb max, 1.0 Sn max, 1.0 Fe max, 0.50 to 3.0 Al

Applications

Typical uses. Building hardware (interior and exterior), architectural and ornamental fittings, marine hardware, floor drain covers, food handling equipment, swimming pool hardware, valves

Mechanical Properties

Tensile properties. Typical data for separately cast test bars. Sand cast: tensile strength, 380 MPa (55 ksi); yield strength, 170 MPa (25 ksi) at 0.5% extension under load; elongation, 25% in 50 mm (2 in.). Die cast: tensile strength, 450 MPa (65 ksi); yield strength, 185 MPa (27 ksi) at 0.5% extension under load; elongation, 15% in 50 mm (2 in.)

Hardness. Sand cast: 110 HB (300 kg load); die cast: 125 HB

Elastic modulus. Tension, 114 GPa (16.5×10^6 psi)

Mass Characteristics

Density. 8.19 g/cm^3 (0.296 lb/in.^{3}) at 20 °C (68 °F)

Patternmaker's shrinkage. 21 mm/m (0.25 in./ft)

Thermal Properties

Liquidus temperature. 900 °C (1655 °F)

Solidus temperature. 800 °C (1615 °F)

Electrical Properties

Electrical conductivity. Volumetric, 3% IACS at 20 °C (68 °F)

Fabrication Characteristics

Machinability. 80% of C36000 (free-cutting brass)

C99750

Specifications

ASTM. Die castings: B 176

Chemical Composition

Composition limits. 0.25 to 3.0 Al, 55.0 to 61.0 Cu, 0.50 to 2.5 Pb, 17.0 to 23.0 Mn, 5.0 Ni max, 17.0 to 23.0 Zn, 1.0 Fe max, (iron content shall not exceed nickel content)

Mechanical Properties

Tensile properties. Typical properties for as-sand-cast separately cast (M01 temper) test bars: tensile strength, 448 MPa (65 ksi); yield strength, 120 MPa (32 ksi) at 0.2% offset; elongation, 30% in 50 mm (2 in.).

Hardness. Typically, 77 HRB, 110 HB (500 kg)

Compressive strength. Typically, 193 MPa (28 ksi) at 0.001 mm/mm (0.001 in./in.) set, 262 MPa (38 ksi) at 0.01 mm/mm (0.01 in./in.) set, and 495 MPa (72 ksi) at 0.1 mm/mm (0.1 in./in.) set

Impact strength. Charpy V-notch, 100 J (75 ft · lbf)

Fatigue strength. 128 MPa (18.5 ksi) at 10^8 cycles

Elastic modulus. Tension, 117 GPa (17×10^6 psi) at 20 °C (68 °F)

Mass Characteristics

Density. 8.0 g/cm^3 (0.29 lb/in.^{3})

Thermal Properties

Liquidus temperature. 843 °C (1550 °F)

Solidus temperature. 819 °C (1505 °F)

Specific heat. 376 J/kg · K (0.09 Btu/lb · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 2% IACS at 20 °C (68 °F)

Fabrication Properties

Stress-relieving temperature. 260% of °C (500 °F)

Beryllium copper 21C
97Cu-2Be-1Co

Commercial Names

Common name. Grain-refined beryllium-copper casting alloy 21C

Chemical Composition

Composition limits. 2.00 to 2.25 Be, 1.0 to 1.2 Co, 0.20 to 0.40 Si, 0.20 Ni max 0.25 Fe max, 0.15 Al max, 0.10 Sn max, 0.02 Pb max, 0.10 Zn max, 0.10 Cr max

Consequence of exceeding impurity limits. See C82500.

Applications

Typical uses. The 1% Co content is a strong grain refiner, and as a result, this alloy is used instead of beryllium-copper alloys C82500 and C82400 when thin sections must be cast at high temperatures or when thick and thin sections are present within the same casting in order to achieve a uniform fine-grained structure. The higher cobalt content imparts better wear resistance but less desirable polishability and machinability. Typical uses are comparable to those of beryllium-copper alloys C82400 and C82500.

Precautions in use. See C82500.

Mechanical Properties

Tensile properties. See Table 9.

Table 9 Typical mechanical properties of beryllium-copper alloy 21C

Temper	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %	Hardness

Hardness. See Table 9.

Poisson's ratio. 0.30

Elastic modulus. Tension, 128 GPa (18.5×10^6 psi); shear, 50 GPa (7.3×10^6 psi)

Mass Characteristics

Density. 8.26 g/cm^3 (0.298 lb/in.^{3}) at 20 °C (68 °F)

Dilation during aging. Linear, 0.2%

Change in density during aging. 0.6% increase

Patternmaker's shrinkage. 1.56%

Thermal Properties

Liquidus temperature. 980 °C (1800 °F)

Solidus temperature. 860 °C (1575 °F)

Incipient melting temperature. 835 °C (1535 °F)

Coefficient of linear thermal expansion. 10 μm/m · K (5.5 μin./in. · °F) at 20 to 200 °C (68 to 392 °F)

Specific heat. 419 J/kg · K (0.10 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 105 W/m · K (61 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. Volumetric, 20% IACS at 20 °C (68 °F)

Electrical resistivity. 862 μΩ· m at 20 °C (68 °F)

Magnetic Properties

Magnetic susceptibility. See C82500.

Nuclear Properties

Effect of irradiation. See C82500.

Chemical Properties

Same as C82500

Fabrication Characteristics

Machinability. As-cast or solution treated, 30% of C36000 (free-cutting brass). Cast and aged or solution treated and aged, 10 to 20% of C36000

Solution temperature. 790 to 800 °C (1450 to 1475 °F)

Aging temperature. 340 °C (650 °F)

Melting temperature. 860 to 980 °C (1575 to 1800 °F)

Casting temperature. Light castings, 1065 to 1175 °C (1950 to 2150 °F); heavy castings, 1000 to 1065 °C (1850 to 1950 °F)

Beryllium copper nickel 72C
C96700
68.8Cu-30Ni-1.2Be

Commercial Names

Common name. Modified beryllium cupro-nickel alloy 72C

Chemical Composition

Composition limits. 1.1 to 1.2 Be, 29.0 to 33.0 Ni, 0.7 to 1.0 Fe, 0.10 to 0.20 Zr, 0.10 to 0.20 Ti, 0.7 Mn max, 0.15 Si max, 0.1 Pb max, bal Cu

Consequence of exceeding impurity limits. High silicon will raise as-cast hardness and lower ductility. High lead will cause hot shortness. High carbon will result in undesirable carbides.

Applications

Typical uses. Alloy 72C is a modified version of beryllium cupro-nickel alloy 71C, its increased beryllium content providing improved castability. Its field of application is the plastic tooling industry. Alloy 72C generally is ceramic mold cast into tooling used for molding flame-retardant plastics containing bromine, bromine-boron, chlorinated paraffins and phosphates, and other halogens. Additionally, alloy 72C tooling is resistant to corrosion by the foaming agents used in structural plastics that generate ammonia at elevated temperatures, as well as to decompositional products of PVC that contain HCl. The good castability of 72C allows it to be cast into tooling of fine detail.

Precautions in use. See C82500.

Mechanical Properties

Tensile properties. See Table 10.

Table 10 Typical mechanical properties of cast beryllium cupro-nickel alloy 72C

Copper Powder Metallurgy Products

Erhard Klar and David F. Berry, SCM Metal Products, Inc.

Introduction

COPPER-BASE POWDER-METALLURGY (P/M) products rank second after iron- and steel-base P/M products in terms of volume, with an estimated weight consumption in 1988 of 15,500 Mg (17,000 short tons) in North America. This consumption is associated with the major copper-base P/M applications, which include bronze bearings, copper and copper alloy structural parts, friction materials, copper carbon brushes, and high-electrical-conductivity copper. Another 4500 Mg (5000 tons) of copper and copper alloy powders were consumed as additions to iron and steel powders and for infiltration of iron and steel P/M parts. Figure 1 shows the total consumption of copper and copper alloy powders since 1950, including powders for other than P/M uses, which during the past ten years accounted for about 10% of the total. A gradual decline in total powder consumption since the early 1970s can be seen. This is attributed in part to the decline of bronze self-lubricating bearings through substitution of less-expensive dilute bronze (that is, iron containing), and iron-base bearing, or, particularly in the low-performance end of the market, by plastic bearings. Use of sintered metallic friction materials also decreased because of substitution by other materials.

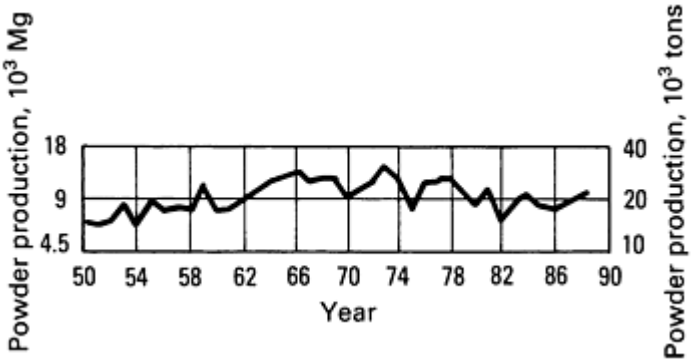

Fig. 1 Copper and copper alloy powder production in North America

This article briefly reviews the subject of copper-base P/M products in terms of powder production methods and the product properties/consolidation practices of the major applications mentioned above. Additional information on copper-base P/M is contained in *Powder Metal Technologies and Applications*, Volume 7 of *ASM Handbook.*

Powder Production

Of the four major methods for making copper and copper alloy powders, atomization and oxide reduction are presently practiced on a large scale in North America; electrolytic and hydrometallurgical copper powders have not been manufactured in the United States since the early 1980s.

Table 1 shows a comparison of some of the typical fundamental powder characteristics of commercial copper powders made by various production processes. These powders are used in all major P/M copper-base products mentioned above except for brass and nickel silver structural parts, which are made exclusively from atomized prealloyed powders.

Table 1 Characteristics of commercial copper powders

Type of powder	Composition, %			Particle shape	Surface area
	Copper	Oxygen	Acid insolubles		
Electrolytic	99.1-99.8	0.1-0.8	0.03 max	Dendritic	Medium to high
Oxide reduced	99.3-99.6	0.2-0.6	0.03-0.1	Irregular; porous	Medium
Water atomized	99.3-99.7	0.1-0.3	0.01-0.03	Irregular to spherical; solid	Low
Hydrometallurgical	97-99.5	0.2-0.8	0.03-0.8	Irregular agglomerates	Very high

Atomization. The disintegration of a liquid metal stream by means of an impinging jet of liquid or gas is known as atomization, or more specially, twin-fluid atomization. This process was originally used for the production of alloy powders but is now used increasingly for the production of plain iron and copper powders. Figure 2 is a schematic representation of the processing stages involved in atomization.

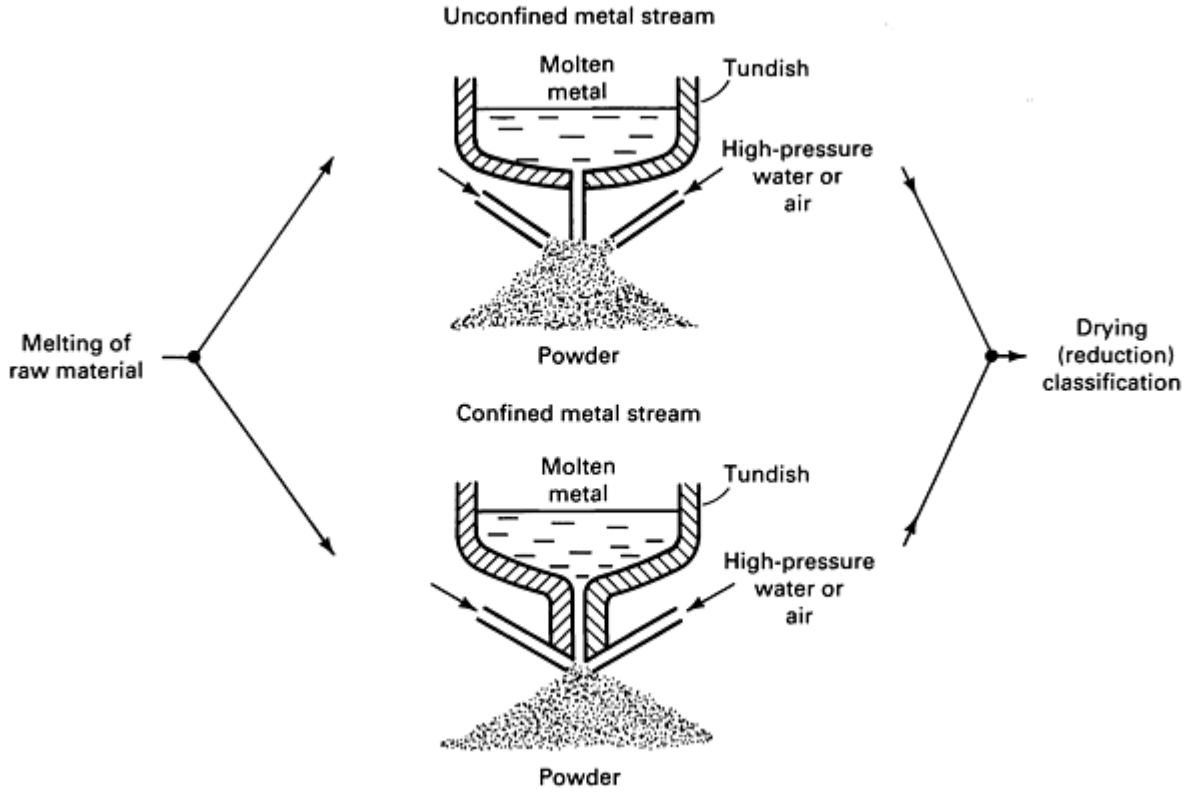

Fig. 2 Processing stages in production of metal powders by atomization

Figure 3 shows copper powders produced from a gas-atomizing medium and a water-atomizing medium. For plain copper powders, water is the preferred atomizing medium. The atomized powder is often subjected to an elevated temperature reduction and agglomeration treatment that improves its compacting properties. Table 2 shows powder properties of commercial grades of water-atomized copper powders.

Table 2 Properties of commercial grades of water-atomized copper powders

Copper	Chemical properties, %		Physical properties						
			Hall flow rate, s/50 g	Apparent density, g/cm^3	Tyler sieve analysis, %				
	Hydrogen loss	Acid Insolubles			+100	-100+150	-150+200	-200+325	-325
99.65[(a)]	0.28	. . .	. . .	2.65	Trace	0.31	8.1	28.2	63.4
99.61[(a)]	0.24	. . .	. . .	2.45	0.2	27.3	48.5	21.6	2.4
99.43[(a)]	0.31	. . .	. . .	2.70	tr	0.9	3.2	14.2	81.7

(a) Water atomized plus reduced.

(b) Contains magnesium

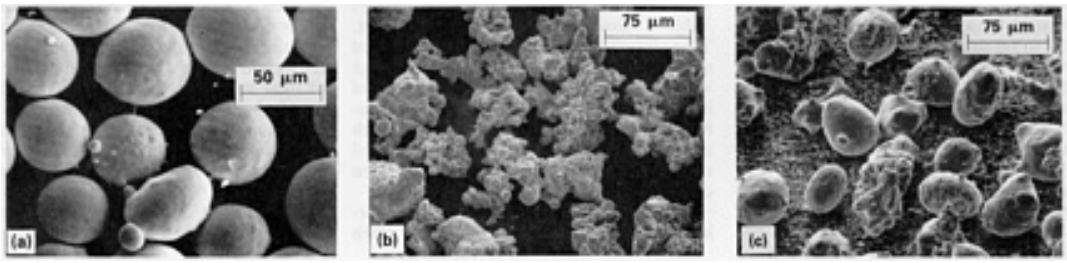

Fig. 3 Scanning electron micrographs of gas- and water-atomized copper powders. (a) Nitrogen atomized. (b) Water atomized, apparent density of 3.04 g/cm^3. (c) Water atomized, apparent density of 4.60 g/cm^3

The particle size of atomized powders can be varied greatly by adjusting processing conditions. Increases in gas or water pressure result in smaller particle sizes. For plain copper powders, average particle sizes less than 325 mesh (45 μm) are feasible.

The Particle shape of water-atomized copper powder also can be controlled from almost spherical (Fig. 3c) to irregular (Fig. 3b) by modifying the water jet/metal stream interaction. Greater particle irregularity is possible through the use of small alloy additions to the copper melt that lower its surface tension.

Prealloyed Powders of Brass and Nickel Silver. Air atomization is used mainly for making prealloyed powders of brass and nickel silver, and to a lesser degree bronze powders, for use in high-density (>7.0 g/cm^3) components. The low surface tension of the molten alloys of these compositions renders the particle shape sufficiently irregular to make the powders compactible (Fig. 4). Reduction of oxides is not necessary for the standard P/M grades. Table 3 shows typical properties of commercial grades of brass, bronze, and nickel silver powders.

Table 3 Physical properties of typical brass, bronze, and nickel silver alloy compositions

Property	**Brass[(a)]**	**Bronze[(a)]**	**Nickel silver[(a)(b)]**
Sieve analysis, %			
+100 mesh	2.0 max	2.0 max	2.0 max

(a) Nominal mesh sizes: brass, -60 mesh; bronze, -60 mesh; nickel silver, -100 mesh.

(b) Contains no lead.

(c) Compressibility and green strength data of powders lubricated with 0.5% lithium stearate

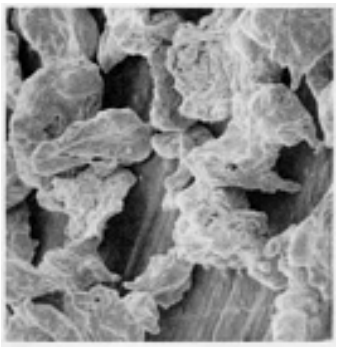

Fig. 4 Prealloyed air-atomized nickel silver powder (63Cu-18Ni-17Zn-2Pb). 165×

Commercial prealloyed brass powders are available in leaded and nonleaded compositions. Commercial brass alloys range from 90Cu-10Zn to 65Cu-35Zn; however, leaded versions of 80Cu-20Zn and 70Cu-30Zn are most commonly used for the manufacture of sintered structural parts that may require secondary machining operations. The only commercially available nickel silver powder has a nominal composition of 65Cu-18Ni-17Zn, which is modified by addition of lead when improved machinability is required.

Prealloyed atomized bronze powders are not used widely for structural parts fabrication because their nodular particle form and high apparent density result in low green strength. However, blends of such powders with irregular copper powders and phosphorus-copper yield sintered parts with good mechanical properties.

Reduction of Oxide. In this process particulate copper oxide is reduced with solid or gaseous reducing agents at elevated temperatures. The resulting sintered porous copper cake is milled to a powder. The raw material for this process was originally copper mill scale, but as demand exceeded supply, copper oxide had to be produced specifically from copper for the reduction process. Sources of raw material include particulate copper scrap, electrolytic copper, and atomized copper. Selection of raw material is based on purity requirements and end use. Table 4 shows properties of commercial grades of copper powder produced by copper oxide reduction.

Table 4 Properties of commercial grades of copper powder produced by the copper oxide process

(b) Carney flow

Particle size is controlled through milling of the starting oxide and the reduced sinter cake. The milled copper powder particles are irregular and porous (Fig. 5). Through control of reduction conditions it is possible to obtain a broad range of pore characteristics. Compacting and other properties may be varied through control of the pore characteristics of the spongy particles.

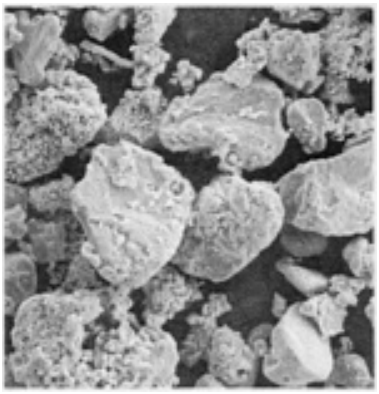

Fig. 5 Oxide-reduced copper powder. 500×

Electrolysis. In this process the variables are adjusted so that a spongy or brittle polycrystalline deposit, rather than a smooth deposit, is formed at the cathode with electroplating. Aqueous electrolytes and soluble anodes are used. The low-metal overvoltage of copper permits its economic deposition as sponge. Electrolytic copper powder normally is of high purity; however, impurities more noble than copper are codeposited.

Typical processing conditions include an electrolyte concentration of 5 to 8 g/L of copper and 100 to 160 g/L of sulfuric acid, a bath temperature of about 50 °C (120 °F), a current density of 0.05 to 0.1 A/cm^2 (50 to 100 A/ft^2), and a cell voltage of about 1 V. A broad range of particle sizes is possible through control of processing conditions. The particle shape of as-deposited powder is dendritic or fernlike (Fig. 6). For applications requiring a powder with a low apparent density and a high surface area, additions to the electrolytic bath can be made that decrease dendrite arm thickness. A final furnace treatment can alter this shape to such an extent that the processing history of the powder is difficult to determine.

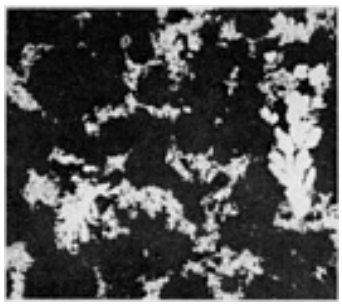

Fig. 6 Electrolytic copper powder showing dendritic structure. 85×

Hydrometallurgy. The basic processing steps include preparing a pregnant liquor by leaching ore or another suitable raw material, followed by precipitation of the metal from its solution. For copper the most important precipitation methods are cementation, reduction with hydrogen, and electrolysis.

In cementation, the copper-bearing solution is passed over scrap iron, which results in precipitation of copper according to:

$$Fe + CuSO_4 \rightarrow Cu + FeSO_4$$

Subsequent separation, washing, thermal reduction, and pulverizing usually produce a copper powder that contains significant amounts of iron and acid insolubles such as alumina and silica. Contamination with gangue varies and depends on the nature of the pregnant liquor. Low purity in general, and high-iron content in particular, restrict the use of cement copper in P/M applications. Its irregular particle shape and high specific surface area (Fig. 7), however, impart good green strength and make it useful in friction applications.

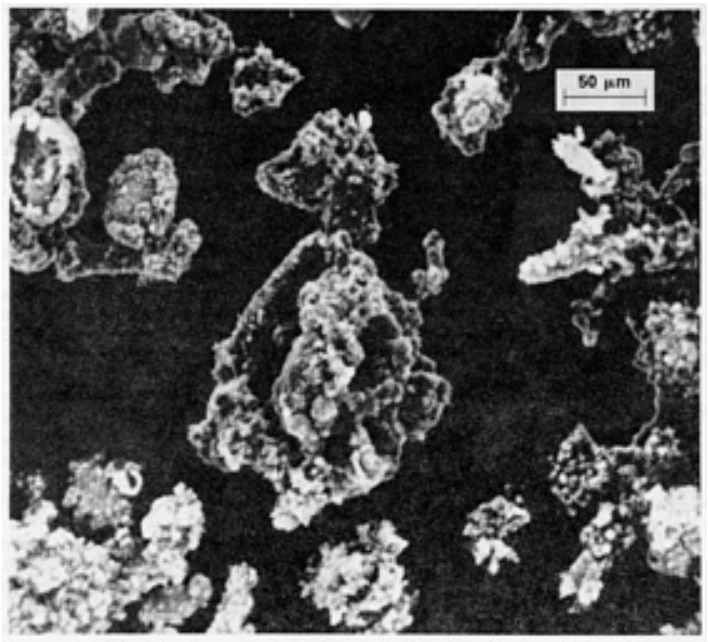

Fig. 7 Scanning electron micrograph of hydrometallurgically produced copper powder (cement copper)

Self-Lubricating Sintered Bronze Bearings

Mechanism of Lubrication. The function of a bearing is to guide a moving part with as little friction as possible. For sintered self-lubricating bearings this is accomplished by using the interconnected porosity of the bearing as an oil reservoir. Figure 8 shows schematically the mechanism of this type of lubrication for a rotating shaft. As the shaft begins to rotate, metal-to-metal friction between the shaft and the bearing causes the temperature of the bearing assembly to rise. As a result, the oil contained in the pores of the bearing expands, and the oil wedge (that is, the space between the shaft and the bearing) is partially filled with oil.

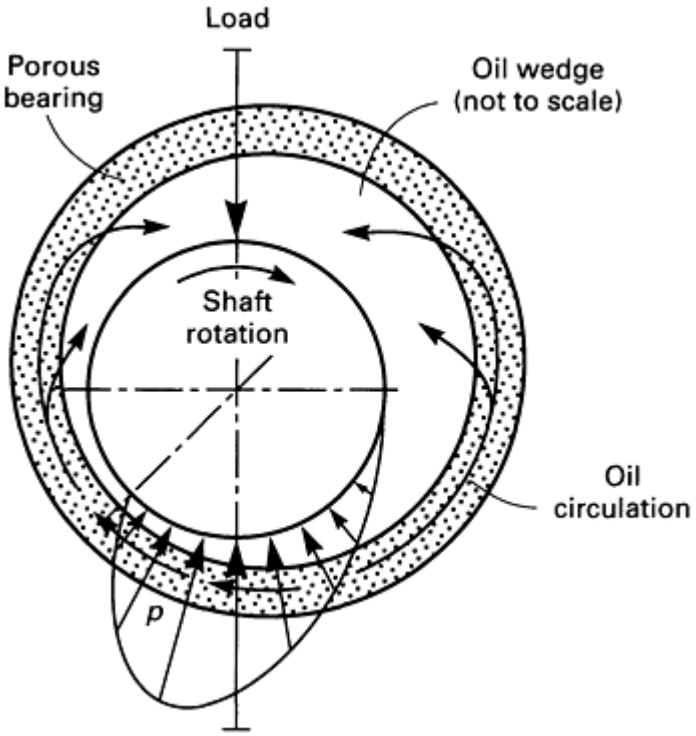

Fig. 8 Schematic of hydrodynamic pressure (*p*) and oil circulation in an oil-impregnated porous bearing

Rotation of the shaft develops a so-called hydrodynamic pressure, *p*, within the oil film that with correct clearance, shaft velocity, and pore structure of the bearing is able to lift the shaft so that it rides on a liquid film of oil. This is known as hydrodynamic lubrication and is a condition of lowest friction. During operation, the oil that passes into the pores of the bearing is being recirculated to the unloaded region. With low shaft velocities and during startup, the hydrodynamic pressure is insufficient to separate shaft and bearing. This leads to co-called "mixed" or even to "boundary" lubrication with attendant friction increase, temperature rise, oil loss, wear, and reduced bearing life. When the shaft ceases to rotate, the temperature of the assembly decreases and the oil within the oil wedge is drawn back into the porous bearing by capillary forces. Thus, the oil can be reused many times.

Uses. For light-duty applications, these bearings are designed to last for the life of the equipment or machine in which they are used. For medium- and heavy-duty applications, relubrication is usually necessary. Table 5 shows examples of applications. These bearings run quietly and may be used in vertical positions, whereas solid bearings would normally be impractical because of lubricant run-out. They are particularly useful if it is difficult to lubricate the part, such as in a refrigerator motor, or where oil splashing may interfere with the operation of the machine.

Composition. The most widely used bearing material is 90Cu-10Sn bronze, often with the addition of up to 1.5% graphite. So-called dilute bronze bearings contain various amounts of iron. Dilution with iron reduces the cost of a bearing at the expense of some loss in performance.

Although bronze bearings can be produced from partially or fully prealloyed powders, they are predominantly made from elemental powder blends. The tin powders used in these blends are typically made by air atomization.

Compaction pressures range from about 10 to 30 tsi. Figure 9 shows an assortment of P/M bronze bearings. The most common shapes are simple or flanged bushings, but self-aligning bearings with spherical external surfaces are also used. Sizes range from about 0.8 to 75 mm ($\frac{1}{32}$ to 3 in.) in diameter.

Fig. 9 Assorted P/M bronze bearings

Sintering is typically done in a continuous-mesh belt furnace at temperatures between 815 to 870 °C (1500 to 1600 °F) for about 3 to 8 min at temperature. Typical furnace atmospheres are dissociated ammonia or endothermic gas. To obtain reproducible sintering results it is important to carefully control time and temperature because of their influence upon the kinetics of the liquid-phase alloying process, which in turn determines the dimensional changes taking place during sintering. The desired microstructure is an alpha-bronze such as shown in Fig. 10.

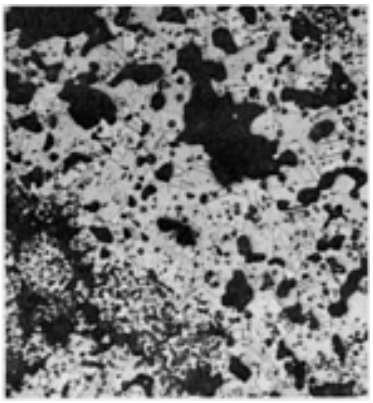

Fig. 10 Microstructure of P/M 90Cu-10Sn bronze

Sizing. Most bearings are sized for improved dimensional accuracy. Sizing pressures range from about 200 to 550 MPa (15 to 40 tsi). During sizing the density increases slightly.

Impregnation. Bearings are marketed either dry or saturated with oil, usually by a vacuum impregnation process that enables oil efficiencies of 90% or more to be achieved (that is, 90% or more of the available porosity is filled with oil). For use, these bearings are force-fitted into a housing.

Load-Carrying Capacity and Bearing Life. Tables 6 and 7 show minimum strength, oil content, densities, and typical loads for two low-graphite bronze compositions. The product of shaft surface velocity, *V*, times specific bearing load, *P*, the so-called *PV* factor, is a useful parameter for describing bearing performance. Strictly speaking, the concept of a permissible or maximum *PV* value means that a bearing should operate under the hydrodynamic (lowest friction) mode of lubrication for any combination of load and velocity not exceeding that maximum *PV* value. For this to be valid it is assumed that other bearing running conditions (shaft clearance, shaft alignment, housing design, oil viscosity, and so forth) have been optimized. For low velocities or for frequent start/stop operation, however, a coherent load-bearing oil film may not be formed. Also, at high velocities, oil losses may be excessive. Under these conditions, higher bearing temperatures and reduced bearing life may apply even at low *PV* values.

Table 6 Properties of sintered bronze (low-graphite) bearings

Material description code	Chemical composition, wt%			Minimum strength constant (*K*)		Minimum oil content, vol%	Density (D_{wet}), g/cm^3

(a) Load in MPa with v expressed in m/min.

(b) Load in ksi with V expressed in ft/min.

For a given configuration the bearing temperature increases with increasing *PV*. With increasing bearing temperature the life of the bearing decreases steeply. Use of a bearing below its maximum *PV* value results in a large increase in bearing life as a result of the lower temperature, which in turn reduces oil losses from evaporation and decomposition. A

reduction in temperature by 10 °C (20 °F) will approximately double the life of the oil (Fig. 11). Under conditions where the lubrication mode changes from hydrodynamic to mixed, the friction coefficient rises with an attendant rise of the oil temperature and decreases in bearing life. For mixed lubrication conditions, addition of up to 1.5% graphite is often made; this has been shown to decrease bearing temperature and increase bearing life in applications including intermittent stop/start operation.

New Developments. In recent years there have been several attempts to improve and expand the performance of sintered bronze bearings. In 1965, Youssef and Eudier (Ref 3) described porous bearings that contained a layer of very fine powder at the inside bore of the bearing, permitting load capacity to be increased by a factor of 10 to 20. This radical improvement was attributed to the fine porous layer that prevented air introduction and subsequent oil loss. In 1980, Kohno *et al.* (Ref 4) described phosphorus, molybdenum disulfide, and graphite-containing bronze bearings that showed excellent performance under both boundary and hydrodynamic lubrication conditions at velocities of up to 800 m/min (2600 ft/min) and *PV* factors of 250 MPa · m/min (120 ksi · ft/min). In 1983, Eudier and Youssef (Ref 5) obtained a patent for P/M bronze bearings containing dispersed hard faces with varying amounts of antimony, bismuth, and nickel. Improved *PV* factors (3 to >6 MPa · m/s, or 85 to 170 ksi · ft/min) and suppression of the temperature peak during the running-in period were attributed to the formation of low-melting glasslike intermetallic phases. In 1985, Shikata *et al.* (Ref 6) described molybdenum disulfide and graphite-containing bronze bearings that exhibited lower and more stable friction coefficients at low speeds (about 0.02 m/s, or 4 ft/min). In the above cases much of the improvement was attributed to the strengthening of the matrix with phosphorus and nickel, respectively, and the presence of MoS_2, which improved lubrication and decreased wear under boundary conditions.

Bearing life is affected by a large number of factors, from powder properties, compaction, sintering, sizing, and choice of oil, to design and thermal properties of the bearing housing. The section "P/M Self-Lubricating Bearings" of *MPIF Standard 35* (Ref 1) provides information on press fits, interference fits, running clearances, and dimensional tolerances, in addition to chemical and mechanical properties. Some bearing manufacturers offer proprietary bearing compositions. It is therefore recommended that the designer consult with the bearing manufacturer for more specific advice. References 7 and 8 by V.T. Morgan give the most comprehensive descriptions of this subject available in the literature.

Copper-Base Structural Parts

Applications of copper-base P/M materials that rely mainly on the load-bearing capacities of the sintered parts are commonly classified as structural applications. The most important copper-base structural-part compositions include brass, nickel silver, and bronze. Structural P/M parts also include pure-copper P/M products and oxide-dispersion-strengthened (ODS) copper for applications where good electrical and thermal conductivity is important. Oxide-dispersion-strengthened copper is described in a separate section so-named in this article.

P/M Structural Parts From Brass, Nickel Silver, or Bronze. The use of P/M techniques for producing these parts is due to economic advantages such as cost savings in labor and materials. These classes of P/M materials are characterized by their combination of mechanical strength, ductility, and corrosion resistance.

Compositions and Properties. Compositions (Table 8) and properties (Table 9) of structural parts of brass, bronze, and nickel silver are covered in *MPIF Standard 35* (Ref 1). The leaded compositions are used whenever secondary machining operations are required.

(a) Suffix numbers represent minimum yield-strength values in ksi.

(b) Additional data in preparation will appear in subsequent editions of *MPIF Standard 35*.

Uses. Typical applications for brass and nickel silver parts include latch bolts and cylinders for locks; shutter mechanism components for cameras; gears, cams, and actuator bars in timing assemblies and in small-generator drive assemblies; and decorative trim and medallions. In many of these applications, corrosion resistance, wear resistance, and aesthetic appearance play important roles. The surface finish may be improved by burnishing. An assortment of brass P/M parts is shown in Fig. 12.

Bronze P/M structural parts, which generally are produced by methods similar to those used for self-lubricating bearings, frequently are selected because of the corrosion and wear resistance of bronze. Bronze P/M components are used in applications such as automobile clutches, copiers, outboard motors, and paint-spraying equipment. Figure 13 illustrates an assortment of bronze P/M parts.

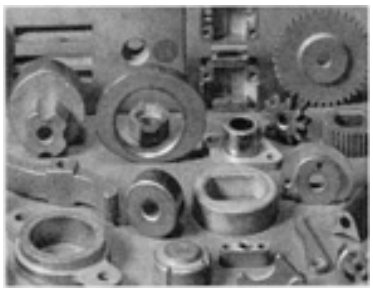

Fig. 13 Assorted P/M bronze parts. Courtesy of Norddeutsche Affinerie

Compaction. Brass and nickel silver alloys are usually blended with lubricants in amounts from 0.5 to 1.0 wt%. Lithium stearate is the preferred lubricant because of its cleansing and scavenging action during sintering. However, bilubricant systems are common, such as lithium stearate and zinc stearate, on a 50/50 basis to minimize the surface staining attributed to excessive lithium stearate. Lubricated powders compact to 75% of theoretical density at 207 MPa (30 ksi) and to 85% of theoretical density at 415 MPa (60 ksi).

Sintering of brass and nickel silver compacts is normally performed in protective atmospheres (that is, dissociated ammonia, endothermic gas, and nitrogen-base atmospheres) at temperatures ranging from 815 to 925 °C (1500 to 1700 °F) depending on alloy composition. To avoid distortion and/or blistering of the compacts, sintering temperatures should not exceed the solidus temperature of the alloy. Through multiple pressing and sintering, yield strength and hardness may approach those of the wrought alloy counterparts. To minimize zinc losses during sintering, yet allow for adequate lubricant removal, protective-sintering-tray arrangements are used. Figure 14 shows the marked effect different lubricants have upon various properties after sintering. Figure 15 shows the effect of sintering time upon sintered strength and dimensional change of a 70Cu-30Zn leaded brass.

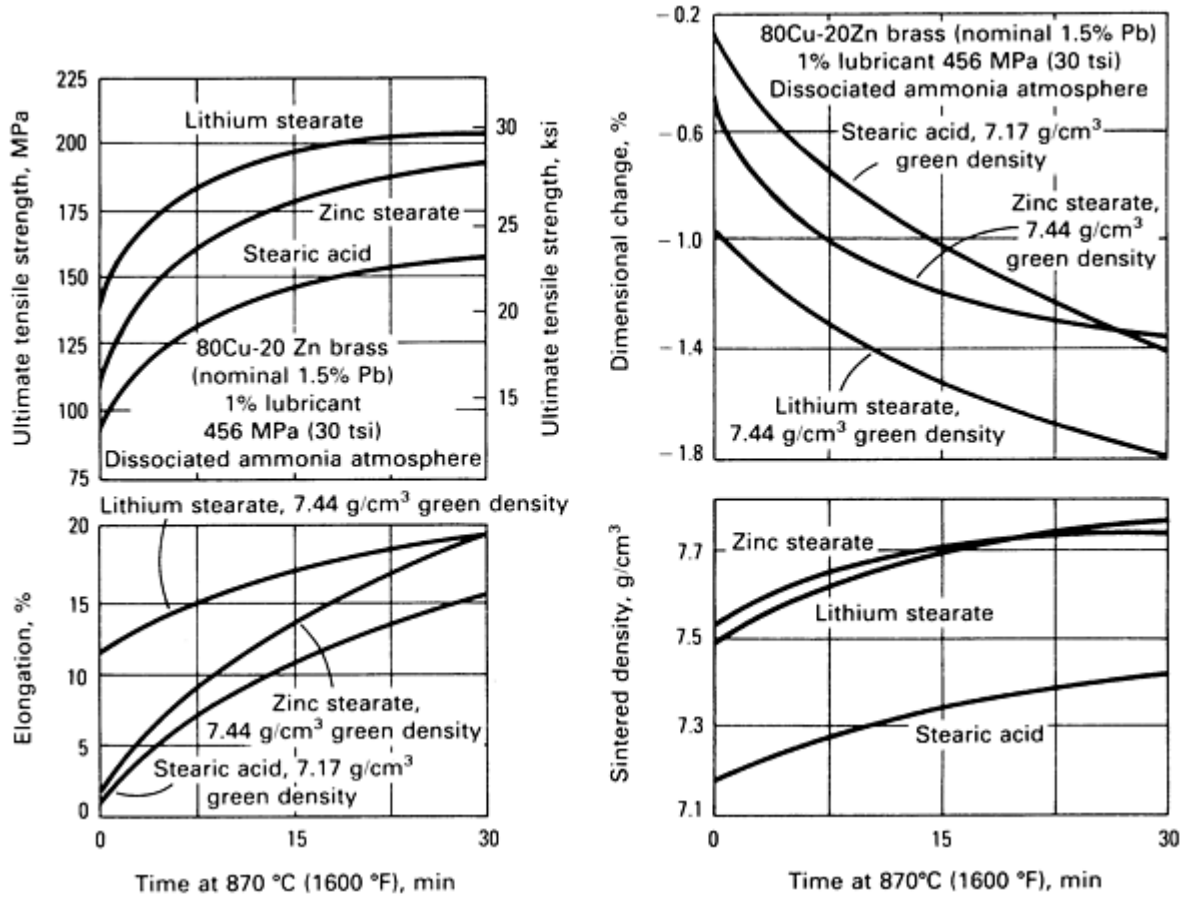

Fig. 14 Effect of lubricants and sintering time at temperature on tensile properties, sintered density, and dimensional change of brass compacts

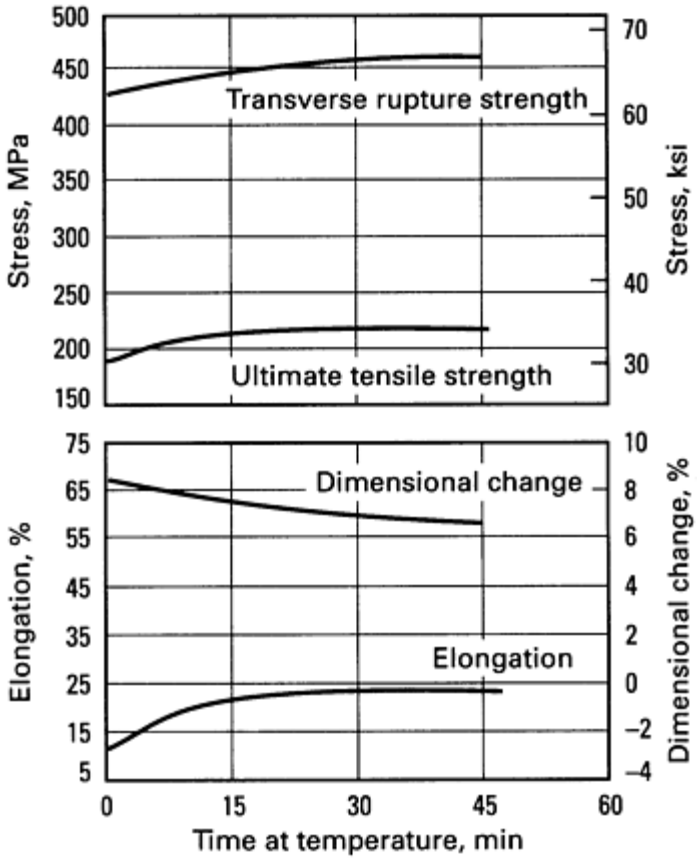

Fig. 15 Effect of varying sintering time on properties of prealloyed 70Cu-30Zn leaded brass (nominal 1.5% Pb). Lubricant: 0.375% lithium stearate and 0.375% zinc stearate; compaction pressure: 415 MPa (30 tsi); green density: 7.3 g/cm^3; sintering temperature and atmosphere: 870 °C (1600 °F) in dissociated ammonia

Pure copper P/M parts are used mainly in electrical and electronic applications, although ODS copper has also been developed for electrical/electronic applications (see the section "Oxide-Dispersion-Strengthened Copper" in this article). Oxide-dispersion-strengthened copper offers better strength at room and elevated temperatures.

In the production of pure-copper P/M parts, it is essential to use very pure copper powders ($\geq$99.95% purity) or to bring about the precipitation of soluble impurities during sintering. As little as 0.023% Fe in solid solution in copper lowers its conductivity to 86% of that of pure copper. Small amounts of iron mechanically mixed with the copper powder lower the conductivity much less, unless the iron dissolves in the copper during sintering. If high-purity copper is used, or if soluble impurities are precipitated during sintering, it is possible to obtain the values of strength and conductivity shown in Fig. 16.

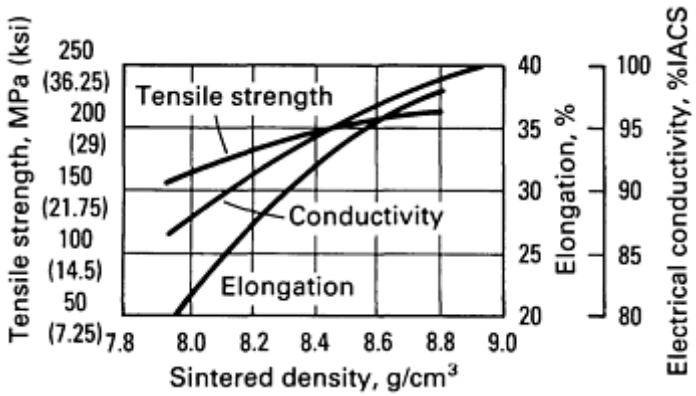

Fig. 16 Effect of density on electrical conductivity and tensile properties of P/M copper

Conductivity is directly related to porosity; the greater the void content, the lower the conductivity. Electrical conductivity of as-pressed and sintered pure copper parts varies from 80 to 90% IACS. Full-density properties, as shown above, are reached or approached by compacting at moderate pressure of 205 to 250 MPa (15 to 18 tsi), sintering at temperatures 50 to 150 °C (90 to 270 °F) below the melting point of copper (1083 °C, or 1981 °F), followed by re-pressing, coining, or forging.

Typical applications of pure copper parts in which high electrical conductivity is required include commutator rings, contacts, shading coils, nose cones, and electrical twist-type plugs. Copper powders also are used in copper-graphite compositions that have low contact resistance, high current-carrying capacity, and high thermal conductivity. Typical applications include brushes for motors and generators and moving parts for rheostats, switches, and current-carrying washers.

Friction Materials

Sintered-metal friction materials were developed in the 1920s and commercialized in the early 1930s by Wellman. They are used in applications involving the transmission of motion through friction (clutches) and for deceleration and braking. In these processes mechanical energy is converted into frictional heat, which is absorbed and dissipated by the friction material (that is, the brake linings or clutch facings).

Metal-base friction materials are strong and heat resistant and were developed in response to energy inputs and temperatures that exceeded the capabilities of the organic-base friction materials used in the 20s and 30s. World War II, with its demands for large quantities of heavy-duty friction materials in military vehicles and aircraft, contributed much to that industry. More recently, improved organic-base friction materials for light- and medium-duty applications have grown at the expense of metal-base friction materials.

Uses. Sintered-metal friction-materials applications or operating conditions may be classified in terms of dry/wet and mild/moderate/severe, as shown in Fig. 17. The majority of the clutch applications are for wet (oil) operation. In oil applications the coefficient of friction is lower, but part life is longer. Also, there are big differences in finishing operations depending on whether parts must perform dry or in oil. Parts operating in oil have surface grooves (Fig. 18a) that help remove oil from the interface and raise the coefficient of friction. Figure 18 shows friction elements used as brake linings and clutch facings.

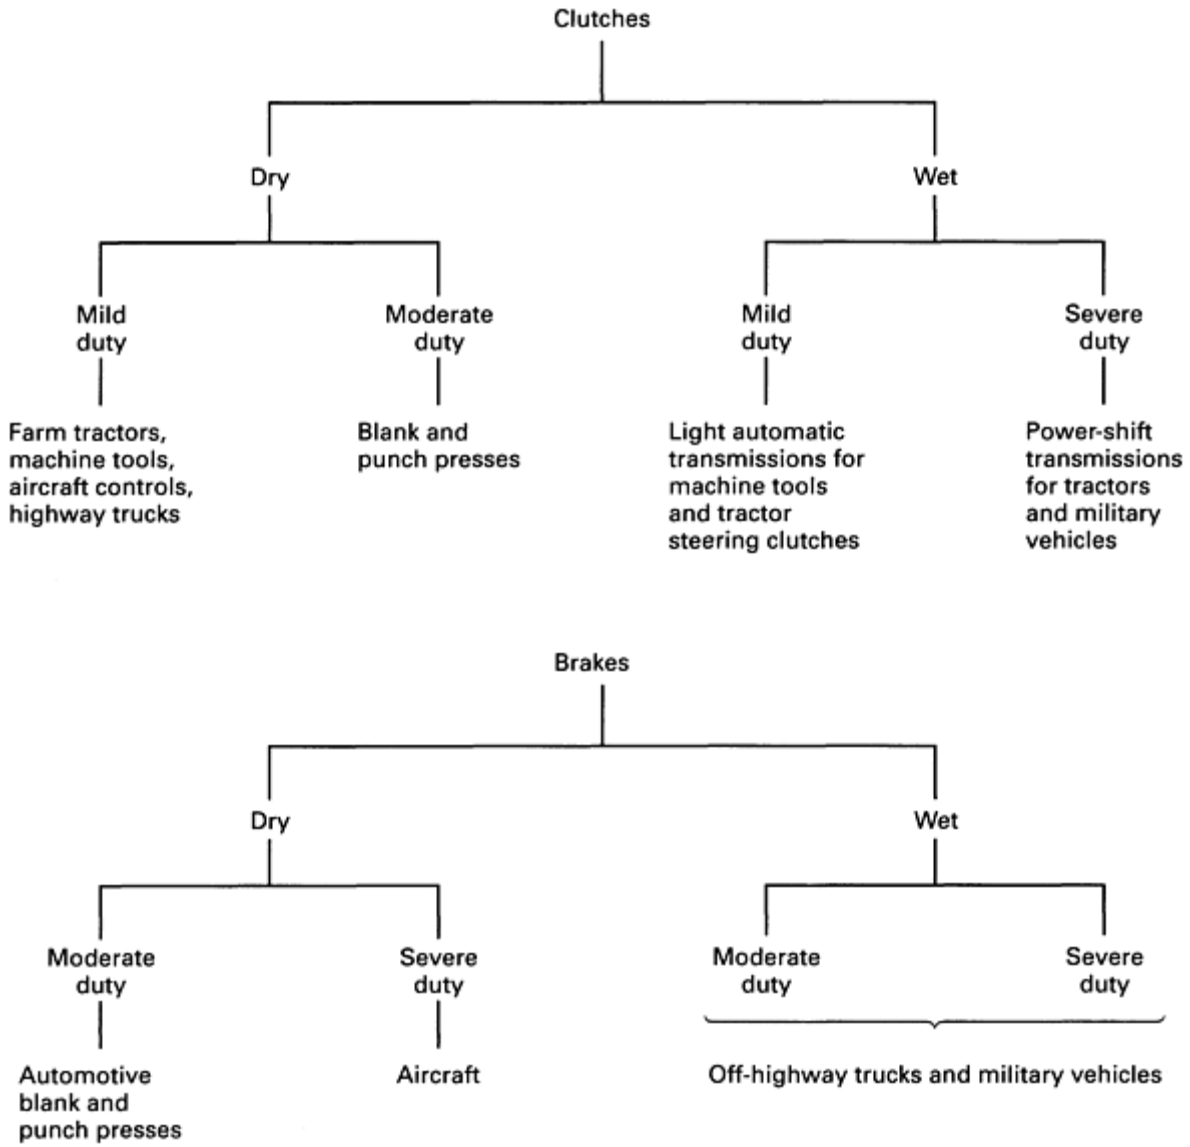

Fig. 17 Applications of sintered-metal friction materials. Source: Ref 9

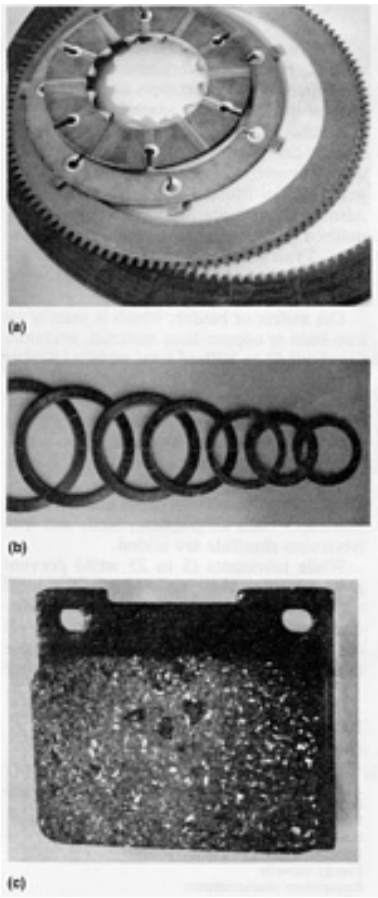

Fig. 18 Copper-base P/M friction elements. (a) Grooved P/M friction elements for wet applications. (b) copper-base P/M clutch plates (280 to 500 mm OD) used in power-shift transmissions for tractors. (c) Copper-base P/M friction pad

Composition. Early P/M friction materials were solely copper-base materials. Today, copper-base materials are still being used in all applications, but lower-cost iron-base compounds have been developed for moderate- to severe-duty dry applications. Some typical friction-material compositions are shown in Table 10 for both dry and wet applications.

(a) W, wet; D, dry.

Copper-base materials are used mainly where semifluid friction occurs. For dry friction they are suitable only where operating conditions are relatively mild (less than 350 °C, or 660 °F).

Processing. The mixtures of metal and ceramic powders (Table 11) are carefully blended. Fine metal powders with high surface area are necessary to provide a strong and thermally conductive matrix for the nonmetallic components.

Table 11 P/M friction material components used for various functions

Function	Components

Friction, strength, heat conductivity	Matrix/binder; Cu- or Fe-base (Sn, Zn, Pb additions)
Lubrication (seizure prevention; stability)	Dispersed lubricants; graphite, MoS_2, Pb
Abrasion/friction	Abrasive (frictional) components: SiO_2 mullite, Al_2O_3, Si_3N_4
Wear resistance	Cementite, cast iron grit, spinels
Filler	Carbon, minerals

Compacting pressures range from 165 to 275 MPa (12 to 30 tsi). Properties are very sensitive to production conditions. Seemingly minor changes in raw materials or processing may lead to drastic changes in performance characteristics of the final product.

Bell-type sintering furnaces usually are used where the friction facing is bonded to a supporting steel backing plate such as in clutch disks. The green disks are placed on the cooper-plated steel plates and stacked. Pressure is applied on the vertical stack of disks. Sintering temperatures range from 550 to 950 °C (1020 to 1740 °F) in a protective atmosphere. Typical sintering times are from 30 to 60 min. The sintered parts are typically machined for dimensional accuracy and surface parallelism.

The friction segments usually are brazed, welded, riveted, or mechanically fastened to supporting steel members or are pressure bonded directly to the assembly.

Function of Components. Only multiphase composites are capable of fulfilling the diverse requirements of high-performance friction materials (Table 12). Also, in developing friction materials compatibility of the opposing member is important. Typical opposing-member materials are cast iron, and hardened and unhardened low-alloy steels.

Fabricability
Temperature coefficient of friction
Time coefficient of friction

The matrix or binder, which is usually an iron-base or copper-base material, accounts for about 50 to 80% of Total weight (greater than 40 vol%). About 5 to 15% consists of a low-melting-point metal such as tin or zinc that alloys with the major constituent through liquid-phase sintering. For maximum friction, soft metals with high coefficients of friction are preferred. To avoid gross seizure between friction liner and pad, lubricants such as graphite, lead, and molybdenum disulfide are added.

While lubricants (5 to 25 wt%) prevent gross seizure, they do not prevent local welding and metal transfer. To minimize these, up to 20% of an abrasive (often called the frictional component) is added. Because these abrasive components also produce wear, the amount added depends on how much wear can be tolerated in a specific application.

An important requirement is thermal stability, which means that the coefficient of friction and the wear rate do not appreciably change up to a specific temperature. Maximum operating temperatures are around 350 °C (660 °F) for copper-base friction materials and range from 600 to 1100 °C (1100 to 2000 °F) for iron-base materials. The wear-resistant components account for up to 10 wt%, essentially for dry applications. Some of these components, such as spinels and mixed metal oxide solutions, may be formed during sintering. Finally, fillers are used, in amounts up to 15 wt%, to decrease costs.

The coefficient of friction is dependent not only on speed, pressure, and temperature of operation, but also on composition and powder characteristics of the components. Because of this complexity, optimum compositions are still derived empirically.

Oxide-Dispersion-Strengthened Copper

The use of pure-copper P/M parts in electrical applications is limited because of the low strength of copper at room and elevated temperatures. Oxide-dispersion-strengthened copper overcomes these limitations and is finding many uses. Basically, in ODS copper a fine and uniform dispersion of aluminum oxide particles (3 to 12 nm) in the copper matrix hardens and strengthens the material and retards recrystallization. Thus, mechanical properties are retained up to very high temperatures. Precipitation-hardened copper alloys lose much of their strength above 400 to 550 °C (750 to 1000 °F).

Manufacture. Oxide-dispersion-strengthened copper can be made by simple mechanical mixing of the metallic and oxidic constituents, by coprecipitation from salt solutions, by mechanical alloying, and by selective or internal oxidation. Dispersion quality and cost vary substantially among these methods; internal oxidation produces the finest and most uniform dispersion.

In internal oxidation, an atomized copper-aluminum alloy is internally oxidized at elevated temperature. This process converts the aluminum into aluminum oxide. Size and uniformity of dispersion of the aluminum oxide depend on several process parameters. Consolidation of the powder to full density and/or various mill forms is accomplished through any of the conventional consolidation processes. Properties of the fully dense material depend upon the amount of deformation introduced during consolidation. Finished parts can be made from consolidated shapes by cold forming, machining, brazing, and soldering. Flash welding and electron-beam welding have also been used successfully.

Properties. Figure 19 shows the ranges in tensile strength, elongation, hardness, and electrical conductivity as a function of aluminum-oxide content. These properties are typical for wrought stock in the hot extruded condition. Cold work broadens these ranges with only minimal effect on conductivity. The three commercial grades of ODS copper are designated as C15760, C15725, and C15715. Other grades can be produced to specified requirements. Oxygen-free compositions immune to hydrogen embrittlement are also available. Rod, bar, tube, wire, strip, plate, and assorted large shapes are available in a wide range of sizes with varying amounts of cold work.

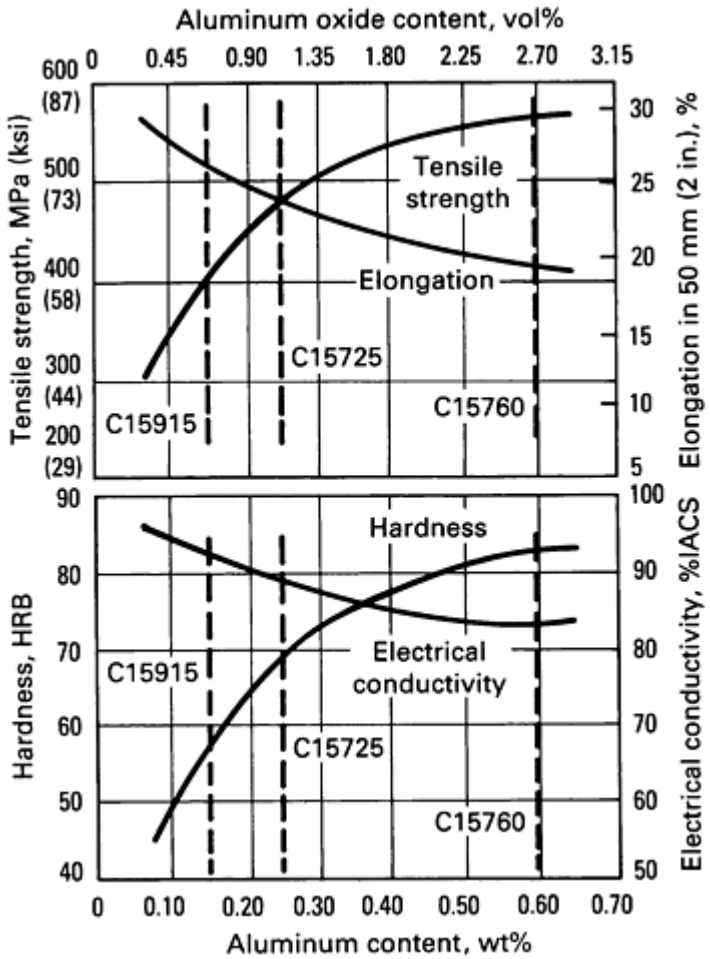

Fig. 19 Properties of three ODS coppers. Source: SCM Metal Products, Inc.

Table 13 gives physical properties of the three grades of ODS copper. Melting point, density, modulus of elasticity, and coefficient of thermal expansion are similar to those of pure copper. Figures 20 and 21 show the fatigue strength and the 100-h stress-rupture strength, respectively, of the C15760 and C15715 ODS coppers produced by SCM Metal Products, Inc. Figure 21 shows the superior strength of ODS copper above 400 °C (750 °F) in comparison to other high-conductivity copper alloys.

Table 13 Physical properties of three ODS coppers and oxygen-free (OF) copper

Property	**Material**			
	C15715[(a)]	**C15725[(a)]**	**C15760[(a)]**	**OF Coppers[(a)]**
Melting point, °C (°F)	1083 (1981)	1083 (1981)	1083 (1981)	1083 (1981)
Density, g/cm^3 (lb/in.)	8.90 (0.321)	8.86 (0.320)	8.81 (0.318)	8.94 (0.323)
Electrical resistivity at 20 °C (68 °F), Ω· mm^2/m (Ω · circular mil/ft)	0.0186 (11.19)	0.0198 (11.91)	0.0221 (13.29)	0.017 (10.20)

Electrical conductivity at 20 °C (68 °F), M mho/m (%IACS)	54 (92)	50 (87)	45 (78)	58 (101)
Thermal conductivity at 20 °C (68 °F), W/m · K (Btu/ft · h · °F)	365 (211)	344 (199)	322 (186)	391 (226)
Linear coefficient of thermal expansion for 20 to 1000 °C (68 to 1830 °F), ppm/ °C (ppm/ °F)	16.6 (9.2)	16.6 (9.2)	16.6 (9.2)	17.7 (9.8)
Modulus of elasticity, GPa (10^6 psi)	130 (19)	130 (19)	130 (19)	115 (17)

(a) Glidcop grades.

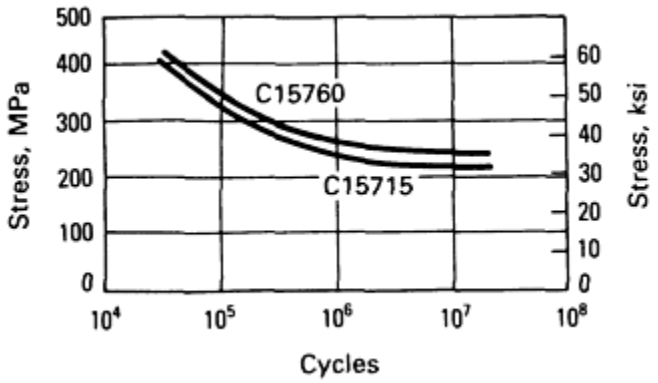

Fig. 20 Fatigue resistance of dispersion-strengthened copper. Tests conducted at room temperature in a Krause cantilever bending-rotating beam made at a frequency of 10,000 cpm. C15760 underwent 14% cold work, and C15715 underwent 94% cold work prior to test. Source: SCM Metal Products, Inc.

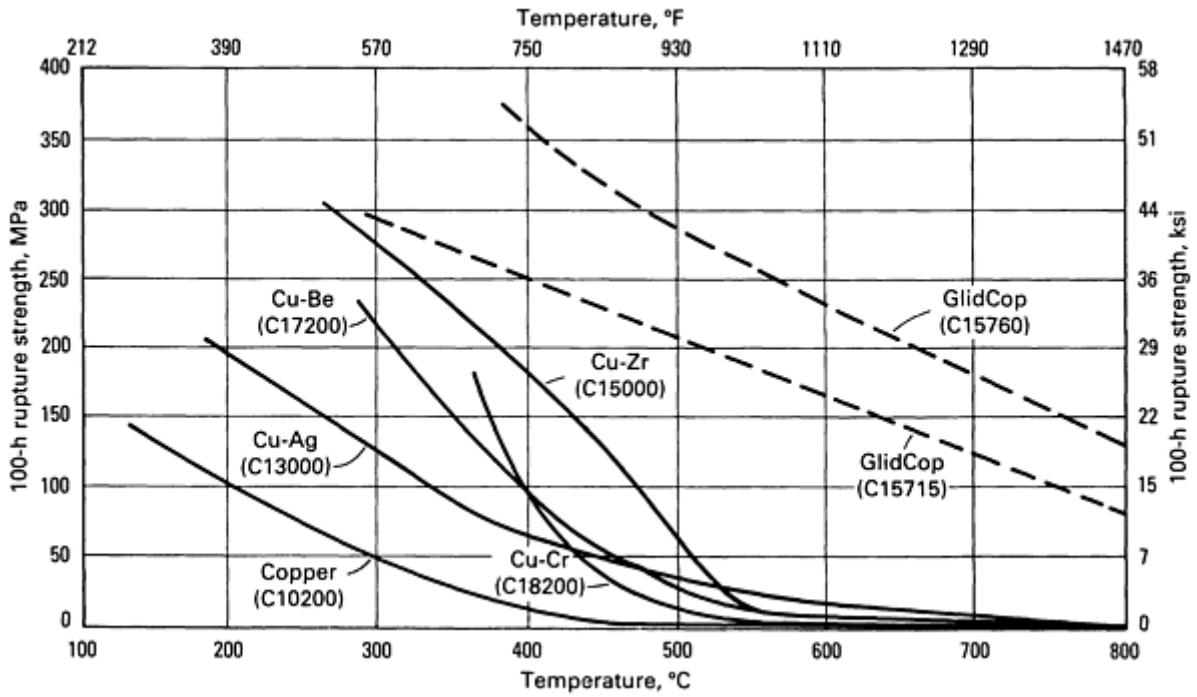

Fig. 21 Elevated-temperature stress-rupture properties of GlidCop compared to several high-conductivity copper alloys. Source: SCM Metal Products, Inc.

Uses. The combination of high electrical and thermal conductivity, outstanding corrosion resistance, ease of fabrication, and retainment of high strength at elevated temperatures make dispersion-strengthened copper useful in many applications. Dispersion-strengthened copper enhances the current-carrying or heat-dissipating capabilities for a given section size and structural strength. Alternatively, it enables reduction of section sizes for component miniaturization.

Welding Electrodes. Important applications of dispersion-strengthened copper include resistance welding electrodes in automotive, appliance, and other sheet metal industries. They outperform Cu-Cr, Cu-Cr-Zr, and Cu-Zr electrodes. For use on galvanized steel, where the latter materials encounter severe sticking problems, and in automatic press and robot welding applications, they minimize downtime from dressing and changing operations. Seam-welding wheels of ODS copper have also proved beneficial in high-speed welding of coated steels.

Lead Wires. As lead wire for incandescent lamps, ODS copper supports the tungsten filament and facilitates pressing of glass stems without undue softening of the leads. This eliminates the need for expensive molybdenum support wires. Higher light output at reduced wattage and reduced heat losses results from the use of thinner lead wires.

Relay Blades and Contact Supports. Strip products of ODS copper are used in relay blades and contact supports where strength retention after exposure to elevated temperature from brazing is important. In these applications it has replaced phosphor bronze and beryllium-copper.

Lead Frames. The use of ODS copper strip is also being evaluated in several high-performance, integrated-circuit lead-frame applications. Its high thermal conductivity effective dissipates heat from the integrated circuit chips. The high strength improves the integrity of the leads during handling, that is, it minimizes bending during insertion in the circuit board.

Porous Bronze Filters

Porous P/M parts are made from various types of metal powders depending on the particular application. The most commonly used powders include bronze, stainless steel, nickel and nickel-base alloys, titanium, and aluminum. Materials used less frequently include the refractory metals (tungsten, molybdenum, and tantalum) and the noble metals (silver, gold, and platinum).

Filters constitute one of the major applications of porous metals. The ability to achieve close control of porosity and pore size is the main reason metal powders are used in filter applications. Most producers of nonferrous filters prefer atomized spherical powder of closely controlled particle size to allow production of filters within the desired pore range. The effective pore size of filters generally ranges from 5 to 125 μm.

Tin bronze is the most widely used P/M filter material, but nickel silver, stainless steel, copper-tin-nickel alloys, and nickel-base alloys also are used. The major advantage of P/M bronze materials over other porous metals is cost. Porous P/M bronze filters can be obtained with tensile strengths ranging from 20 to 140 MPa (3 to 20 ksi) and appreciable ductility, up to 20% elongation. Also, P/M bronze has the same corrosion resistance as cast bronze of the same composition and thus can be used in a wide range of environments. Figure 22 shows assorted product forms of bronze P/M filters.

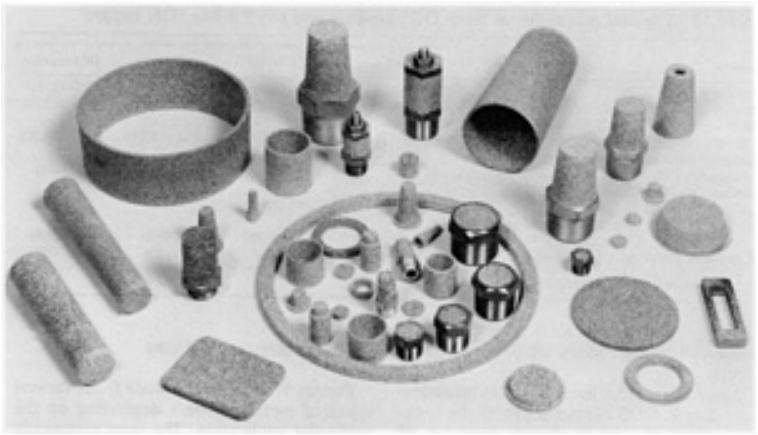

Fig. 22 Assorted filters made from P/M bronze. Courtesy of Arrow Pneumatics, Inc.

Fabrication. Bronze filters usually are made by gravity sintering of spherical bronze powders, which are generally made from the atomization of molten prealloyed bronze. These powders typically contain 90 to 92% Cu and 8 to 10% Sn. Filters made from atomized bronze have sintered densities ranging from 5.0 to 5.2 g/cm^3. To produce filters with the highest permeability for a given maximum pore size, powder particles of a uniform particle size must be used.

Although not widely used, coarser powders for bronze filters can be obtained by chopping copper wire the tumbling the choppings. Filters made from tin-coated cut copper wire with tin contents ranging from 2.5 to 8% are also used to a lesser extent. Filters made from these materials have sintered densities ranging from 4.6 to 5.0 g/cm^3.

During sintering the filters shrink slightly--as much as 8%. To avoid excessive shrinkage, filters from powders with fine particle size require lower sintering temperatures in the neighborhood of 815 °C (1500 °F). Because of the shrinkage during sintering, filters must be designed with a slight draft, so they can be removed from the mold.

Properties of four grades of bronze filter materials are presented in Table 14. By far the most common of these grades is the third. The two coarsest grades are no longer widely used.

Table 14 Properties of four grades of filter materials produced by loose powder sintering spherical powders

Particle size of spherical powder particles		Tensile strength		Recommended minimum filter thickness		Largest dimensions of particles retained, μm	Viscous permeability coefficient, m^2
Mesh range	Range in μm	MPa	ksi	mm	in.		
20-30	850-600	20-22	2.9-3.2	3.2	0.125	50-250	2.5×10^{-4}
30-40	600-425	25-28	3.6-4.1	2.4	0.095	25-50	1×10^{-4}
40-60	425-250	33-35	4.8-5.1	1.6	0.063	12-25	2.7×10^{-5}
80-120	180-125	33-35	4.8-5.1	1.6	0.063	2.5-12	9×10^{-6}

Source: Ref 11

Applications. Powder metallurgy bronze filters are used to filter gasses, oils, refrigerants, and chemical solutions. They have been used in fluid systems of space vehicles to remove particles as small as 1 μm. Bronze diaphragms can be used to separate air from liquids or mixtures of liquids that are not emulsified. Only liquids capable of wetting the pore surface can pass through the porous metal part.

Bronze filter materials can be used as flame arrestors on electrical equipment operating in flammable atmospheres, where the high thermal conductivity of the bronze prevents ignition. They can also be used as vent pipes on tanks containing flammable liquids. In these applications, heat is conducted away rapidly so that the ignition temperature is not reached.

Additional information on the manufacture, properties, performance characteristics, and applications of P/M bronze filters can be found in the article "Porous Powder Metallurgy Technology" in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook.*

Other Applications

Flaked (ball milled) and other forms of copper are used in combination with graphited materials to form carbon brushes, which are used extensively as sliding electrical contacts in electrical motor units (see the article "Electrical Contact Materials" in this Volume).

Cupronickel powders are widely used in the production of coins, tokens, and medallions. They also find use in components for marine applications because of their good corrosion resistance in sea water.

Age- (precipitation-) hardening alloys based on the systems Cu-Cr, Cu-Co-Be, Cu-Be, Cu-Ti, and Cu-Ni-Sn have attractive combinations of strength, wear, and corrosion resistance. In recent years there have been studies to extend the solubility of copper alloys by rapid solidification processing.

Beryllium-Copper and Other Beryllium-Containing Alloys

John C. Harkness, William D. Spiegelberg, and W. Raymond Cribb, Brush Wellman Inc.

Introduction

BERYLLIUM ADDITIONS, up to about 2 wt%, produce dramatic effects in several base metals. In copper and nickel, this alloying addition promotes strengthening through precipitation hardening. In aluminum alloys, a small addition improves oxidation resistance, castability, and workability. Other advantages are produced in magnesium, gold, zinc, and other base metals.

The most widely used beryllium-containing alloys by far are the wrought beryllium-coppers. They rank high among copper alloys in attainable strength while retaining useful levels of electrical and thermal conductivity. Applications for these alloys include:

- Electronic components, where the strength, formability, and favorable elastic modulus of these alloys make them well suited for use as electronic connector contacts
- Electrical equipment, where their fatigue strength, conductivity, and stress relaxation resistance lead to their use as switch and relay blades
- Control bearings, where antigalling features are important
- Housings for magnetic sensing devices, where low magnetic susceptibility is critical
- Resistance welding systems, where hot hardness and conductivity are important in structural and consumable welding components

Precipitation hardening is a critical attribute for the cast beryllium-copper alloys. Hardness, thermal conductivity, and castability are important in most of their applications. For example, they are used in molds for plastic component production where fine cast-in details such as wood or leather grain is desired. Cast alloys are also used for thermal management in welding equipment, for waveguides, and for mold components such as core pins. High-strength alloys are used in sporting equipment such as investment cast golf club heads.

Master alloys of beryllium in copper, nickel, and aluminum are available for foundry use in preparing casting alloys or otherwise treating alloy melts. Beryllium-copper atomized powder is used in several applications, notably as a conductive matrix for carbide or diamond cutters and as permeable electric contacts.

Because beryllium-copper and other beryllium-containing alloys are precipitation hardenable, they can be tailored across a wide range of property combinations. Recent advances in composition control, processing techniques, and recycling technology have broadened their capabilities and expanded their range of application. This article describes the important features of this alloy group, including information on safe handling.

Beryllium-Copper Alloys

Beryllium-copper alloys are available in all common commercial mill forms, including strip, wire, rod, bar, tube, plate, casting ingot, and cast billet. Free-machining beryllium-copper is offered as rod. Beryllium-nickel alloys are supplied primarily as strip, rod, and casting ingot, although other wrought forms are obtainable.

Beryllium-copper alloys respond readily to conventional forming, plating, and joining processes. Depending on mill form and condition (temper), the wrought materials can be stamped, cold formed by a variety of conventional processes, or machined. Cast billet can be hot forged, extruded, or machined, and castings can be produced by a variety of foundry techniques. Finished components can be conventionally plated with tin, nickel, semiprecious metals, or precious metals. Alternatively, strip can be clad or inlayed with other metals. Surfaces can also be modified by various techniques to enhance performance or appearance. Beryllium-copper alloys are solderable with standard fluxes and, if care is taken to preserve the properties achieved by heat treatment, can be joined by normal brazing and many fusion welding processes.

Composition

Commercial beryllium-copper alloys are classified as high-copper alloys. Wrought products fall in the nominal range 0.2 to 2.00 wt% Be, 0.2 to 2.7 wt% Co (or up to 2.2 wt% Ni), with the balance consisting essentially of copper. Casting alloys are somewhat richer, with up to 2.85 wt% Be. Within this compositional band, two distinct classes of commercial materials have been developed, the high-strength alloys and the high-conductivity alloys. Compositions of the commercial alloys are listed in Table 1.

Table 1 Composition of commercial beryllium-copper alloys

Note: Copper plus additions, 99.5% min

The wrought high-strength alloys (C17000 and C17200) contain 1.60 to 2.00 wt% Be and nominal 0.25 wt% Co. A free-machining version of C17200, which is modified with a small lead additional and available only as rod and wire, is designated C17300. The traditional wrought high-conductivity alloys (C17500 and C17510) contain 0.2 to 0.7 wt% Be and nominal 2.5 wt% Co (or 2 wt% Ni). The leanest and most recently developed high-conductivity alloy is C17410, which contains somewhat less than 0.4 wt% Be and 0.6 wt% Co.

The high-strength casting alloys (C82400, C82500, C82600, and C82800) contain 1.60 to 2.85 wt% Be, nominal 0.5 wt% Co, and a small silicon addition. Grain refinement in these foundry products is achieved by a minor titanium addition to the casting ingot or by increased cobalt content (up to a nominal content of 1 wt% Co) as in C82510. The high-conductivity casting alloys (C82000, C82100, and C82200) contain up to 0.8 wt% Be.

The beryllium in the high-strength alloys, at a level of close to 12 at.%, imparts a gold luster to these copper-base materials. The lower atomic fraction in the high-conductivity alloys produces a reddish or coral-gold color.

Physical Metallurgy

The binary beryllium-copper phase diagram in Fig. 1 is a useful, although somewhat simplified, tool for understanding the metallurgy of these alloys. The diagramshows that the solid solubility of beryllium in the α-copper matrix decreases as the temperature is lowered, and thus the beryllium-copper alloys are precipitation hardenable. Heat treatment typically consists of solution annealing followed by precipitation treatment (also known as age hardening). Cold work can be performed on wrought products between annealing and age hardening to enhance the magnitude of the age-hardening response.

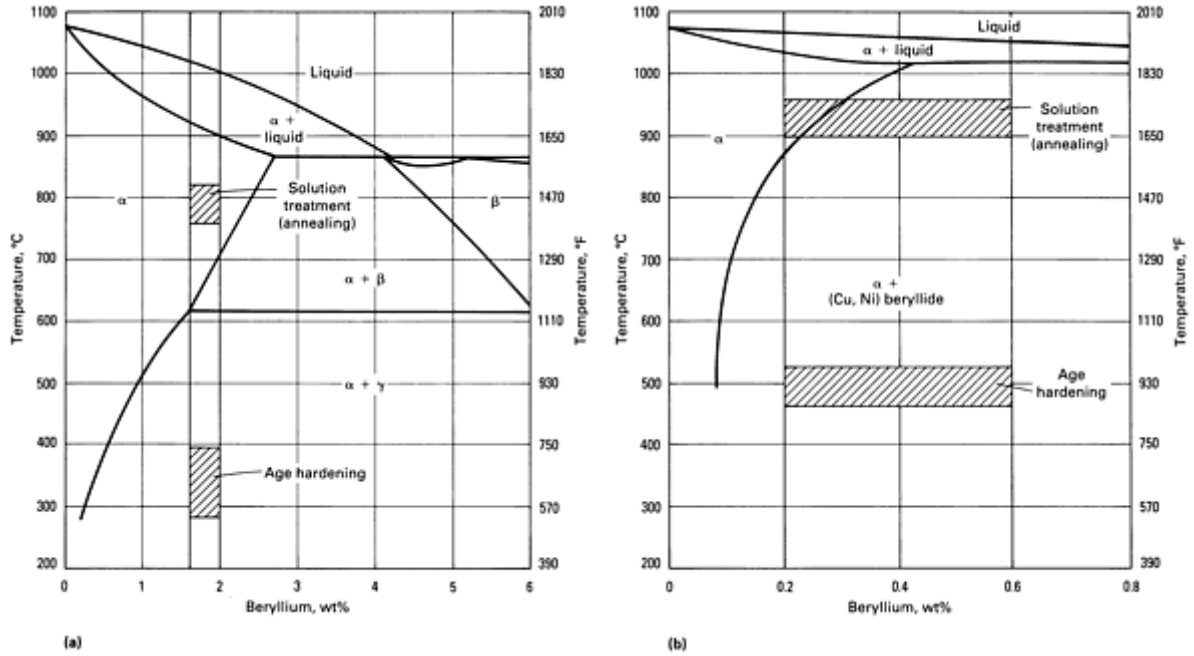

Fig. 1 Phase diagrams for beryllium-copper alloys. (a) Binary composition for high-strength alloys such as C17200. (b) Pseudobinary composition for C17510, a high-conductivity alloy

The precipitation sequence in C17200 commences with homogeneous nucleation of Guinier-Preston (G-P) zones. As age hardening progresses, coherent metastable γ" and subsequent γ' precipitates form from the G-P zones. Strength increases with aging time as a result of the coherency strains that develop as the copper matrix attempts to accommodate the growing submicroscopic precipitates. At certain age-hardening time-temperature combinations, the optically resolvable equilibrium γ phase develops, either homogeneously in the matrix or heterogeneously at grain boundaries. This phase is partially coherent with the copper matrix. The associated loss of coherency strains results in a decrease in strength compared to that developed by the formation of the metastable precipitates.

Commercial beryllium-copper alloys contain a third element addition, either of cobalt or of nickel. This addition to the binary alloy system restricts grain growth during annealing by establishing a dispersion of beryllide particles in the matrix. The addition also enhances the magnitude of the age-hardening response and retards the tendency to overage or soften at extended aging times and higher aging temperatures. In C17500 and C17200, the beryllides are (Cu,Co) Be with an ordered body-centered cubic CsCl (B2) superlattice. The beryllides in C17510 are (Cu,Ni)Be; they also display the B2 superlattice.

Microstructure

Distinctive features in the microstructure of beryllium-copper alloys are easily revealed by conventional metallographic and scanning electron microscope techniques. Beryllides, other phases, and surface effects can be examined on as-polished specimens; however, etchants (Table 2) must be used to reveal other features of interest.

Table 2 Recommended etching reagents for beryllium-copper alloys

Etchant	Composition[(a)]	Comments
1. Ammonium persulfate hydroxide	1 part NH_4OH (concentrated) and 2 parts $(NH_4)_2S_2O_8$ (ammonium persulfate) 2.5% in H_2O	Used for observation of the general structure of all beryllium-copper alloys. Preheat sample in hot water (optional); swab etch 2-20 s; use fresh.

2. Ammonium persulfate hydroxide (variation)	2 parts 10% $(NH_4)_2S_2O_8$, 3 parts NH_4OH (concentrated), 1 part 3% H_2O_2, and 5-7 parts H_2O	Used for all beryllium-copper alloys. Offers improved grain boundary delineation in unaged material. A, $\frac{1}{4}$H, $\frac{1}{2}$H, H tempers (unaged, use less H_2O. AT through HT and aged, use more H_2O). Use fresh; swab or immerse 5-60 s. Preheat specimen in hot H_2O if etching rate is slow.
3. Dichromate	2 g $K_2Cr_2O_2$ (potassium dichromate), 8 mL H_2SO_4 (concentrated), 1 drop HCl per 25 mL of solution, and 100 mL H_2O	Used for observation of the grain structure of wrought C17000, C17200, C17300. Use for AT through HT and mill hardened (aged) tempers. Etch first with ammonium persulfate hydroxide (No. 1 or 2); wipe dichromate 1-2 times over specimen to remove dark etch color. Do not overetch; sample may pit. Can be used with laboratory aging of annealed or as-rolled material at 370 °C (700 °F) for 15-20 min to enhance grain boundary delineation for grain size determination
4. Hydroxide/peroxide	5 parts NH_4OH (concentrated), 2-5 parts 3% H_2O_2, and 5 parts H_2O	Common etchant for copper and brass, also applicable to beryllium-copper alloys. Use fresh.
5. Ferric chloride	5 g $FeCl_3$ (ferric chloride), 50 mL HCl, and 100 mL H_2O	Common etchant for copper alloys, also applicable to cold-rolled tempers of beryllium-copper alloys C17500 and C17510 to show grain structure. Immerse 3-12 s.
6. Cyanide	1 g KCN (potassium cyanide) and 100 mL H_2O	General structure of beryllium-copper alloys C17500, C17510 (No. 6). Immerse 1-5 min; stir slowly while etching; use etchant 7 if others are too weak to bring out structure. A two-step technique for improved results on C17510 includes immersion in etchant 6 followed by swabbing with etchant 8. *Caution: Poison fumes. Use fume hood. Do not dispose of used solutions directly into drains. Pour used solution into beaker containing chlorine bleach. Let stand 1 h, then flush down drain with plenty of running water.*
7. Persulfate hydroxide/cyanide	4 parts ammonium persulfate hydroxide etchant (etchant 1 or 2) and 1 part cyanide etchant (etchant 6)	
8. Cyanide peroxide hydroxide	20 mL KCN, 5 mL H_2O_2, and 1-2 mL NH_4OH	
9. Phosphoric acid electrolyte	20 mL H_2O (tap, not distilled), 58 mL 3% H_2O_2, 48 mL H_3PO_4, and 48 mL ethyl alcohol	For deep etching of beryllium-copper. Polished specimen through 1 μm or finer Al_2O_3. Use 0.5-1 cm^2 (0.08-0.16 $in.^2$) mask. 0.1 A to etch (higher amperes to polish). Low-to-moderate flow rate. 3 to 6 s to etch, up to 60 s to polish

(a) Where H_2O is indicated, use distilled water unless otherwise noted.

Cast beryllium-copper alloy microstructures exhibit α-copper dendrites and blue-gray intermetallic beryllide particles of the order of 10 μm in the longest dimension. Primary beryllides formed during solidification display a Chinese script morphology. Secondary beryllides formed after solidificationof the primary phase exhibit a rodlike morphology and preferred orientation. The βphase forms peritectically from the liquid and can be observed in high-strength alloy castings as an interdendritic network surrounding the primary copper-rich α-phase. The β phase decomposes to α and γ phases by eutectoid transformation on cooling to room temperature. The transformed β phase exists as angular milky-white patches surrounded by a dark outline in the aspolished microstructure. Subsequent thermomechanical processing of wrought products refines the primary beryllides to a population of smaller, roughly spherical, blue-gray particles and normally dissolves the transformed β-phase.

The coherent precipitates responsible for age hardening in both the high-conductivity and the high-strength beryllium-copper alloys are too small to be resolved optically and can be detected only by transmission electron microscopy. Age-hardened microstructures of the high-strength alloys are distinguishable from unaged material by a dark etching response associated with striations resulting from surface relief accompanying metastable precipitation. Overaged and slack-quenched unaged high-strength alloys exhibit colonies of equilibrium γ-phase at grain boundaries. The fine lamellar morphology of these cellular precipitates can be observed by transmission electron microscopy or by scanning electron microscopy of an etched metallographic specimen. In the age-hardened state, these γ-phase colonies are softer than the coherent precipitate-strengthened matrix.

Age-hardened microstructures of the high-conductivity alloys are indistinguishable from unaged microstructures in the optical microscope. Coherency strains associated with metastable precipitates are insufficient to cause a dark etching response. In these alloys, the equilibrium γ-phase forms not by a discontinuous reaction at the grain boundaries, but instead by a continuous transformation in the matrix.

Heat Treatment

Solution annealing is performed by heating the alloy to a temperature slightly below the solidus to dissolve a maximum amount of beryllium, then rapidly quenching the material to room temperature to retain the beryllium in a supersaturated solid solution. Users of beryllium-copper alloys are seldom required to perform solution annealing; this operation is almost always done by the supplier.

Typical annealing temperature ranges are 760 to 800 °C (1400 to 1475 °F) for the high-strength alloys and 900 to 955 °C (1650 to 1750 °F) for the high-conductivity alloys. Temperatures below the minimum can result in incomplete recrystallization. Too low a temperature can also result in the dissolution of an insufficient amount of beryllium for satisfactory age hardening. Annealing at temperatures above the maximum can cause excessive grain growth or induce incipient melting.

Once the set temperature is reached, it is not necessary to hold the metal at the annealing temperature for more than a few minutes to accomplish solution treatment. In general, thin strip or wire can be annealed in less than 2 min; heavy-section products usually are held at the annealing temperature for 30 min or less. It is important to be sure to reach the set temperature; as a guide, heat-up time is usually estimated as $\frac{1}{2}$ to 1 h per inch of thickness. The use of thermal measurement equipment is helpful in establishing these parameters because they depend on the size and quantity of parts being treated. Prolonged annealing time does not increase the solution of beryllium at a given annealing temperature. At the high end of the annealing temperature range, extended dwell time can promote undesirable secondary grain growth.

Interrupted or slow quenching rates should be avoided because they permit precipitation of beryllium during cooling, resulting in an unacceptably high level of as-quenched hardness and an inadequate final age-hardening response. This is caused by the annealing out of quenched-in vacancies at these lower quenching rates. The annealing practice for beryllium-copper is in distinct contrast to that for many copper alloys that do not strengthen by heat treatment. These alloys are typically subjected to lower-temperature and longer-time annealing for recovery of cold-working strains and control of recrystallized grain size.

Age hardening involves reheating the solution-annealed material to a temperature below the equilibrium solvus for a time sufficient to nucleate and grow the beryllium-rich precipitates responsible for hardening. For the high-strength alloys, age hardening is typically performed at temperatures of 260 to 400 °C (500 to 750 °F) for 0.1 to 4 h. The high-conductivity alloys are age hardened at 425 to 565 °C (800 to 1050 °F) for 0.5 to 8 h.

Within limits, cold working the alloy between solution annealing and age hardening increases both the rate and the magnitude of the age-hardening response in wrought products. As cold work increases to about a 40% reduction in area, the maximum peak-age hardness increases. Further cold work beyond this point is nonproductive and results in decreased hardness after age hardening and diminished ductility in the unaged condition (Fig. 2). Commercial alloys intended for user age hardening are therefore limited to a maximum of about 37% cold work in strip (H temper). For wire, the maximum amount of cold work is commonly somewhat greater.

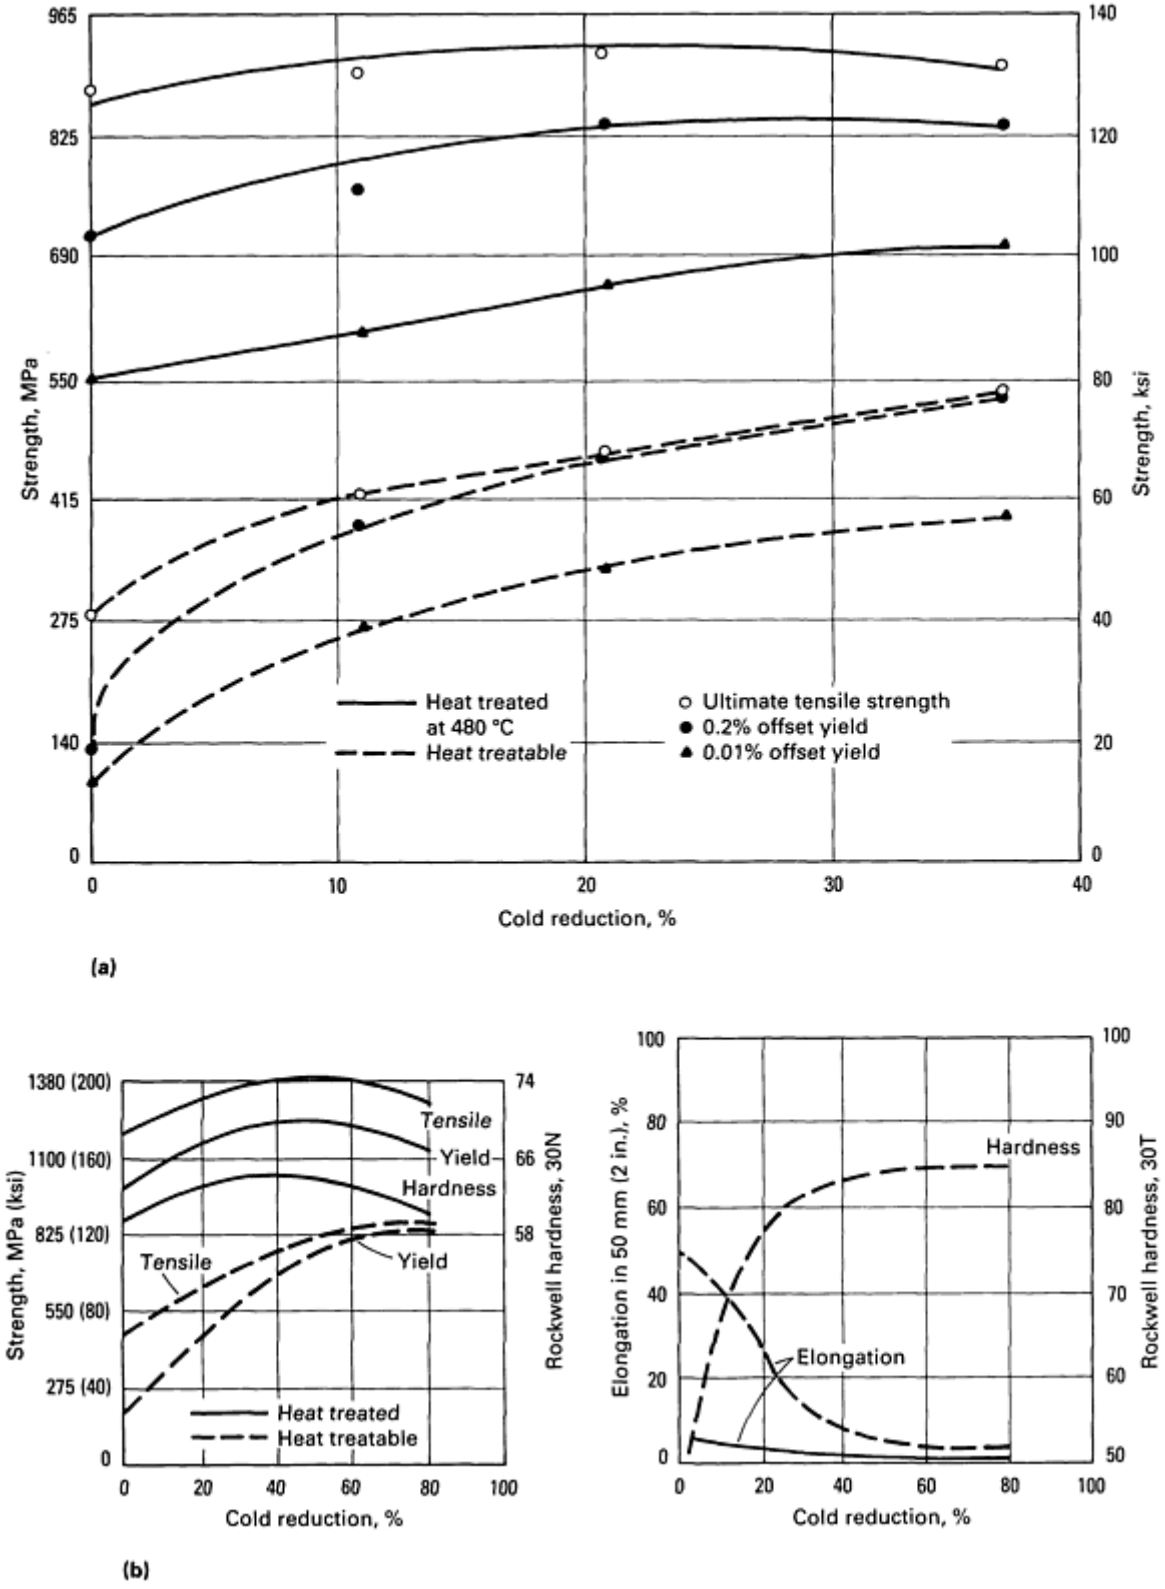

Fig. 2 Influenced of cold reduction and age hardening on the mechanical properties of beryllium-copper alloys. (a) C17510 aged at 480 °C (895 °F) for 2 or 3 h. (b) C17200 aged at 315 °C (600 °F) for 2 or 3 h

Electrical conductivity is lowest when the alloy is in the solution-annealed condition because of the large amount of beryllium dissolved in the copper matrix. During age hardening, electrical conductivity increases as dissolved beryllium precipitates from solid solution. Conductivity increases monotonically with both aging time and temperature; aging temperature has the more pronounced effect (Fig. 3). In the high-conductivity alloys, electrical conductivity is 20 to 30%

IACS in the unaged condition and 45 to 60% IACS in the peak-aged condition. The conductivity of unaged high-strength alloys is 15 to 19% IACS, increasing to 22 to 28% IACS after peak aging.

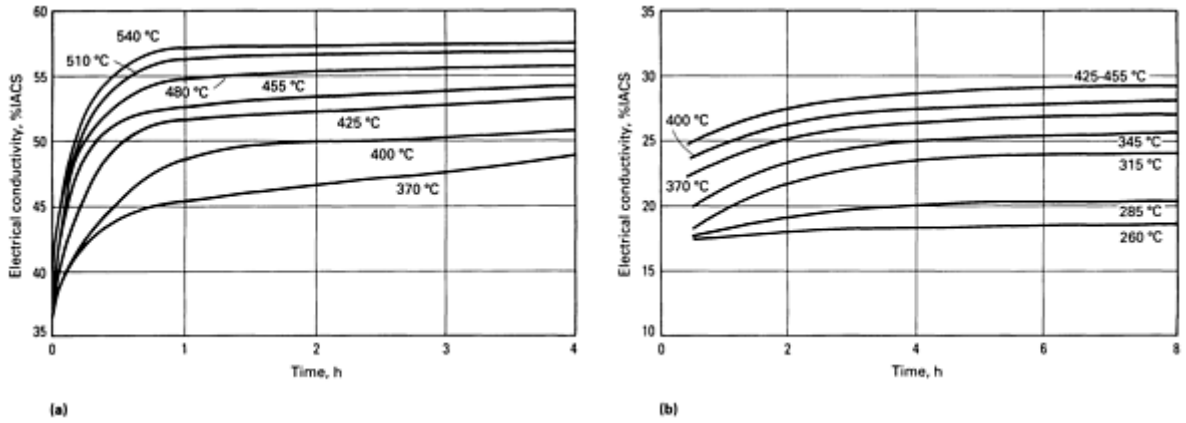

Fig. 3 Effect of aging temperature and time on the electrical conductivity of beryllium-copper. (a) Roll-hardened (TD04 temper) C17510. (b) Composite data for C17200 in the annealed, $\frac{1}{4}$ hard, $\frac{1}{2}$ hard, and hard conditions (TB00 and TD04 tempers)

Mill-hardened high-strength alloys can be produced either slightly underaged or moderately overaged. Electrical conductivity of these products thus can range from about 17 to 28% IACS.

High-Strength Wrought Alloys. Typical aging response curves for solution-annealed and annealed and cold worked C17200 are shown in Fig. 4. When age hardened at 315 to 335 °C (600 to 635 °F), strength increases to a plateau in about 3 h for annealed material or about 2 h for cold-worked material and remains essentially constant thereafter. At lower age-hardening temperatures, longer aging times are required to reach an aging response plateau.

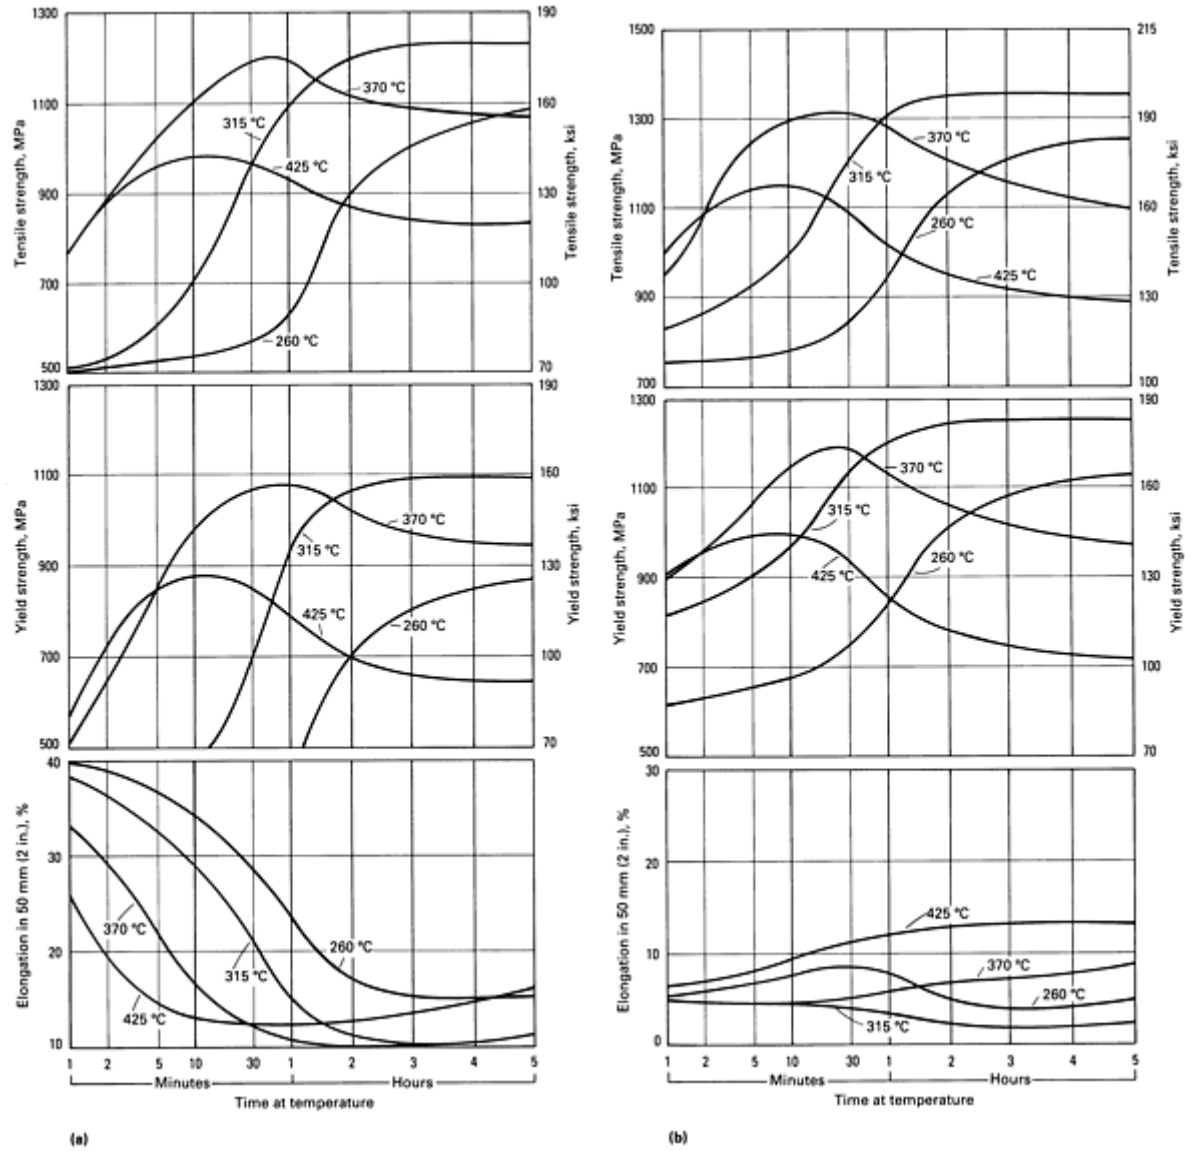

Fig. 4 Age-hardening response curves for the tensile strength, yield strength, and elongation of C17200. (a) Annealed (TB00) temper. (b) Roll-hardened (TD04) temper

At higher temperatures, such as 340 °C (640 °F) or above, a relative maximum appears in the age-hardening response curve. At constant cold work, the strength associated with this relative maximum and its time of occurrence diminish with increasing age-hardening temperature. If the alloy is kept at a constant aging temperature but is subjected to an increasing amount of cold work (to about 40% reduction in cross section), the magnitude of the relative maximum strength increases slightly and its time of occurrence diminishes. Below about 330 °C (625 °F), age hardening results almost exclusively from formation of the metastable coherent precipitates. Above this temperature, both metastable and equilibrium precipitates form; the latter concentrate at grain boundaries.

High-Conductivity Wrought Alloys. Typical aging response curves for solution-annealed C17500 and C17510 are shown in Fig. 5. Aging at 450 to 480 °C (840 to 900 °F) for 2 to 3 h is commonly recommended. Overaging is less pronounced than in the high-strength alloys and can be employed to advantage because the appreciable cobalt or nickel content of these alloys increases the thermal stability of the age-hardening precipitates.

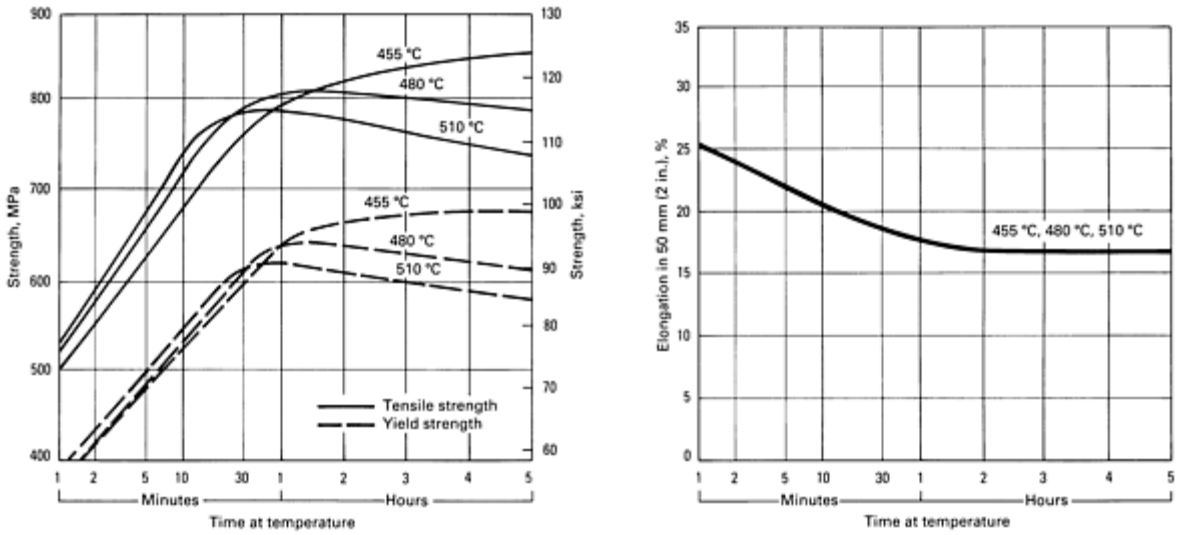

Fig. 5 Age-hardening response curves for annealed (TB00 temper) C17510

Underage, Peak-Age, and Overage Treatments. Material that has been aged for an insufficient amount of time to attain the maximum possible hardness at a particular temperature is said to be underaged. Material aged at time-temperature combinations resulting in maximum attainable hardness is said to be peak aged. Material aged beyond the relative maximum in the aging response curve is said to be overaged. Underaged material retains the capacity to increase in hardness through additional age hardening; overaged material does not.

Considerable latitude exists for achieving target strength levels with combinations of cold work and age-hardening temperature and time. When strength less than maximum is desired, for example, for increased ductility, cold work can be reduced and underaging (lower-temperature/longer-time, higher-temperature/shorter-time) or overaging (higher-temperature/longer-time) heat treatments can be employed to attain the desired properties.

If parts are inadvertently overaged to lower-than-desired hardness, they require re-solution annealing to restore the age-hardening response. In this case, the strengthening contribution of any cold work imparted before the original age-hardening treatment is erased, and the maximum strength attainable in the salvaged components is that available from solution-annealed and peak-aged material.

From a process control standpoint, peak aging at intermediate temperatures is relatively insensitive to minor fluctuations in temperature. Appreciable extension in time beyond that to attain the aging response plateau is tolerable. The low sensitivity of final strength to aging conditions once this plateau has been attained accounts for the recommendation of age-hardening temperatures of 315 °C (600 °F) for the high-strength alloys and 480 °C (900 °F) for the high-conductivity alloys. Peak-aging treatments are ideally suited for hardening large lots of components on reels or in baskets or trays. Greater precision is needed to select the correct temperature and time to achieve the desired properties when using (in order of increasing need for precision) overaging, low-temperature underaging, high-temperature underaging, and aging to the relative maximum hardness at higher temperatures.

Age-hardening treatments involving precise temperature and time combinations pose problems for batch-type heat-treating processes. Furnace loads must be evenly distributed to ensure uniform heating rates and soaking times in all components for a consistent part-to-part aging response. The use of vacuum furnaces for age-hardening necessitates the shielding of parts from direct radiation. The furnace should be backfilled with an inert gas to provide a more uniform convective heat transfer to the load than that which can be achieved by radiation alone.

Physical Properties

Beryllium and ternary elements in beryllium-copper modify physical properties, but in most cases the effects are not as dramatic as those they produce in mechanical properties. Data for selected physical properties of beryllium-copper alloys are given in Table 3. These data, when examined in tandem with the composition data from Fig. 1, show that beryllium

reduces density and lowers liquidus and solidus temperatures. Thermal expansion is relatively unaffected by beryllium content; thermal and electrical conductivities are reduced in proportion to the amount of alloying additions.

Table 3 Physical properties of beryllium-copper alloys

Tabulated properties apply to age-hardened products.

Alloy	Density		Elastic modulus		Thermal expansion coefficient from 20-200 °C (70-390 °F)		Thermal conductivity		Melting range

(a) Density before age hardening, 8.25 g/cm^3 (0.298 $lb/in.^3$).

(b) Density before age hardening, 8.75 g/cm^3 (0.316 lb/in.^{3})

Comparing the high-strength and high-conductivity alloys reveals differences in density, thermal conductivity, and melting behavior, but little difference in modulus or thermal expansion coefficient. The thermal expansion coefficients of both alloy families are similar to those of steel. This means that beryllium-coppers and steels are compatible in the same assemblies over wide temperature ranges.

The specific heat of beryllium-copper increases with temperature. For both the high-strength and high-conductivity alloys it ranges from 375 J/kg · °C (0.09Btu/lb · °F) at room temperature to 420 J/kg · °C (0.10 Btu/lb · °F) at 90 °C (200 °F). The magnetic permeability of beryllium-copper is very close to unity, meaning that these alloys are nearly perfectly transparent to slowly varying magnetic fields. All beryllium-copper alloys and product forms have a Poisson's ratio of 0.3.

Mechanical Properties

Strength, hardness, and ductility data for the various tempers of beryllium-copper alloy strip and selected tempers of other wrought products are shown in Tables 4, 5, and 6.

Wrought products are supplied in a range of both heat-treatable and mill-hardened conditions (tempers). The heat-treatable conditions include the solution-annealed temper (commercial designation A, or ASTM designation TB00) and a range of annealed and cold-worked tempers ($\frac{1}{4}$ H through H, or TD01 through TD04) that must be age hardened by the user after forming. Increasing cold work, within limits, increases the strength obtained during age hardening. Heat-treatable tempers are the softest and generally most ductile materials in the as-shipped condition, and they can be formed into components of varying complexity depending upon the level of cold work. Age hardening these heat-treatable tempers develops strength levels that range higher than those in any other copper-base alloys. After age hardening by the user, the solution-annealed material is redesignated AT, or TF00, and the annealed and cold-worked tempers are redesignated $\frac{1}{4}$HT through HT, or TH01 through TH04.

Mill-hardened tempers, designated AM through XHMS, or TM00 through TM08, receive proprietary cold-working and age-hardening treatments from the supplier prior to shipment, and they do not require heat treatment by the user after forming. Mill-hardened tempers exhibit intermediate-to-high strength and good-to-moderate ductility; these property levels satisfy many component fabrication requirements.

Strip. Wrought high-strength beryllium-copper alloy C17200 strip attains ultimate tensile strengths as high as 1520 MPa (220 ksi) in the peak-age-hardened HT (TH04) condition; the corresponding electrical conductivity is on the order of 20% IACS (Table 4). Because of its slightly lower beryllium content, alloy C17000 achieves maximum age-hardened strengths slightly lower than those of C17200. Mill-hardened C17200 strip is supplied in a range of tempers that have ultimate tensile strengths from 680 to 1320 MPa (99 to 190 ksi).

Ductility varies inversely with strength. It decreases with increasing cold work in the heat-treatable tempers and with increasing strength in the mill-hardened tempers. Beryllium-copper C17500 and C17510 strip can be age hardened to tensile strengths up to 940 MPa (136 ksi) and electrical conductivities in excess of 45% IACS. Mill-hardened strip tempers of these high-conductivity alloys span the tensile strength range of 510 to 1040 MPa (74 to 150 ksi) and include one specially processed temper with a minimum electrical conductivity of 60% IACS.

Other Wrought Products. Plate, bar, wire, rod, and tube also are available in the solution-annealed temper, the annealed and cold-worked heat-treatable temper, and the mill-hardened temper (Tables 5 and 6). Strength and ductility combinations in wire are similar to those of corresponding alloys in strip form. Age-hardened strengths of plate, bar, and tube products range somewhat lower than those of strip or wire and, to a minor degree, vary inversely with section thickness. In addition to these traditional heavy-section product properties, unique property combinations often can be developed by proprietary mill-hardening treatments in response to the changing requirements of emerging applications.

Forgings and hot-finished extruded products are available in the solution-annealed temper and the annealed and age-hardened temper. Cold work is not imparted prior to age hardening. Mechanical properties of beryllium-copper forgings and extrusions are shown in Table 7.

Cast Products. Typical mechanical property ranges for the beryllium-copper casting alloys are shown in Table 8. Four conditions exist for castings:

- As-cast (C temper, or ASTM M01 through M07; the ASTM temper designation depends upon the casting practice, such as sand, permanent mold, investment, continuous casting, and so on)
- As-cast plus age hardened (CT temper, no ASTM designation)
- As-cast plus solution annealed (A temper, or ASTM TB00)
- As-cast plus solution annealed and age hardened (AT temper, or ASTM TF00)

Table 8 Mechanical properties of beryllium-copper casting alloys

UNS designation	Temper	Yield strength at 0.2% offset		Tensile strength		Elongation in 50 mm (2 in.), %	Hardness
		MPa	ksi	MPa	ksi

	Solution annealed and aged	1070-1170	155-170	1140-1240	165-180	1-2	40-45 HRC
C82800	As-cast	345-410	50-60	590-620	85-90	5-25	80-90 HRB
	As-cast and aged	410-480	60-70	655-720	95-105	10-15	20-25 HRC
	Solution annealed and aged	1140-1240	165-180	1240-1340	180-195	0.5-3	43-47 HRC

The solution-annealing temperature range for the high-strength casting alloys, C82400 through C82800, is 760 to 790 °C (1400 to 1450 °F); these alloys are age hardened at 340 °C (640 °F). The high-conductivity casting alloys, C82000 and C82200, are annealed at 870 to 900 °C (1600 to 1650 °F) and age hardened at 480 °C (895 °F). Annealing times of 1 h per inch of casting section thickness are recommended, with a minimum soak of 3 h for the high-strength alloys to ensure maximum property uniformity. An age-hardening time of 3 h is recommended for the temperatures indicated.

Maximum strength is obtained from the casting alloys in the AT (TF00) temper. These alloys reach strength levels slightly lower than those of the corresponding wrought AT temper beryllium-coppers. The CT temper produces strengths slightly lower than those of the AT temper; however, the lower strength is offset by reduced processing costs. In addition, CT temper components experience less shrinkage and age-hardening distortion than do the AT temper castings.

The CT temper strengths shown in Table 8 apply to castings poured in metal molds. The slower solidification and cooling rates associated with sand or ceramic molds or heavy sections can result in lower CT temper strength. Casting in the solution-annealedand age-hardened (AT) temper are less susceptible to the effects of a slow cooling rate or variable section size. Water quenching of annealed temper castings with a large cast grain size may cause cracking. Slowing the

cooling rate during quenching is recommended in such cases; however, this will reduce the AT temper aging response of the materials.

Fabrication Characteristics

Formability. Strip products can be fabricated, depending on their temper, into components by stamping, coining, deep drawing, or hydroforming. The severe strains associated with the latter two cold-forming processes generally confine their application to the solution-annealed (TB00) or $\frac{1}{4}$ hard (TD01) tempers.

Bend formability is commonly measured by 90° or 180° plane-strain bend tests and is reported as the ratio of minimum bend radius for no cracking to the strip thickness. As indicated by the data given in Table 9, formability is highest and most isotropic in the annealed (TB00) and $\frac{1}{4}$ hard (TD01) tempers. Slightly anisotropic but good formability is retained as cold work increases to the hard (TD04) temper; these formability characteristics are also exhibited by the low-to-intermediate strength mill-hardened tempers (TM00 through TM04). Moderate-to-limited, more anisotropic formability is displayed by the high-strength mill-hardened tempers through TM08 and in mill-hardened C17410 TH04 strip. Formability data provided by strip producers are typically based on test results for strip as thick as 1.2 mm (0.05 in.); the reported figures generally are conservative. Users will experience better forming characteristics in thinner strip and in components with smaller width-to-thickness ratios, such as those typical of electronic connector contact springs.

Table 9 Relative formability of beryllium-copper strip

Formability rating	Specific formability	Suitable alloy condition for specified formability rating and approximate formability ratio (*R*/*t*) for a 90° bend[a]								
		Alloy C17000			Alloy C17200			Alloys C17500 and C17510		
		Alloy condition[b]	Transverse[c] (*R*/*t*) ratio	Longitudinal[d] (*R*/*t*) ratio	Alloy condition[b]	Transverse[c] (*R*/*t*) ratio	Longitudinal[d] (*R*/*t*) ratio	Alloy condition[b]	Transverse[c] (*R*/*t*) ratio	Longitudinal[d] (*R*/*t*) ratio
Excellent	Used for deep-drawn and severely cupped or formed parts	TB00	0.0	0.0	TB00	0.0	0.0	TB00	0.0	0.0
	As formable as the annealed (TB00) temper but easier to blank	TD01	0.0	0.0	TD01	0.0	0.0	. . .	. . .	. . .
					TM00[e]	0.0	0.0			
					TM02[e]	0.0	0.0			
Very good	Used for moderately drawn or cupped parts	TD02	1.0	0.5	TD02	1.0	0.5	TD04	0.6	0.5
		TM00	1.0	1.0	TM00	0.8	0.8	TF00	1.0	1.0
					TM01	1.0	1.0	HTC	1.0	1.0
					TM04[e]	1.0	1.0			
Good	Formable to a 90° bend around a radius <3× stock thickness	TD04	2.9	1.0	TD04	2.9	1.0	TH04	2.0	2.0
		TM01	1.7	1.5	TM02	1.3	1.3			

		TM02	2.2	1.9	TM04	2.5	2.5			
					TM06[e]	2.0	2.5			
Moderate[f]	Suitable for light drawing; used for springs	. . .	. . .	. . .	TM05	3.2	2.8	HTR	3.5	2.8
					TM06	3.8	3.0			
					TM08[e]	3.0	3.5			
Limited	For essentially flat parts; forming requires very generous punch radii	TM04	5.1	3.8	TM08	6.0	4.1	. . .	. . .	. . .
		TM05	7.7	5.0						
		TM06	10.4	6.1						

(a) Formability ratios of punch radius (*R*) to stock thickness (*t*) are valid for strip up to 1.3 mm (0.050 in.) thick. Strip less than 0.25 mm (0.010 in.) thick will form somewhat better than shown. Values reflect the smallest punch radius that forms a strip sample into a 90° vee-shaped die without failure.

(b) See Table 4 for descriptions of the alloy condition designations.

(c) Transverse bend direction has a bend axis parallel to the rolling direction (see Fig. 8).

(d) Longitudinal bend direction has a bend axis perpendicular to the rolling direction.

(e) Special mill processing for high formability.

(f) Moderately formable strip includes alloy C17410 in the TH04 condition with a longitudinal *R*/*t* ratio of 1.0 and a transverse *R*/*t* ratio of 6.0.

Elastic Springback. As with any metallic material, cold-formed beryllium-copper alloys exhibit elastic springback upon release of the forming tool pressure. Compensation is often incorporated into forming tools to enable the material to attain target dimensions. Angular springback curves for heat-treatable and mill-hardened strip formed longitudinally in a 90° V-block (plane-strain bends) are shown in Fig. 6.

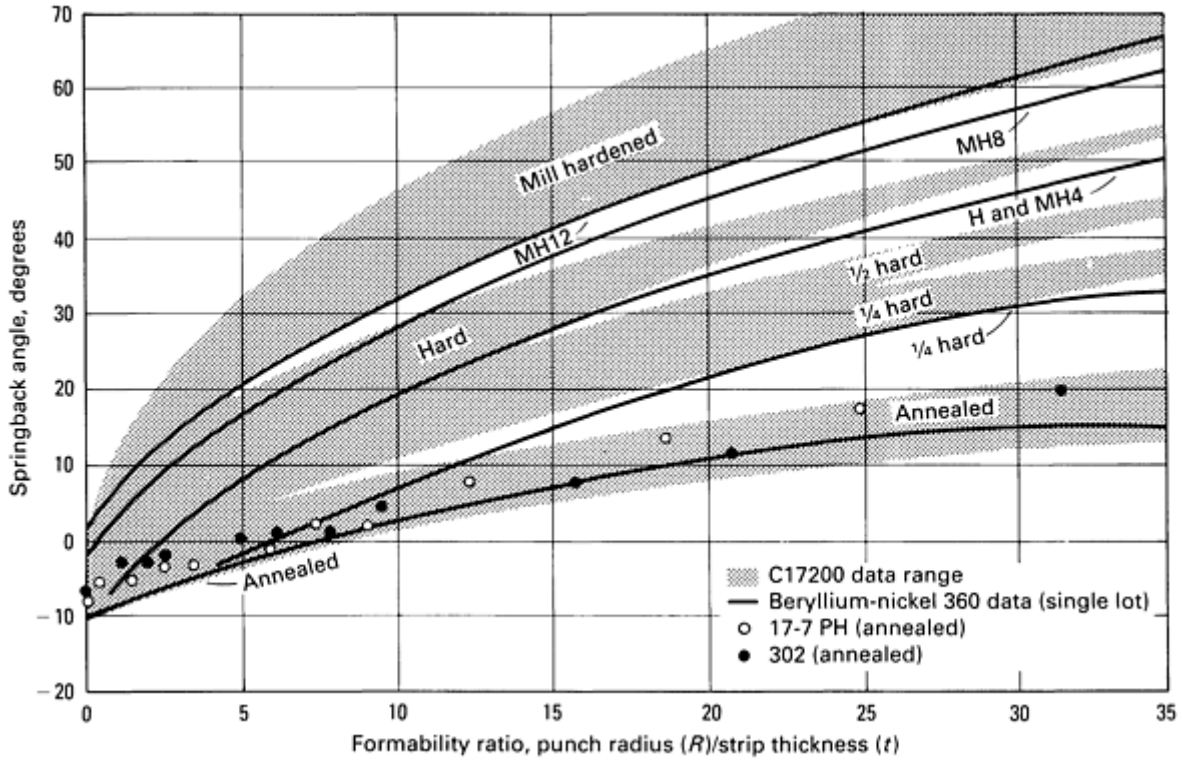

Fig. 6 Angular springback of heat-treatable and mill-hardened tempers of beryllium-copper C17200 and beryllium-nickel N03360 strip (90° V-block plane-strain bends)

Springback of C17200 increases with increasing yield strength. It is lowest in the solution-annealed (TB00) temper and highest in the high-strength mill-hardened tempers. Springback also increases with the forming ratio (punch radius divided by strip thickness) as elastic strain becomes a larger fraction of the total forming strain. Negative angular springback (collapse of the formed part against the punch) is evident at very small forming ratios in these V-block bends and is associated with a substantial shift of the neutral bend axis toward the inner bend radius.

Figure 6 shows that consistency of elastic springback in a component formed with a tool of fixed punch radius depends more on uniformity of thickness than on yield strength within a given temper. Springback also depends on the strains imparted during forming and varies with factors such as punch clearance and method of forming. Wiping bends and coining deformations produce less springback than plane-strain V-block bends.

Age-Hardening Dimensional Change. Selecting mill-hardened tempers allows the user to avoid the effects of dimensional change upon age hardening because these tempers do not need to be heat treated after stamping and forming. However, for those users who form parts before age hardening, this section contains information about factors that can contribute to dimensional change during age hardening and suggestions on how to control these factors.

Causes. The coherent age-hardening precipitates have a slightly higher density than the copper-rich matrix, and their formation is accompanied by shrinkage of the matrix. The magnitude of this shrinkage depends on the beryllium content, temper, and age-hardeningconditions, but it is nominally only 0.6% in volume or 0.2% in linear dimension in the high-strength alloys (C17000, C17200, and C17300). The high-conductivity alloys (C17500 and C17510) have a negligible volume change on age hardening.

The rate of precipitation and accompanying shrinkage depend upon residual stresses in the matrix. Compressive stresses locally intensify the aging process, whereas tensile residual stresses slow the process. When the residual stress distribution is nonuniform, as in many formed components, nonuniform shrinkage can promote distortion from as-formed dimensions. In a 90° bend, for example, the inner bend radius is under compression and exhibits a greater aging response and more shrinkage than the outer bend radius. The included angle decreases during age hardening in this case. Distortion is greater in flatter components than in other shapes unless stiffening features are included in the design. Distortion tends to be magnified over long dimensions. Bending, twist, waviness, and angular changes can occur in unsupported parts during age hardening, but each of these problems can be controlled with stiffening in the design or with one or more of the approaches suggested below.

Controls. Opportunities for distortion control are present in the forming operation itself. For example, a two-step bending process promotes a more uniform residual stress distribution in the formed part. The part can be initially bent past the intended angle and then bent back to the desired position. Rather than having compressive stresses on the inner bend radius and tensile stresses on the outer bend radius (as in a single-stage bend), the two-stage bend component will exhibit compressive stresses on both the inner and outer bend radii, thus promoting more uniform through-thickness shrinkage.

Larger bend radii promote more uniform residual stresses, but bends with an excessively large radius exhibit elastic springback sufficiently great to reverse the sign of residual stresses on the inner and outer bend surfaces. When this occurs, aging distortion appears in the direction opposite to the tighter-radius bends. Dull tooling or excessive die clearances will increase material distortion at the stamped edge, imparting localized residual stresses that can increase age-hardening distortion.

Temper selection is another means of distortion control. The product temper that results in the lowest nonuniformity of final residual stress distribution in the component to be aged will show the least distortion. For example, distortion in parts machined from large-diameter cold-worked rod can be controlled by substituting an annealed rod temper that is free from the residual stress of cold drawing. On the other hand, many components formed from thin strip benefit from the selection of more heavily cold-worked tempers in which the nonuniformity of residual stress from forming is less significant than in lightly cold-worked strip. Selecting the hardest heat-treatable strip temper consistent with the formability requirements of the part will result in the least aging distortion.

Fixturing can be employed to constrain parts during age hardening; the exact technique varies substantially with component shape. Long, flat rod or tubular parts can be secured to rigid beams or between flat plates; other parts can be packed tightly in a supporting and heat-distributing medium such as sand. Thin, flat parts can be self-fixtured by incorporating in-plane stiffening features into the design.

Special heat-treating conditions can be employed to lessen age-hardening distortion in the high-strength alloys as compared with that obtained by peak aging at 315 °C (600 °F) for 2 or 3 h. Aging at a higher temperature for a shorter time corresponding to the relative maximum in the aging response curve will reduce distortion by increasing the proportion of incoherent precipitates relative to coherent precipitates in the age-hardening process, thereby reducing the net shrinkage tendency of the material. For example, the magnitude of distortion reduction achieved by aging at 370 °C (700 °F) for about 30 min is significant, but it depends on the initial residual stress distribution in the part. Some sacrifice in peak strength also accompanies this high-temperature short-time age-hardening approach. In C17200, the decrease in strength is about 100 MPa (14 ksi).

The desired strength level and the process control techniques used during aging (which are influenced by lot size, furnace type, and part configuration) will dictate the optimal age-hardening temperature for this approach. Thermal stress-relieving treatments at temperatures below the age-hardening range may reduce some residual stress. A treatment at 175 °C (350 °F) for 3 to 4 h is a simple and effective stress-relief process.

Cleaning. Beryllium-copper products are thoroughly cleaned and provided with a tarnish inhibitor before delivery. They therefore need no cleaning or other preparation prior to use. After stamping and forming, age hardening, or any type of thermal treatment, these products should be cleaned as a preparatory step to plating, coating, or joining processes.

The first step in the surface preparation of beryllium-copper is the removal of soils, oils, and grease. These are normally present as residual traces of lubricants used in forming or from exposure of the material to shop atmospheres laden with oil mist. Surface soils such as fingerprints also should be removed. Conventional cleaners, such as organic solvents and

alkaline solutions, are normally adequate for removing organic residues. Vapor degreasing is effective, as is ultrasonic agitation for augmenting the cleaning medium action.

Like all copper alloys, beryllium-copper forms a thin surface oxide, or tarnish, when exposed to air. Tarnish formation is accelerated by moisture and by elevated temperature. Even when protective atmospheres are used, heat treatment usually oxidizes the surface to such a degree that cleaning is required for materials intended for precision applications.

The surfaces of user-heat-treated beryllium-copper components can be prepared with a procedure such as:

- Immerse parts in an aqueous solution of 20 to 25 vol% sulfuric acid plus 2 to 3 vol% hydrogen peroxide held at 45 to 60 °C (115 to 140 °F). Immerse for sufficient time to remove any dark coloration
- Rinse thoroughly and dry. Joining or plating should immediately follow the cleaning process

Pretesting should be done to avoid removal of measurable amounts of metal caused by a high acid concentration or an excessive immersion time. Special cases such as the removal of oxides left by annealing or welding processes should be reviewed with the material supplier.

Soldering is specified when the service temperature is below about 150 °C (300 °F), where higher joining temperatures might damage components, and where electrical and thermal continuity require more strength than a mechanical bond can provide. Soldering is the most common joining technique for beryllium-copper in electrical and electronic applications, where component thickness is typically less than 0.3 mm (0.012 in.). Soldering can be performed with localized heating by resistance, induction, infrared, and flame techniques; by selective application techniques such as wave soldering; or by general techniques such as bulk immersion and vapor phase deposition.

Parts to be soldered must first be thoroughly cleaned to remove oil, grease, tarnish, and oxides. Soldering should immediately follow cleaning. The mildest flux suitable for the job should be used. Noncorrosive (rosin) fluxes that are active only when heated and need only a warm-water cleanup are the most common choice for beryllium-copper. Gas fluxes (containing hydrazine in nitrogen or argon) can also be used and leave no deleterious reaction products.

Tin-lead compositions are the most commonly used solders for joining beryllium-copper. A 63Sn-37Pb solder generally is selected for high-volume electronic work. The 50Sn-50Pb type is typically chosen for hand soldering. Special silver- or indium-containing solders are used where higher bond strength and ductility are required or where silver coatings on electronic components might otherwise be dissolved by tin-lead solders. Melting temperatures for the indicated tin-lead solders range from 180 °C (350 °F) to about 240 °C (460 °F). These temperatures are low enough in the beryllium-copper age-hardening range that mechanical properties will not be affected during soldering.

The solderability of bare beryllium-copper is adequate for manual- or moderate-speed automated joining. High-speed soldering is aided by precoating with a minimum of 0.007 mm (0.275 mil) of 60-40 solder or pure tin, applied by hot dipping or electroplating. Overheating must be avoided to minimize oxidation, to prevent flux degradation, to retard formation of undesirable intermetallic compounds at the solder/substrate interface, and to prevent metallurgical changes in the substrate. Soldering beryllium-copper to itself poses no special problems, but the high conductivity of these alloys may necessitate the use of heat sinks to concentrate heat at joints made with lower-conductivity materials.

Brazing provides stronger, more heat-resistant joints than those formed by soldering. For beryllium-copper, brazing temperatures are higher than age-hardening levels. It is therefore preferable that brazing be performed before age hardening; however, with a rapid cycle, hardened beryllium-copper can be brazed effectively. The brazing temperature should not exceed the solution-annealing temperature. Braze integrity depends on joint design and assembly size, as well as on heat input and dissipation rates. Heat sinks are recommended to confine increases in temperature to the joint area.

Two general brazing techniques are used for joining beryllium-copper. A low-temperature approach employs brazing filler metals that melt at temperatures below 620 °C (1150 °F), such as American Welding Society (AWS) BAg-1. It is performed after age hardening and is accompanied by a very minor loss of hardness. This technique is recommended for joining small parts of similar size; it requires a localized and rapid application of heat to the joint area for a dwell time of 1 min maximum, followed by rapid-forced-air cooling or water quenching. Small brazed assemblies may allow the incorporation of short-time high-temperature age hardening into the brazing cycle.

A high-temperature technique is better suited to larger parts or joints between components of dissimilar size. The process is applied after solution annealing but before age hardening. It uses brazing filler metals that melt near the annealing temperature of the beryllium-copper alloy being joined. Where practical, large furnace-brazed parts can be quenched after brazing in preparation for subsequent age-hardening treatments.

The high-strength beryllium-coppers require a brazing alloy that melts at a temperature near 760 °C (1400 °F) (for example, AWS BAg-8). The high-conductivity alloys require a filler metal that will flow at temperatures between 900 and 950 °C (1650 and 1740 °F), such as AWS RBCuZn-D. Heat can be applied by torch, induction, resistance, or furnace methods. Heating must be followed by rapid cooling, preferably water quenching, to preserve the age-hardening response. As with soldering, the surfaces to be joined must be thoroughly cleaned immediately before brazing to remove oils, grease, dirt, or oxides. Flux residues should be removed after joining by hot water and brushing or with warm dilute sulfuric acid.

Welding is useful for joining beryllium-copper, and a variety of processes are available. Common techniques include electron beam and laser welding, resistance welding for face-to-face sheet joining, gas tungsten arc welding for overlay or thick section joining, and friction welding for tubular sections.

Careful metallurgical process planning is essential for any welding process. Consideration must be given to joint design, preheat (which must be held below the age-hardening temperature), weld technique, and postweld practice. It is best to weld beryllium-copper in the annealed condition with subsequent precipitation hardening. Previously age-hardened material can be welded, but the higher thermal conductivity of the base metal and the complex metallurgical conditions in the heat-affected zone make postweld heat treatments desirable for these materials.

Adhesive bonding is being used with increasing frequency for beryllium-copper assemblies because of its low cost and good performance at temperatures up to 150 °C (300 °F). Good bond strength can be obtained with a variety of adhesive formulations without complex surface preparation. Joint design is important, and loads should be transmitted along rather than across the bond joint where possible.

Thermosetting epoxy formulations achieve lap shear strengths of 20 MPa (3 ksi) or more and peel strengths of 0.8 to 1.4 MPa per millimeter of width (3 to 5 ksi per inch of width) with a 35 °C (95 °F) cure. A two-component modified epoxy applied to degreased mill-hardened strip can achieve this level of strength. Higher cure temperatures, special resin additives, and surface-etching techniques are sometimes used to increase strength even further when needed.

Hot-Working Processes. Beryllium-copper alloys are readily hot worked to produce dimensionally accurate and sound parts that respond well to subsequent age hardening. The forgeability of these alloys is considered good. The principal variables affecting product integrity are preheating time and temperature, temperature control during processing, and deformation ratio.

Forging. For the high-conductivity alloys C17500 and C17510, the forging range is 760 to 925 °C (1400 to 1700 °F). The forging range for the high-strength alloys C17000 and C17200 is 705 to 775 °C (1300 to 1425 °F). Free-machining alloy C17300 is not hot forgeable, but it can be hot extruded.

The amount and rate of deformation dictate forging temperature selection, with larger reductions and faster rates (which increase adiabatic heating) requiring a starting temperature low in the indicated range. Forging must be conducted at a temperature sufficiently high to recrystallize the material without promoting excessive grain growth. Reheating is called for when the surface temperature cools because of radiation loss and die contact and when adiabatic heating is insufficient to maintain surface temperature above the working range minimum.

Open die forging processes (including ring rolling and roll forging) are applicable to short-run items or relatively large parts of simple geometry. Closed die forging is better suited to longer runs or more complex and precision component designs. During either type of forging process, the workpiece must be maintained within a controlled temperature range to avoid forging defects associated with incipient melting on the high-temperature side and surface cracking on the low-temperature side of the range.

Room-temperature billets should be brought to temperature at a rate of 1 h per inch of section and then soaked at the forging temperature for a short time to ensure temperature uniformity. On reheating, 0.5 h per inch of section is sufficient heating time. Furnace temperature uniformity and control should be within ±5 °C (±10 °F). Furnace atmospheres should

be neutral or only slightly oxidizing to prevent excessive scale formation. The use of high-sulfur fuel in gas-fired furnaces should be avoided.

Reduction ratios should be sufficiently large to promote deformation penetration through the entire workpiece section. Partial penetration of deformation from light hammer blows, particularly on the final passes, can result in undesirable nonuniform dynamic recrystallization and associated nonuniformity in microstructure and mechanical properties after age hardening. The desirable range of reduction ratios is 3:1 to 5:1, but reduction ratios as large as 8:1 to 10:1 can be obtained in some cases. Deformation should not exceed the elevated-temperature ductility limit of the material (Table 10).

Table 10 Mechanical properties of beryllium-copper alloys at hot-working temperatures

Alloy	Temperature		Yield strength in tension		Elongation, %	Deformation resistance	
	°C	°F	MPa	ksi		MPa	ksi
High-strength beryllium-copper alloys (C17000 and C17200)[(a)]	705	1300	48	7	60	70-193	10-28
	760	1400	14	2	105	55-138	8-20
	815	1500	7	1	130	48-117	7-17
High-conductivity beryllium-copper alloys (C17500 and C17510)	705	1300	76	11	35	110-228	16-33
	760	1400	55	8	45	83-186	12-27
	815	1500	34	5	55	69-159	10-23
	870	1600	20	3	70	41-138	6-20

(a) Alloy C17300 cannot be forged. Extrusion of C17300 requires special conditions and processes.

Extrusion. The temperature ranges for extruding beryllium-copper alloys are:

- C17000 and C17200, 705 to 775 °C (1300 to 1425 °F)
- C17500 and C17510, 815 to 900 °C (1500 to 1650 °F)

Free-machining C17300 is more difficult to extrude than the other beryllium-coppers and requires special control of process parameters.

Key variables in the extrusion process are temperature, speed, extrusion ratio, die design, die material, dummy block configuration, and lubrication. A temperature above the recommended range can promote oxidation of the extruded product. Cracking, coarse grain size, or incipient melting are possible under extreme conditions. The somewhat wider extrusion temperature range of alloys C17500 and C17510 renders these alloys less susceptible to heat checking.

Too low a billet temperature causes high press loads and may promote nonuniform deformation. Near-neutral preheating furnace atmospheres retard oxidation that might increase die wear. Billets can be economically heated by induction with minimum oxidation. The press speed and extrusion ratio depend on die design and the ability of the tooling and metal system to distribute adiabatic heat generated during deformation. Reduction ratios as high as 10:1 are feasible. Dummy blocks are typically flat, and a die half angle of 35° is satisfactory for the high-strength beryllium-coppers. Die materials include tool steels, high-temperature cobalt- or nickel-base alloys, and zirconia or alumina ceramics. Ceramic dies have the advantages of a lower coefficient of friction with beryllium-coppers and lower wear rates. Mandrels for tube extrusion are typically made of high-strength materials such as Inconel 718. Lubrication reduces friction and die wear and is typically provided by graphite-base, sulfur-free formulations.

Heading and Forming. Heat-treatable tempers of rod and wire can be formed by cold heading. Mill-hardened C17500 and C17510 rod and bar products, by virtue of their moderate strength and good ductility, can also be cold formed by bending.

Heat Treatment and Properties (Hot-Worked Products). Forgings and extrusions require heat treatment to attain maximum strength (Table 7); solution annealing, rapid quenching, and age hardening at temperatures and times recommended for other wrought beryllium-copper products are the methods generally employed. As an alternative to solution annealing, hot-finished beryllium-copper components (extrusions in particular) can be quenched directly from the press by immersion in a well-agitated medium. Spray quenching is usually inadequate, and the resultant age-hardening response depends on both the hot finishing temperature and the rapidity of the quench.

Machining. Beryllium-copper can be machined at metal removal rates comparable to those used for other high-performance copper alloys and stainless steels. Machining can be done on annealed or cold-worked products, but tough, continuous chips may lead to difficulty in some instances. Machining in the age-hardened condition (AT or HT) eliminates this difficulty and alleviates the need for postaging cleaning. Alloy C17300 is generally used for automated machining operations because the minor lead additive is an effective lubricant and chip breaker.

Cutting tools should be kept sharp and should have a positive rake angle between 5° and 20° for best performance. Chip breakers are recommended for turning. Cutting fluid is recommended as a coolant; water-soluble oils and synthetic emulsions are commonly used for this purpose. Although the best finishes are obtained from sulfurized oils, these oils will discolor the surface. The stain is not harmful, but should be removed after machining, particularly if the parts are to undergo subsequent age hardening.

Surface grinding is also commonly used for beryllium-copper alloys. Guidelines on wheels, speeds, and metal removal rates are available from abrasives manufacturers. Grinding should always be done with a coolant. Other machining methods, such as photochemical etching, electrical discharge machining, and electrochemical machining, are practiced by numerous vendors.

Design and Alloy Selection Considerations

To perform effectively in an engineering system, an alloy often must satisfy a set of complex requirements. These requirements consist of a list of mechanical and physical properties in which two or three predominate in importance. The combination of properties must provide measurable benefits over the lifetime of the system to justify the choice of one alloy over another. The beryllium-copper family of alloys, by virtue of its ability to be tailored to fit a wide variety of strength, conductivity, and fabricability parameters, provides benefits in a number of diverse industries. This section presents examples of the beneficial properties of beryllium-copper alloys and quantifies some of the major reasons for their selection for particular applications.

Resilience and Formability (Electronic Contact Spring Applications). The ratio of yield strength to elastic modulus measures the ability of a spring to apply a high force from a relatively large deflection without taking a permanent set. The property, which can be termed resilience, is shown in Fig. 7 for two tempers of beryllium-copper, several other electronic component alloys, and one steel. Mechanical properties shown in this and other graphs in this section are the minimum values from property ranges provided in current alloy specifications. The striking feature of this chart is the high ratio displayed by the beryllium-copper tempers, meaning that they can grip the edge of a printed circuit board or a mating pin member with positive action, and this action will be retained through repeated insertion cycles.

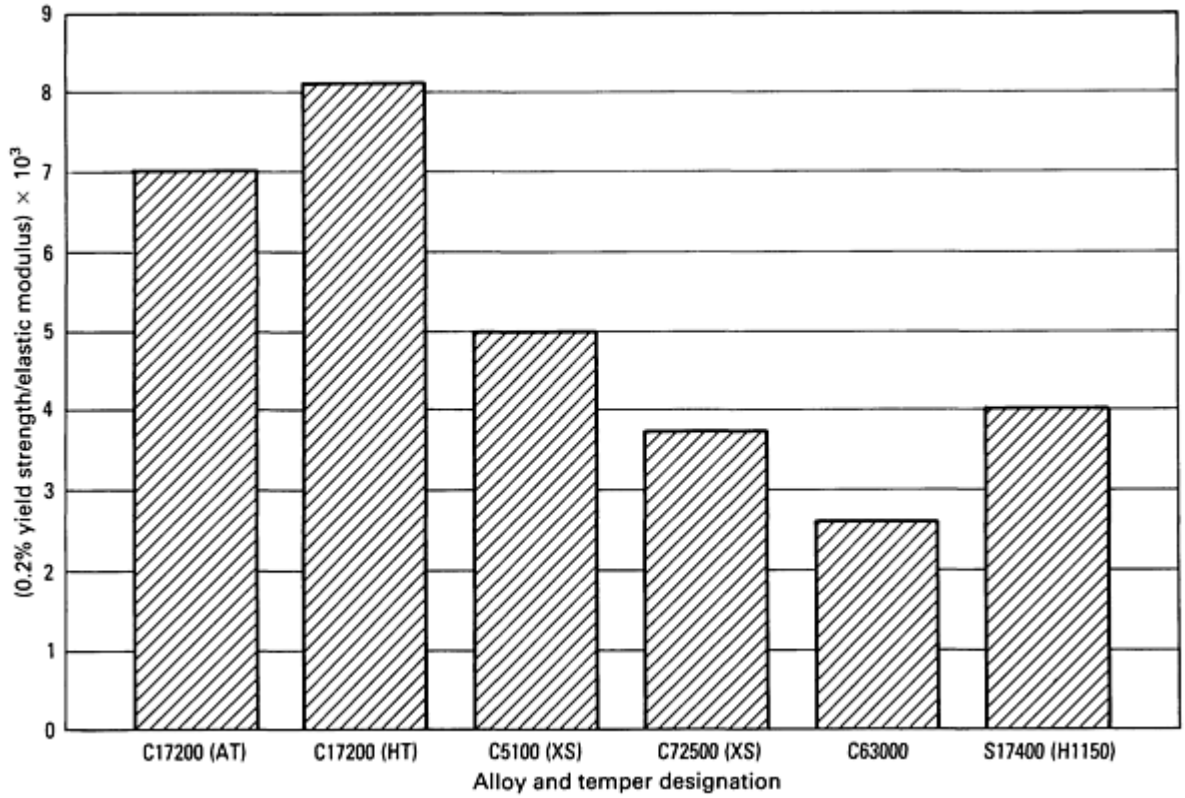

Fig. 7 Ratio of yield strength to elastic modulus for several connector alloys

Electronic connector contact springs require resilience, and, because of high demands on space in miniaturized electronics, they also require the ability to be formed into complex spring configurations. In electronic connectors, these springs are most often formed from strip, less frequently from wire. In either case, formability is important. Bend formability in strip, discussed earlier in this article (Table 9), is the minimum ratio of bend radius to strip thickness that avoids visible cracking at the outside surface of the bend. Smaller values of this ratio represent an improved ability to form a small, tightly formed part and thus to conserve both space and material. The bend formabilities of selected copper-base alloys are compared in Fig. 8, which shows the formability ratio (R/t) as a function of the 0.2% yield strength. Alloy selection from this chart can be performed by plotting a point representing the R/t of the tightest bend in a contact spring design against the yield strength (or resilience) determined from normal force/stress analysis of that design. The alloy selected should be the one corresponding to the curve immediately below the plotted point.

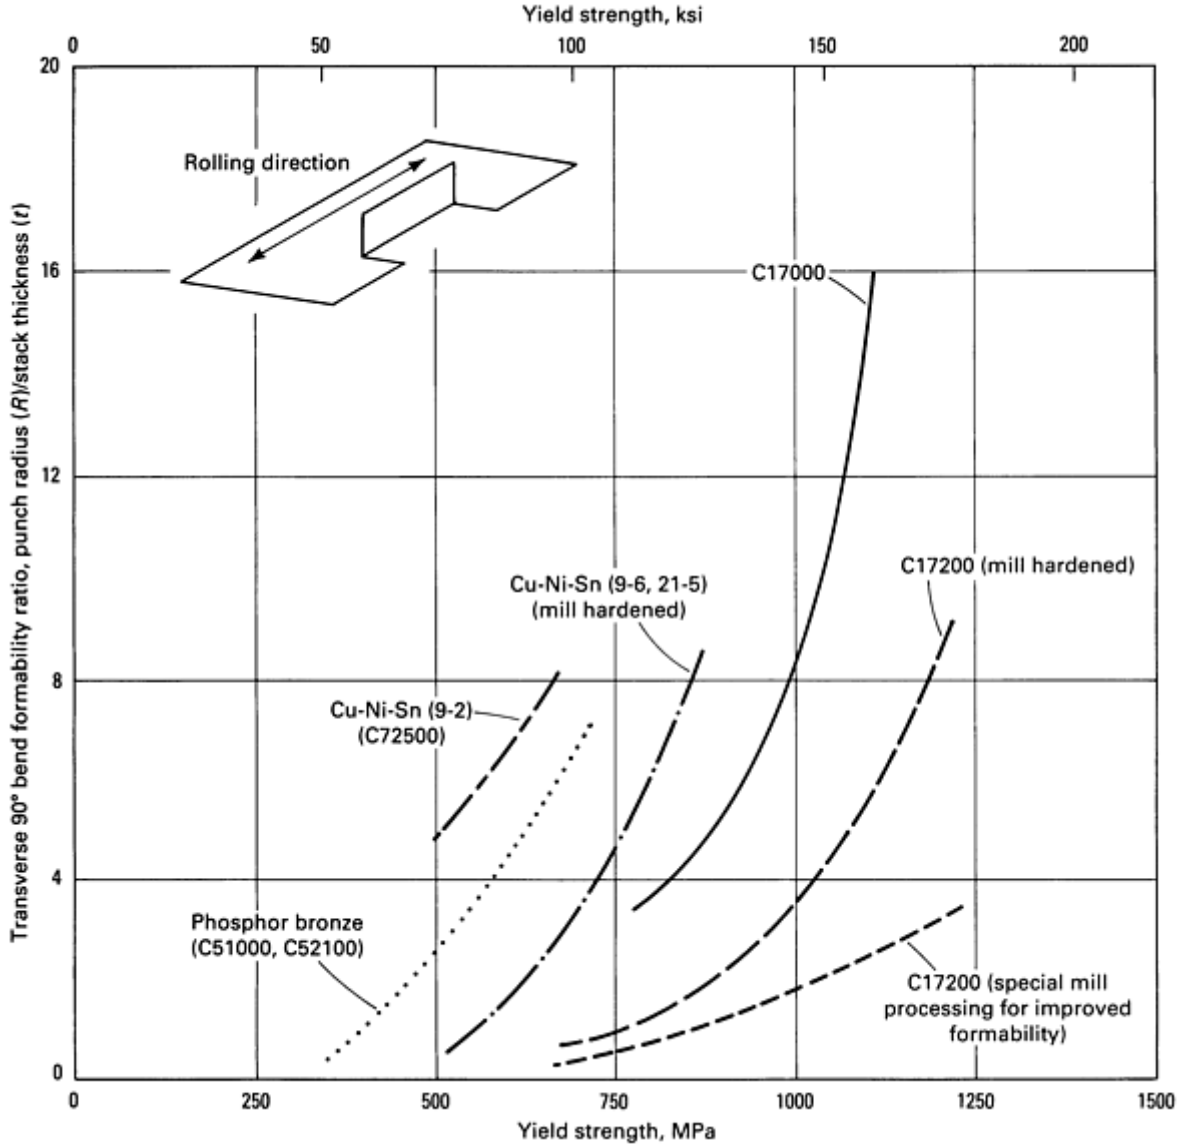

Fig. 8 Strength and transverse bend formability relationships in selected connector alloys (90° plane-strain bends)

Other attributes influence designer selection of a particular connector alloy for electronic contacts. Electrical conductivity plays a role; however, because these connectors operate at extremely low (signal level) currents, they are almost always plated, clad, or otherwise provided with a coating that has a high electrical conductivity. This coating can be a precious or semiprecious metal or a conductive polymer, but in all cases it must be oxidation resistant and soft enough to present a nascent metal surface under the wiping action of connector insertion. Because of this coating, electrical conductivity is a secondary consideration in alloy selection. Electronic contact alloys are chosen on the basis of resilience and formability properties from among those alloys having an electrical conductivity of at least 15% IACS. These selection criteria have resulted in the evolution of a relatively small number of alloy families (Table 11(a) commonly used for electrical connectors.

(e) 98% of yield strength remaining after 1000-h exposure at 105 °C (220 °F)

Typical connector design requirements call for longitudinal and transverse formabilities of the order of 1 to 2 *R*/*t* and 0.2% yield strengths of 940 MPa (136 ksi) and more. Many exceptions to these guidelines exist among the various connector classes. Insulation-displacement connectors need isotropic formability and somewhat higher hardness to maintain a sharp knife edge to cut through insulation. Surface-mount connectors need stress relaxation resistance to withstand soldering cycles. In general, automotive electronic connectors require less formability, but because they must operate in hot environments, alloys such as C17510 and C17410 frequently are specified for these applications.

Thermal Stability of Spring Properties. Many electrical and electronic connectors must operate reliably for extended periods at elevated temperatures. Others must carry appreciable currents that may cause a temperature rise in the device. In either circumstance, stability of spring properties over the operating life of the connector is important for satisfactory performance. Beryllium-containing connector alloys are suited to a wide range of elevated-temperature or moderately high-current applications.

Exposure of mechanically stressed springs to elevated temperatures can cause relaxation of spring force and permanent set, even at stresses below the yield strength of the material. The ability of a material to resist such loss of spring force over time at elevated temperature is called stress relaxation resistance. The typical stress relaxation behavior of several copper-base connector alloys and beryllium-nickel is shown in Fig. 9. Stress relaxation increases slightly with increases in the initial stress level at constant temperature; it becomes more pronounced as the exposure temperature increases. The copper alloys strengthened by work hardening (for example, C51000, C68800, and C72500) exhibit appreciably lower resistance to stress relaxation than do the copper alloys strengthened by heat treatment (for example, C72400, the beryllium-coppers, and spinodal alloys such as C72700 and C72900).

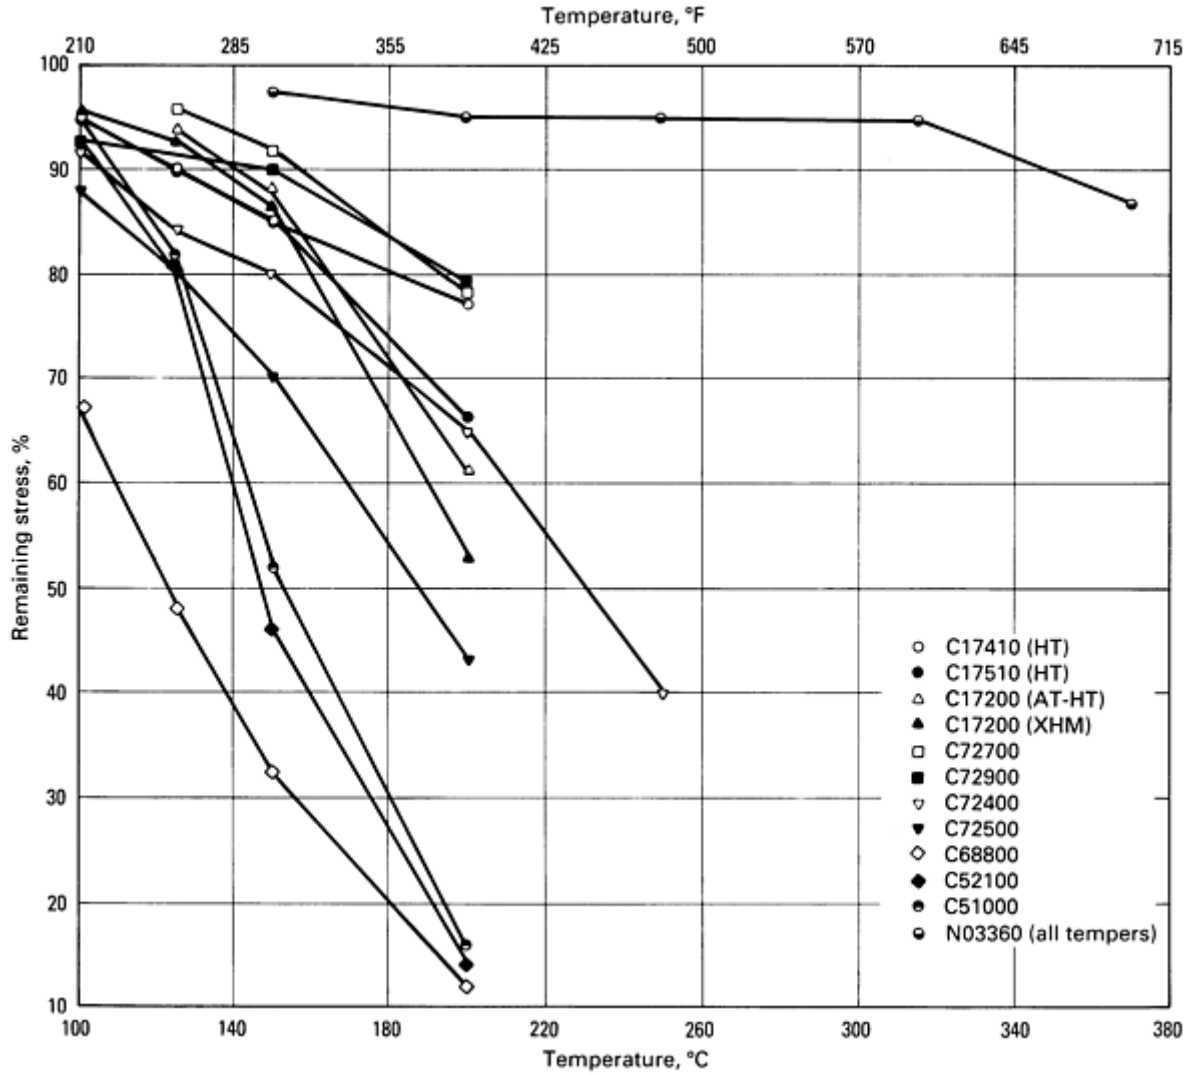

Fig. 9 Isochronal (1000-h) stress relaxation behavior of selected connector alloys at an initial stress level of 50 to 75% of the room-temperature 0.2% offset yield strength

Because of their higher aging temperatures, the high-conductivity beryllium-copper alloys are proportionately more relaxation resistant than the high-strength beryllium-coppers (C17000 and C17200). However, the yield strengths of the latter alloys are generally higher than those of the high-conductivity alloys, permitting greater initial stress levels in the connector design. Peak-age-hardened C17000 and C17200 in the AT to HT tempers (TF00 to TD04) are slightly more relaxation resistant than the mill-hardened tempers of these alloys (TM01 to TM08). The stress relaxation resistance of beryllium-nickel N03360 exceeds that of the beryllium-copper and spinodal alloys.

The increase in temperature in a connector beam of fixed length and cross-sectional area is directly proportional to the square of the applied current and inversely proportional to the electrical and thermal conductivities of the material. Because of their lower solute contents, beryllium-copper alloys, the high conductivity compositions in particular, exhibit a markedly lower temperature rise than do other copper alloys of similar or lower strength. The consequences of increased temperature include increased loss of spring force through accelerated stress relaxation, increased contact resistance from heat-induced oxidation at the connector interface, and, in extreme cases, distortion and melting of the plastic connector housing.

Strength and Electrical Conductivity in Interference Grounding. Electronic device containers, from connector shells to cabinets, must be shielded from the emission of radio frequency electromagnetic energy that can cause interference. These devices also must seal tightly to minimize the possibility of picking up minute quantities of atmospheric dust or particulates. The solution is to line the device at sealing surfaces with a conductive strip that has been

cut into formed fingerlike spring members. Upon closure, the strip fingers fold elastically into a very thin configuration. High fracture strength in bending is required to eliminate cracking at the compressed bend, and electrical conductivity is needed to effectively and reliably ground out the small interference signal. Beryllium-copper thin strip is a common choice for this application. Typical strength and electrical conductivity combinations of commercial conductive spring alloys are compared in Fig. 10.

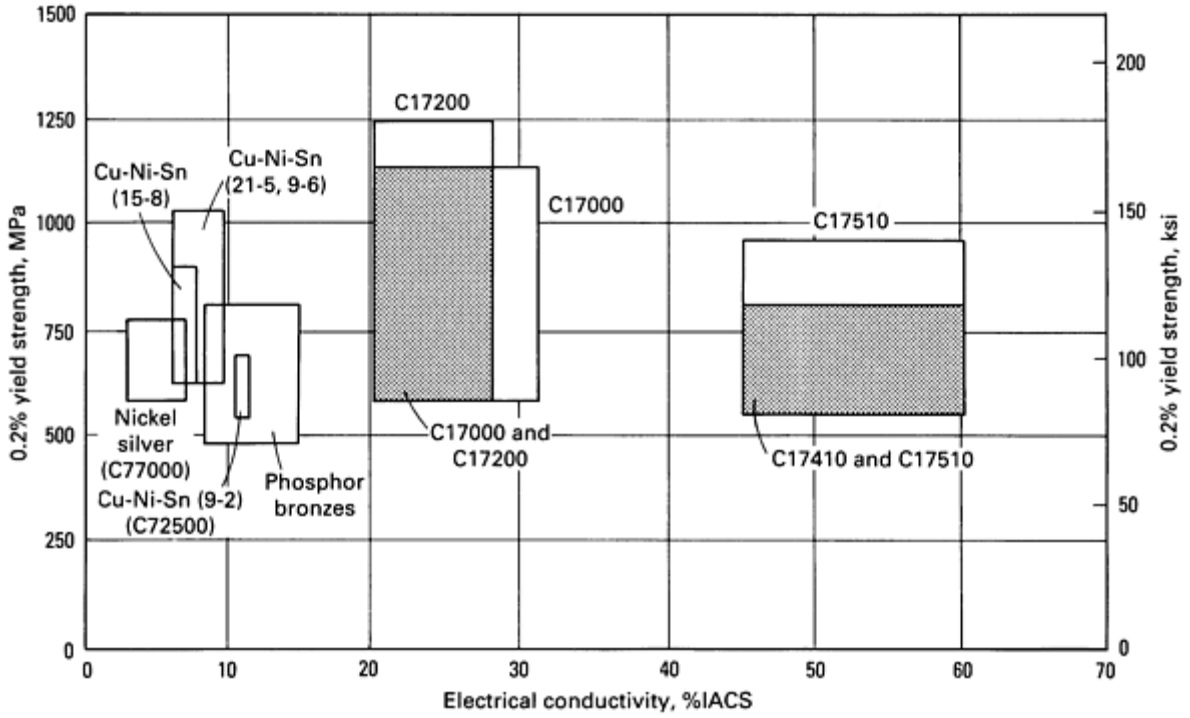

Fig. 10 Strength and electrical conductivity relationships in selected copper alloys. Each box represents the range of properties spanned by available tempers of the indicated alloy.

Fatigue Strength and Resilience (Mechanical Spring and Electrical Switch Applications). Beryllium-copper has long been noted for having the highest fatigue strength among copper alloys. This properly and the high resilience of beryllium-copper in strip form have resulted in the use of the alloys as blades in many different types of switches, thermostatic controls, and electromechanical relays. A switch, for example a snap-acting type, undergoes a high flexural load with each cycle. The lifetime of the device is ultimately limited by the fatigue life of the switch or relay contact blade. The *S-N* curves shown in Fig. 11 illustrate the fatigue behavior of beryllium-copper for two different values of the stress ratio *R*, the ratio of minimum stress to maximum stress. Switch action almost always involves unidirectional bending ($R = 0$), and therefore a very large number of cycles can be sustained by even a miniaturized switch or relay configuration. Switch designers often specify beryllium-copper in the HT condition to achieve the highest strength possible. If mill-hardened alloys are used, it is common to choose the highest-strength SHM or XHMS (TM05 through TM08) tempers when forming requirements are not severe. Relay and thermostatic control users typically select the high-conductivity alloys such as C17510 or C17410 because their current levels are higher, and thermal management is critical in these applications.

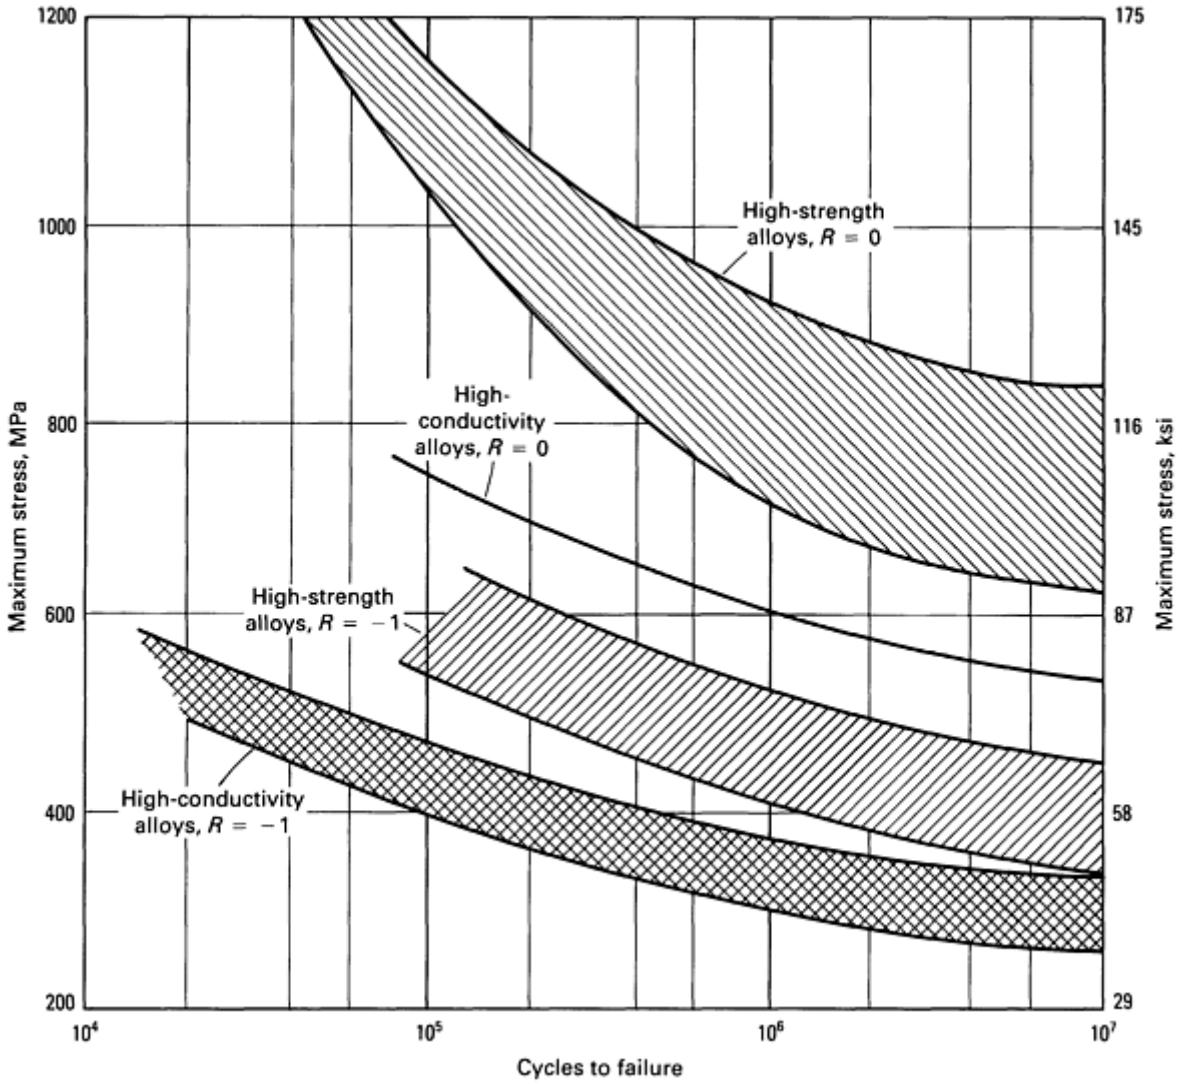

Fig. 11 Fatigue behavior of beryllium-copper strip according to the stress ratio *R* in unidirectional (*R* = 0) and fully reversed (*R* = -1) bending

Other types of devices also use the spring resilience and fatigue strength of beryllium-copper to advantage. Detectors for seismic, ultrasonic, or other types of vibratory energy, for example, must have very high sensitivity to small signals. Springs for these devices are produced in foil thicknesses and are usually designed to have very high stiffness to vibration modes other than those in the direction of greatest interest.

Resilience and High Galling Stress (Dynamically Loaded Bearing Applications). A high ratio of yield strength to elastic modulus (Fig. 7) is a desirable attribute for an alloy used in journal bearings. The ratio measures the ability of a sleeve bearing to take a radial load from a journal (or a rod-end bearing to take a thrust load applied to a race) and to distribute this load elastically without deforming permanently. As the chart shows, beryllium-copper is higher in resilience than other coppers and steels used for this purpose in, for example, aircraft landing gear. Resilience in itself is not enough, however; the alloy also must resist galling and have high wear resistance. The wear characteristics of a variety of common alloys are compared in Fig. 12. Although beryllium-copper is not the highest on this chart, when galling resistance and resilience are also taken into account, its combination of properties usually makes it a leading candidate for bearing applications.

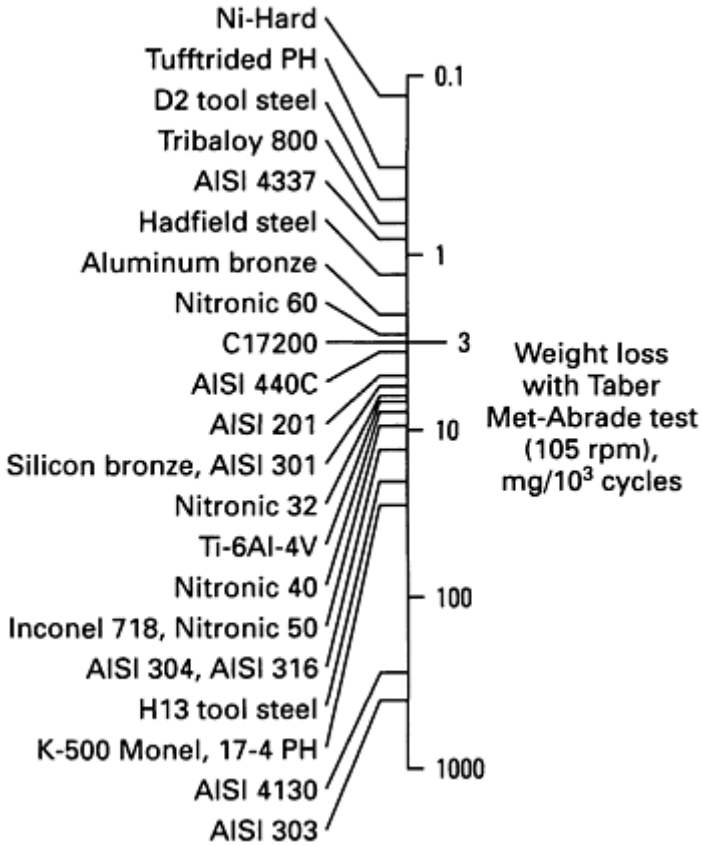

Fig. 12 Wear characteristics of C17200 beryllium-copper compared to those of other materials

Low Magnetic Susceptibility and Galling Resistance (Magnetic Sensor Housing Applications). The sensing of low-level magnetic fields, such as by oil field, biomedical, and navigational instruments, requires tubular housings that are transparent to magnetic fields. Thin-wall instrument tubes house sensitive magnetometers that are responsive to fields at up to 10^{-4} tesla (1 G) or less. For example, in oil and gas exploration and logging, devices are lowered to depths of 300 to 6000 m (1000 to 20,000 ft) to determine the azimuth and inclination of a well-bore in drilling or production. Instrument tubes for this application can be thin-wall devices lowered on wire lines than transmit data electrically, or they can be heavy-wall tubes that make up part of the bottom-hole assembly of the drilling string near the drilling bit. The latter application is important in the recently developed technology known as measurement while drilling.

Alloys selected for service in these instruments require corrosion resistance, especially resistance to chloride stress cracking, and galling resistance to minimize the maintenance expense associated with galled threads in frequently disassembled instrument packages. Freedom from magnetic hot spots is essential; as Fig. 13 shows, beryllium-copper has low initial susceptibility that remains stable and is not influenced by cold work resulting from rigorous service and rugged handling.

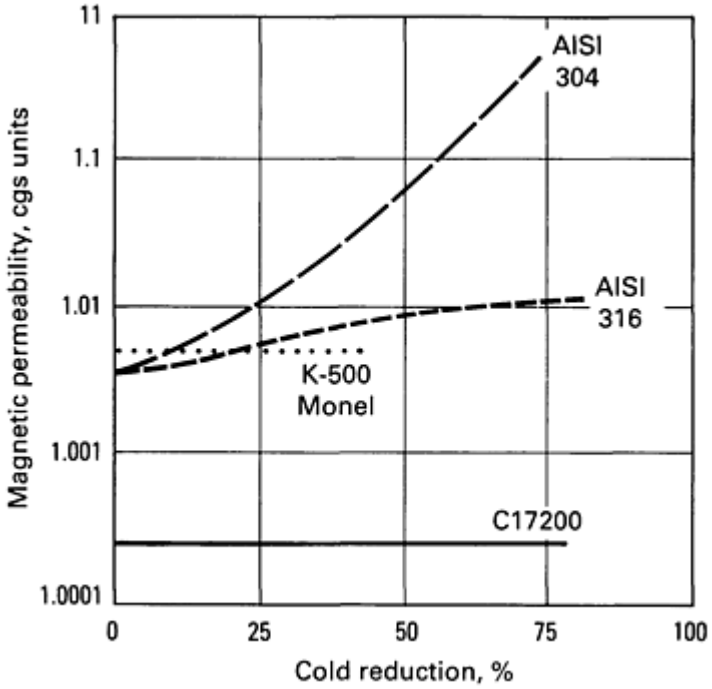

Fig. 13 Influence of cold work on the magnetic permeability of C17200 and selected other materials

Thermal and Electrical Conductivity Product and Hardness (Resistance Welding Applications). The product of electrical and thermal conductivity is a measure of the ability of an alloy to manage Joule heating in an electrical system. An alloy with a high value for this products, which is plotted in Fig. 14 for a variety of copper-base alloys, minimizes the amount of $I^2 \cdot R$ heat generated with its low electrical resistivity and distributes the heat for effective convection and radiation cooling with its high thermal conductivity.

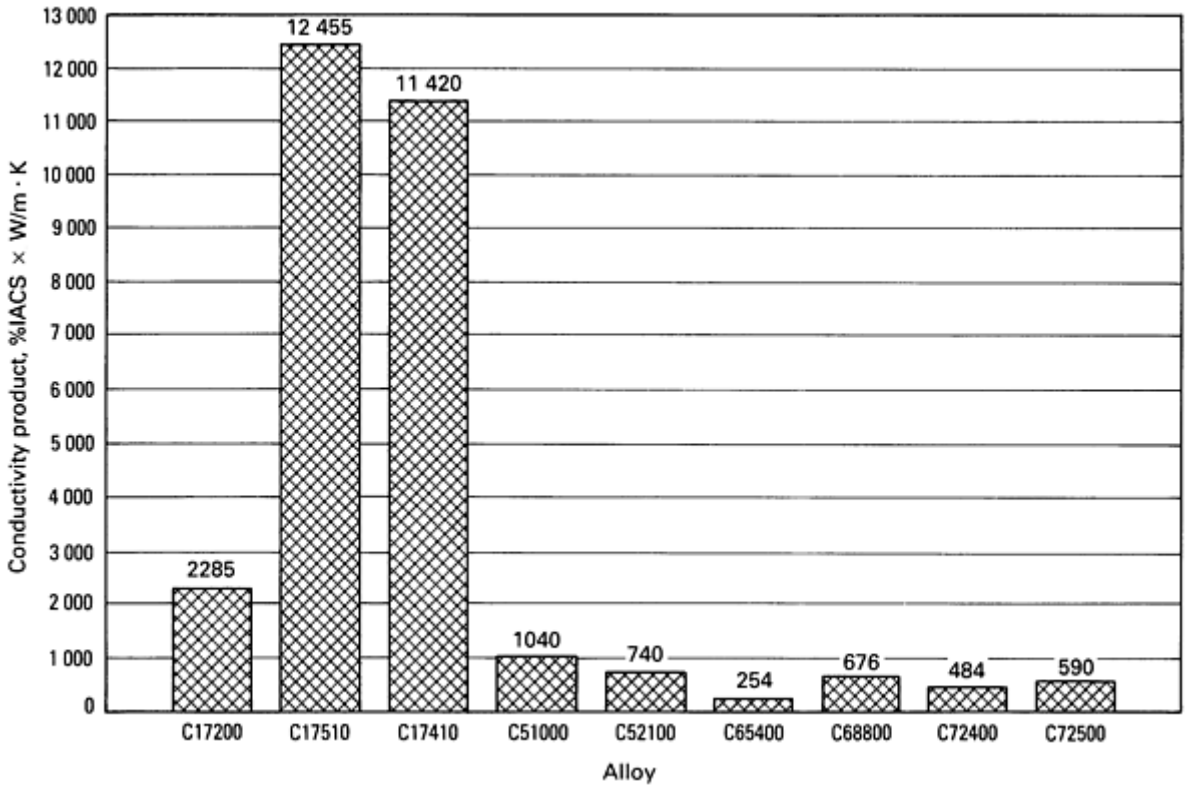

Fig. 14 Product of electrical and thermal conductivity for selected connector alloys. The product is inversely proportional to the temperature increase in a current-carrying contact beam.

An alloy with a high product of thermal and electrical conductivity provides good thermal management, but this property by itself is not enough to make the material well suited for high-productivity resistance welding applications such as in autobody steel assembly systems. These welding systems require hardness at moderately elevated temperatures to resist tooling deformation from the sheet steel clamping pressure while pulsed current is applied. A minimum room-temperature hardness of 95 HRB is required for the demands of this application, and a substantial fraction of this hardness must be retained at a temperature of 200 °C (400 °F) and above. Typical elevated-temperature strength and hardness values for beryllium-copper alloys are shown in Fig. 15.

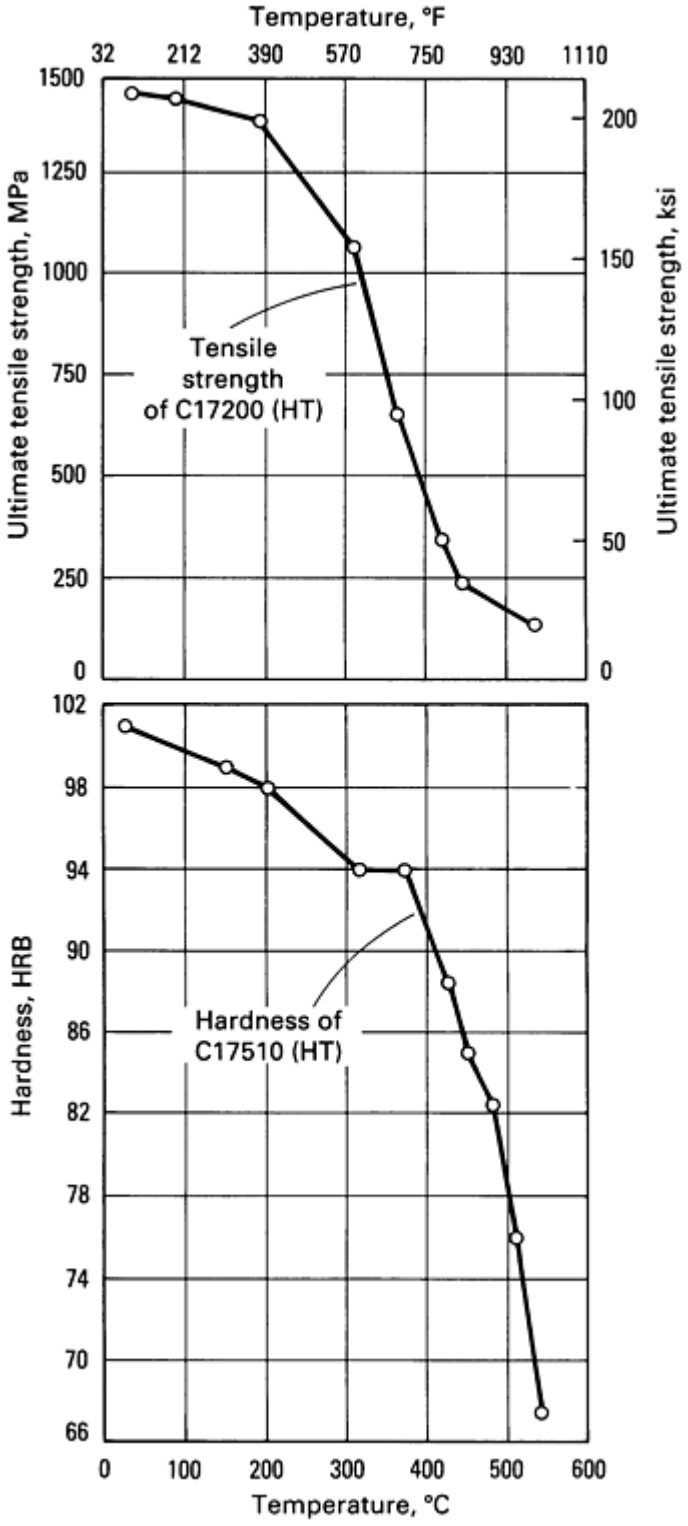

Fig. 15 Hardness of C17510 (HT) beryllium-copper and strength of C17200 (HT) beryllium-copper at elevated temperatures

Thermal Conductivity and Fatigue Strength (Injection Molding Tooling Applications). Modern plastic injection molding systems require high thermal conductivity for productivity. Tooling designers continually strive for lower cycle time by developing increasingly complex die cavities to nest as may parts as possible. The life of the tooling component is a major economic factors also, and this life is often limited by erosion or heat checking caused by thermal fatigue. Modern design techniques allow the injection molder to control the flow of the plastic resin through the management of die and insert temperatures.

Alloys C17200 and C17510 are frequently selected for mold components because they provide the thermal stress resistance required for long life as well as the thermal conductivity needed for effective heat control. Typically, wrought alloys in the hardness range from 36 to 42 HRC with a thermal conductivity equivalent to that of aluminum are specified for these applications. This grade has mechanical properties typical of alloy C17200 and is usually machined into mold components from plate or heavy-section round products. Higher thermal conductivity is available in a wrought version with a specified hardness of 90 to 102 HRB; this material has mechanical properties equivalent to those of alloy C17510.

Cast alloys have long been used for castability advantages in molding because they are able to accurately replicate intricate pattern details. The alloy most commonly used for this work is C82200, but each of the casting alloys has found application in the field of plastic molding.

Thermal and Electrical Conductivity Product at Cryogenic Temperatures and Strength (Magnetic Coil Applications). A copper solenoid or toroidal coil attached to a current source generates a magnetic field at the bore proportional to the electrical current flowing through the coil. In an air core coil the magnitude of the attainable magnetic field is not limited by a saturization magnetization as an iron core electromagnet would be. Thus it is possible to generate a very large magnetic field in the open bore of a resistive magnet. The field is limited only by the magnitude of the electric current, the heat generated in the coil turns of the magnet, and the magnetic stresses applied to the coils by the magnetic field itself. Thermal management in this type of magnet is provided by cryogenic cooling. Therefore, the thermal conductivity (Fig. 16) and the electrical conductivity at cryogenic temperatures must both be reasonably high. However, it is not sufficient to consider just the product of thermal and electrical conductivity when selecting an alloy for magnet design. A pure copper would have a very high conductivity product, but it would not perform well as a magnet because it undergoes creep deformation under the stress applied in a high-field magnet device. Many systems require a relatively high yield strength for successful operation.

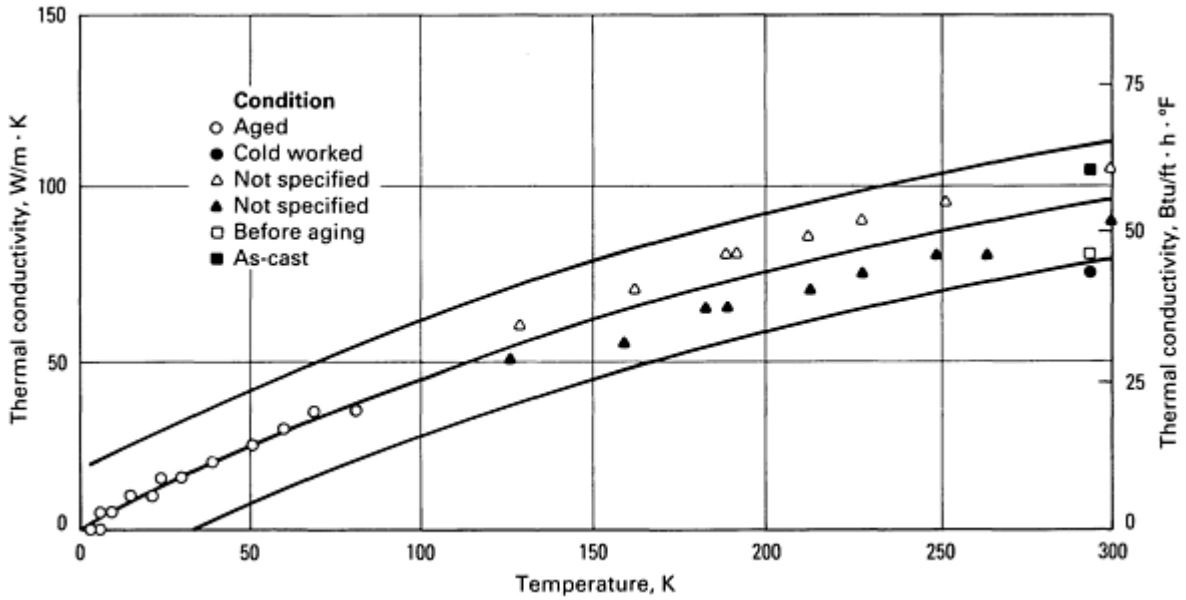

Fig. 16 Thermal conductivity of C17200 at cryogenic temperatures. Source: Ref 1

For example, alloy C17510 can be tailored for an electrical conductivity of 60% IACS minimum and a minimum yield strength of 725 MPa (105 ksi). This property combination is satisfactory for many designs, but others might benefit from higher conductivity. For these needs, it is feasible to produce a version of the same alloy with an electrical conductivity of 70% IACS and a yield strength of 510 MPa (74 ksi) or more. Magnets of this type are important in research on field effects and for development of advanced electrical power generation systems. Analytical chemistry and medical systems also can benefit from this rapidly developing technology.

Corrosion Resistance for Demanding Service. Many electronic, marine, structural, industrial, and hydrocarbon applications benefit from the combination of corrosion resistance and desirable mechanical and physical properties of beryllium-copper alloys. In electronics, for example, the shelf life of unprotected beryllium-copper strip exposed for 2

years is comparable to that of C51000 or C72500; all of these alloys retain limited solderability with an activated rosin flux. Surface inhibition with benzotriazole extends the shelf life of beryllium-copper beyond this 2-year period.

Good machinability, an ability to withstand rigorous handling, low corrosion rates, and resistance to biofouling qualify beryllium-copper for various marine applications. One such use is submarine cable repeater housings. The corrosion (penetration) rate of C17200 in seawater is nominally on the order of 0.025 to 0.050 mm per year (1 to 2 mil/year) for short-term exposure at a low-to-moderate flow velocity; the rate diminishes with longer exposure times because of the formation of corrosion products and microorganism films.

Beryllium-copper is immune to cracking in chloride and sulfide environments. In hydrogen sulfide, the alloy shows general rather than localized corrosion. For example, at 150 °C (300 °F) and a concentration of 1%, the penetration rate is less than 0.050 mm per year (2 mil/yr), and the alloy maintains structural integrity. Moisture is required for the attack of beryllium-copper and other copper alloys by halogens such as fluorine gas. Copper alloys will exhibit stress-corrosion cracking only in the combined presence of ammonia, high relative humidity, and oxygen.

Structural and industrial applications expose materials to a wide variety of atmospheric, chemical, and gaseous environments. Table 12 summarizes the corrosion behavior of beryllium-copper in various environments. Factors such as temperature, concentration, velocity, and the presence of impurities affect actual performance.

Table 12 Room-temperature corrosion properties of beryllium-copper

Type of environment	Acceptable application	Application not recommended
Atmosphere	Industrial Marine Rural	
Water	Fresh Softened Brine Sewage	
Gas (dry)	Chlorine Oxygen/ozone Carbon dioxide Sulfur dioxide Ammonia Fuel gases	Acetylene
Organic compounds	Most organic acids Alcohols Ketones Chlorinated solvents Fuels Lubricating/hydraulic oils	Pyridine
Inorganic chemicals	Nonoxidizing acids Acetic acid Hydrochloric acid Dilute sulfuric acid Phosphoric acid Aqueous solutions Chlorides Carbonates Sulfates	Ammonium hydroxide Sodium hydroxide Hydrogen peroxide Oxidizing acids/salts Chromic acid Nitric acid Ferric chloride Mercury

Plastics vary in their effect on beryllium-copper, depending on the nature of volatiles emitted. In polymer molding processes, resins cause no attack. Upon combustion, however, polyvinyl chloride and room-temperature vulcanized silicone, for example, are reported to produce fumes, that corrode copper alloys. Other plastics, such as acetal, nylon 6/6, and polytetrafluoroethylene (PTFE) do not. In addition, commercial polymers can contain flame retardants such as brominated organic compounds that attack copper alloys under some circumstances. Ionic species, particularly alkali metals, can be leached from some polymers and cause corrosion.

Production Metallurgy

Melting, Casting, and Hot Working. The first step performed by commercial manufacturers of beryllium-copper alloys is the production of a nominal copper and 4 wt% Be master alloy by the carbothermic reduction of BeO in a bath of molten copper in an arc furnace. The master alloy is remelted in coreless induction furnaces are diluted with additional copper, cobalt (or nickel), and recycled mill scrap to adjust the final composition. Melts are semicontinuously cast into rectangular or round billets for hot working into wrought product forms, or they are poured as small casting ingots for foundry use.

Semicontinously cast rectangular billets are hot rolled into plate or into coils of hot band for conversion to strip. Round billets are hot extruded into bar, seamless tube, or rod coil. As-cast billets exhibit an inverse segregation layer, rich in beryllium, that cannot be eliminated by normal thermal homogenizing treatments and must be removed mechanically. This operation is typically performed by turning round billets prior to extrusion and by slab milling hot-rolled flat products prior to intermediate cold working. The hot-working temperatures typically coincide with the solution-annealing temperatures for the respective alloys, that is, about 705 to 815 °C (1300 to 1500 °F) for the high-strength alloys and about 815 to 925 °C (1500 to 1700 °F) for the high-conductivity alloys.

Hot-worked products are softened as needed by solution annealing before further processing. Heavy-section mill products and coiled hot band or rod can be annealed by heating in car-bottom furnaces equipped with transfer racks and water quenching pits. Hot band coils also can be strand annealed. Accumulated mill scale from hot working and annealing is then removed by chemical cleaning or mechanical surface conditioning.

Cold Working and Age Hardening. Subsequent processing of wrought beryllium-copper alloys typically includes one or more cycles of cold working and intermediate solution annealing until a ready-to-finish size is reached. At the ready-to-finish size, a final solution anneal is applied that establishes the final grain size and age-hardening response of the alloy. Chemical cleaning is necessary after each anneal because, even in the best of commercial vacuums or protective atmospheres, a tenacious oxide film will form. If not removed, this oxide can cause roll wear in cold working, die wear in stamping, and poor adhesion of solder or plating layers in finished components. The high-conductivity alloys are prone to subsurface oxidation unless they are annealed in protective atmospheres. This internally oxidized surface layer lacks age-hardening response and should be suppressed with the use of a protective atmosphere or subsequently removed by chemical or mechanical cleaning.

Processing after the final anneal can include cold rolling, heat treatment to specified strength levels (mill hardening), and, for strip, slitting to specified width. Also, wrought products are treated with corrosion-inhibiting films to extend shelf life. During manufacture, mill products are monitored for stringent control of as-cast composition, nonmetallic inclusion content, intermediate and finish annealed grain size, dimensional consistency, as-shipped mechanical properties, age-hardening response, and surface condition.

Cast Products. In addition to the strengths afforded by age-hardening response, the beryllium-coppers as casting alloys display appreciable fluidity and ability to replicate very fine pattern detail. Melting and casting procedures recommended for these alloys are designed to minimize beryllium loss through oxidation and maintain the excellent castability.

The beryllium-copper casting alloys can be melted in most commercial resistance, gas, coreless induction, and arc furnaces. Coreless induction furnaces afford greater control; consequently, they reduce hydrogen pickup, beryllium loss, and dross contamination as compared with channel-type furnaces. The alloys can be air or vacuum melted. Furnace refractories suitable for melting beryllium-copper casting alloys include clay graphite, silicon carbide, alumina, magnesia, and zirconia. High-silica refractories may react with beryllium-copper melts.

Charge materials should be clean, dry, and free of contamination. Impurities derived from scrap input can affect the finished casting. Zinc, tin, phosphorus, lead, and chrome impurities can induce brittleness and loss of strength. Aluminum and iron can reduce age-hardening response and degrade electrical or thermal conductivity and corrosion resistance.

Where low magnetic permeability is desired in the finished casting, iron must be held to as low a level as possible. Silicon is normally added at the 0.20 to 0.35 wt% level to many of the high-strength beryllium-copper casting alloys, and it is added at the nominal 0.15 wt% level or below to the high-conductivity alloys to promote fluidity and control drossing. Excess silicon, however, increases brittleness.

Castings for critical applications usually employ virgin ingot. However, where acceptable, up to 50% clean scrap returns, such as gates and risers, can be added to the melt. Grain refinement is afforded by the optional addition of a small amount of titanium to C82400 through C82800 casting ingot. The increased cobalt content of C82510 also provides grain refinement.

Care must be exercised in any melting system to avoid extreme superheating, which can increase beryllium loss, drossing and gas absorption. The high affinity of beryllium for oxygen also mandates that melt agitation and melt hold times be kept to a minimum. The recommended pouring temperature range decreases with increasing beryllium content:

- C82000 and C82200, 1090 to 1180 °C (2000 to 2150 °F)
- C82400 through C82510, 1010 to 1120 °C (1850 to 2050 °F)
- C82600, 970 to 1070 °C (1775 to 1960 °F)
- C82800, 960 to 1040 °C (1760 to 1900 °F)

Drossing can be minimized by melting under an inert gas or graphite cover or by pouring the instant the pouring temperature is reached. Drosses are easily removed, but the use of a commercial fluoride-containing flux can assist the separation of dross from entrapped metal. Melts can be degassed by bubbling with dry nitrogen or argon (nominal -40 °C, or -40 °F, dew point) or with commercial solid degassers such as the PTFE plastic types.

No special pouring rate requirements exist for beryllium-copper casting alloys. Strainer cores can be a source of dross-promoting turbulence and are not recommended. Nonmetallic inclusions can be controlled, however, by the use of ceramic foam filters.

Most common casting methods suitable for copper-base alloys are applicable to beryllium-copper. These include pressure casting, investment casting, centrifugal casting, the Shaw process, die casting, and casting in permanent, ceramic, and various types of sand molds. The solidification shrinkage of beryllium-copper is similar to that of tin bronze and less than that of aluminum bronze, silicon bronze, or manganese bronze. Metal or graphite chills can be placed in sand molds to promote directional solidification and reduce shrinkage porosity.

Beryllium-Nickel Alloys

Beryllium-nickel alloys, like their beryllium-copper counterparts, are age hardenable. The alloys are distinguished by very high strength, excellent formability, and excellent resistance to fatigue, elevated temperature softening, stress relaxation, and corrosion. Wrought beryllium-nickel is available in strip, rod, and wire forms. The wrought product is used primarily as mechanical and electrical/electronic components that must exhibit good spring properties at elevated temperatures (for example, thermostats, bellows, diaphragms, burn-in connectors, and sockets).

A variety of beryllium-nickel casting alloys exhibit strengths nearly as high as those of the wrought products, and they have the advantage of excellent castability. Many of the casting alloys are used in molds and cores for glass and polymer molding, other glass-forming tools, diamond drill bit matrices, and cast turbine parts. Some casting alloys are also used in jewelry and dental applications by virtue of their high replication of detail in the investment casting process.

Compositions of the wrought and cast beryllium-nickel alloys are shown in Table 13. Only one composition is supplied in wrought form UNS N03360, which contains 1.85 to 2.05 wt% Be, 0.4 to 0.6 wt% Ti, and a balance of nickel. Commercially available beryllium-nickel casting alloys include a 6 wt% Be master alloy, a series with 2.2 to 2.6 wt% Be that includes one alloy with a minor carbon addition for enhanced machinability, and a series of ternary nickel-base alloys with up to 2.75 wt% Be and 12 wt% Cr.

Table 13 Nominal compositions of commercial beryllium-nickel alloys

Product form	Alloy	Composition, wt%			
		Be	Cr	Other	Ni
Wrought	N03360	1.85-2.05	. . .	0.4-0.6 Ti	bal[(a)]
Cast	M220C	2.0	. . .	0.5 C	bal
Cast	41C	2.75	0.5	. . .	bal[(b)]
Cast	42C	2.75	12.0	. . .	bal[(b)]

(a) 99.4 Ni + Be + Ti + Cu min, 0.25 Cu max.

(b) 0.1 C max.

(c) Master alloys with 10, 25, and 50 wt% Be are also available.

Physical Metallurgy. The metallurgy of beryllium-nickel alloys is analogous to that of the high-strength beryllium-copper alloys. The alloys are solution annealed at a temperature high in the α nickel region to dissolve a maximum amount of beryllium, then rapidly quenched to room temperature to create a supersaturated solid solution. Precipitation hardening involves heating the alloy to a temperature below the equilibrium solvus to nucleate and grow metastable beryllium-rich precipitates, which harden the matrix. In the high-strength beryllium-coppers, the equilibrium γ precipitate forms at grain boundaries only at higher age-hardening temperatures; commercial beryllium-nickel alloys, on the other hand, exhibit a degree of equilibrium grain-boundary precipitate formation at all temperatures in the age-hardening range.

Microstructure. Metallographic sample preparation of beryllium-nickel is identical to the technique used for beryllium-copper. Descriptions of the swab etchants suitable for revealing the microstructure of all tempers of wrought and cast beryllium-nickel alloys are shown in Table 14.

Table 14 Recommended etchants for beryllium-nickel alloys

Etchant	Composition	Comments
1. Nitric acid and water	30 ml HNO_3 (concentrated) and 70 ml H_2O[(a)]	Use for observation of the general structure of all tempers of beryllium-nickel. Swab etch
2. Modified Marble's etchant	4 g $CuSO_4$ (copper sulfate), 20 ml HCl (concentrated), and 20 ml H_2O[(a)]	Used for observation of the general structure of all tempers of beryllium-nickel. Swab etch. Can also be used with sensitive tint illumination to reveal the grain structure of hot-worked or annealed material
3. Nitric and acetic acids	50 ml HNO_3 (concentrated) and 50 ml glacial CH_3COOH (acetic acid), optionally diluted with 25-50 ml CH_3COCH_3 (acetone)	Used for observation of the general structure of beryllium-nickel casting alloys. Swab etch

(a) Use distilled water.

Wrought unaged beryllium-nickel microstructures exhibit nickel-beryllide intermetallic compound particles containing titanium in a nickel-rich matrix of equiaxed or deformed grains, depending on whether the alloys is in the solution-annealed or a cold-worked temper. After age hardening, a small volume fraction of equilibrium nickel-beryllium phase is generally observed at the grain boundaries. In other respects, unaged and aged beryllium-nickel microstructures are essentially indistinguishable when viewed in an optical microscope. Cast beryllium-nickel alloys containing carbon exhibit graphite nodules in a matrix of nickel-rich dendrites with an interdendritic nickel-beryllium phase. Cast chromium-containing alloys exhibit primary dendrites of nickel-chromium-beryllium solid solution and an interdendritic nickel-beryllium phase. Solution annealing cast beryllium-nickel partially spheroidizes, but does not appreciably dissolve, the interdendritic nickel-beryllium phase.

Heat treatment. Wrought UNS N03360 is typically solution annealed at about 1000 °C (1830 °F). Cold work up to about 40% can be imparted between solution annealing and aging to increase the rate and magnitude of the age-hardening response. Aging to peak strength is performed at 510 °C (950 °F) for up to 2.5 h for annealed material and for up to 1.5 h for cold-worked material. Aging response curves for hard-temper beryllium-nickel strip are presented in Fig. 17. The underaging, peak-aging, and overaging behavior of N03360 is similar to that of C17200. The cast binary alloys are solution annealed at about 1065 °C (1950 °F) and aged at 510 °C (950 °F) for 3 h. Cast ternary alloys are annealed at a temperature of approximately 1090 °C (1990 °F) and given the same aging treatment. Castings are typically used in the solution-annealed and aged (AT) temper for maximum strength. The cast plus aged (CT) temper is not employed.

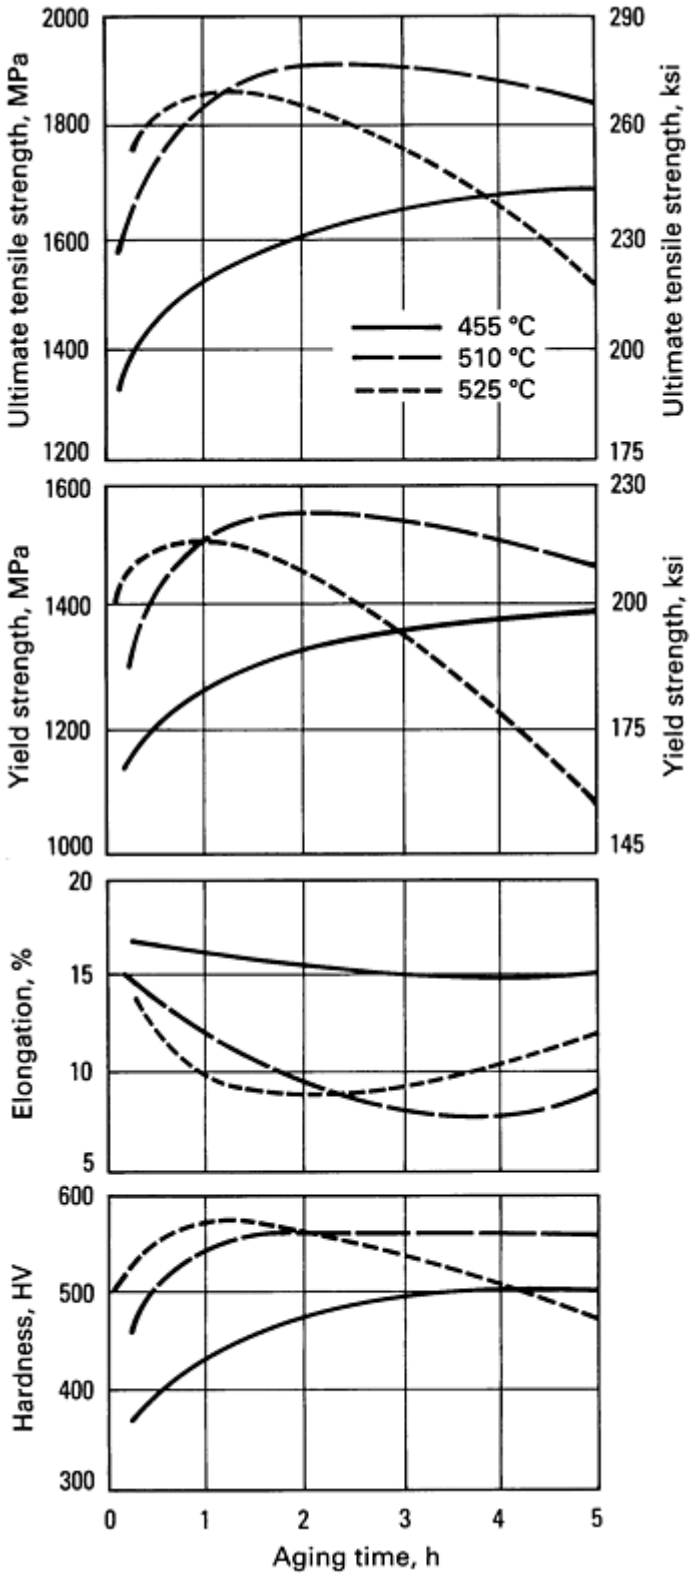

Fig. 17 Aging response curves for beryllium-nickel alloy N03360 strip

Mechanical and Physical Properties of Wrought Beryllium-Nickel. Annealed beryllium-nickel is designated the A temper, and cold worked material is designated $\frac{1}{4}$H through H temper. As with the wrought beryllium-copper alloys, increasing cold work through about a 40% reduction in area increases the rate and magnitude of the age-hardening response. Use age-hardened materials are designated the AT through HT tempers. As with the high-strength beryllium-

coppers, beryllium-nickel strip is processed by proprietary cold-working and age-hardening techniques to provide a series of ascending-strength mill-hardened tempers designated MH2 through MH12; these tempers do not require heat treatment by the user after stamping and forming.

Mechanical properties of beryllium-nickel strip and casting alloys are given in Tables 15 and 16, respectively. The ultimate tensile strengths of wrought materials range from a minimum of 1480 MPa (215 ksi) in the annealed and aged AT temper to a minimum of 1860 MPa (270 ksi) in the cold-rolled and aged HT temper. Tensile strengths of mill-hardened strip range from 1065 MPa (155 ksi) to over 1790 MPa (260 ksi). Ductility decreases with increasing strength in both the heat-treatable and age-hardened conditions. In addition to high strength in tension, beryllium-nickel strip exhibits high fatigue strength in fully reversed bending (Fig. 18). A significant fraction of room-temperature strength is maintained through short exposure to temperatures as high as 540 °C (1000 °F) (Fig. 19).

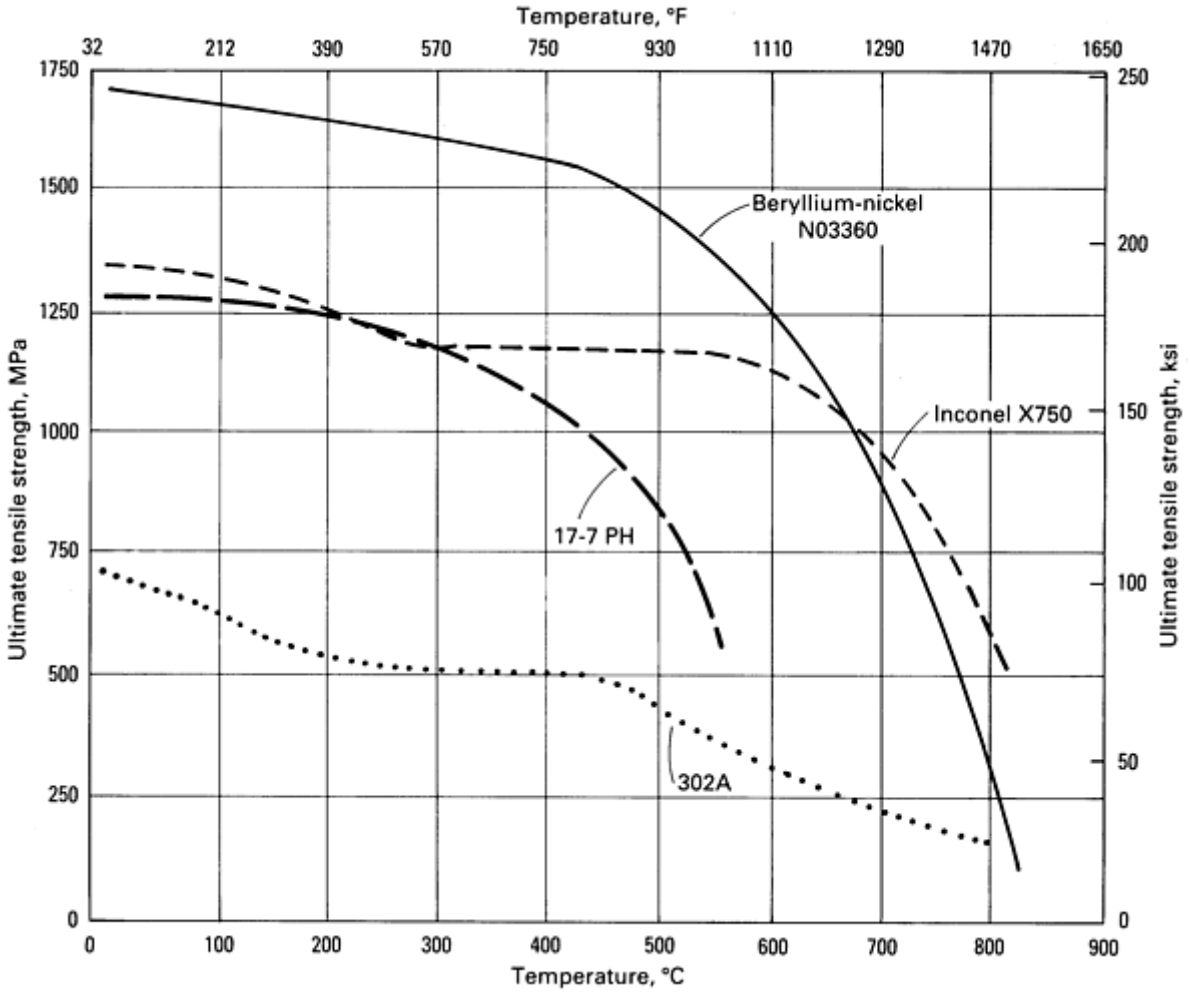

Fig. 19 Elevated-temperature strength of beryllium-nickel alloy N03360 strip compared with that of selected stainless steels

Physical and electrical properties of selected beryllium-nickel alloys are given in Table 17. Electrical conductivity is about 6% IACS in the age-hardened condition. Beryllium-nickel displays only a fraction of the conductivity of the beryllium-coppers, but its conductivity exceeds that of stainless steel.

Table 17 Typical physical and electrical properties of selected beryllium-nickel alloys

Product form	Alloy	Condition	Density, g/cm^3	Thermal expansion from 20-550 °C (70-1020 °F), 10^{-6}/°C	Thermal conductivity, W/m · K	Electrical resistivity, μΩ· cm	Electrical conductivity, %IACS	Elastic modulus

Fabrication Characteristics of Wrought Products. Beryllium-nickel strip exhibits excellent to good formability in all heat-treatable and mill-hardened tempers (Table 18). The anisotropy of formability in the unaged cold-rolled and mill-hardened tempers is less pronounced than in beryllium-copper alloys. The strength and formability combinations available in beryllium-nickel strip surpass those of the beryllium-coppers and stainless steels.

Table 18 Relative formability of beryllium-nickel alloy N03360 strip

Formability rating	**Specific formability**	**Alloy condition**		**Formability ratio (*R*/*t*) for 90° bend[a]**	
		Rolled tempers	**Mill-hardened tempers**	**Longitudinal**	**Transverse**
Excellent	Excellent formability, used for deep-drawn and severely cupped or formed parts; can be bent flat through 180° angle in any direction.	A	. . .	0	0
		$\frac{1}{4}$H	. . .	0	0
		. . .	MH2	0	0
		. . .	MH4	0.5	0.5
Very good	Very good formability, used for moderately drawn and cupped parts; formable to 90° bend around a radius.	$\frac{1}{2}$H	. . .	0.7	1.2
		. . .	MH6	1.0	1.2

		. . .	MH8	1.2	1.6
Good	Slightly reduced formability, formable to 90° bend around a radius.	H	. . .	1.2	2.0
		. . .	MH10	1.5	2.2
		. . .	MH12	2.0	3.0

(a) For strip ≤ 1.3 mm (≤ 0.050 in.) thick. Strip <0.25 mm (<0.010 in.) thick will exhibit formability somewhat better than shown. This chart should not be used for part design because punch radius, not part dimension, is used to calculate formability, and springback is not considered.

Despite the significantly greater yield strength available in mill-hardened beryllium-nickel, these beryllium-nickel tempers do not display any greater amounts of elastic springback than beryllium-copper (Fig. 6). This parity is due to the higher elastic modulus of beryllium-nickel. The total strain associated with a given bend is the sum of the plastic deformation (permanent set) and elastic springback. The elastic component of this total strain, from the stress-strain curve, is equal to the yield strength divided by elastic modulus. Consequently, for a fixed bend, different materials with comparable ratios of yield strength to elastic modulus will exhibit comparable springback. This ratio is about 0.009 for the strongest mill-hardened tempers of both beryllium-copper C17200 (TM08) and beryllium-nickel strip (MH12).

As with the high-strength beryllium-copper alloys, beryllium-nickel alloys can have their densities increased by the age-hardening process. Precipitation hardening is accompanied by lineal shrinkage of about 0.2%. Fixture heat treatment, increased preage-hardening cold work, or two-stage bending to provide more uniform through-thickness residual stress distribution can be used to reduce aging distortion in wrought products. The aging response mechanism of beryllium-nickel does not afford users the option of age hardening at temperatures above the recommended 510 °C (950 °F) peak-aging temperature to reduce distortion while preserving near-peak strength.

Beryllium-nickel strip, either heat-treatable or mill-hardened, is harder than similarly designated tempers of beryllium-copper or other copper-base alloys. Tool wear in stamping will accordingly be greater than that for the copper alloys as a class and will approximate die life associated with the stamping of stainless steel or other nickel-base alloys.

Cleaning. No special atmosphere is required for the age hardening of beryllium-nickel, but oxidation can be minimized through the use of a protective atmosphere such as nitrogen. Thin oxide films acquired during aging can be removed by one of two methods:

- Immersion for 1 h in a 70 °C (160 °F) aqueous solution of 50 vol% sulfuric acid, followed by a thorough water rinse
- Immersion for 1 to 2 min in a 54 to 77 °C (130 to 170 °F) aqueous solution of 15 vol% hydrochloric acid, 15 vol% sulfuric acid, and 75 to 110 g/L (10 to 15 oz/gal) of ferric nitrate

Heavier oxide films formed during aging can be removed by brief application of a solution of 2 parts acetic acid, 1 part nitric acid, a few drops of hydrochloric acid (for activation), and a suitable wetting agent. Precautions are necessary because this solution becomes extremely hot during use.

Joining. Wrought or cast beryllium-nickel can be satisfactorily joined to itself or to other metals by welding, brazing, or soldering. As with any other alloy, surfaces to be joined must be thoroughly cleaned to remove dirt, oil, and oxide films. Soldering is typically performed with 50Sn-50Pb alloy and a flux of 50% zinc chloride and 50% ammonium chloride. Brazing can be performed with AWS BAg-la filler metal, using a short heating cycle after solution annealing but before age hardening. Applicable welding processes include metal arc, tungsten inert-gas, and gas welding; procedures and commercial nickel alloy filler rods recommended for the joining of other nickel-base alloys should be used. These filler metals will mix with molten beryllium-nickel in the weld pool and will exhibit a limited postjoining age-hardening response. An improved aging response in the welded joints can be obtained by using beryllium-nickel filler metal.

Melting and Casting Characteristics (Foundry Products). Beryllium-nickel casting alloys are readily air melted, preferably in electric or induction furnaces. Gas- or oil-fired furnaces should use fuel with a very low sulfur content. The melt surface forms a protective beryllium oxide film, which retards beryllium loss. Additional melt surface protection can be supplied by a blanket of argon gas or an alumina-base slag cover. Furnace linings or crucibles of magnesia are preferred; Alundum, zirconium silicate, or mullite are adequate.

Charges should be clean, dry, and free of oil or grease, particularly leaded or sulfurized lubricants. Scrap additions should not exceed about 50% of the charge weight and should be free of low-melting-point film-forming elements such as antimony, arsenic, bismuth, boron, lead, lithium, selenium, sulfur, tellurium, tin, and phosphorus. Small amounts of these tramp elements render beryllium-nickel (and other nickel-base) casting alloys red short and susceptible to hot tearing during solidification. Beryllium in the composition is an effective deoxidizer and scavenger of sulfur and nitrogen. Additional deoxidation by silicon or magnesium is not usually necessary, but a small amount of titanium can be added to stabilize residual nitrogen as TiN. Degasing of melts that have absorbed hydrogen from moisture can be accomplished by bubling dry argon through the melt or by the addition of a PTFE-type solid degassing agent. A carbon boil, commonly used to degas molten nickel-base alloys, should not be used. With limited available oxygen, addition of nickel oxide to initiate a carbon boil will only deplete the beryllium content.

The pouring temperature for most of the beryllium-nickel casting alloys is about 1370 °C (2500 °F). Castings should be poured soon after this temperature is attained, with a minimum of turbulence and exposure of the pouring stream to air. Mold design should incorporate appropriate numbers, sizes, and positions of chills, risers, and exothermic or insulating sleeves. The use of these design elements will ensure progressive directional solidification and thus minimize shrinkage porosity. Sand, shell, investment, ceramic, graphite, and permanent mold materials are appropriate for these alloys. The excellent castability of beryllium-nickel alloys makes them particularly well suited for precision casting processes.

Production Metallurgy. The production process for beryllium-nickel alloys parallels that for beryllium-copper in many respects. The primary differences lie in higher processing temperatures and higher mill loads imposed by the wrought nickel-base alloy. Processing commences with induction melting in air of charges consisting of a 6Be-Ni master alloy, additive elements, and mill scrap. The 6Be-Ni master is produced by induction melting commercial-purity beryllium and nickel rather than by carbothermic reduction of BeO as for the 4Be-Cu master alloy. Casting alloys are poured as small ingots for foundry use. The wrought alloy is semicontinuously cast into rectangular or round billets for hot working into strip or round products.

Hot rolling or extrusion is performed in the vicinity of the solution-annealing temperature, about 980 °C (1800 °F). The elevated-temperature deformation resistance of beryllium-nickel is appreciably greater than that of beryllium-copper; as a result, the hot mill loads or extrusion pressures for beryllium-nickel are substantially higher than those for the copper-base alloys. The hot-worked products are then brought to a ready-to-finish size by one or more iterations of solution annealing and cold working. Chemical cleaning is required after each anneal because of the propensity of beryllium-nickel to form oxide films even in protective commercial furnace atmospheres.

A final solution anneal establishes the finished grain size and age-hardening response of the alloy. Cold working and mill hardening can follow the final anneal.

Other Beryllium-Nickel Casting Alloys. Nonprecious-metal dental alloys for precision investment cast crown and bridgework include several proprietary beryllium-containing nickel-base compositions. These alloys contain from 0.5 to 2 wt% Be and include varying amounts of chromium, molybdenum, aluminum, cobalt, and titanium, depending upon the supplier. Beryllium enhances the castability of these alloys for replication of fine detail and provides a favorable oxide film morphology on the casting surface that enhances the adhesion of porcelain enamel coatings. The overall compositions are formulated to match the thermal expansion of the porcelain enamel.

Other Beryllium-Containing Alloys

Beryllium in Aluminum Alloys. Small additions of beryllium to aluminum and magnesium systems improve casting consistency. When as little as 0.005 to 0.05 wt% Be is added to an aluminum-base alloy in the liquid state, a protective oxide film forms on the surface. This film reduces drossing, increases metal yield and cleanliness, and improves fluidity; the result is cleaner, higher-quality castings with improved surface finish, consistent strength, and improved ductility. The protective film reduces the absorption of hydrogen into the melt and thus decreases the propensity of the material for internal gas-related defects. Also, the film tends to reduce metal reaction with sand molds during casting. Preferentially

oxidizable alloy additions to aluminum, such as magnesium and sodium, also withstand composition fade because of oxidation during melting and casting. Vaporization of the base metal is also positively affected by beryllium additions.

End-use benefits imparted to aluminum alloys by beryllium include a reduction in tarnishing, an improved buffing and polishing response, and a consistent aging response, particularly in alloys containing magnesium or silicon. Applications for beryllium-containing aluminum alloys include aircraft premium castings (ASTM A 357, for example) and certain wrought age-hardenable alloys.

Beryllium in Magnesium. Magnesium systems are particularly sensitive to oxidation and are even susceptible to ignition when oxygen is readily available. Small additions of beryllium, as little as 10 ppm residual, increase the ignition temperature of magnesium by as much as 200 °C (360 °F) and can provide a safety factor during melting and casting. Fluxes accomplish similar results but can add to the system cost through increased equipment corrosion and the need for increased melt cleanliness. Beryllium is one of the few elements that is more reactive to oxygen than magnesium is, and it can be used in place of fluxes for further benefits. Beryllium is known to getter iron and similar impurities from the melt, thus providing some degree of refinement in purity where needed. As in aluminum alloys, the film-forming characteristics of beryllium reduce moisture interaction and mold reactions.

End-use benefits of adding beryllium to magnesium alloys include resistance to high-temperature oxidation and corrosion. Applications include aircraft-quality castings and automotive engine blocks.

Safe Handling of Beryllium-Containing Alloys

Beryllium-containing materials, like many other materials used in industry, can present a health risk unless precautions are employed. These alloys present a hazard only if a person who has become sensitized to beryllium inhales a sufficiently large concentration of beryllium-containing dust, mist, or fumes. Excessive inhalation of beryllium particulates can cause serious chronic pulmonary illness. Although only a small percentage of people (of the order of 1 in 100) ever become sensitized to beryllium, there is no way to identify these sensitive people in advance. As a result, everyone must be protected.

Controls. While the hazard associated with dilute beryllium alloys is not to be minimized, years of experience have shown that risks in the occupational environment can be controlled with proper ventilation and other safeguards. Care must be exercised in the processing and fabrication of these alloys to avoid inhalation of airborne particles, such as dust, mist, or fumes, in excess of the permissible exposure level.

Permissible Levels. The U.S. Occupational Safety and Health Administration (OSHA) has adopted the following in-plant permissible exposure level standards designed to keep airborne concentrations well below the levels known to cause health problems:

- Daily time-weighted average exposure over an 8-h day is not to exceed 2 μg of beryllium per cubic meter of air
- Short-term exposure above 5 but not more than 25μg of beryllium per cubic meter of air is to be limited to 30 min or less during an 8-h work period.

As demonstrated by over 40 years of documented experience, even the most sensitive person is safe if exposure is below these threshold values.

To protect the general public from environmental exposure to airborne beryllium, the U.S. Environmental Protection Agency has established an emission standard of 10 g of elemental beryllium per day as a permissible emission into the air surrounding a plant.

Nickel and Nickel Alloys

W.L. Mankins and S. Lamb, Inco Alloys International, Inc.

Introduction

NICKEL in elemental form or alloyed with other metals and materials has made significant contributions to our present-day society and promises to continue to supply materials for an even more demanding future. This article provides a historical overview of nickel, highlights alloy developments achieved to the present, and provides a discussion of the physical metallurgy of nickel alloys. Emphasis has been placed on alloys developed for corrosion-resistant applications. Alloys developed for heat-resistant applications, low-expansion alloys, electrical resistance alloys, and mechanically alloyed/dispersion-strengthened alloys are only briefly reviewed as these materials are described elsewhere in this Volume or in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook.* Nickel-base alloy castings, which like their wrought counterparts are also used extensively in corrosive-media and high-temperature applications, will not be described in the present article. Detailed information on cast alloys can be found, however, in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition of Metals Handbook and in the aforementioned Volume 1 of the *ASM Handbook.*

Changes in supply and demand in a technology-driven economy have spawned a diverse range of nickel-base alloys with various properties. Commercial nickel-base alloys, which account for approximately 13% of all nickel consumed, can be divided into groups or families by their major elemental constituents. Compositions, typical mechanical and physical properties, and applications are shown for representative alloys in each group. Other uses for nickel are:

Historical Development

Nickel has been used in alloys that date back to the dawn of civilization. Chemical analysis of artifacts has shown that weapons, tools, and coins contain nickel in varying amounts. Perhaps the earliest nickel-containing white alloy was Pai-Thong or white copper. This Chinese-made material added zinc to nickel-copper ores. Many decorative pieces such as candlesticks were produced and were ultimately brought to Europe by the East India Company in the seventeenth century (Ref 1).

Early in the eighteenth century, miners in the Saxony region of Germany tried to smelt some newly discovered copper-appearing ores, only to discover that the white metal they produced was too hard to be hammered into useful items. The miners thought the material was cursed, calling it "Old Nick's Copper" or "Kupfer-Nickel." Similar ores were discovered in the following years in other locations, and these were also called nickel because the hard, white metal resisted efforts to deform it.

A.F. Cronstedt, working for the Swedish Department of Mines, worked five years with these curious ores and was finally able to separate and identify a new element that he named nickel. Five years after the identification of elemental nickel in 1751, another Swedish scientist, Von Engestrom, found that nickel was a major component of Pai-Thong and this led to the invention of German silver or nickel-silver (Cu-Sn-Pb-Zn alloys containing 12 to 25 wt% Ni).

Use	Amount consumed, %
Stainless steel	57
Alloy steel	9.5
Nickel-base alloys	13
Copper-base alloys	2.3
Plating	10.4
Foundry	4.4
Other	3.3

Nickel plating, coinage, and nickel-silver were the main applications for the small quantity of nickel that was produced through the second half of the nineteenth century. Additional nickel was provided from Norwegian mines beginning in the mid-1800s, and significant ones were discovered in the South Pacific island of New Caledonia.

The chance finding of the huge nickel-containing ore deposits in the Sudbury district of Ontario, Canada, during the construction of the trans-Canada railroad aroused the interest of prospectors, miners, industrialists, and investors. Initially, the ores were sought for the contained copper that was in demand. The sulfide ores were found to contain nickel, copper, cobalt, iron, and precious metals (gold, silver, and the platinum-group metals).

Attempts to separate the metals were plagued with many problems. Bessemer-type converters were explored but the heavy, acrid, sulfur-dioxide-laden fumes rendered the process impractical. Researchers continued to find ways to separate the nickel from the more needed copper. The selling price for nickel was ten times that of copper, and once a separation process was perfected, there would be a glut on the market. This prompted the need for markets other than coinage, plating, and nickel-silver to be found.

While searching for an alternative material to substitute for cast iron in an ammonia refrigeration unit, inventor John Gamgee discovered nickel steel (Ref 2). This led to other nickel-iron combinations resulting in alloys for cryogenic applications and tough nickel steel armor plate. Further experimental work in America and Europe convinced governments that the nickel steel plate was superior to other known materials in resisting penetration from armor-piercing projectiles. Consequently, the demand for nickel to produce armor plate for the world's navies would exceed the supply unless improved methods for producing nickel could be found.

Early Refining Advances. The Orford Tops and Bottoms process in which sodium sulfate was added to molten nickel-copper-sulfide ores in the smelter was the solution to the problem. This process caused the nickel sulfides and the copper sulfides to separate into distinct portions when slow cooled in a mold. Nickel sulfides comprised the shiny "bottoms" while the copper sulfide "tops" remained in the upper end of the mold. A hammer blow separated the two fractions. Refinement of the two sulfide mattes using different techniques provided both high-quality nickel and copper. In the case of the nickel-containing bottoms, these were crushed, leached with sulfuric acid, dried, sintered, crushed again, fused in reverberatory furnaces with low ash coal, and cast as anodes (Ref 3). Final purification of these anodes was achieved through electrolytic refining, resulting in a pure nickel cathode sheet.

The Orford process was replaced by more efficient refining techniques in 1948. With much improved ore beneficiation processes, resulting from more efficient and effective methods of separation of the metallic ores and rock (gangue), it became more economical to process lower-grade ores. In the case of the sulfide deposits, the ore can be separated into distinct particles so that after crushing, mechanical separation is practical. Froth flotation, followed by thickening and dewatering, allowed the separation of both nickel and copper concentrates, as well as iron concentrates. Pyrometallurgical, hydrometallurgical, and vapometallurgical processes were and are still used to refine the concentrates to the elemental metal. Each of these processes is briefly described below. Refining practices vary among nickel producers. The methods selected are dictated by the composition of the ores and sources of economic energy available, as well as by technical and historical factors.

Pyrometallurgy. The concentrates are calcined in a roasting furnace, smelted in a reverberatory or other similar furnace using coal or natural gas for fuel, and blown with air in a converter. Nickel and copper concentrates are further refined to increase the purity of the metals. Nickel is refined to lower to an acceptable level those elements that would have a deleterious effect on subsequent metal performance. The elements removed include antimony, arsenic, bismuth, copper, iron, lead, phosphorus, sulfur, tin, and zinc. The major and minor impurities removed are also recovered if economically viable. Precious metals present at minute levels in sulfide ores are ultimately recovered to complete the total refining/recovery process.

Hydrometallurgy. Electrorefining and electrowinning both are electrolytic processes used to produce pure nickel cathode sheet. In the former process, a nickel electrolytic refining cell consisting of a slab of crude nickel to be refined (anode) and a thin nickel starting sheet (cathode) are immersed in an aqueous electrolyte, and direct current is passed through the cell. Nickel and some impurities are dissolved in the electrolyte (anolyte). The solution is pumped from the cell and the impurities are chemically removed. Purified electrolyte is returned to the cell as catholyte and deposited on the cathode as pure nickel. Electrowinning, also an electrolytic process, can electrolyze soluble anodes of nickel sulfide or utilize insoluble anodes to extract the nickel from a leach liquor.

Vapometallurgy. The carbonyl process uses gas-to-metal transformation to extract pure nickel from an impure nickel oxide. In this process, the oxide is reduced with hydrogen and the nickel reacts selectively with carbon monoxide to form gaseous nickel carbonyl (Ref 4). The gas is decomposed by heat to yield pure nickel. This is acknowledged as the best method of refining nickel that is available. The powder or pellet produced is of a very high purity, the process is energy efficient, and there are no polluting waste by-products.

Alloy and Market Developments. There have been a number of significant developments in nickel technology that have served to shape the present industry. A number of these are listed below. Additional information can be found in the cited references.

- The discovery in 1905 of Monel, a high tensile strength nickel-copper alloy that was found to be highly resistant to atmospheric corrosion, salt water, and various acid and alkaline solutions
- Developmental work by Marsh (Ref 5) on nickel-chromium alloys that led to the discovery of the Nimonic (Ni-Cr+Ti) series of alloys, which are primarily used for creep resistance, high strength, and stability at high temperature
- The work of Elwood Haynes on binary nickel-chromium and cobalt-chromium alloys used for

oxidation-resistant and wear-resistant applications (Ref 6)

- The work of Paul D. Merica on the use of nickel in cast irons, bronzes, and steel as well as his significant discovery that aluminum and titanium led to precipitation hardening of nickel-base alloys (Ref 7). This mechanism continues to provide the basis for material strengthening in today's superalloys
- The work of William A. Mudge on a precipitation hardening nickel-copper alloy (K-Monel)
- The establishment of the Kure Beach, and Harbor Island, NC, corrosion testing facilities by F.L. LaQue. These two facilities, established in 1935, comprise the LaQue Center for Corrosion Technology
- The addition of ferrochrome (70Cr-30Fe) to nickel to create Inconel alloys known for their high strength at high temperatures, oxidation resistance, and carburization resistance
- Developmental work during the 1920s of nickel-molybdenum alloys that led to the discovery of the Hastelloy series of alloys, known for their high corrosion resistance
- Further advances in high-temperature alloys used for aircraft applications led to the development of Nimonic alloy 80 and Nimonic alloy 80A during the 1940s (Ref 8)
- The development of the turbo-supercharger for aircraft engines, which operated at temperatures ranging from 650 to 815 °C (1200 to 1500 °F) as the rotor turned at speeds of 20,000 to 30,000 rpm, led to improved precipitation-hardened alloys Hastelloy alloy B and Hastelloy alloy X
- The production of the first gas turbine engine led to developments in new alloys for blades, vanes, and disks with improved creep and fatigue resistance
- The introduction of a new family of Fe-Ni-Cr alloys (Incoloy series) based on a lower nickel content (20 to 40 wt%) designed to meet the need for high-temperature oxidation resistance and aqueous corrosion protection
- Advances in powder metallurgy (P/M) processing that led to the development of mechanically alloyed dispersion-strengthened superalloys
- New melting technologies (vacuum induction melting, electron beam melting, plasma melting/refining and vacuum arc skull melting) in concert with net shape investment casting led to the development of fine grained equiaxed castings as well as directionally solidified and single-crystal superalloys (Ref 9, 10)

Physical Metallurgy of Nickel and Nickel Alloys

Nickel is a versatile element and will alloy with most metals. Complete solid solubility exists between nickel and copper. Wide solubility ranges between iron, chromium, and nickel make possible many alloy combinations. The face-centered cubic structure of the nickel matrix (γ) can be strengthened by solid-solution hardening, carbide precipitation, or precipitation hardening. An overview of each of these hardening mechanisms as they apply to wrought alloys, follows.

Cast alloy physical metallurgy is described in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook* (see Ref 9 and 10). Detailed reviews on the metallurgy and microstructures of wrought nickel alloys can be found elsewhere in the *ASM Handbook* series (see Ref 11 and 12).

Solid-Solution Hardening. Cobalt, iron, chromium, molybdenum, tungsten, vanadium, titanium, and aluminum are all solid-solution hardeners in nickel. The elements differ with nickel in atomic diameter from 1 to 13%. Lattice expansion related to atomic diameter oversize can be related to the hardening observed (Ref 13 and 14). Above 0.6 T_m (melting temperature), which is the range of high-temperature creep, strengthening is diffusion dependent and large slow diffusing elements such as molybdenum and tungsten are the most effective hardeners (Ref 15).

Carbide Strengthening. Nickel is not a carbide former. Carbon reacts with other elements alloyed with nickel to form carbides that can be either a bane or a blessing to the designer of alloys. An understanding of the carbide class and its morphology is beneficial to the alloy designer.

The carbides most frequently found in nickel-base alloys are MC, M_6C, M_7C_3, and $M_{23}C_6$ (where M is the metallic carbide-forming element or elements). MC is usually a large blocky carbide, random in distribution, and generally not desired. M_6C carbides are also blocky; formed in grain boundaries they can be used to control grain size, or precipitated in a Widmanstätten pattern throughout the grain these carbides can impair ductility and rupture life. M_7C_3 carbides (predominately Cr_7C_3) form intergranularly and are beneficial if precipitated as discrete particles. They can cause embrittlement if they agglomerate, forming continuous grain-boundary films. This condition will occur over an extended period of time at high temperatures. $M_{23}C_6$ carbides show a propensity for grain-boundary precipitation. The $M_{23}C_6$ carbides are influential in determining the mechanical properties of nickel-base alloys. Discrete grain-boundary particles enhance rupture properties. Long time exposure at 760 to 980 °C (1400 to 1800 °F) will cause precipitation of angular intragranular carbides as well as particles along twin bands and twin ends.

Heat treatment provides the alloy designer with a means of creating desired carbide structures and morphologies before placing the material in service. The alloy chemistry, its prior processing history, and the heat treatment given to the material influence carbide precipitation and ultimately performance of the alloy. Each new alloy must be thoroughly examined to determine its response to heat treatment or high temperature.

Precipitation Hardening. The precipitation of γ', $Ni_3(Al,Ti)$ in a high-nickel matrix provides significant strengthening to the material. This unique intermetallic phase has a face-centered cubic structure similar to that of the matrix and a lattice constant having 1% or less mismatch in the lattice constant with the γ matrix (Ref 15). This close matching allows low surface energy and long time stability.

Precipitation of the γ' from the supersaturated matrix yields an increase in strength with increasing precipitation temperature, up to the overaging or coarsening temperature. Strengthening of alloys by γ' precipitation is a function of γ' particle size. The hardness of the alloy increases with particle size growth, which is a function of temperature and time. Several factors contribute to the magnitude of the hardening, but a discussion of the individual factors is beyond the scope of this paper.

The volume percent of γ' precipitated is also important because high-temperature strength increases with amount of the phase present. The amount of gamma prime formed is a function of the hardener content of the alloy. Aluminum, titanium, niobium, and tantalum are strong γ' formers. Effective strengthening by γ' decreases above about 0.6 T_m as the particles coarsen. To retard coarsening, the alloy designer can add elements to increase the volume percent of γ' or add high-partitioning, slow-diffusing elements such as niobium or tantalum to form the desired precipitate.

The γ' phase can transform to other (Ni_3X) precipitates if the alloy is supersaturated in titanium, niobium, or tantalum. Titanium-rich metastable γ' can transform to (Ni_3Ti), or eta phase (η), a hexagonal close-packed phase. Formation of η-phase can alter mechanical properties, and effects of the phase must be determined on an individual alloy basis. Excess niobium results in metastable ηtransforming to γ" (body-centered tetragonal phase) and ultimately to the equilibrium phase Ni_3Nb (orthorhombic phase). Both γ' and γ" can be present at peak hardness, whereas transformation to the coarse, elongated Ni_3Nb (orthorhombic) results in a decrease in hardness. The phases precipitated are functions of alloy chemistry and the heat treatment given the material prior to service or the temperature/time exposure of in-service application.

Table 1 summarizes the effects of adding various elements to nickel-base and iron-base superalloys. Table 2 provides additional detail on the various phases precipitated in wrought heat-resistant alloys.

Table 1 Role of elements in iron-base and nickel-base superalloys

Effect	**Iron base**	**Nickel base**
Solid-solution strengtheners	Cr, Mo	Co, Cr, Fe, Mo, W, Ta
Fcc matrix stabilizers	C, W, Ni	. . .
Carbide form MC type	Ti	W, Ta, Ti, Mo, Nb
M_7C_3 type	. . .	Cr
$M_{23}C_6$ type	Cr	Cr, Mo, W
M_6C type	Mo	Mo, W
Carbonitrides M(CN) type	C, N	C, N
Forms γ' Ni_3 (Al,Ti)	Al, Ni, Ti	Al, Ti
Retards formation of hexagonal η(Ni_3Ti)	Al, Zr	. . .
Raises solvus temperature of γ'	. . .	Co
Hardening precipitates and/or intermetallics	Al, Ti, Nb	Al, Ti, Nb
Forms γ'' (Ni_3Nb)	. . .	Nb
Oxidation resistance	Cr	Al, Cr
Improves hot corrosion resistance	La, Y	La, Th
Sulfidation resistance	Cr	Cr
Increases rupture ductility	B	B[(a)], Zr
Causes grain-boundary segregation	. . .	B, C, Zr
Facilitates working	. . .	. . .

(a) If present in large amounts, borides are formed.

Table 2 Constituents observed in wrought heat-resistant alloys

Phase	Crystal structure	Lattice parameter, mm	Formula	Comments
γ'	fcc (ordered $L1_2$)	0.3561 for pure Ni_3Al to	Ni_3Al	Principal strengthening phase in many nickel- and nickel-iron-base superalloys; crystal lattice varies slightly in size (0-0.5%) from that of austenite matrix; shape varies from spherical to cubic; size varies with exposure time and temperature
		0.3568 for $Ni_3(Al_{0.5}Ti_{0.5})$	$Ni_3(Al,Ti)$	
η	hcp ($D0_{24}$)	a_0 = 0.5093	Ni_3Ti (no solubility for other elements)	Found in iron-, cobalt-, and nickel-base superalloys with high titanium/aluminum ratios after extended exposure; may form intergranularly in a cellular form or intragranularly as acicular platelets in a Widmanstätten pattern
		c_0 = 0.8276		
γ''	bct (ordered $D0_{22}$)	a_0 = 0.3624	Ni_3Nb	Principal strengthening phase in Inconel 718; γ'' precipitates are coherent disk-shaped particles that form on the {100} planes (average diameter approximately 60 nm, thickness approximately 5-9 nm); metastable phase
		c_0 = 0.7406		
Ni_3Nb (δ)	Orthorhombic (ordered Cu_3Ti)	a_0 = 0.5106-0.511	Ni_3Nb	Observed in overaged Inconel 718; has an acicular shape when formed between 815 and 980 °C (1500 and 1800 °F); forms by cellular reaction at low aging temperatures and by intragranular precipitation at high aging temperatures
		b_0 = 0.421-0.4251		
		c_0 = 0.452-0.4556		
MC	Cubic	a_0 = 0.430-0.470	TiC	Titanium carbide has some solubility for nitrogen, zirconium, and molybdenum; composition is variable; appears as globular, irregularly shaped particles that are gray to lavender; M elements can be titanium, tantalum, niobium, hafnium, thorium,or zirconium
			NbC	
			HfC	
$M_{23}C_6$	fcc	a_0 = 1.050-1.070 (varies with composition)	$Cr_{23}C_6$ $(Cr,Fe,W,Mo)_{23}C_6$	Form of precipitation is important; it can precipitate as films, globules, platelets, lamellae, and cells; usually forms at grain boundaries; M element is usually chromium, but nickel-cobalt, iron, molybdenum, and tungsten can substitute
M_6C	fcc	a_0 = 1.085-1.175	Fe_3Mo_3C	Randomly distributed carbide; may appear pinkish; M elements are generally molybdenum or tungsten; there is some solubility for chromium, nickel-niobium, tantalum, and cobalt
			Fe_3W_3C-Fe_4W_2C	

			Fe_3Nb_3C	
			Nb_3Co_3C	
			Ta_3Co_3C	
			Cr_7C_3	
M_7C_3	Hexagonal	a_0 = 1.398		Generally observed as a blocky intergranular shape; observed only in alloys such as Nimonic 80A after exposure above 1000 °C (1830 °F), and in some cobalt-base alloys
		c_0 = 0.4523		
M_3B_2	Tetragonal	a_0 = 0.560-0.620	Ta_3B_2	Observed in iron-nickel- and nickel-base alloys with about 0.03% B or greater; borides appear similar to carbides, but are not attacked by preferential carbide etchants; M elements can be molybdenum, tantalum, niobium, nickel, iron, or vanadium
		c_0 = 0.300-0.330	V_3B_2	
			Nb_3B_2 $(Mo,Ti,Cr,Ni,Fe)_3B_2$	
			Mo_2FeB_2	
MN	Cubic	a_0 = 0.4240	TiN (Ti,Nb,Zr)N (Ti,Nb,Zr) (C,N)	Nitrides are observed in alloys containing titanium, niobium, or zirconium; they are insoluble at temperatures below the melting point; easily recognized as-polished, having square to rectangular shapes and ranging from yellow to orange
			ZrN	
			NbN	
μ	Rhombohedral	a_0 = 0.475	Co_7W_6 $(Fe,Co)_7(Mo,W)_6$	Generally observed in alloys with high levels of molybdenum or tungsten; appears as coarse, irregular Widmanstätten platelets; forms at high temperatures
		c_0 = 2.577		
Laves	Hexagonal	a_0 = 0.475-0.495	Fe_2Nb	Most common in iron-base and cobalt-base superalloys; usually appears as irregularly shaped globules, often elongated, or as platelets after extended high-temperature exposure
		c_0 = 0.770-0.815	Fe_2Ti	
			Fe_2Mo	
			Co_2Ta	
			Co_2Ti	

σ	Tetragonal	a_0 = 0.880-0.910	FeCr	Most often observed in iron- and cobalt-base superalloys, less commonly in nickel-base alloys; appears as irregularly shaped globules, often elongated; forms after extended exposure between 540 and 980 °C (1005 and 1795 °F)
		c_0 = 0.450-0.480	FeCrMo	
			CrFeMoNi	
			CrCo	
			CrNiMo

Applications and Characteristics of Nickel Alloys

Nickel and nickel alloys are used for a wide variety of applications, the majority of which involve corrosion resistance and/or heat resistance. Some of these include:

- *Aircraft gas turbines:* disks, combustion chambers, bolts, casings, shafts, exhaust systems, cases, blades, vanes, burner cans, afterburners, thrust reversers (Ref 9, 10, and 12)
- *Steam turbine power plants:* bolts, blades, stack gas reheaters (Ref 16)
- *Reciprocating engines:* turbochargers, exhaust valves, hot plugs, valve seat inserts
- *Metal processing:* hot-work tools and dies (Ref 17)
- *Medical applications:* dentistry uses (Ref 18), prosthetic devices (Ref 19)
- *Space vehicles:* aerodynamically heated skins, rocket engine parts (Ref 20)
- *Heat-treating equipment:* trays, fixtures, conveyor belts, baskets, fans, furnace mufflers (Ref 21)
- *Nuclear power systems:* control rod drive mechanisms, valve stems, springs, ducting (Ref 22)
- *Chemical and petrochemical industries:* bolts, fans, valves, reaction vessels, piping, pumps (Ref 23, 24, and 25)
- *Pollution control equipment:* scrubbers, flue gas desulfurization equipment (liners, fans, stack gas reheaters, ducting) (Ref 16, 26)
- *Metals processing mills:* ovens, afterburners, exhaust fans
- *Coal gasification and liquefaction systems:* heat exchangers, reheaters, piping

- *Pulp and paper mills:* tubing, doctor blades, bleaching circuit equipment, scrubbers (Ref 27)

A number of other applications for nickel alloys involve the unique physical properties of special-purpose nickel-base or high-nickel alloys. These include:

- Low-expansion alloys
- Electrical resistance alloys
- Soft magnetic alloys
- Shape memory alloys

Each of these special-purpose alloys, which are briefly discussed below, are also described in separate articles elsewhere in this Handbook.

Heat-Resistant Applications

Nickel-base alloys are used in many applications where they are subjected to harsh environments at high temperatures. Nickel-chromium alloys or alloys that contain more than about 15% Cr are used to provide both oxidation and carburization resistance at temperatures exceeding 760 °C (1400 °F). The chromium in the alloys promotes the formation of a protective surface oxide, and the nickel provides good retention of the protective coating, especially during cyclic exposure to high temperatures.

In atmospheres that are oxidizing to chromium but reducing to nickel, nickel-chromium alloys may be subject to internal oxidation. The addition of iron to these alloys greatly reduces the susceptibility to internal oxidation.

Increasing the nickel content provides good resistance to carburizing environments. High nickel contents in nickel-chromium-iron alloys also improve resistance to nitriding. In addition, the high percentage of nickel improves resistance to thermal fatigue and maintains an austenitic structure so the alloy remains ductile.

Sulfidation resistance at high temperatures is enhanced in nickel-base alloys with the addition of chromium. While the addition of chromium is beneficial to properties at high temperatures, it also makes the alloys more difficult to produce. More detailed information on the high-temperature properties of nickel-base alloys can be found in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*(see Ref 9, 10, and 12) and in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Corrosion Resistance

This section will briefly review the types of corrosion resulting from exposure of nickel alloys to aqueous environments. More detailed information can be found in Ref 28 and in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

General Corrosion. Nickel-base alloys offer excellent corrosion resistance to a wide range of corrosive media. However, as with all types of corrosion, many factors influence the rate of attack. The corrosive media itself is the most important factor governing corrosion of a particular metal. Acidity, temperature, concentration, motion relative to metal surface, degree of oxidizing power and aeration, and presence or absence of inhibitors or accelerators should always be considered. Most of these factors interact, and often this interaction is very complex. For instance, sulfuric acid is generally considered a reducing acid, but in high concentrations the acid becomes oxidizing and this shift usually overshadows other factors in the corrosion behavior of the acid.

As a general rule, increases in temperature increase reaction rates, but increasing temperature also tends to drive dissolved gases out of solution so that a reaction that requires dissolved oxygen can often be slowed down by heating.

Chemical Pitting. Although pitting can arise from various causes, certain chemicals--mainly halide salts and particularly chlorides--are recognized as well-known pit producers. The passive metals are particularly susceptible to

pitting in chloride environments, especially oxidizing chlorides such as ferric, cupric, and mercuric chloride. It seems that the chloride ions accumulate at anodic areas and either penetrate or dissolve the passive film at these points. Since the chloride corrosion product is hydrolyzed to hydrochloric acid, the acidity at the anode increases as more chloride migrates to the anode, and the corrosion rate increases with time. Self-accelerating reactions of this kind are described as autocatalytic reactions.

The effect of molybdenum added to nickel-containing alloys offers higher degrees of nobility and resistance to these chloride types of attack. Figure 1 shows these effects on the corrosion resistance of various alloys.

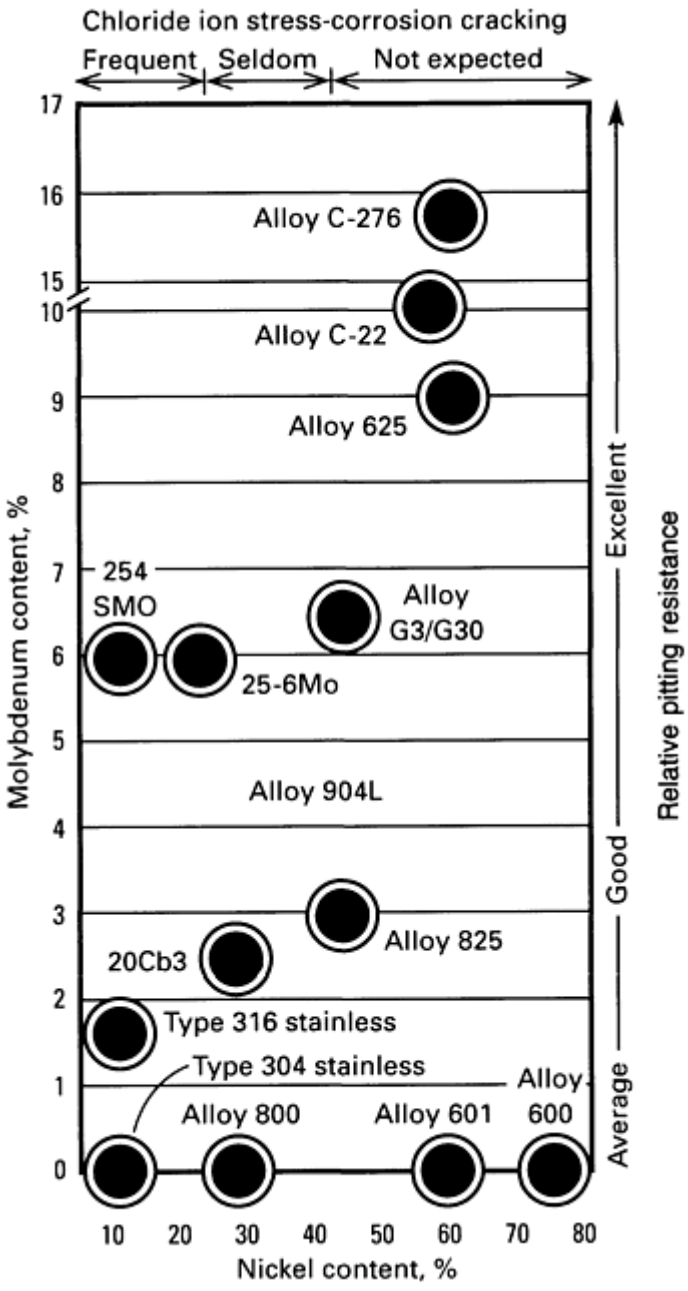

Fig. 1 Effect of molybdenum and nickel contents on the corrosion resistance of selected commercial alloys

Intergranular Corrosion. The austenitic stainless steels containing ~8 to 40 wt% Ni comprise a class of materials in which this form of attack is most common. It is usually caused by an improper heat treatment or heat from welding that causes the precipitation of certain alloy components at the grain boundary. Chromium combines with carbon in solution to form a chromium carbide. This precipitation causes a depletion of corrosion-resisting elements in the area surrounding the grain boundary, and this area becomes anodic to the remainder of the grain.

This condition occurs when these alloys are held at temperatures between 425 and 760 °C (800 and 1400 °F). The depleted chromium region becomes sensitized to the corrosive environment resulting in attack at this point. The condition is known as sensitization.

There are three methods of combating intergranular corrosion in cases where susceptible materials must be heated in the sensitizing range. The first method is to reheat the metal to a temperature high enough to redissolve the precipitated phase and then to cool it quickly enough to maintain this phase in solution. The second method, called stabilization, is to add certain elements such as niobium, tantalum, and titanium in order to make use of their ability to combine more readily than chromium with carbon. In this way, chromium is not depleted and the metal retains its corrosion resistance. This technique is used in redesigning austenitic stainless and nickel-base alloys to suitably resist various acidic aqueous environments. The third is to restrict the amount of one of the constituents of the precipitate--usually carbon, for example, 316L stainless steel--and to thereby reduce the extent of the precipitation and resulting alloy depletion.

Corrosion Fatigue. Metals that fail as a result of being alternately or cyclicly stressed are said to fatigue. Failure is by transgranular cracking and is usually only a single crack. (High-temperature fatigue is intergranular, since above the equicohesive temperature, grain boundaries are weaker than the grains.) Endurance limit and fatigue strength are measures of a metal's ability to withstand cyclic stressing in air.

Fatigue data determined in air are useless as design criteria for a part to be placed in service in a corrosive environment. When the metal is cyclicly stressed in corrosive environments, the joint action of corrosion and fatigue greatly intensifies the damage. Cracking is again transgranular, but there are usually multiple cracks and they quite often begin at the base of

a corrosion pit. Unfortunately, corrosion fatigue data for environments other than water or sea water are almost totally lacking.

The most important consideration in selecting a metal for resistance to corrosion fatigue is the resistance of the metal to the corrosive environment. One of the major characteristics of the nickel-base alloys is that the higher the nickel content, the better the corrosion fatigue resistance.

Stress-Corrosion Cracking (SCC). In contrast to corrosion fatigue, which will occur in any corrosive media, stress-corrosion cracking requires a specific combination of alloy and environment. Austenitic stainless steels that contain surface tensile stresses, either locked in during fabrication or externally applied, may fail by transgranular cracking in *chloride* solutions. Similarly, Alloy 400 that is in a stressed condition may fail by intergranular cracking when exposed in *mercury* or *mercury salts.* The following table lists some of the common alloy systems and the specific media in which they are subject to this attack:

Alloy	**Environment**	**Cracking**
Aluminum-magnesium	Cl^-	Intergranular
Brass	NH_4^+	Intergranular
Steel	NO_3^-, OH^-	Intergranular
300 series stainless steel	Cl^-, OH	Transgranular (can be intergranular if sensitized)
Alloy 400	Hg, Hg^+, chromic acid, aerated hydrofluoric acid vapor	Intergranular and transgranular
Alloy 600	Fused caustic	Intergranular
Nickel 200, 201	Hg, Hg_2^+, molten metals	Intergranular

Since stress-corrosion cracking requires three simultaneous factors--surface tensile stress, alloy, and environment--the alteration or elimination of any one of them can prevent this attack. Where it is possible, the alteration of the environment or the choice of a different alloys is the best solution. Elimination of stress is usually attempted through heat treatment, but it is often difficult or impossible to completely eliminate stresses on complex fabricated equipment, and the procedure is always costly.

The most common form of stress-corrosion cracking is that involving chloride and halide ions, which may be present in a wide variety of water and process streams. Standard ASTM tests have been established to evaluate the sensitivity of nickel alloys to cracking under these types of conditions, using boiling magnesium chloride solutions, U-bend tests, and slow strain tensile tests (Ref 29). Iron-chromium-nickel alloys with nickel contents greater than 50% are immune to cracking in boiling 42% magnesium chloride (Fig. 2). However, SCC of nickel and high-nickel alloys has been experienced in high-temperature caustic soda and caustic potash solutions and in molten caustic.

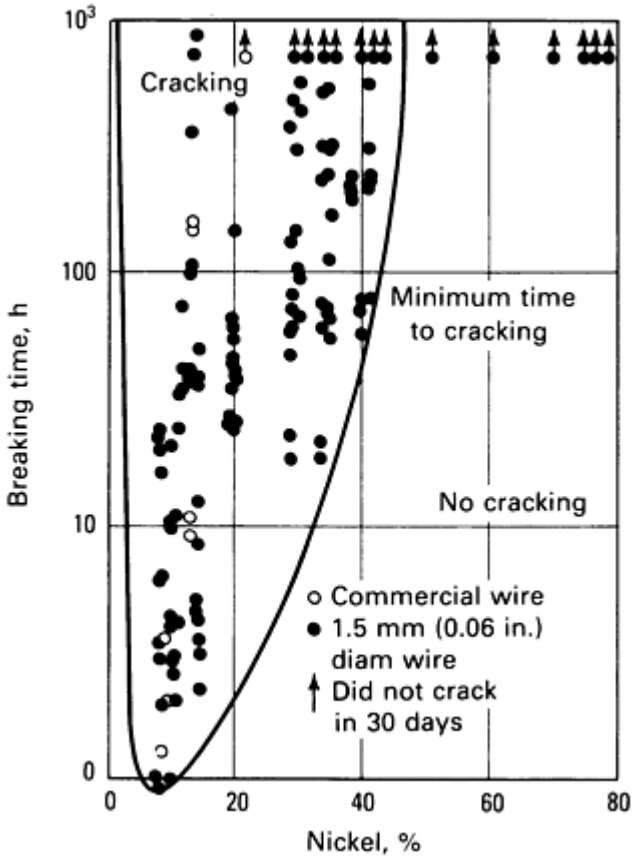

Fig. 2 Effect of nickel additions to a 17 to 24% Cr steel on resistance to SCC in boiling 42% magnesium chloride. 1.5 mm (0.06 in.) diam wire specimens deadweight loaded to 228 or 310 MPa (33 or 45 ksi) Source: Ref 30

Cracking of some nickel-base alloys has also occurred under special conditions in fluosilicic acid, hydrofluoric acid, mercuric salt solutions, and high-temperature water and steam that are contaminated with trace amounts of oxygen, lead, fluorides, or chlorides. Sensitized alloys are susceptible to SCC in sulfur compounds such as sodium sulfite, sodium thiosulfate, and polythionic acids (Ref 29).

Low-Expansion Alloys

French physicist C.E. Guillaume discovered in 1896 that alloys of nickel-iron had low thermal expansion characteristics. Nickel was found to have a profound effect on the thermal expansion of iron. Alloys can be designed to have a very low thermal expansion or display uniform and predictable expansion over certain temperature ranges.

Iron-36% Ni alloy (Invar) has the lowest expansion of the Fe-Ni alloys and maintains nearly constant dimensions during normal variations in atmospheric temperature, as shown in Fig. 3. Higher nickel results in greater thermal expansion, which allows for specific expansion rates to be selected by adjusting the nickel content. It can be seen in Fig. 4 that uniform expansion is exhibited up to the inflection point, which also increases with nickel content. Nickel-iron alloys are ferromagnetic at room temperature, and their inflection point is closely associated with the Curie temperature.

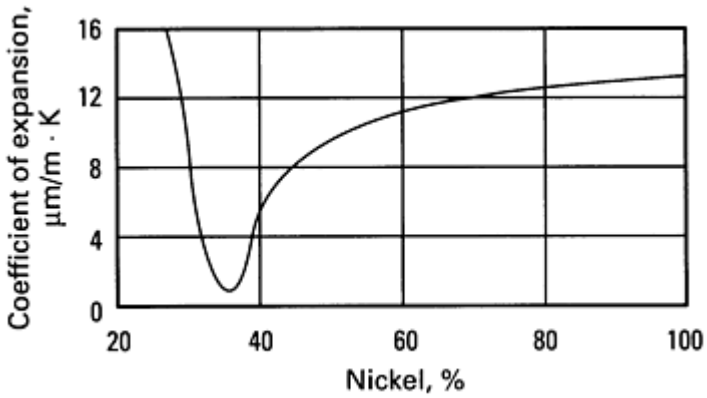

Fig. 3 Coefficient of linear expansion at 20 °C (68 °F) versus nickel content for iron-nickel alloys containing 0.4% Mn and 0.1% C

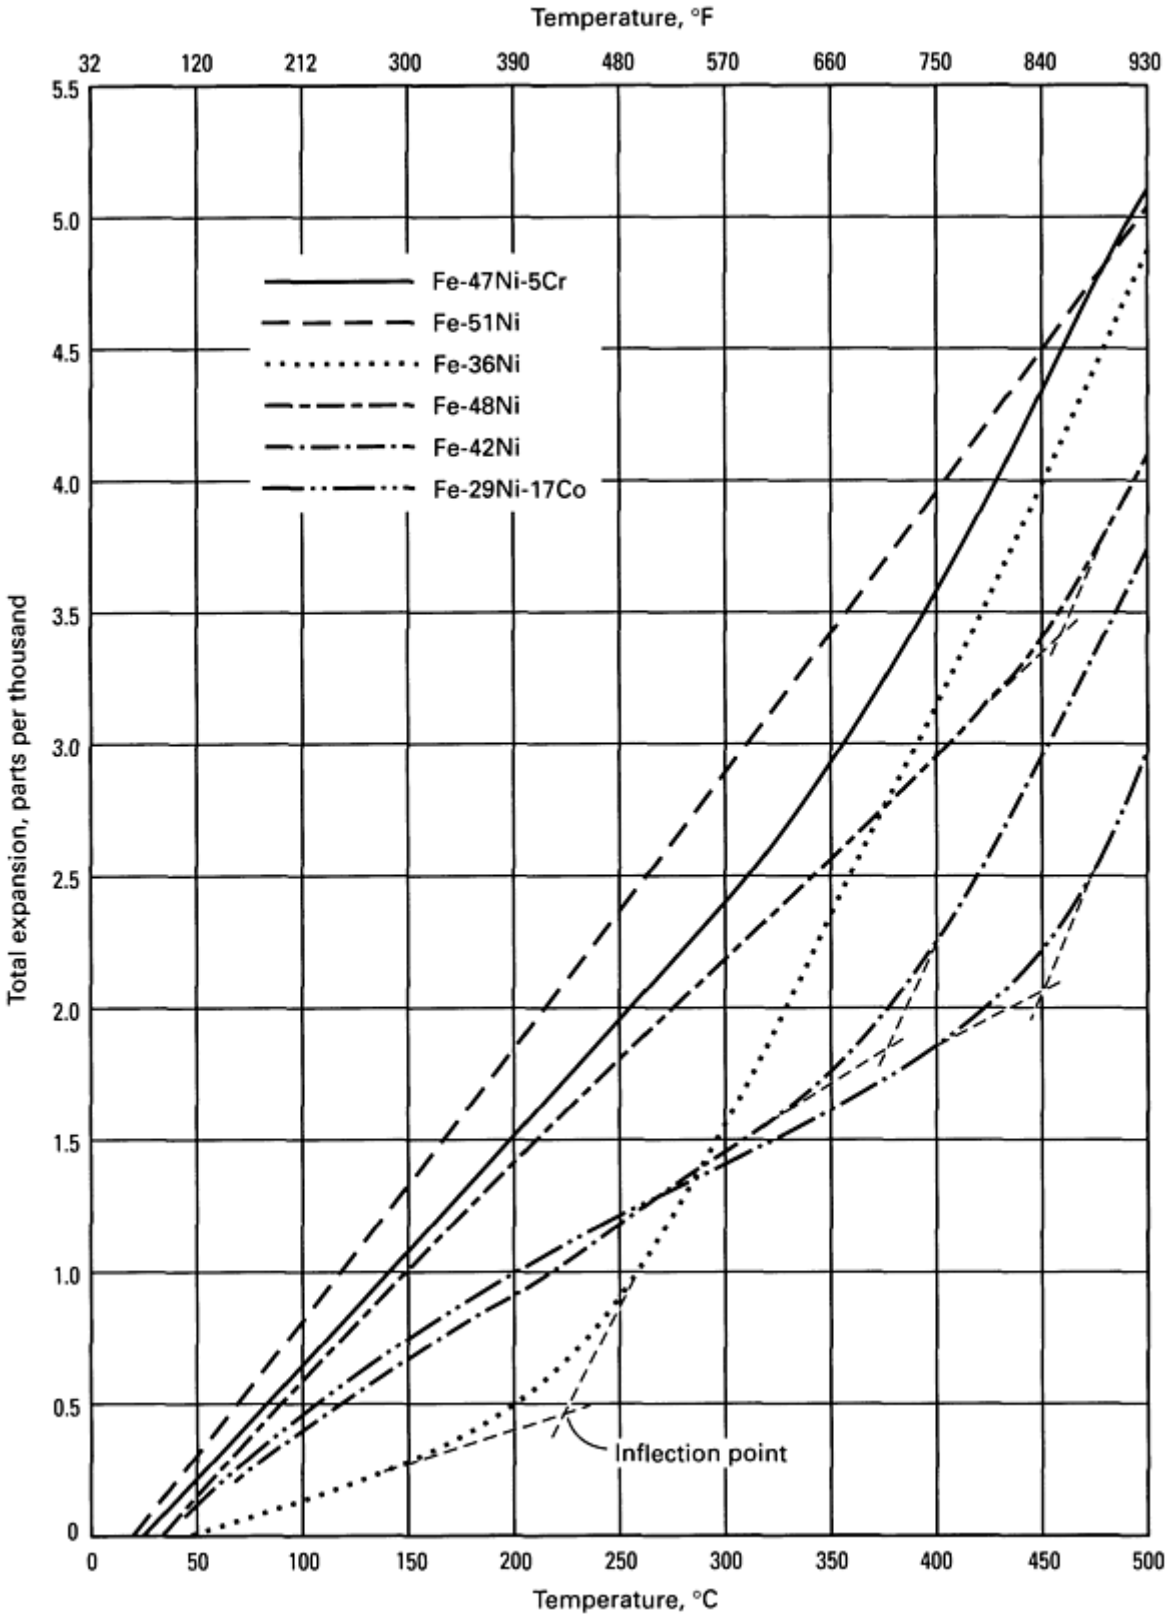

Fig. 4 Total thermal expansion of iron-nickel alloys showing the effect of third elements

The addition of cobalt to the nickel-iron matrix produces alloys with a low coefficient of expansion, a constant modulus of elasticity, and high strength. The alloys can also be strengthened by precipitation-hardening heat treatments made possible by the addition of niobium and titanium. Additional information on low-expansion alloys can be found later in

this article (see the following section on Commercial Nickel and Nickel Alloys) and in the article "Low-Expansion Alloys" in this Volume.

Electrical Resistance Alloys

Several alloy systems based on nickel or containing high nickel contents are used in instruments and control equipment to measure and regulate electrical characteristics (resistance alloys) or are used in furnaces and appliances to generate heat (heating alloys).

The primary requirements for resistance alloys are uniform resistivity, stable resistance (no time-dependent aging effects), reproducible temperature coefficient of resistance, and low thermoelectrical potential versus copper. Properties of secondary importance are coefficient of expansion, mechanical strength, ductility, corrosion resistance, and the ability to be joined to other metals by welding, brazing, or soldering.

Types of resistance alloys containing nickel include:

- Cu-Ni alloys containing 2 to 45% Ni
- Ni-Cr-Al alloys containing 35 to 95% Ni
- Ni-Cr-Fe alloys containing 35 to 60% Ni
- Ni-Cr-Si alloys containing 70 to 80% Ni

The primary requirements of materials used for heating elements are high melting point, high electrical resistivity, reproducible temperature coefficient of resistance, good oxidation resistance in furnace environments, absence of volatile components, and resistance to contamination. Other desirable properties are good elevated-temperature creep strength, high emissivity, low thermal expansion and low modulus (both of which help minimize thermal fatigue), good resistance to thermal shock, and good strength and ductility at fabrication temperatures.

Types of resistance heating alloys containing nickel include:

- Ni-Cr alloys containing 65 to 80% Ni with 1.5% Si
- Ni-Cr-Fe alloys containing 35 to 70% Ni with 1.5% Si + 1% Nb

Additional information on electrical resistance alloys can be found later in this article (see the following section on Commercial Nickel and Nickel Alloys) and in the article "Electrical Resistance Alloys" in this Volume.

Soft Magnetic Alloys

Two broad classes of magnetically soft materials have been developed in the Fe-Ni system. The high-nickel alloys (about 79% Ni with 4 to 5% Mo; bal Fe) have high initial permeability and low saturation induction. The low-nickel alloys (about 50% Ni) are lower in initial permeability but higher in saturation induction (see the article "Magnetically Soft Materials" in this Volume for specific property data). Additional information on these alloys can also be found later in this article (see the following section on Commercial Nickel and Nickel Alloys).

Shape Memory Alloys

Metallic materials that demonstrate the ability to return to their previously defined shape when subjected to the appropriate heating schedule are referred to as shape memory alloys. Nickel-titanium alloys (50Ni-50Ti) are one of the few commercially important shape memory alloys. The physical metallurgy, properties, and applications of equiatomic NiTi alloys are described in the article "Shape Memory Alloys" in this Volume.

Commercial Nickel and Nickel Alloys

The commercial forms of nickel and nickel-base alloys are fully austenitic and are used/selected mainly for their resistance to high temperature and aqueous corrosion. From a tariff definition, these are alloys where nickel is in the predominance. From a nomenclature perspective, they are alloys which contain greater than 30% Ni in their content.

Figure 5 categorizes these alloys by nickel content, while relating the alloys to the more common austenitic stainless steels. All of these materials are characterized by having 15 to 23% Cr and, therefore, can be ranked by nickel content. The austenitic steels, thus, are iron-chromium-nickel alloys (ranking elements by declining predominance). Any nickel-chromium-iron containing alloys can therefore be identified and related by family to one another and their general corrosion characteristics identified. Omitted from Fig. 5 is the Ni-Cu (Monel) series of alloys.

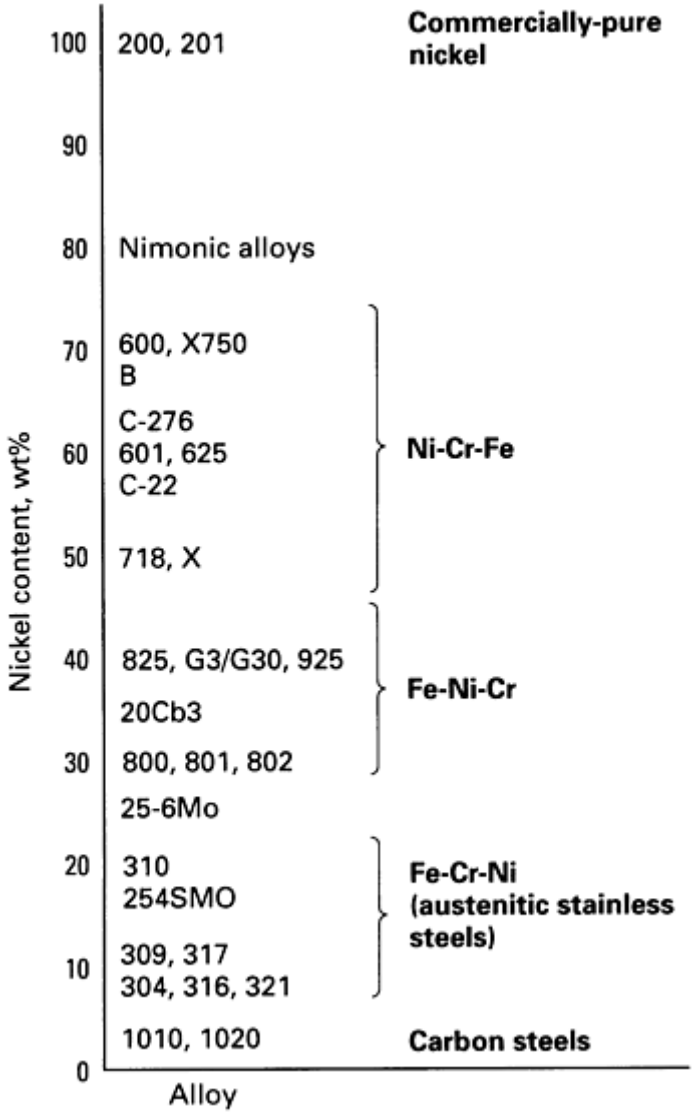

Fig. 5 Nickel-base alloy chart showing alloys containing varying amounts of nickel and iron. Chromium contents are constant at approximately 18 to 20%.

Maximum suggested operating temperatures for each of the characterized groupings are as follows:

- Fe-Cr-Ni 1050 °C (1920 °F)
- Fe-Ni-Cr 1150 °C (2100 °F)
- Ni-Cr-Fe 1200 °C (2200 °F)

Variations exist for each of these series to enhance their corrosion characteristics or their mechanical properties. Hence, molybdenum and nitrogen may be added to this series of alloys to improve their resistance to pitting and crevice corrosion; chromium additions improve sulfidation resistance; aluminum, titanium, and niobium allow strengthening through precipitation hardening (age hardening). But in all cases, the nickel content allows improvements in fatigue strength and high-temperature performance, especially in reducing environments such as those involving carburization and nitriding.

Figure 6 compares the corrosion characteristics of several nickel-base alloys using the Materials Technology Institute (MTI) test procedure, which involves the use of 6% ferric chloride solution for determining the relative resistance of alloy to crevice corrosion in oxidizing chloride environments (Ref 31). This method proposes alloy rankings on the merits of

increased critical crevice temperature. As shown in Fig. 6, increased molybdenum content is the major contributor to crevice corrosion resistance in aggressive chloride-containing environments.

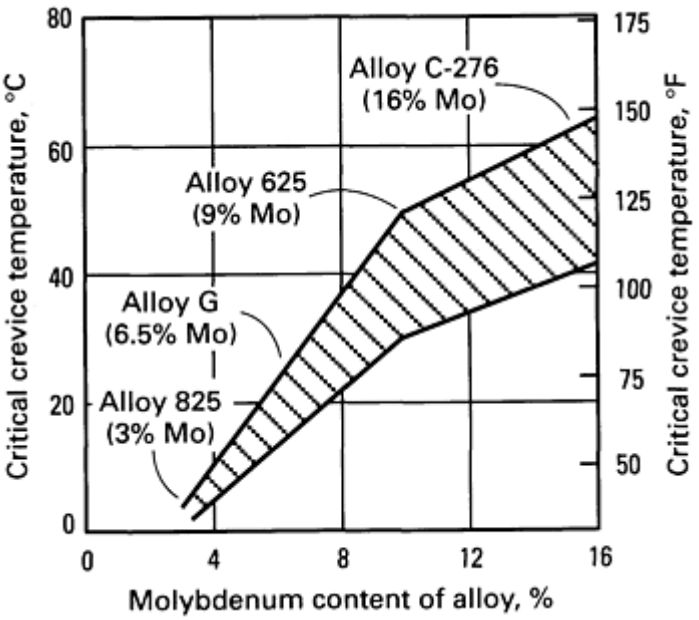

Fig. 6 Molybdenum content versus critical crevice temperature range for several nickel-base alloys. The range of critical crevice temperatures was obtained by varying test procedure.

Hastelloys Alloy B-2, which contains 27% Mo, offers the best resistance to hot hydrochloric acid environments of any of the nickel-base alloys. Selection of the other molybdenum-containing alloys will depend upon the operating conditions and severity of the environment in question.

Table 3 provides a general perspective of corrosion resistance for the groups of alloys. Generally, the higher the nickel in an alloy, the greater is its inherent resistance to reducing environment, both acid and alkali. By contrast, the austenitic stainless steels (Fe-Cr-Ni alloys) rely on oxygen or oxidizing conditions to assist in maintaining a protective oxide film for their corrosion resistance. Breakdown of these films makes them susceptible to pitting and crevice corrosion attack. The transition group of alloys offers degrees of resistance to both oxidizing and reducing conditions. These alloys generally contain varying amounts of molybdenum in their content, and they offer a broad range of resistance to these mixed environments.

Table 3 General corrosion resistance of nickel-base alloys

Alloy series	Applications	Aqueous environments[(a)]
Nickel 200; Alloys 400, 600	Good general fabricable alloys for vessels and pipelines handling complex chemical derivatives from petrochemical (organic) feedstock	Reducing
Alloys C-276, 625, G3/G30, C-22/622, 825	Molybdenum-containing alloys for pitting and crevice corrosion resistance	Neutral, reducing, oxidizing
Alloys 800, 904L; type 304, 316, 317 stainless steels	Alloys commonly used in food processing, pulp and paper industries, and chemical transportation	Oxidizing

(a) Reducing environments; caustic soda (NaOH), hydrochloric acid, sulfuric acid (dilute solutions), hydrofluoric acid; hydrochloric acid requires high-molybdenum alloys. Neutral environments: organic acid salts (NaCl, bisulfates). Oxidizing environments: sulfuric acid (concentrated), phosphoric acid, nitric acid; nitric acid requires high-chromium alloys.

Figures 7 and 8 show the high-temperature performance and capabilities for the nickel-base alloys. The higher the nickel content, the better the resistance. In Fig. 7, the nickel-chromium-iron alloys exhibit excellent oxidation resistance. This characteristic is most desired in alloys specified for aerospace jet engine applications and for thermal processing requirements. Alloy 230 with tungsten additions (Ni-22Cr-14W-2Mo-3Fe-5Co) combines excellent high-temperature strength with outstanding resistance to oxidizing environments up to 1150 °C (2100 °F). Nickel-chromium-iron alloys also exhibit excellent carburization resistance (Fig. 8).

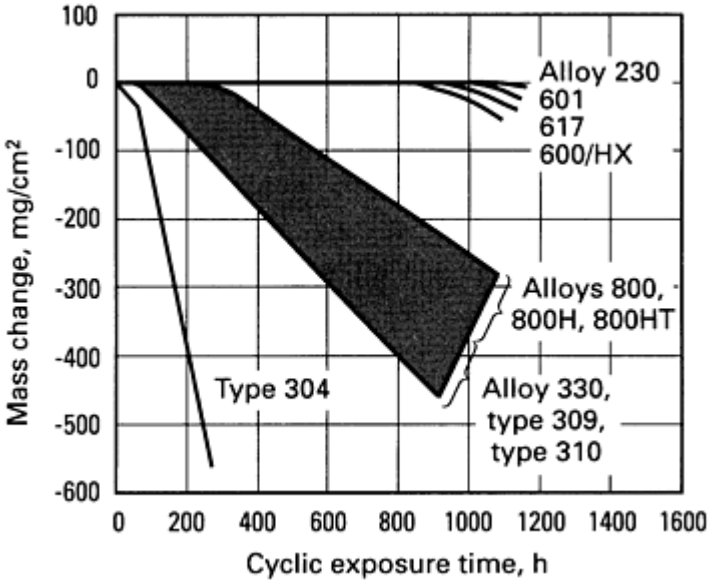

Fig. 7 Cyclic oxidation resistance at 1095 °C (2000 °F). Each cycle consisted of 15 min heating followed by 5 min of cooling in air.

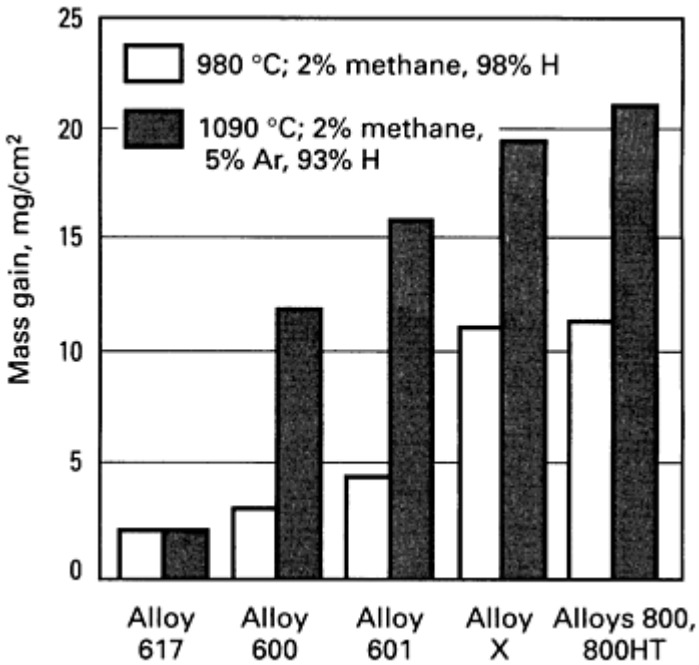

Fig. 8 Resistance to gas carburization at 980 and 1090 °C (1800 and 2000 °F). Test duration, 100 h

Summaries of wrought nickel-base alloy compositions, typical properties, and applications are provided in Tables 4, 5, and 6.

	MPa	**ksi**	**MPa**	**ksi**		**GPa**	**10^6 psi**		
Commercially pure and low-alloy nickels									
Nickel 200	462	67	148	21.5	47	204	29.6	109 HB	Commercially pure wrought nickel with good mechanical properties and excellent resistance to many corrosives. Nickel 201 has low carbon (0.02% max) for applications over 315 °C (600 °F). Used for food processing equipment, chemicalshipping drums, caustic handling equipment and piping, electronic parts, aerospace and missile components, rocket motor cases, and magnetostrictive devices
Nickel 201	403	58.5	103	15	50	207	30	129 HB	
Nickel 205	345	50	90	13	45	. . .	. . .	. . .	Wrought nickel similar to Nickel 200 but with compositional adjustments to enhance performance in electrical and electronic applications. Used for the anodes and grids of electronic valves, magnetostrictive transducers, lead wires, transistor housings, and battery cases

Nickel 211	530	77	240	35	40	. . .	. . .	. . .	Nickel-manganese alloy that is slightly harder than Nickel 200. The manganese addition provides resistance to sulfur compounds at elevated temperatures. Used as fuses in light bulbs, as grids in vacuum tubes, and in assemblies where sulfur is present in heating flames
Nickel 212	483	70	. . .	. . .	. . .	. . .	. . .	. . .	Wrought nickel strengthened with an addition of manganese. Used for electrical and electronic applications such as lead wires, supporting components in lamps and cathode ray tubes, and electrodes in glow-discharge lamps
Nickel 222	380	55	. . .	. . .	. . .	. . .	. . .	. . .	Wrought nickel with an addition of magnesium for electronic applications. The magnesium provides activation for cathodes of thermionic devices. Used for sleeves of indirectly heated oxide-coated cathodes
Nickel 270	345	50	110	16	50	. . .	. . .	30 HRB	A high-purity grade of nickel made by powder metallurgy. It has a low base hardness and high ductility. Its extreme purity is useful for components of hydrogen thyratrons. Also used for electrical resistance thermometers
Duranickel 301 (precipitation hardened)	1170	170	862	125	25	207	30	30-40 HRC	Nickel-aluminum-titanium alloy used for applications that require the corrosion resistance of commercially pure nickel but with greater strength or spring properties. These applications include diaphragms, springs, clips, press components for extrusion of plastics, and molds for production of glass articles
Nickel-copper alloys									
Alloy 400	550	80	240	35	40	180	26	110-150 HB	A nickel-copper alloy with high strength and excellent corrosion resistance in a range of media, including seawater, hydrofluoric acid, sulfuric acid, and alkalies. Used for marine engineering, chemical and hydrocarbon processing equipment, valves, pumps, shafts, fittings, fasteners, and heat exchangers
Alloy 401	440	64	134	19.5	51	. . .	. . .	. . .	A copper-nickel alloy designed for specialized electrical and electronic applications. It has a very low temperature coefficient of resistance and medium-range electrical resistivity. Used for wire-wound precision resistors and bimetal contacts
Alloy R-405	550	80	240	35	40	180	26	110-140	The free-machining version of Alloy 400. A controlled amount of sulfur is added to the

								HB	alloy to provide sulfide inclusions that act as chip breakers during machining. Used for meter and valve parts, fasteners, and screw machine products
Alloy 450	385	56	165	24	46	. . .	. . .	. . .	A copper-nickel alloy of the 70-30 type having superior weldability. It is resistant to corrosion and biofouling in seawater, has good fatigue strength, and has relatively high thermal conductivity. Used for seawater condensers, condenser plates, distiller tubes, evaporator and heat exchanger tubes, and saltwater piping
Alloy K-500 (precipitation hardened)	1100	160	790	115	20	180	26	300 HB	A precipitation-hardenable nickel-copper alloy that combines the corrosion resistance of Alloy 400 with greater strength and hardness. It also has low permeability and is nonmagnetic to under -100 °C (-150 °F). Used for pump shafts, oil well tools and instruments, doctor blades and scrapers, springs, valve trim, fasteners, and marine propeller shafts
Nickel-chromium and nickel-chromium-iron alloys									
Alloy 230[(a)]	860	125	390	57	47.7	211	30.6	92.5 HRB	Nickel-chromium-tungsten alloy that combines excellent high-temperature strength with resistance to oxidizing environments up to 1150 °C (2100 °F) and resistance to nitriding environments. Used for aerospace gas turbine components, chemical processing equipment, and heat-treating equipment
Alloy 600	655	95	310	45	40	207	30	75 HRB	A nickel-chromium alloy with good oxidation resistance at high temperatures and resistance to chloride ion stress-corrosion cracking, corrosion by high-purity water, and caustic corrosion. Used for furnace components, in chemical and food processing, in nuclear engineering, and for sparking electrodes
Alloy 601	620	90	275	40	45	207	30	65-80 HRB	A nickel-chromium alloy with an addition of aluminum for outstanding resistance to oxidation and other forms of high-temperature corrosion. It also high mechanical properties at elevated temperatures. Used for industrial furnaces; heat-treating equipment such as baskets, muffles, and retorts; petrochemical and other process equipment; and gas turbine components
Alloy 617 (solution annealed)	755	110	350	51	58	211	30.6	173 HB	A nickel-chromium-cobalt-molybdenum alloy with an exceptional combination of metallurgical stability, strength, and oxidation resistance at high temperatures.

									Resistance to oxidation is enhanced by an aluminum addition. The alloy also resists a wide range of corrosive aqueous environments. Used in gas turbines for combustion cans, ducting, and transition liners; for petrochemical processing; for heat-treating equipment; and in nitric acid production
Alloy 625	930	135	517	75	42.5	207	30	190 HB	A nickel-chromium-molybdenum alloy with an addition of niobium that acts with the molybdenum to stiffen the alloy's matrix and thereby provide high strength without a strengthening heat treatment. The alloy resists a wide range of severely corrosive environments and is especially resistant to pitting and crevice corrosion. Used in chemical processing, aerospace and marine engineering, pollution-control equipment, and nuclear reactors
Alloy 690	725	105	348	50.5	41	211	30.6	88 HRB	A high-chromium-nickel alloy with excellent resistance to many aqueous media and high-temperature atmospheres. Used for various applications involving nitric or nitric/hydrofluoric acid solutions. Also useful for high-temperature service in gases containing sulfur
Alloy 718 (precipitation hardened)	1240	180	1036	150	12	211	30.6	36 HRC	A precipitation-hardenable nickel-chromium alloy containing significant amounts of iron, niobium, and molybdenum along with lesser amounts of aluminum and titanium. It combines corrosion resistance and high strength with outstanding weldability, including resistance to postweld cracking. The alloy has excellent creep-rupture strength at temperatures up to 700 °C (1300 °F). Used in gas turbines, rocket motors, spacecraft, nuclear reactors, pumps, and tooling
Alloy X750 (precipitation hardened)	1137	165	690	100	20	207	30	330 HB	A nickel-chromium alloy similar to Alloy 600 but made precipitation hardenable by additions of aluminum and titanium. The alloy has good resistance to corrosion and oxidation along with high tensile and creep-rupture properties at temperatures up to about 700 °C (1300 °F). Its excellent relaxation resistance is useful for high-temperature springs and bolts. Used in gas turbines, rocket engines, nuclear reactors, pressure vessels, tooling, and aircraft structures
Alloy 751 (precipitation hardened)	1310	190	976	141.5	22.5	214	31	352 HB	A nickel-chromium alloy similar to Alloy X750 but with increased aluminum content for greater precipitation hardening. Designed for use as exhaust valves in internal-combustion engines. In that application, the alloy offers high strength at operating temperatures, high hot hardness

									for wear resistance, and corrosion resistance in hot exhaust gases containing lead oxide, sulfur, bromine, and chlorine
Alloy MA 754	965	140	585	85	22	. . .	. . .	. . .	A mechanically alloyed nickel-chromium alloy with oxide dispersion strengthening. The strength, corrosion resistance, and microstructural stability of the alloy make it useful for gas turbine vanes and other extreme-service applications.
Alloy C-22	785	114	372	54	62	. . .	. . .	209 HB	A nickel-chromium-molybdenum alloy with outstanding resistance to pitting, crevice corrosion, and stress-corrosion cracking. Also exhibits high resistance to oxidizing media, including wet chlorine and mixtures containing nitric and oxidizing acids. Used for pollution control and pulp and paper equipment
Alloy C-276	790	115	355	52	61	205	29.8	90 HRB	A nickel-molybdenum-chromium alloy with an addition of tungsten having excellent corrosion resistance in a wide range of severe environments. The high molybdenum content makes the alloy especially resistant to pitting and crevice corrosion. The low carbon content minimizes carbide precipitation during welding to maintain corrosion resistance in as-welded structures. Used in pollution control, chemical processing, pulp and paper production, and waste treatment
Alloy G3	690	100	320	47	50	199	28.9	79 HRB	A nickel-chromium-iron alloy with additions of molybdenum and copper. It has good weldability and resistance to intergranular corrosion in the welded condition. The low carbon content helps prevent sensitization and consequent intergranular corrosion of weld heat-affected zones. Used for flue gas scrubbers and for handling phosphoric and sulfuric acids
Alloy HX (solution annealed)	793	115	358	52	45.5	205	29.7	90 HRB	A nickel-chromium-iron-molybdenum alloy with outstanding strength and oxidation resistance at temperatures up to 1200 °C (2200 °F). Matrix stiffening provided by the molybdenum content results in high strength in a solid-solution alloy having good fabrication characteristics. Used in gas turbines, industrial furnaces, heat-treating equipment, and nuclear engineering
Alloy S (solution annealed)	835	121	445	64.5	49	212	30.8	52 HRA	High-temperature alloy with excellent thermal stability, low thermal expansion, and oxidation resistance to 1095 °C (2000 °F). Retains strength and ductility after aging at temperatures of 425 to 870 °C (800 to 1600 °F). Developed for applications involving severely cyclical heating

									conditions. Used extensively as seal rings in gas turbine engines
Alloy W (solution annealed)	850	123	370	53.5	55	. . .	. . .	. . .	A solid-solution-strengthened alloy that was developed primarily for the welding of dissimilar alloys. It is available as straight cut-length wire for gas tungsten arc welding, layer-wound wire for gas metal arc welding, and coated electrodes for shielded metal arc welding. It has also been produced in the form of sheet and plate for structural applications up to 760 °C (1400 °F).
Alloy X (solution annealed)	785	114	360	52.5	43	196	28.5	89 HRB	A nickel-chromium-iron-molybdenum alloy that possesses an exceptional combination of oxidation resistance, fabricability, and high-temperature strength. It has also been found to be exceptionally resistant to stress-corrosion cracking in petrochemical applications. Exhibits good ductility after prolonged exposure at temperatures of 650, 760, and 870 °C (1200, 1400, and 1600 °F) for 16,000 h
Iron-nickel-chromium alloys									
Alloy 556	815	118.1	410	59.5	47.7	205	29.7	91 HB	An iron-nickel-chromium-cobalt alloy that combines effective resistance to sulfidizing, carburizing, and chlorine-bearing environments at high temperatures with good oxidation resistance, good fabricability, and excellent high-temperature strength. It has also been found to resist corrosion by molten salts and is resistant to corrosion from molten zinc. Used for waste incinerator, chemical process, and pulp and paper mill equipment
Alloy 800	600	87	295	43	44	193	28	138 HB	An iron-nickel-chromium alloy with good strength and excellent resistance to oxidation and carburization in high-temperature atmospheres. It also resists corrosion by many aqueous environments. The alloy maintains a stable, austenitic structure during prolonged exposure to high temperatures. Used for process piping, heat exchangers, carburizing equipment, heating-element sheathing, and nuclear steam-generator tubing
Alloy 800HT	See Alloy 800.								An iron-nickel-chromium alloy having the same basic composition as Alloy 800 but with significantly higher creep-rupture strength. The higher strength results from close control of the carbon, aluminum, and titanium contents in conjunction with a high-temperature anneal. Used in chemical and petroleum processing, in power plants for superheater and reheater tubing, in industrial furnaces, and for heat treating

									equipment.
Alloy 825	690	100	310	45	45	206	29.8	. . .	An iron-nickel-chromium alloy with additions of molybdenum and copper. It has excellent resistance to both reducing and oxidizing acids, to stress-corrosion cracking, and to localized attack such as pitting and crevice corrosion. The alloy is especially resistant to sulfuric and phosphoric acids. Used for chemical processing, pollution-control equipment, oil and gas well piping, nuclear fuel reprocessing, acid production, and pickling equipment
Alloy 925 [(b)]	1210	176	815	118	24	. . .	. . .	36.5 HRC	A precipitation-hardenable iron-nickel-chromium alloy with additions of molybdenum and copper. The alloy has outstanding resistance to general corrosion, pitting, crevice corrosion, and stress-corrosion cracking in many aqueous environments, including those containing sulfides and chlorides. Used for surface and down-hole hardware in sour gas wells and for oil production equipment
20Cb3	550	80	240	35	30	. . .	. . .	90 HRB	A high-nickel austenitic stainless steel with excellent resistance to chemicals containing chlorides and sulfuric, phosphoric, and nitric acids. Resists pitting, crevice corrosion, and intergranular attack used for tanks, piping, heat exchangers, pumps, valves, and other chemical process equipment
20Mo-4	615	89	262	38	41	186	27	80 HRB	Alloy is designed for applications requiring improved resistance to pitting and crevice corrosion. It should be considered for acid environments where pitting and crevice corrosion problems are encountered. Applications include heat exchangers, chemical process piping and equipment, mixing tanks, and metal-cleaning and pickling tanks
20Mo-6	607	88	275	40	50	186	27	. . .	An austenitic stainless steel that is resistant to corrosion in hot chloride environments with low pH. It has good resistance to pitting, crevice corrosion, and stress-corrosion cracking in chloride environments. It is also resistant to oxidizing media. Applications include commercial fume scrubbers, offshore platforms, and equipment for pulp and paper mills.
Controlled-expansion alloys									

Alloy 902 (precipitation hardened)	1210	175	760	110	25	. . .	. . .	. . .	A nickel-iron-chromium alloy made precipitation hardenable by additions of aluminum and titanium. The titanium content also helps provide a controllable thermoelastic coefficient, which is the outstanding characteristic of the alloy. The alloy can be processed to have a constant modulus of elasticity at temperatures from -45 to 65 °C (-50 to 150 °F). Used for precision springs, mechanical resonators, and other precision elastic components
Alloy 903 (precipitation hardened)	1310	190	1100	160	14	. . .	. . .	. . .	A nickel-iron-cobalt alloy with additions of niobium, titanium, and aluminum for precipitation hardening. The alloy combines high strength with a low and constant coefficient of thermal expansion at temperatures up to about 430 °C (800 °F). It also has a constant modulus of elasticity and is highly resistant to thermal fatigue and thermal shock. Used in gas turbines for rings and casings
Alloy 907	See Alloy 903.								A nickel-iron-cobalt alloy with additions of niobium and titanium for precipitation hardening. It has the low coefficient of expansion and high strength of Alloy 903 but with improved notch-rupture properties at elevated temperatures. Used for components of gas turbines, including seals, shafts, and casings
Alloy 909 (precipitation hardened)	1275	185	1035	150	15	159	23	. . .	A nickel-iron-cobalt alloy with a silicon addition and containing niobium and titanium for precipitation hardening. It is similar to Alloys 903 and 907 in that it has low thermal expansion and high strength. However, the silicon addition results in improved notch-rupture and tensile properties that are achieved with less-restrictive processing and significantly shorter heat treatments. Used for gas turbine casings, shrouds, vanes, and shafts

(a) Cold rolled and solution annealed at 1230 °C (2250 °F). Sheet thickness, 1.2 to 1.6 mm (0.048 to 0.063 in.).

(b) Annealed at 980 °C (1800 °F) for 30 min, air cooled, and aged at 760 °C (1400 °F) for 8 h, furnace cooled at a rate of 55 °C (100 °F)/h, heated to 620 °C (1150 °F) for 8 h, air cooled

Table 6 Room-temperature physical properties of selected nickel-base alloys

Properties are for annealed sheet unless otherwise indicated.

Commercially Pure and Low-Alloy Nickels. Nickel is supplied to the producers of nickel alloys in powder, pellets, or anode forms. Purity is important, and these products constitute Grade 1 nickel in the primary metals marketplace. The feedstock is either melted and cast into ingots, or direct rolled or powder compacted into semifinished forms. This has led to a whole series of alloy modifications, with controlled compositions having nickel contents ranging from about 94% to virtually 100%.

These materials are characterized by high density, offering magnetic and electronic property capabilities. They also offer excellent corrosion resistance to reducing environments, along with reasonable thermal transfer characteristics. Hence, they find utilization in heat exchangers, evaporators, and various food processing applications, where purity of finished products is important. Some nickels of commercial importance include:

- Nickel 200. 99.5% Ni min, 0.10% C max, other minor additions include manganese and silicon
- Nickel 201. Low-carbon version (0.02% C max) for service temperatures above 290 °C (550 °F)
- Nickel 205. Controlled magnesium levels (0.01 to 0.08%) for electronic characteristics
- Nickel 270 and 290. High-purity powder alloys (99.95% Ni) made from water-atomized and carbonyl powders
- Permanickel Alloy 300. Age-hardenable nickel containing 0.2 to 0.6 Ti: spring properties with higher thermal and electrical properties
- Duranickel Alloy 301. Age-hardenable nickel containing 4.00 to 4.75 Al and 0.25 to 1.00 Ti: spring applications for electrical hardware

Applications for Nickel 200 and 201 are found in the chemical processing industry. These alloys are important in handling hot-concentrated caustic soda and dry chlorine. Caustic is a key ingredient in dissolving wood products for production of paper and in the extraction of aluminum from its ores.

Originally, Nickel 200 was used for food processing, kitchen hardware, and roofing. It continues to be selected for use as a coinage material. Today, it finds major applications in the electronics industry (plated pins for printed circuit board interconnects), battery applications (molten lithium, long-life storage batteries), and synthetic diamond production. In all instances, corrosion resistance and the need for end-product purity have played prime roles in its selection and utilization.

Nickel-copper alloys have been found to possess excellent corrosion resistance in reducing chemical environments and in sea water, where they deliver excellent service in nuclear submarines and various surface vessels.

These alloys have excellent ductility and can be readily fabricated and formed into a variety of shapes. By changing the various proportions of nickel and copper in the alloy, a whole series of alloys with different electrical resistivities and Curie points (magnetic/nonmagnetic transition temperatures) can be created. Some nickel-copper alloys of commercial importance include:

- Alloy 400 (66% Ni, 33% Cu). The base alloy in the series; can be magnetic depending upon composition and previous work history (Curie point is 20 to 50 °C, or 70 to 120 °F)
- Alloy R-405. Controlled sulfur addition (0.025 to 0.06% S) for improved machinability
- Alloy K-500. Added aluminum and titanium for age hardening; totally nonmagnetic and spark resistant

This series of alloys finds major applications in the fastener industry serving the marine, aerospace, and chemical processing industries. The nonmagnetic characteristics of Alloy K-500 are used for gyroscope application and anchor cable aboard minesweepers. Alloy K-500 is also used for propeller shafts on a wide variety of vessels and exhibits high fatigue strength in seawater.

This series of alloys also finds application in chemical process applications for handling of organic acids, caustic, and dry chlorine. The age-hardenable Alloy K-500 is used in valves and pumps--both as castings and wrought forms. The oil and gas industry has used this alloy extensively for sucker rods and associated Christmas tree well-head applications, especially in sour gas environments.

The nickel-chromium and nickel-chromium-iron series of alloys led the way to higher strength and resistance to elevated temperatures. While these series of alloys were finding their way into the early European jet engine problem, these alloys found their initial applications in North American in thermal process equipment and the chemical process industry, where carburizing environments and elevated temperatures were service limiting to stainless steels. Today they also form the basis for both commercial and military power systems. Two of the earliest developed Ni-Cr and Ni-Cr-Fe alloys were:

- Alloy 600 (76Ni-15Cr-8Fe). The basic alloy in the Ni-Cr-Fe system; high nickel content makes it resistant to reducing environments
- Nimonic alloys (80Ni-20Cr + Ti/Al). The basic alloy for jet engine development (see Ref 12 for compositions and properties)

Some high-temperature variants include:

- Alloy 601. Lower nickel (61%) content with aluminum and silicon additions for improved oxidation and nitriding resistance
- Alloy X750. Aluminum and titanium additions for age hardening: originally used for skin of Bell X-1 experimental aircraft
- Alloy 718. Titanium and niobium additions to overcome strain-age cracking problems during welding and weld repair
- Alloy X (48Ni-22Cr-18Fe-9Mo + W), High-temperature flat-rolled product for aerospace applications
- Waspaloy (60Ni-19Cr-4Mo-3Ti-1.3Al). Proprietary alloy for jet engine applications

To achieve higher design strengths, dispersion-strengthened powder metallurgy alloys have been developed. Mechanical alloying represents the technology by which these materials can be made. In this process, a controlled mixture of alloy powder and about 1 vol% oxides (typically Y_2O_3) are charged into a high-energy ball mill. The metal particle size initially is in the 2 to 200 μm range, whereas the oxide particles are less than 10 μm in size. The milling operation, carried out dry, causes the superalloy particles to weld repeatedly to the oxide particles and then break apart. The resultant acicular or platelike powders are composites with extremely fine, homogeneous microstructures. Consolidation is carried out by placing the powders in steel cylinders, aligning the ends closed, and either extruding to bar or rolling to plate or sheet.

Alloy MA 754 (Ni-20Cr-1.0Fe-0.6Y_2O_3) was the initial alloy produced by this new technology and specifically developed for gas turbine engine vanes. It is superior to cast cobalt-base alloys in dimensional stability, thermal fatigue, and strength at 1100 °C (2010 °F). More detailed information on mechanically alloyed materials can be found in the article "Dispersion-Strengthened Nickel-Base and Iron-Base Alloys" in this Volume and *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook* (see Ref 12).

Some corrosion-resistant variants in the Ni-Cr-Fe system include:

- Alloy 625. The addition of 9% Mo plus 3% Nb offers both high-temperature and wet corrosion resistance; resists pitting and crevice corrosion
- Alloy G3/G30 (Ni-22Cr-19Fe-7Mo-2Cu). The increased molybdenum content in these alloys offers improved pitting and crevice corrosion resistance
- Alloy C-22 (Ni-22Cr-6Fe-14Mo-4W). Superior corrosion resistance in oxidizing acid chlorides, wet chlorine, and other severe corrosive environments
- Alloy C-276 (17% Mo plus 3.7W). Good seawater corrosion resistance and excellent pitting and crevice corrosion resistance
- Alloy 690 (27% Cr addition). Excellent oxidation and nitric acid resistance; specified for nuclear waste disposal by the vitreous encapsulation method

Throughout most of the nuclear power era, Alloy 600 has been the preferred alloy for all steam generator tubing, both in commercial and military reactor design. With the recognition of the potential for Alloy 600 to suffer stress-corrosion cracking in superheated pure waters, Alloy 690 has become the alternate material for future replacement steam generator tubing and new designs.

All of the high-temperature variants and the Nimonic series of alloys find application in many of the hot sections of aircraft gas turbine engines--blades, turbine rings, fasteners, and so forth. The alloys are also used for thermal processing equipment, much of which is used in annealing and heat treating of the age-hardenable aerospace alloys.

The molybdenum-containing systems are notable for their multipurpose capabilities in chemical processing, pulp and paper production (bleachers and washers), and pollution-control equipment (flue gas desulfurization, scrubbers, precipitators). These alloys also find use in oil country tubular goods for handling highly corrosive sour gases. In critical applications, this series of alloys has found use in various instrumentation applications (sensors and safety diaphragms). Bellows-quality material is used in honeycomb applications and for improved low cycle fatigue capabilities.

As described earlier in this article, a series of alloys has also been designed for electrical resistance heating applications. These nickel-chromium alloys offer oxidation and thermal shock resistance in on-off service, with the electrical resistance characteristics being realized through variations of chemistry, wire diameters, and processing history (grain size effects). Some alloys of commercial importance include:

- 80Ni-20Cr (plus 1.5 Si). Operating conditions up to 1150 to 1175 °C (2100 to 2150 °F). High electrical resistivity characteristics
- 60Ni-24Fe-16Cr. Suitable for less exacting applications and operating conditions up to 950 °C (1750 °F); for example, clothes dryer elements
- 35Ni-45Fe-20Cr. Cost effective consideration for operating conditions up to 1065 °C (1950 °F). However, large temperature coefficient of resistance must be taken into effect during element design

A common application today is the spiral-wound electrical element contained within a metal sheath, for use as an appliance heating element. However, these alloys have also been used extensively for heating in other applications such as domestic fan heaters and thermal storage units. They exhibit good resistance to oxidation up to their recommended maximum operating temperatures.

Iron-Nickel-Chromium Alloys. The development of this series of alloys took place in the early 1950s with their introduction during the Korean War period. Incoloy Alloy 800 was designed as a leaner nickel version of the nickel-chromium series of materials. It offered good oxidation resistance and was introduced as a sheathing material for electronic stove elements. Since that time, even leaner nickel alloys have been designed for selected sheathing applications.

This series of alloys has also found extensive use in the high-temperature petrochemical environments, where sulfur-containing feedstocks (naphtha and heavy oils) are cracked into component distillate parts. Not only were they resistant to chloride-ion stress-corrosion cracking, but they also offered resistance to polythionic acid cracking. Some alloys of commercial importance include:

- Alloy 800 (Fe-32Ni-21Cr). The basic alloy in the Fe-Ni-Cr system; resistant to oxidation and carburization at elevated temperatures
- Alloy 800H. Modification with controlled carbon (0.05 to 0.10%) and grain size (>ASTM 5), to optimize stress-rupture properties
- Alloy 800HT. Similar to 800H with further modification to combined titanium and aluminum levels (0.85 to 1.2%) to ensure optimum high-temperature properties
- Alloy 801. Increased titanium content (0.75 to 1.5%); exceptional resistance to polythionic acid cracking
- Alloy 802. High-carbon version (0.2 to 0.5%) for improved strength at high temperatures
- Alloy 825 (Fe-42Ni-21.5Cr-2Cu). Stabilized with titanium addition (0.6 to 1.2%). Also contains molybdenum (3%) for pitting resistance in aqueous corrosion applications. Copper content bestows resistance to sulfuric acid
- Alloy 925. Addition of titanium and aluminum to 825 composition for strengthening through age hardening

The 800 alloy series offers excellent strength at elevated temperature (creep and stress rupture). These alloys are consequently useful for catalytic cracking tubes, pigtails, and reformer tubes. For optimum performance in the new millisecond design of crackers, Alloy 800HT internally finned tubing is being used. This offers greater heat exchanger wall area. For environments where polythionic acid can form during downtime periods, Alloy 801 offers optimum resistance. Alloy 802 offers competitive high-temperature strength capabilities because of its high carbon level and has been used extensively in sinter deck plate applications for handling abrasive, high-temperature environments.

Some corrosion variants in the Fe-Ni-Cr system include:

- 20Cb3 (Fe-35Ni-20Cr-3.5Cu-2.5Mo + Nb). This alloy was developed for the handling of sulfuric acid environments
- 20Mo-4 and 20Mo-6 (Fe-36Ni-23Cr-5Mo + Cu). Increased corrosion resistance in pulp and paper industry environments

The corrosion-resistant series of alloys (825, 925, and 20Cb3) all contain molybdenum for enhanced corrosion resistance. This series of alloys has excellent resistance to sulfuric acid. The alloys have found extensive use as tubing and plate for production of fertilizer and associated products.

Alloy 925 has found use for downhole components in sour gas wells around the world. It has been forged into block master valves for well-head applications, along with associated Christmas tree well-head components. Alloy 825 is used for downhole tubular components where hydrogen sulfide, carbon dioxide, and sodium chloride (salt) are at elevated temperatures. For very aggressive corrosion sour gas environments, the nickel-chromium-iron-molybdenum series of alloys has to be considered.

Controlled-expansion alloys include alloys in both the Fe-Ni-Cr and Fe-Ni-Co series. Some alloys of commercial importance include:

- Alloy 902 (Fe-42Ni-5Cr with 2.2 to 2.75% Ti and 0.3 to 0.8% Al). This is an alloy with a controllable thermoelastic coefficient
- Alloys 903, 907, 909 (42Fe-38Ni-13Co with varying aging elements such as niobium, titanium, and aluminum). These alloys offer high strength and low coefficient of thermal expansion

The 900 alloy series offers very unusual characteristics and properties. Alloys 903, 907, and 909 were all designed to provide high strength and low coefficient of thermal expansion for applications up to 650 °C (1200 °F). These advantages have been used by the aerospace industry to design near net-shape components and to provide closer clearance between the tips of rotating turbine blades and retainer rings. This allows for greater power output and fuel efficiencies. These high-strength alloys also allow increased strength-to-weight ratios in engine design, resulting in weight savings. Alloy

909 offers attractive properties for rocket engine thrust chambers, ordnance hardware, springs, gage blocks, and instrumentation.

Alloy 902 is used extensively in spring, pressure sensor, and instrumentation applications for its thermoelastic coefficient. It is particularly useful in the design of pressure-sensing devices, and can be used in both low-frequency components (Bourdon tubing, aneroid capsules, and springs) and high-frequency components (tuning forks, mechanical filters, and vibrating reeds).

Nickel-Iron Low-Expansion Alloys. This series of alloys plays a very important role in both the lamp industry and electronics, where glass-to-metal seals in encapsulated components are important. The nickel alloys are chosen for a variety of reasons:

- They have readily reducible oxides and offer a capacity for easy outgassing
- They are readily fabricated and retain structural integrity at temperature
- They offer good thermal conductivity and low electrical resistance

Some alloys of commercial importance include

- Invar (Fe-36Ni). This alloy has the lowest thermal expansion of any metal from ambient to 230 °C (450 °F)
- Alloy 42 (Fe-42Ni). This alloy has the closest thermal expansion match to alumina, beryllia, and vitreous glass
- Alloy 426. Additions of 6% Cr are added to this alloy for vacuum-tight sealing applications
- Alloy 52 (Fe-51.5Ni). This alloy has a thermal expansion that closely matches vitreous potash-soda-lead glass

Alloy 42, along with Kovar, an Fe-29Ni-17Co alloy, formed the core of the lead frame market in servicing the computer industry in its early days. They offered, and still offer, high-integrity electronic components that are required for military packages. Alloy 42, aluminum striped, remains in prime demand for ceramic dual-in-line packages (CERDIP) components, while Kovar is used in lids and closures for hybrid electronic packages today.

Invar (Alloy 36) also finds use in the electronic industry for printed circuit boards. Used in conjunction with copper, it offers a clad composite product that can be designed with controlled-expansion characteristics depending upon the proportions of each alloy present in the composite. The copper allows excellent thermal and electrical transference, while the Invar offers very low expansion to provide constraint to the copper, which otherwise wants to expand rapidly. The low expansion of Invar with other alloys of differing expansion can provide a series of thermomechanical control and switchgear devices. Other applications for this alloy have been found in cryogenic tanks for handling liquid gases and a variety of instrumentation and fixturing applications.

The chromium-bearing grades find a major use in television shadow mask screens and for headlight ferrules, where vacuum-tight sealing is required for performance. In less demanding glass sealing applications, copper-coated Alloy 42 (Dumet) is used for traditional incandescent lamp production. More detailed information can be found in the article "Low-Expansion Alloys" in this Volume.

Soft Magnetic Alloys. The nickel-iron alloys also offer an interesting set of magnetic permeability properties, which have played an important part in switchgear and for direct current (dc) motor and generator designs.

As described earlier in this article, such nickel-iron alloys are known as "soft" magnetic alloys as compared with the "hard" iron and silicon-iron materials (differences in magnetic materials are described in the articles "Magnetically Soft Materials" and "Permanent Magnet Materials" in this Volume). The magnetically soft materials found initial major applications in telegraph applications and later in telephone equipment.

With high initial and maximum permeability, these products offer excellent magnetic shielding. The lower-nickel alloys (~50% Ni) offer fairly constant permeabilities over a narrower range of flux densities and have found their primary use

in rotors, armatures, and low level transformers. High-nickel alloys (~77% Ni) are useful for applications in which power requirements must be minimized such as transformers, inductors, magnetic amplifiers, magnetic shields, tape recorder heads, and memory storage devices.

Welding Alloys. Welding products for nickel alloys have similar compositions to the base metals, although additions of aluminum, titanium, magnesium, and other elements are made to the filler metals and welding electrodes to ensure proper deoxidation of the molten weld pool and to overcome any hot-short cracking and malleability problems.

Nickel-base welding products are also used for welding of dissimilar materials, for example, stainless steels to cast iron, as in a drive shaft and yoke for automotive assemblies. In other cases, overmatching filler materials (high-molybdenum products) can be used to ensure adequate corrosion resistance in welds where matching-composition electrodes may not provide enough molybdenum in the final weld deposit to resist pitting and crevice corrosion. Alloy 625 welding materials, with 9% Mo, are widely used for joining many corrosion-resistant materials with less molybdenum.

Pure nickel and nickel-iron welding electrodes are established products for welding of cast iron, especially ductile iron. The nickel-iron composition is more suitable for welding the higher-sulfur grades of cast iron and for repair welding. Nickel-iron filler metals and flux-core wire are also used, especially for automatic, single-pass welding.

Tables 7 and 8 provide compositions of nickel-base welding electrodes and consumables, and their major uses.

Welding procedures for nickel alloys are similar to those used for stainless steel. However, the nickel-base molten weld deposit is less fluid than that for stainless steel, so joint configurations and joint angles must be opened up to accommodate manipulation of the weld rod or torch during placement of the weld metal in the joint area. Cleaning of the base metal is also important before welding the nickel-base alloys.

These materials can be joined by any one of the basic welding processes--gas-tungsten arc (GTAW), metal gas arc (GMAW), shielded metal-arc (SMAW), brazing, and soldering. In more sophisticated applications, laser welding,

electron beam welding, and ultrasonic welding have all been used. The choice of welding processes should be based upon the thickness of the metal to be joined, design of the unit, design of the joint, position in which the weld is to be made, need for jigs and fixtures, service conditions and corrosive environments, and any special shop or field construction conditions.

Cobalt and Cobalt Alloys

Paul Crook, Haynes International, Inc.

Introduction

COBALT is a tough silver-gray magnetic metal that resembles iron and nickel in appearance and in some properties. Cobalt is useful in applications that utilize its magnetic properties, corrosion resistance, wear resistance, and/or its strength at elevated temperatures. Some cobalt-base alloys are also biocompatible, which has prompted their use as orthopedic implants (see the article "Corrosion of Cobalt-Base Alloy" in Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

This article provides a general overview of cabalt-base alloys as wear-resistant, corrosion-resistant, and/or heat-resistant materials. Particular emphasis is placed on cobalt-base alloys for wear resistance, because this is the single largest application area of cobalt-base alloys. In heat resistant applications, cobalt is more widely used as an alloying element in nickel-base alloys with cobalt tonnages in excess of those used in cobalt-base heat-resistant alloys.

Elemental Cobalt

Mining and Processing. Much of cobalt today derives from copper and copper-nickel rich sulfide deposits in Zaire and Zambia. Other countries where the mining of cobalt is significant include Canada and Finland.

The largest deposits, in the Shaba Province of Zaire, are mined using both open pit and underground methods. Here the ore is subjected to crushing, grinding, and flotation, prior to a magnetic concentration process. This concentrate is then leached in sulfuric acid and the cobalt and copper extracted by electrolysis (Ref 1).

Alternative future sources of cobalt include the manganese-rich nodules discovered on the floor of the Pacific Ocean.

Physical Properties. With an atomic number of 27, cobalt falls between iron and nickel on the periodic table. The density of cobalt is 8.8 g/cm^3 similar to that of nickel. Its thermal expansion coefficient (Fig. 1) lies between those of iron and nickel. At temperatures below 417 °C (783 °F), cobalt exhibits a hexagonal close-packed structure. Between 417 °C (783 °F) and its melting point of 1493 °C (2719 °F), cobalt has a face-centered cubic structure.

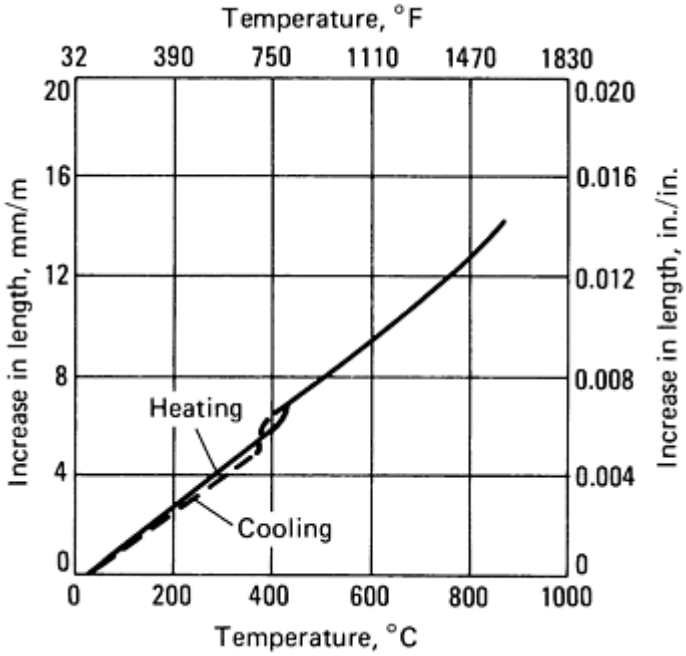

Fig. 1 Linear expansion of cobalt from 30 °C (86 °F)

Typical tensile properties of pure cobalt are given in Table 1. The elastic modulus of cobalt is about 210 GPa (30×10^6 psi) in tension and about 183 GPa (26.5×10^6 psi) in compression. Electrical and magnetic properties of pure cobalt are summarized in Table 2. More information on the properties of cobalt is contained in the article "Properties of Pure Metals" in this Volume.

Uses of Cobalt. As well as forming the basis of the cobalt-base alloys discussed in this article, cobalt is also an important ingredient in other materials:

- Paint pigments
- Nickel-base superalloys
- Cemented carbides and tool steels
- Magnetic materials
- Artificial γ-ray sources

Of these applications, paint pigment represents the single largest use of cobalt.

In the nickel-base superalloys, cobalt (which is present typically in the range 10 to 15 wt%) provides solid-solution strengthening and decreases the solubility of aluminum and titanium, thereby increasing the volume fraction of gamma prime (γ') precipitate. Cobalt in nickel-base superalloys also reduces the tendency for grain boundary carbide precipitation, thus reducing chromium depletion at the grain boundaries (Ref 2).

In Cemented Carbides. The role of cobalt in cemented carbides is to provide a ductile bonding matrix for tungsten-carbide particles. Cobalt is used as a bonding matrix with tungsten carbide because its wetting or capillary action during liquid phase sintering allows the achievement of high densities (Ref 3). The commercially significant cemented carbides contain cobalt in the range of 3 to 25 wt%. As cutting tool materials, cemented carbides with 3 to 12 wt% Co are commonly used (see the article "Cemented Carbides" in this Volume for more details). Cobalt is also used in tool steels,

which are covered in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of the *ASM Handbook.*

In Magnetic Materials. Cobalt, which is naturally ferromagnetic, provides resistance to demagnetization in several groups of permanent magnet materials. These include the aluminum-nickel-cobalt alloys (in which cobalt ranges from about 5 to 35 wt%), the iron-cobalt alloys (approximately 5 to 12 wt%), and the cobalt rare-earth intermetallics (which have some of the highest magnetic properties of all known materials). Further information is contained in the article "Permanent Magnet Materials" in this Volume.

As Radioactive Source. The artificial isotope cobalt-60 is an important γ-ray source in medical and industrial applications. Table 3 compares the characteristics of cobalt-60 γ-ray sources with other γ-ray sources used in industrial radiography.

Table 3 Characteristics of γ-ray sources used in industrial radiography

γ-ray source	Half-life	Photon energy, MeV	Radiation output, RHM/Ci[(a)]	Penetrating power of steel, mm (in.)
Thulium-170	128 days	0.054 and 0.084[(b)]	0.003	13 ($\frac{1}{2}$)
Iridium-192	74 days	12 rays from 0.21-0.61	0.48	75 (3)

Cobalt-Base Alloys

As a group, the cobalt-base alloys may be generally described as wear resistant, corrosion resistant, and heat resistant (strong even at high temperatures). Table 4 lists typical compositions of present-day cobalt-base alloys in these three application areas. Many of the properties of the alloys arise from the crystallographic nature of cobalt (in particular its response to stress), the solid-solution-strengthening effects of chromium, tungsten, and molybdenum, the formation of metal carbides, and the corrosion resistance imparted by chromium. Generally, the softer and tougher compositions are used for high-temperature applications such as gas-turbine vanes and buckets. The harder grades are used for resistance to wear.

Historically, many of the commercial cobalt-base alloys are derived from the cobalt-chromium-tungsten and cobalt-chromium-molybdenum ternaries first investigated by Elwood Haynes at the turn of the century. He discovered the high strength and stainless nature of the binary cobalt-chromium alloy, and he later identified tungsten and molybdenum as powerful strengthening agents within the cobalt-chromium system. When he discovered these alloys, Haynes named them the Stellite alloys after the Latin, *stella,* for star because of their starlike luster. Having discovered their high strength at elevated temperatures, Haynes also promoted the use of Stellite alloys as cutting tool materials.

Following the success of cobalt-base tool materials during World War I, they were then used from about 1922 in weld overlay form to protect surfaces from wear. These early cobalt-base "hardfacing" alloys were used on plowshares, oil well drilling bits, dredging cutters, hot trimming dies, and internal combustion engine valves and valve seats. Since the 1920s, some of these applications have ceased, some have continued, and many more have been added. In 1982, 1360 Mg (1500 tons) of cobalt-base alloys were sold for the purpose of hardfacing, one-third of this quantity being used to protect valve seating surfaces (both fluid control and engine valves).

Later in the 1930s and early 1940s, cobalt-base alloys for corrosion and high-temperature applications were developed in a series of related events involving the Austenal Laboratories and the Haynes Stellite Division of Union Carbide (Ref 4). Of the corrosion-resistant alloys, a cobalt-chromium-molybdenum alloy with a moderately low carbon content was developed to satisfy the need for a suitable investment cast dental material. This bicompatible material, which has the tradename Vitallium, is in use today for surgical implants. In the 1940s this same alloy also underwent investment casting trials for World War II aircraft turbocharger blades, and, with modifications to enhance structural stability, was used successfully for many years in this and other elevated-temperature applications. This early high-temperature material, Stellite alloy 21, is still in use today, but predominantly as an alloy for wear resistance.

Cobalt-Base Wear-Resistant Alloys

The cobalt-base wear alloys of today are title changed from the early alloys of Elwood Haynes. The most important differences relate to the control of carbon and silicon (which were impurities in the early alloys). Indeed, the main differences in the current Stellite alloy grades are carbon and tungsten contents (hence the amount and type of carbide formation in the microstructure during solidification). As will be discussed, carbon content influences hardness, ductility, and resistance to abrasive wear. Tungsten also plays an important role in these properties.

Types of Wear. There are several distinct types of wear which generally fall into three main categories:

- Abrasive wear
- Sliding wear
- Erosive wear

The type of wear encountered in a particular application is an important factor that influences the selection of a wear-resistant material.

Abrasive wear is encountered when hard particles, or hard projections (on a counterface) are forced against, and moved relative to, a surface. The terms high and low stress abrasion relate to the condition of the abrasive medium (be it hard

particles or projections)after interaction with the surface. If the abrasive medium is crushed, then the high stress condition is said to prevail. If the abrasive medium remains intact, the process is described as low stress abrasion. Typically, high stress abrasion results from the entrapment of hard particles between metallic surfaces (in relative motion), while low stress abrasion is encountered when moving surfaces come into contact with packed abrasives, such as soil and sand.

In alloys such as the cobalt-base wear alloys, which contain a hard phase, the abrasion resistance generally increases as the volume fraction of the hard phase increases. Abrasion resistance is, however, strongly influenced by the size and shape of the hard phase precipitates within the microstructure, and the size and shape of the abrading species.

Sliding Wear. Of the three major types of wear, sliding is perhaps the most complex, not in concept, but in the way different materials respond to sliding conditions. Sliding wear is a possibility whenever two surfaces are force together and moved relative to one another. The chances of damage are increased markedly if the two surfaces are metallic in nature, and if there is little or no lubrication present.

Sliding wear generally occurs by one or more of three mechanisms. In the first mechanism, oxide control of the sliding wear process, and low wear rates, are experienced when surface temperatures are high, by virtue of either a high ambient temperature or frictional heating. This is because oxide growth rates increase dramatically with temperature. In some cases, so-called "oxide glazes" are formed on the surfaces. These "oxide glazes" are very smooth, highly reflective regions, caused by the shearing of oxide asperities (peaks) and redistribution of the oxide debris in the surface valleys. There are times when the oxide debris, if trapped as discrete particles or flakes between the sliding surfaces, can become abrasive. This is an important consideration when the surfaces oscillate with respect to one another over small amplitudes. The combined sliding/abrasive wear mechanism set up under these conditions is known as fretting.

The second mechanism of sliding wear is normally associated with high contact stresses and assumes breakdown of the oxide films to the point where true metal-to-metal contact is established. Under these conditions, there is an opportunity for cold welding of the surfaces to occur, and for subsequent movement to result in fracture of small pieces away from the original interface (normally in the weaker of the two mating materials). Damage caused by this mechanism is termed galling. Substantial metal transfer from one surface to the other and gross deformation of surface materials are typical of this condition.

The third mechanism of sliding wear, which can also produce substantial metallic damage, is one of subsurface fatigue. This mechanism is associated with cyclic stress conditions caused by materials periodically pressing on one another. Material is lost through fatigue crack nucleation and growth at a specific depth.

The metallic materials which perform well under sliding conditions do so either by virtue of their oxidation behavior or their ability to resist deformation and fracture. Little is known of the influence of metal-to-metal bond strength during cold welding. For materials such as the cobalt-base wear alloys with a hard phase dispersed throughout a softer matrix, the sliding-wear properties are controlled predominantly by the matrix. Indeed, within the cobalt alloy family, resistance to galling is generally independent of hard practice volume fraction and overall hardness.

Erosive Wear. Four distinct forms of erosive wear have been identified:

- Solid-particle erosion
- Liquid-droplet erosion
- Cavitation erosion
- Slurry erosion

Solid-particle erosion is caused by the impingement of small, solid particles against a surface. The solid particles themselves are typically airborne or entrained in some other gaseous environment. Particle sizes typically range from 5 to 500 μm. Typical velocities associated with solid-particle erosion range from 2 m/s (6 ft/s) in fluid bed combustors to 500 m/s (1650 ft/s). The rate of solid-particle erosion is dependent upon the velocity of the particles, their impingement angle (the angle dependency generally being different for ductile materials than it is for brittle materials), and the nature of the erodent (shape, size, strength).

Slurry erosion, or liquid-solid particle erosion, is similar to solid-particle erosion, except that there are differences in the viscosity of the carrier fluid (gas in solid-particle erosion, liquid carrier in slurry erosion). Slurry erosion occurs at the

surfaces impinged by the solid particles in the liquid stream. The similarity to abrasion arises from the fact that the particles are hydrodynamically forced against the surface.

Although quite different mechanistically, liquid-droplet erosion and cavitation erosion have a similar effect upon a surface. They both result in a succession of shock (or stress) waves into the surface. For this reason, those materials which resist liquid-droplet erosion also perform well under cavitation conditions and vice versa.

Liquid-droplet erosion is easily envisaged, whereas cavitation erosion is a more complex phenomenon. For the latter to occur, the surface must be in contact with a liquid undergoing pressure changes. Surface damage results from the collapse of near-surface bubbles in the liquid, or, more precisely, from the action of liquid jets which arise during bubble implosion. The bubbles themselves are created when the pressure in the liquid falls below its vapor pressure. Collapse is induced by subsequent pressure increases.

The abrasion resistance of cobalt-base alloys, like other wear-resistant alloys, generally depends on the hardness of the carbide phases and/or the metal matrix. With the complex mechanisms of solid-particle and slurry erosion, however, such generalizations may not be warranted. In solid-particle erosion, for example, ductility may also be a factor (see the discussion on solid-particle erosion in the section "Wear Data" of this article).

As for liquid-droplet or cavitation erosion, the performance of a material is largely dependent upon its ability to absorb the shock (stress) waves without, essentially, microscopic fracture. In cobalt-base wear alloys, it has been found that carbide volume fraction (hence, bulk hardness) has very little effect upon resistance to liquid-droplet and cavitation erosion (Ref 5). Much more important are the properties of the matrix.

Alloy Compositions and Product Forms. The nominal compositions of various cobalt-base wear-resistant alloys are listed in Table 4, with six popular cobalt-base wear alloys listed first. Stellite alloys 1, 6, and 12 are derivatives of the original cobalt-chromium-tungsten alloys developed by Haynes. These alloys are characterized by their carbon and tungsten contents, with Stellite alloy 1 being the hardest, most abrasion resistant, and least ductile. Their microstructures (in weld overlay form) are presented in Fig. 2(a) to 2(c) and illustrate the extent of carbide precipitation. These carbides are generally of the chromium-rich M_7C_3 type, although in high-tungsten alloys (such as Stellite alloy 1) tungsten-rich M_6C carbides usually are present also.

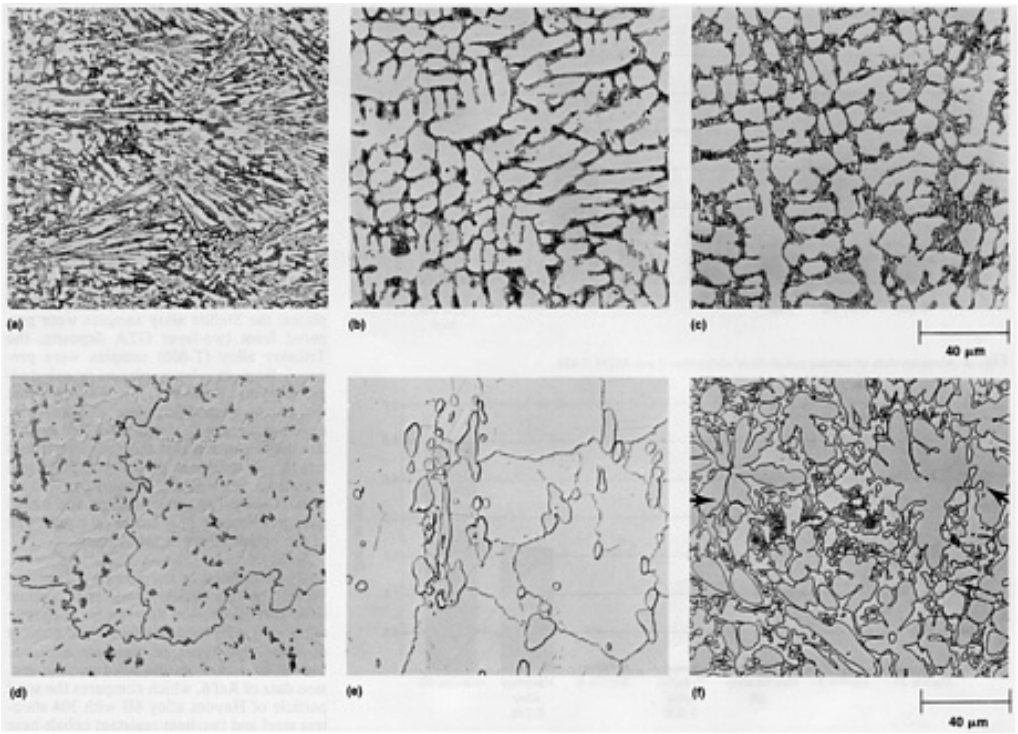

Fig. 2 Microstructures of various cobalt-base wear-resistant alloys. (a) Stellite 1, two-layer GTA deposit. (b) Stellite 6, two-layer GTA deposit. (c) Stellite 12, two-layer GTA deposit. (d) Stellite 21, two-layer GTA deposit. (e) Haynes alloy 6B, 13 mm (0.5 in.) plate. (f) Tribaloy alloy (T-800) showing the Laves precipitates (the

largest continuous precipitates some of which are indicated with arrows). All 500×

Stellite alloy 21 (Fig. 2d) differs from the first three alloys in that it employs molybdenum, rather than tungsten, to strengthen the solid solution. Stellite alloy 21 also contains considerably less carbon. By virtue of the high molybdenum content, and the fact that most of the chromium is in solution (rather than in Cr_7C_3 carbides), the alloy is more resistant to corrosion than Stellite alloys 1, 6, and 12.

Unlike these four alloys described above, which are generally used in the form of castings and weld overlays, Haynes alloy 6B is a wrought product available in plate, sheet, and bar form. Subtle compositional differences between alloy 6B and Stellite alloy 6 (such as silicon control) facilitate processing. The advantages of wrought processing include greatly enhanced ductility, chemical homogeneity, and resistance to abrasion by virtue of the coarse, blocky carbides within the microstructure (Fig. 2e).

The sixth wear-resistant alloy in Table 2 is the Tribaloy alloy (T-800), which is from an alloy family developed by DuPont in the early 1970s. In the search for resistance to abrasion and corrosion, workers at DuPont took the unprecedented step of alloying with excessive amounts of molybdenum and silicon to induce the formation during solidification of a hard and corrosion-resistant intermetallic compound, known as Laves phase. These carbon in T-800 is held as low as possible to discourage the precipitation of carbides (which, if encouraged to form, would tie up the vital elements chromium and molybdenum). The extent and nature of the Laves precipitates in T-800 are illustrated in Fig. 2(f). The Laves precipitates confer outstanding resistance to abrasion, but limit ductility. As a result of this limited ductility, the alloy is now generally used in the form of plasma-sprayed coatings.

Powder metallurgy (P/M) versions of several Stellite alloys (typically containing low levels of boron to enhance sintering) are available for applications where the P/M process is cost effective (that is, high volumes of relatively small components).

Wear Data. Abrasion data are presented for the six popular wear alloy compositions in Fig. 3, along with data for 316L stainless steel and D2 tool steel (60 HRC) for comparison. These data were generated using the ASTM G 65B (dry sand/rubber wheel) test and, except in the case of Haynes alloy 6B (samples of which were prepared from solution annealed plates with a thickness of 13 mm, or $\frac{1}{2}$ in.), samples were prepared from two-layer gas-tungsten-arc (GTA) deposits. Within the Stellite alloy family, it is evident from Fig. 3 that abrasion resistance is a function of carbon and tungsten content (Table 4). As the carbon content increases in the chromium-tungsten Stellite alloys, so does the tungsten content. This results in an increase in carbide content and thus hardness. In Fig. 3, the benefits of wrought processing in alloy 6B and the effectiveness of the Laves phase in T-800 are also evident.

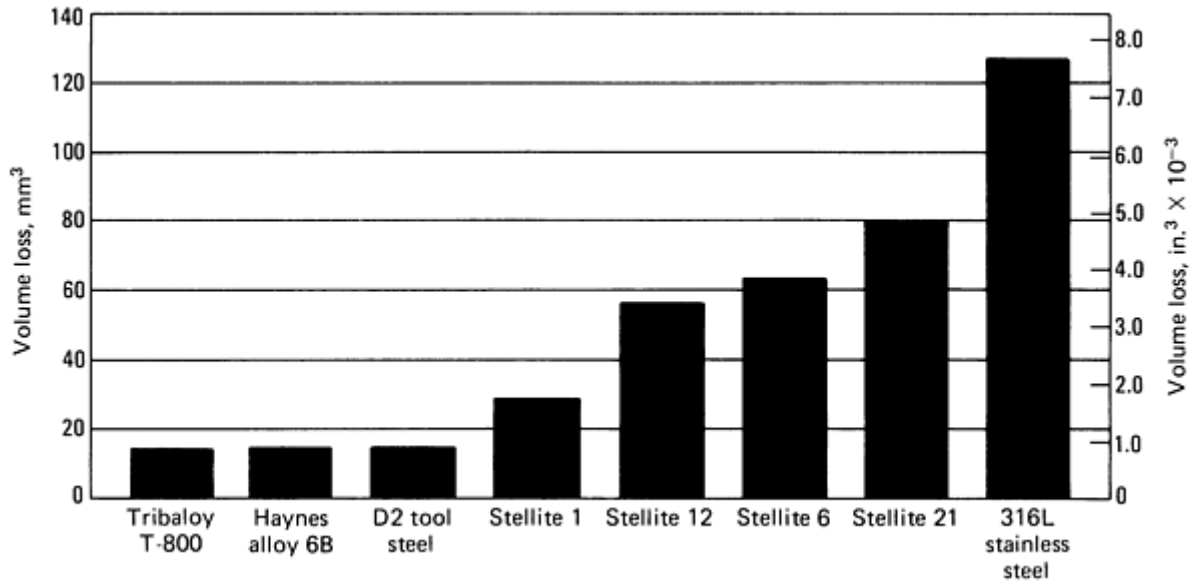

Fig. 3 Abrasion data of various cobalt-base alloys tested per ASTM G 65B

Galling data (under self-mated conditions) are presented for five of the popular alloys in Fig. 4, along with data for corrosion-resistant Ni-Cr-Mo alloy (Hastelloy alloy C-276) and stainless steel noted for its resistant to galling (Nitronic 60). The test, which was too severe for 316L stainless steel in that it failed by total seizure, involved twisting cylindrical pins with diameters of 16 mm (or 0.63 in.) back and forth 10 times through an arc of 120° at a load of 26.7 kN (6000 lbf). The amount of damage to the test surfaces was determined by use of a surface profilometer. The Haynes 6B, Nitronic 60, and Hastelloy C-276 samples were prepared from solution-annealed plates; the Stellite alloy samples were prepared from two-layer GTA deposits; the Tribaloy alloy (T-800) samples were prepared from two-layer plasma-transferred-arc deposits. From Fig. 4 it is evident that the cobalt wear alloys are exceptionally resistant to galling when coupled against like materials, and that this characteristic is largely independent of the compositional variations between the commonly used alloys. It should be noted that the self-mated galling resistance of Nitronic 60 equals that of the cobalt alloys at lower loads.

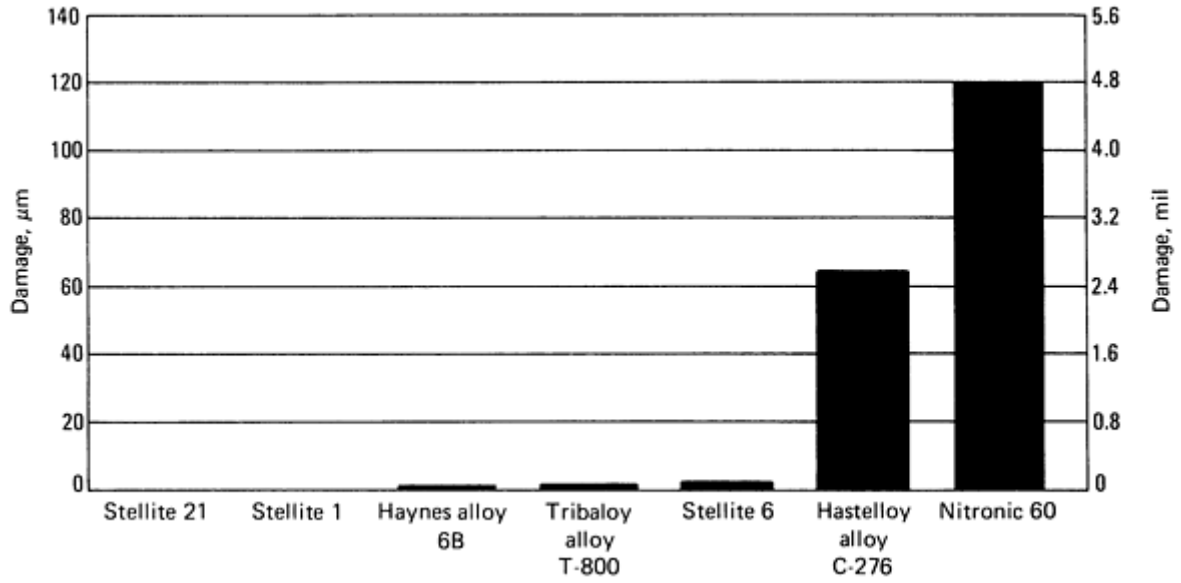

Fig. 4 Galling data of various cobalt-base alloys, Hastelloy C-276, and Nitronic-60 stainless steel. Data are from a 120°-10 stroke test with a 26.7 kN (6000 lbf) load.

Solid-Particle Erosion Data. As previously mentioned in the section "Types of Wear" in this article, resistance against solid-particle erosion may not be as closely correlated with hardness or carbon content as with other types of wear mechanisms. This is evident from the solid-particle erosion data of Ref 6, which compares the solid particle of Haynes alloy 6B with 304 stainless steel and two heat-resistant cobalt-base alloys (Haynes alloys 25 and 188) listed in Table 4. The tests involved solid-particle erosion with 127 μm alumina particle impacting the test specimens at a 90° impact angle and with a speed of 170 m/s (560 ft/s). The weight loss of each alloy, as a fraction of th weight loss for Haynes alloy 6B, were as follows at room temperature:

Alloy	Erosion weight loss compared with alloy 6B
304 stainless steel	Same
Haynes alloy 25	96% of alloy 6B
Haynes alloy 188	97% of alloy 6B

From this data, there is little difference in the solid-particle erosion resistance of the wear-resistant 6B alloy and the two heat-resistant cobalt alloys. The two-resistant alloys (which have lower carbon contents and are more ductile than 6B) even exhibit slightly more erosion resistance than alloy 6B in this particular test. At temperatures of 700 °C (1290 °F), the advantage of the more ductile cobalt alloys became more pronounced, with weight loss fractions of 0.85 and 0.83 for Haynes alloys 25 and 188, respectively.

Cavitation Erosion Data. The outstanding cavitation erosion properties of the cobalt-base wear alloys as compared with Hastelloy alloy C-276 and 316L stainless steel are illustrated in Fig. 5. This information was generated using ASTM G-32 procedures. The samples were prepared from solution-annealed plates (in the case of Haynes alloy 6B, Hastelloy alloy C-276, and 316L stainless steel) or from two-layer GTA deposits (in the case of Stellite alloys 6 and 21). The remaining three wear alloy compositions (from Table 4) lacked sufficient ductility for this test because the samples were of an intricate nature and subjected to high mechanical stresses during attachment to, and detachment from, the ultrasonic horn.

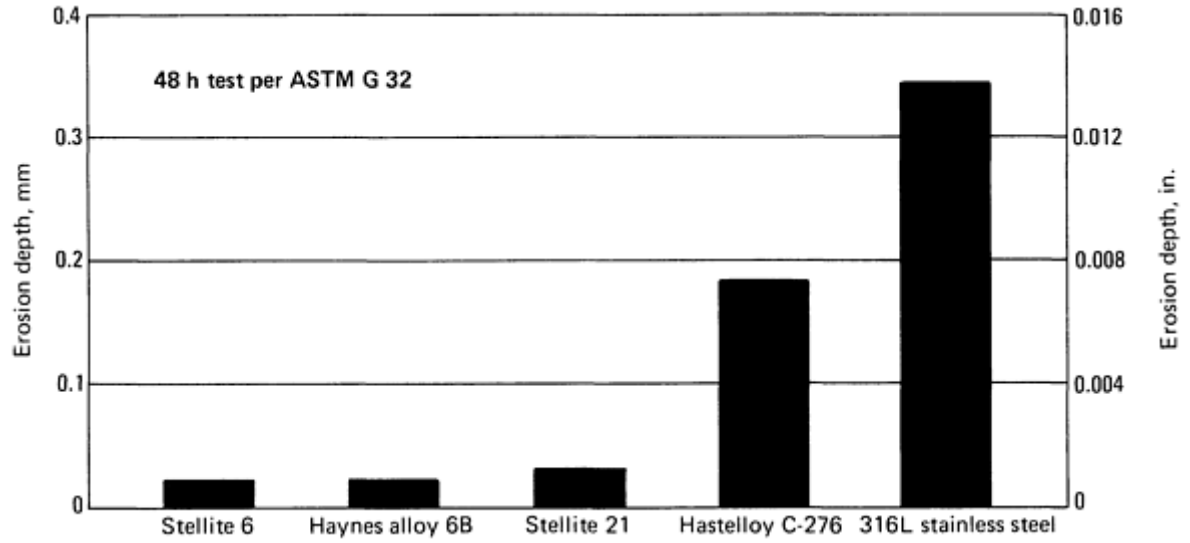

Fig. 5 Cavitation erosion data on various cobalt-base alloys, Hastelloy alloy C-276, and 316L stainless steel

The physical and mechanical properties of six commonly used cobalt wear alloys are presented in Table 5. In the case of the Stellite and Tribaloy alloys, this information pertains to sand castings. Notable are the moderately high yield strengths and hardnesses of the alloys, the inverse relationship between carbon content and ductility (in the case of the Stellite alloys), and the enhanced ductility imparted to alloy 6B by wrought processing. A list of typical applications of the cobalt wear-resistant alloys of Table 4 is given in Table 6. Generally, the alloys are used in moderately, corrosive and/or elevated-temperature environments.

Cobalt-Base High-Temperature Alloys

For many years, the predominant user of high-temperature alloys was the gas turbine industry. In the case of aircraft gas turbine power plants, the chief material requirements were elevated-temperature strength, resistance to thermal fatigue, and oxidation resistance. For land-base gas turbines, which typically burn lower grade fuels and operate at lower

temperatures, sulfidation resistance was the major concern. Today, the use of high-temperature alloys is more diversified, as more efficiency is sought from the burning of fossil fuels and waste, 0and as new chemical processing techniques are developed.

Although cobalt-base alloys are not as widely used as nickel and nickel-iron alloys in high-temperature applications, cobalt-base high-temperature alloys nevertheless play an important role, by virtue of their excellent resistance to sulfidation and their strength at temperatures exceeding those at which the gamma-prime- and gamma-double-prime-precipitates in the nickel and nickel-iron alloys dissolve. Cobalt is also used as an alloying element in many nickel-base high-temperature alloys. The various types of iron-base, nickel-base, and cobalt-base alloys for high-temperature application are discussed in the article "Wrought and P/M Superalloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.* Nickel-base and cobalt-base castings for high-temperature service are also covered in the article "Polycrystalline Cast Superalloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Alloy Compositions and Product Forms. As previously noted, Stellite 21 was an early type of cobalt-base high-temperature alloy that is used now primarily for wear resistance. Since the early use of Stellite 21, cobalt-base high-temperature materials have gone through various stages of development to increase their high-temperature capability. The use of tungsten rather than molybdenum, moderate nickel contents, lower carbon contents, and rare-earth additions typify cobalt-base high-temperature alloys of today.

Typical wrought and cast cobalt alloy compositions developed for high-temperature use are presented in Table 4. Haynes alloys 25 (also known as L605) and 188 are wrought alloys available in the form of sheets, plates, bars, pipes, and tubes (together with a range of matching welding products for joining purposes). MAR-M alloy 509 is an alloy designed for vacuum invested casting. Selected mechanical properties of the three alloys are given in Table 7. Stress rupture data are presented in Fig. 6. Other cobalt-base alloys for high-temperature service are covered in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook.*

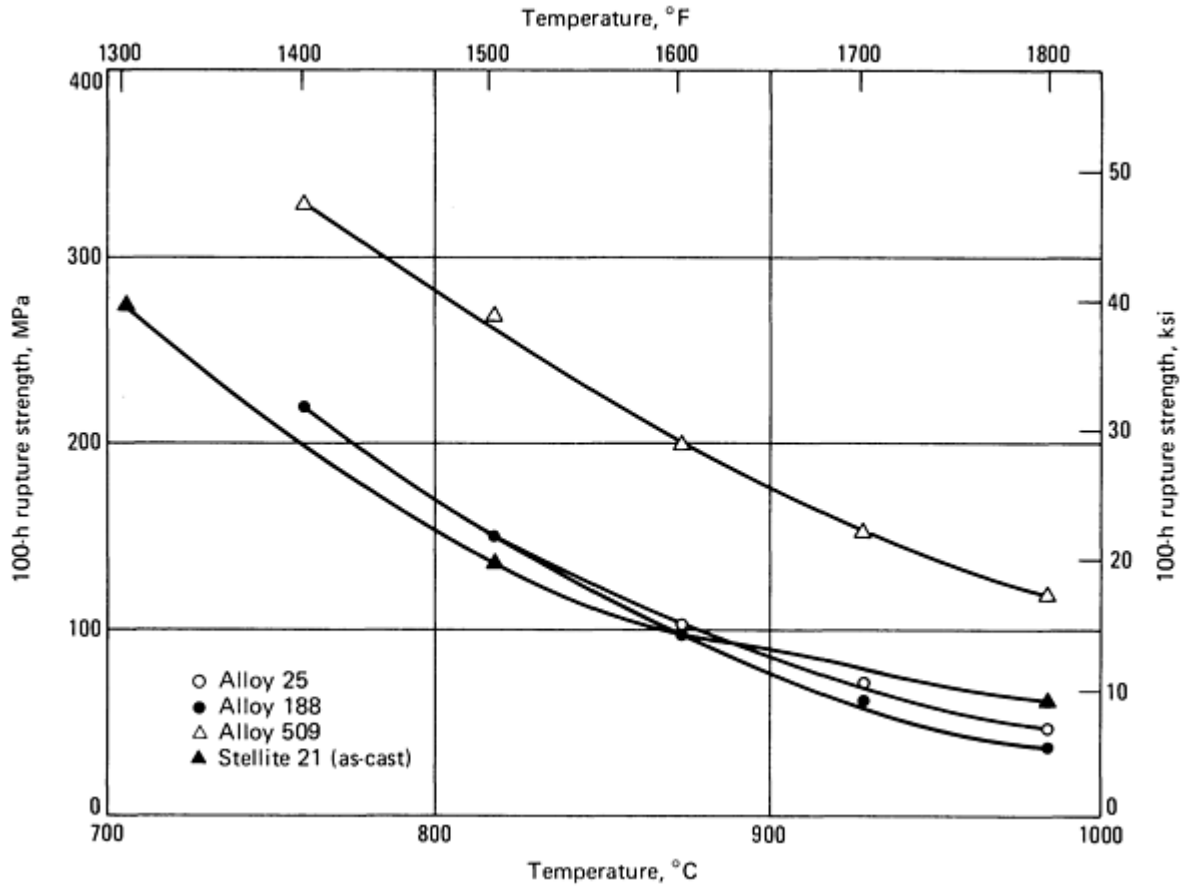

Fig. 6 100-h stress-rupture strengths of selected cobalt-base superalloys. See Table 7 for 1000-h rupture strengths. Stellite 21 included for comparison with MAR-M alloy 509

In the three high-temperature alloys of Table 4, chromium and tungsten are the chief solid-solution strengtheners, and nickel is present to stabilize the face-centered cubic structure (that is, to reduce the allotropic phase transformation temperature). During the design of Haynes alloy 188, consideration was also given to control of the electron hole number (N_v) to restrict the formation of topologically close-packed phases (for example, Laves) in the material (Ref 7). Oxidation resistance is enhanced in the case of Haynes alloy 188 by the rare-earth addition, lanthanum.

Carbides serve to increase high-temperature strength and, in the wrought alloys, control grain size. In the solution-annealed condition, the carbides in Haynes alloy 188 are of the M_6C type. Aging in the temperature range 650 to 1175 °C (1200 to 2150 °F) promotes secondary carbide precipitation (M_6C at the higher aging temperatures and $M_{23}C_6$ at the lower temperatures). In the MAR-M alloy 509 (which has a higher carbon content) the active carbide-forming elements, tantalum, titanium, and zirconium, exhibit a predominant Chinese-script MC carbide in the as-cast condition (Ref 8). Further information on the carbides in cobalt-base superalloys is provided in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook.*

Resistance to Oxidation and Sulfidation. Dynamic oxidation data for Haynes alloys 25 and 188 relative to the nickel-base alloys X and 601 are presented in Fig. 7. The values represent the total depth of metal affected (that is, the

depth of metal turned to oxide plus the depth subjected to internal oxidation). The 100-hour test involved cooling the samples every half hour to 540 °C (1000 °F). The test atmosphere contained the combustion products of A-640 aviation kerosene, using an air-to-fuel ratio of 40 to 1. The test gas velocity was approximately 390 km/h (355 ft/s). The improved performance of Haynes alloy 188 in this test is attributable to effects of lanthanum upon oxide scale adherence.

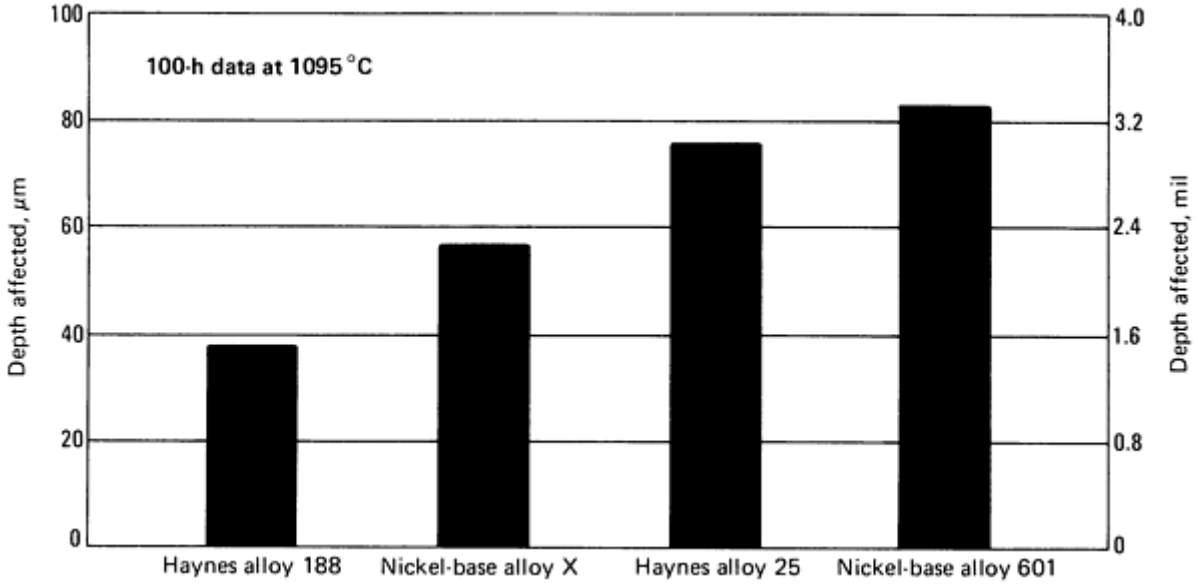

Fig. 7 Dynamic oxidation data for selected high-temperature cobalt alloys and nickel-base alloys at 1095 °C (2000 °F)

Sulfidation test results at 980 °C (1800 °F) for alloys 25 and 188, relative to the nickel-base alloys, X, 601, and Waspaloy alloy, are presented in Fig. 8. These results, which were generated in an environment with a sulfur partial pressure of 0.4 Pa (4×10^{-6} atmosphere) and an oxygen partial pressure of 3×10^{-12} Pa (3×10^{-17} atm), show the outstanding sulfidation resistance of the cobalt-base high-temperature alloys relative to both gamma-prime-strengthened and solid-solution-strengthened high-temperature nickel alloys. Of the alloys tested under these conditions, only Haynes alloy 6B (Table 4) and Haynes alloy HR-160 (a high-silicon, cobalt-containing alloy) exhibit superior properties.

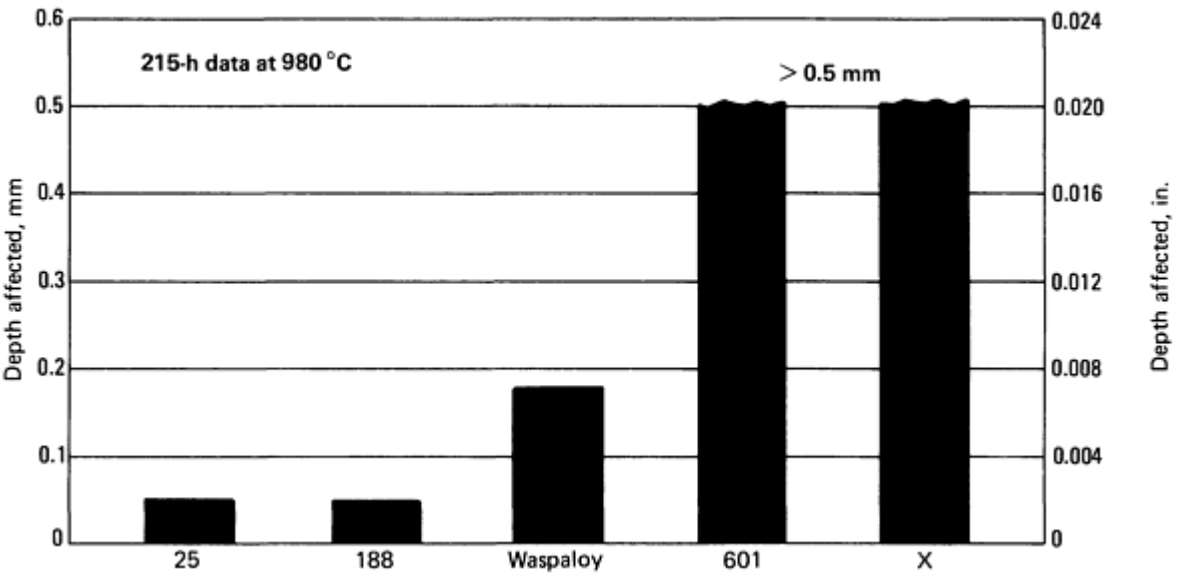

Fig. 8 Sulfidation data of Haynes alloys 25 and 188 relative to selected nickel-base alloys at 980 °C (1800 °F)

Applications. Haynes alloys 25 and 188, and MAR-M alloy 509 are well established in the gas turbine industry. As a casting alloy, 509 is generally used for complex shapes such as nozzle guide vanes. As wrought alloys, 25 and 188 are used for fabricated assemblies and ductwork. In particular, Haynes alloy 188 is the alloy of choice for combustor cans and afterburner liners in high-performance aircraft gas turbines. Haynes alloy 25 has also been used successfully in a variety of industrial furnace applications (for example, muffles and liners).

Cobalt-Base Corrosion-Resistant Alloys

Although the cobalt-base wear-resistant alloys possess some resistance to aqueous corrosion, they are limited by grain boundary carbide precipitation, the lack of vital alloying elements in the matrix (after formation of the carbides or Laves precipitates) and, in the case of the cast and weld overlay materials, by chemical segregation in the microstructure.

By virtue of their homogeneous microstructures and lower carbon contents, the wrought cobalt-base high-temperature alloys (which typically contain tungsten rather than molybdenum) are even more resistant to aqueous corrosion, but still fall well short of the nickel-chromium-molybdenum alloys in corrosion performance.

To satisfy the industrial need for alloys which exhibit outstanding resistance to aqueous corrosion, yet share the attributes of cobalt as an alloy base (resistance to various forms of wear, and high strength over a wide range of temperatures), several low-carbon, wrought cobalt-nickel-chromium-molybdenum alloys are produced. The compositions of two of these are presented in Table 4. In addition, the cobalt-chromium-molybdenum Vitallium alloy is still widely used today for prosthetic devices and implants on account of its excellent compatibility with body fluids and tissues (see the article "Corrosion of Cobalt-Base Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Types of Aqueous Corrosion. Just as there are several types of wear, there are several types of aqueous corrosion. Of concern in this article are:

- Uniform corrosion
- Localized corrosion (pitting)
- Stress-corrosion cracking

Other forms of attack, such as galvanic corrosion and intergranular corrosion, can be overcome by judicious design and by appropriate alloy heat treatments.

Uniform attack is the most common form of corrosion and is so named because loss of surface material is of a uniform nature. From an electrochemical standpoint, uniform corrosion occurs because of the continual shifting of anodic and cathodic surface sites.

Localized attack, or pitting, occurs when anodic surface sites remain stationary. Deep pits may form on such surfaces, giving rise to rapid and unpredictable failures of components. Chloride ions are particularly strong promoters of this type of attack.

Stress-corrosion cracking is caused by the combined effects of corrosion and tensile stresses. As with localized corrosion, failures of components by this mechanism can be rapid and unpredictable. The generally held view of stress-corrosion cracking is that it is initiated by localized corrosion then progress by virtue of a combination of mechanical crack propagation and corrosion at the crack tip (this becoming anodic with respect to surrounding surfaces).

Alloy Compositions and Product Forms. The two corrosion-resistant alloys presented in Table 4 rely for their corrosion resistance on chromium and molybdenum. The corrosion properties of alloy 1233 are also enhanced by tungsten. Both alloys are available in a variety of wrought product forms (plates, sheets bars, tubes, and so forth). They are also available in the form of welding consumables for joining purposes.

Corrosion Properties. The uniform corrosion properties of alloy 1233, relative to a number of well-known nickel- and iron-base corrosion alloys, are summarized in Table 8. The outstanding pitting resistance of alloy 1233 is illustrated in Fig. 9. Although not as resistant to pitting as alloy 1233, MP35N alloy is nevertheless excellent in a wide range of mineral acid environments and chloride solutions.

Table 8 Comparison of corrosion rates for selected cobalt-base, iron-base,and nickel-base alloys in various solutions

Alloy	Corrosion rate, mm/year							
	Boiling 99% acetic acid	Boiling 65% nitric acid	Boiling 1% hydrochloric acid	Boiling 2% hydrochloric acid	54% P_2O_5at 116 °C (240 °F)	Boiling 10% sulfuric acid	Boiling ASTM-G28A solution	Boiling ASTM-G28B solution
1233	<0.01	0.15	0.01	13.49	0.19	2.52	0.20	0.02
C-276	<0.01	21.51	0.52	1.90	0.58	0.51	8.05	0.86
625	0.01	0.51	0.03	14.15	0.30	0.64	0.43	71.08
20CB-3	0.11	0.19	1.80	5.77	0.92	0.40	0.25	69.08
316L	0.19	0.24	13.31	25.15	5.11	47.46	0.94	80.51

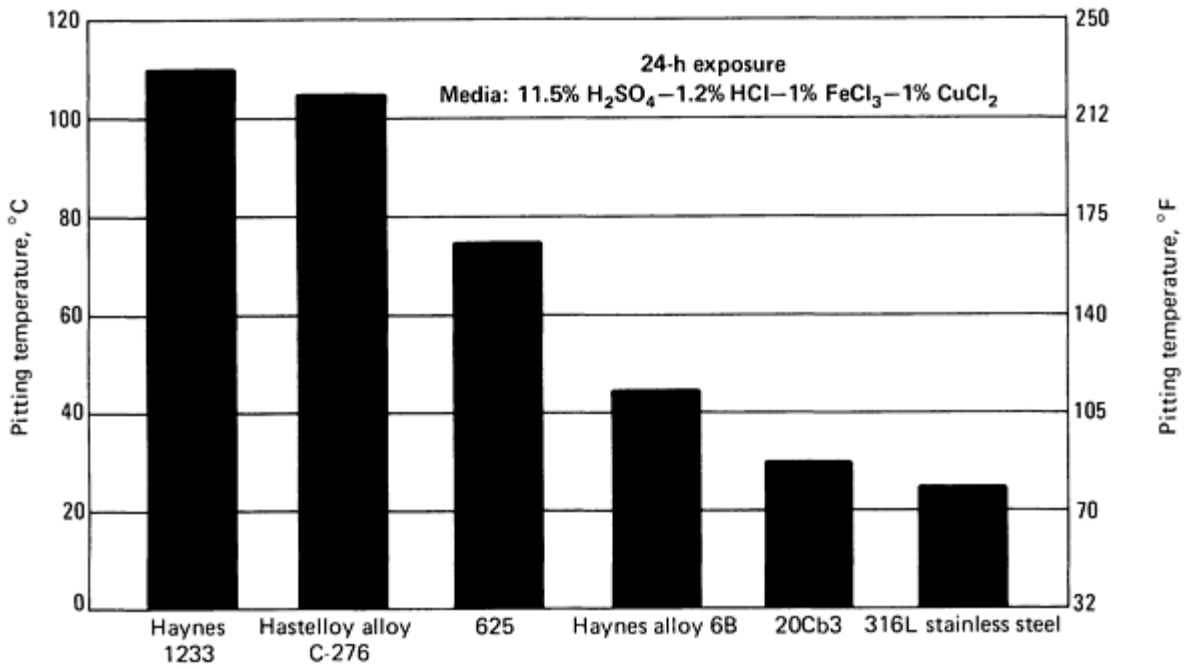

Fig. 9 Critical pitting temperature of the cobalt-base corrosion-resistant alloy 1233 compared with various other alloys

Alloy 1233 is less resistant to stress-corrosion cracking than the nickel-chromium-molybdenum Hastelloy alloys; however, it offers better resistance than 316L stainless steel to this form of failure. By virtue of its higher nickel content, MP35N alloy is very resistant to stress-corrosion cracking and is suitable for hydrogen sulfide service.

Mechanical Properties. An advantage of the two corrosion-resistant alloys in Table 4 is that they may be strengthened considerably by cold working. In the case of MP35N alloy, the alloy is intended for use in the work-hardened (or work-

hardened and aged) condition, and the manufacturers have supplied considerable data concerning the mechanical properties of the alloy at different levels of cold work. Some of these data (0.2% offset yield strengths and elongation values) are plotted in Fig. 10. Other mechanical and physical properties of the two alloys are given in Table 9.

Selection and Application of Magnesium and Magnesium Alloys

Revised by Susan Housh and Barry Mikucki, Dow Chemical U.S.A., and Archie Stevenson, Magnesium Elektron, Inc.

Introduction

MAGNESIUM and magnesium alloys are used in a wide variety of structural and nonstructural applications. Structural applications include automotive, industrial, materials-handling, commercial, and aerospace equipment. The automotive applications include clutch and brake pedal support brackets, steering column lock housings, and manual transmission housings. In industrial machinery, such as textile and printing machines, magnesium alloys are used for parts that operate at high speeds and thus must be lightweight to minimize inertial forces. Materials-handling equipment includes dockboards, grain shovels, and gravity conveyors. Commercial applications include hand-held tools, luggage, computer housings, and ladders. Magnesium alloys are valuable for aerospace applications because they are light-weight and exhibit good strength and stiffness at both room and elevated temperatures.

Magnesium is also employed in various nonstructural applications. It is used as an alloying element in alloys of aluminum, zinc, lead, and other nonferrous metals. It is used as an oxygen scavenger and desulfurizer in the manufacture of nickel and copper alloys; as a desulfurizer in the iron and steel industry; and as a reducing agent in the production of

beryllium, titanium, zirconium, hafnium, and uranium. Another important nonstructural use of magnesium is in the Grignard reaction in organic chemistry. In finely divided form, magnesium finds some use in pyrotechnics, both as pure magnesium and alloyed with 30% or more aluminum. The relative position of magnesium in the electromotive series allows it to be used for cathodic protection of other metals from corrosion and in construction of dry-cell, seawater, and reserve-cell batteries. Gray iron foundries use magnesium and magnesium-containing alloys as ladle addition agents introduced just before the casting is poured. The magnesium makes the graphite particles nodular and greatly improves the toughness and ductility of the cast iron. Because of its rapid but controllable response to etching and its light weight, magnesium is also used in photoengraving.

Table 1 presents figures for the global shipments of primary magnesium from 1983 to 1988, broken down into its major uses. Primary magnesium is furnished to ASTM B 92, grade 9980A, with a specified minimum magnesium content of 99.8%. Also available are special grades of primary magnesium in which manganese, aluminum, and iron impurities are held to especially low levels. These special grades are employed in chemical and metallurgical applications, such as the preparation of uranium metal and other reactive metals.

Aluminum and zinc are relatively soluble in solid magnesium, but their solubilities decrease at low temperatures. The solubility of aluminum is 12.7% by weight at 437 °C (819 °F) and 3.0% at 93 °C (200 °F); solubility of zinc is 6.2% at 340 °C (644 °F) and 2.8% at 204 °C (400 °F), Solubilities of manganese, zirconium, and cerium are less than 1.0% by weight at 482 °C (900 °F). At the eutectic temperature, 4.5% thorium is soluble in magnesium. Manganese is effective in improving the corrosion stability of magnesium alloys that contain aluminum and zinc. Several of these alloys, which employ manganese to control both the iron content and activity in the alloy, are available and have excellent corrosion resistance. Other alloys not containing aluminum and zinc, but containing yttrium, are also available and exhibit good corrosion resistance.

Designations. A standard system of alloy and temper designations, adopted in 1948, is explained in Table 2. As an example of how the system works, consider magnesium alloy AZ91E-T6, the nominal composition and typical properties of which are given in Table 3. The first part of the designation, AZ, signifies that aluminum and zinc are the two principal alloying elements. The second part of the designation, 91, gives the rounded-off percentages of aluminum and zinc (9 and 1, respectively). The third part, E, indicates that this is the fifth alloy standardized with 9% Al and 1% Zn as the principal alloying additions. The fourth part, T6, denotes that the alloy is solution treated and artificially aged.

Table 2 Standard four-part ASTM system of alloy and temper designations for magnesium alloys

See text for discussion.

First part	Second part	Third part	Fourth part
Indicates the two principal alloying elements	Indicates the amount of the two principal alloying elements	Distinguishes between different alloys with the same percentages of the two principal alloying elements	Indicates condition (temper)
Consists of two code letters representing the two main alloying elements arranged in order of decreasing percentage (or alphabetically if percentages are	Consists of two numbers corresponding to rounded-off percentages of the two main alloying elements and arranged in same order as alloy designations in first part	Consists of a letter of the alphabet assigned in order as compositions become standard	Consists of a letter followed by a number (separated from the third part of the designation by a hyphen)

equal)			
A--aluminum B--bismuth C--copper D--cadmium E--rare earth F--iron G--magnesium H--thorium K--zirconium L--lithium M--manganese N--nickel P--lead Q--silver R--chromium S--silicon T--tin W--yttrium Y--antimony Z--zinc	Whole numbers	Letters of alphabet except I and O	F--as fabricated O--annealed H10 and H11--slightly strain hardened H23, H24, and H26--strain hardened and partially annealed T4--solution heat treated T5--artificially aged only T6--solution heat treated and artificially aged T8--solution heat treated, cold worked, and artificially aged

(a) Minimum.

(b) RE, rare earth; Di, didymium (a mixture of rare-earth elements made up chiefly of neodymium and praseodymium).

(c) 500 kg load, 10 mm ball.

(d) Properties of C and E are identical, but AZ91E castings have maximum contaminant levels of 0.005% Fe, 0.0010% Ni, and 0.015% Cu.

(e) Properties of A and B are identical, but AM60B castings have maximum contaminant levels of 0.005% Fe, 0.002% Ni, and 0.010% Cu.

(f) Properties of A and XB are identical, but AS41XB castings have maximum contaminant levels of 0.0035% Fe, 0.002% Ni, and 0.020% Cu.

(g) Properties of A, B, and D are identical, except that 0.30% max residual Cu is allowable in AZ91B, and AZ91D castings have maximum contaminant levels of 0.005% Fe, 0.002% Ni, and 0.030% Cu.

(h) For battery applications.

(i) Properties of B and C are identical, but AZ31C has 0.15% min Mn, 0.1% max Cu, and 0.03% max Ni.

(j) Photoengraving grade

Casting Alloys

High-Pressure Die Casting Alloys. There are three systems of magnesium alloys used commercially for high-pressure die casting: magnesium-aluminum-zinc-manganese (AZ), magnesium-aluminum-manganese (AM), and magnesium-aluminum-silicon-manganese (AS). Nominal compositions and typical properties of these alloys are given in Table 3. General characteristics of high-pressure die casting alloys are given in Table 4.

Table 4 Characteristics of high-pressure die cast alloys

Alloy[(a)]	General characteristics
AZ91D	Most commonly used die casting alloy. Good strength at room temperature, good castability, good atmospheric stability, excellent saltwater corrosion resistance
AM60B	Good elongation and toughness, excellent saltwater corrosion resistance, good yield and tensile properties
AS21X1	Best creep resistance of die casting alloys, good room-temperature properties, useful in high-temperature applications
AS41XB	Good creep resistance up to 175 °C (350 °F), good room-temperature properties, excellent saltwater corrosion resistance, useful in high-temperature applications

(a) All alloys are in the as-cast condition.

The most commonly used magnesium die casting alloy is AZ91D. The AZ91D alloy exhibits good mechanical and physical properties in combination with excellent castability and saltwater corrosion resistance. The excellent corrosion resistance of high-purity AZ91D is essentially the result of controlling the impurity level of three critical contaminants: iron, nickel, and copper. High-purity AZ91D alloy has replaced less-pure AZ91B as the workhorse for die casting. The AZ91B alloy is still used because it can be easily produced from scrap or secondary metal. This cost-saving alternative can be used for applications in which corrosion resistance is not an important consideration, for example, painted parts in a noncorrosive environment. Die castings are used in the as-cast condition.

For applications requiring greater ductility than available with AZ91D, high-purity die cast alloy AM60B is used. The AM60B alloy has better elongation and toughness than AZ91D. Despite the decrease in aluminum content, the tensile and yield strengths of AM60B are only slightly lower than those of AZ91D. The AM60B alloy is used in the production of die cast automobile wheels and in some archery and other sports equipment. As with AZ91D, AM60B exhibits excellent saltwater corrosion resistance.

Die cast alloy AS41A has creep strength much superior to that of the AZ91D or AM60B alloys at temperatures up to 175 °C (350 °F); it also has good elongation, yield strength, and tensile strength. The AS41A alloys was used in crankcases of air-cooled automotive engines. A high-purity version of AS41A, which exhibits excellent saltwater corrosion resistance, is being introduced as AS41XB.

The AS21 alloy exhibits even better creep strength than AS41A. However, AS21 has lower room-temperature tensile and yield strengths, and it is somewhat more difficult to cast.

Sand and Permanent Mold Casting Alloys. Several systems of magnesium alloys are available for sand and permanent mold castings:

- Magnesium-aluminum-manganese with and without zinc (AM and AZ)
- Magnesium-zirconium (K)
- Magnesium-zinc-zirconium with and without rare earths (ZK, ZE, and EZ)
- Magnesium-thorium-zirconium with and without zinc (HK, HZ, and ZH)

- Magnesium-silver-zirconium with rare earths or thorium (QE and QH)
- Magnesium-yttrium-rare-earth-zirconium (WE)
- Magnesium-zinc-copper-manganese (ZC)

Nominal compositions and typical properties of these alloys are given in Table 3. A summary of general characteristics of the sand and permanent mold casting alloy is given in Table 5.

Table 5 Characteristics of sand and permanent mold cast alloys

Alloy	Temper	General characteristics
AM100A	T4, T6	Permanent mold alloy. Pressure tight, weldable, good atmospheric stability
AZ63A	T4, T6	Good saltwater corrosion resistance even with a high iron level, good toughness, difficult to cast. Very seldom used today
AZ91E	T6	General-purpose alloy. Good strength at room temperature, useful properties up to 175 °C (350 °F), good atmospheric stability, and excellent saltwater corrosion resistance. The most commonly used alloy in the Mg-Al-Zn family
AZ92C	T6	General-purpose alloy. Excellent strength at room temperature, useful properties up to 175 °C (350 °F), good atmospheric stability
EQ21A	T6	Heat-treated alloy. High yield strength up to 250 °C (480 °F), pressure tight, weldable
EZ33A	T5	Creep resistant up to 250 °C (480 °F), excellent castability, pressure tight, weldable
HK31A	T6	Creep resistant up to 345 °C (650 °F) for short-time applications, pressure tight, weldable
HZ32A	T5	Creep resistant up to 345 °C (650 °F), pressure tight, weldable
QE22A	T6	Heat-treated alloy. High yield strength up to 250 °C (480 °F), pressure tight, weldable
QH21A	T6	Good creep resistance, high yield strength up to 300 °C (570 °F), pressure tight, weldable
WE43	T6	Heat-treated alloy. Good properties up to 250 °C (480 °F) for extended periods of time, pressure tight, weldable, good corrosion resistance
WE54A	T6	The first of a new family of alloys containing yttrium. Exceptional strength at both room and elevated temperatures
ZC63A	T6	Good room-temperature properties, useful strength at moderately elevated temperatures, excellent castability, pressure tight, weldable
ZE41A	T5	Easily cast, weldable, pressure tight, useful strength at elevated temperatures

ZE63A	T6	Excellent castability, pressure tight, weldable, highly developed properties in thin-wall castings
ZH62A	T5	Stronger than, but as castable as, ZE41A. Weldable, pressure tight
ZK51A	T5	Good strength at room temperature
ZK61A	T6	Excellent strength at room temperature. Only fair castability but capable of developing excellent properties in castings

Source: Ref 1

Magnesium-Aluminum Casting Alloys. The magnesium sand and permanent mold casting alloys that contain aluminum as the primary alloying ingredient (AM100A, AZ63A, AZ81A, AZ91C, AZ91E, and AZ92A) exhibit good castability, good ductility, and moderately high yield strength at temperatures up to approximately 120 °C (~250 °F). Of these alloys, AZ91E has become prominent; it has almost completely replaced AZ91C because it has superior corrosion performance. In AZ91E, the iron, nickel, and copper contaminants are controlled to very low levels. As a result, it exhibits excellent saltwater corrosion resistance.

In any of the magnesium-aluminum-zinc alloys, an increase in aluminum content raises yield strength but reduces ductility for comparable heat treatment. Final selection of the specific composition may be based on tests of the finished castings.

The K1A alloy is used primarily where high damping capacity is required. It has low tensile and yield strength.

Magnesium alloys that contain high levels of zinc (ZK51A, ZK61A, ZK63A, and ZH62A) develop the highest yield strengths of the casting alloys and can be cast into complicated shapes. However, these grades are more costly than the alloys of the AZ series. Therefore, these alloys are used where exceptionally good yield strengths are required. They are intended primarily for use at room temperature.

Because ZK61A has a higher zinc content, it has significantly greater strength than ZK51A (Table 3). Both alloys maintain high ductility after an artificial aging treatment (T5). The strength of ZK61A can be further increased (3 to 4%) by solution treatment plus artificial aging (T6), without impairing ductility. Both of these alloys have fatigue strengths equal to those of the magnesium-aluminum-zinc alloys, but they are more susceptible to microporosity and hot cracking, and are less weldable. Addition of either thorium or rare-earth metals overcomes these deficiencies. The strength properties of ZE63A are equivalent to those of ZK61A, and those of ZH62A are equivalent to or better than those of ZK51A (Table 3).

Alloy ZE63A is a high-strength grade with excellent tensile strength and yield strength; these superior properties are obtained by heat treating in a hydrogen atmosphere. Because hydriding proceeds from the surface, heat-treating time, wall thickness, and penetrability are limiting factors. This alloy has excellent casting characteristics.

The ZE41A alloy was developed to meet the growing need for an alloy with medium strength, good weldability, and improved castability in comparison with AZ91C and AZ92A. It has good fatigue and creep properties and maximum freedom from microshrinkage. Unlike the AZ alloys, there is a very close relationship between separately cast test bar properties and those obtained from the casting itself, even where relatively thick cast sections are involved. Alloy ZE41A is used at temperatures up to 160 °C (320 °F) in such applications as aircraft engines, helicopter and airframe components, and wheels and gear boxes.

Alloy ZC63 is a member of a new family of magnesium alloys containing neither aluminum nor zirconium. The alloy exhibits good castability, and it is pressure tight and weldable. No grain refining or hardeners are required to obtain its properties, but a heat treatment must be used to achieve the full properties. The alloy has attractive room-temperature and moderately elevated temperature properties. The corrosion resistance of the alloy is similar to that of AZ91C, but it is less than that of AZ91E.

The magnesium-rare-earth-zirconium alloys are used at temperatures between 175 and 260 °C (350 and 500 °F). Because their high-temperature strengths exceed those of the magnesium-aluminum-zinc alloys, thinner walls can be used, and a savings in weight is possible.

The magnesium-rare-earth-zinc-zirconium alloy EZ33A has good strength stability when exposed to elevated temperatures. (Strength stability is the ability to resist deterioration of strength from extended exposure to elevated temperatures.) This alloy is more difficult to cast in some designs than magnesium-aluminum-zinc alloys. Castings of EZ33A have excellent pressure tightness. Alloy ZE41A, discussed earlier, is similar to EZ33A, but it has higher tensile and yield strengths because of its higher zinc content. Some sacrifice is made in castability and weldability in ZE41A to obtain the higher mechanical properties.

When the operating temperature of an engine housing was increased from 120 to 205 °C (250 to 400 °F), alloy EZ33A-T5 was successfully substituted for AZ92A-T6. The change was based on creep tests of separately cast bars of the two alloys; stress values for 0.1% creep in 1000 h were:

Alloy	Temperature		Stress	
	°C	°F	MPa	ksi
AZ92A-T6	205	400	6.9	1.0
	260	500	2.1	0.3
EZ33A-T5	205	400	58	8.4
	260	500	26	3.7

The magnesium-thorium-zirconium alloys HK31A and HZ32A are intended primarily for use at temperatures of 200 °C (400 °F) and higher; at these temperatures, properties superior to those of EZ33A are required. For full development of properties, HK31A requires the T6 treatment (solution heat treatment plus artificial aging), whereas HZ32A, which contains zinc, requires only the T5 treatment (artificial aging). Castings of HK31A and HZ32A have been used at temperatures as high as 345 to 370 °C (650 to 700 °F) in a few applications. The magnesium-zinc-thorium-zirconium alloy ZH62A differs from other magnesium-thorium-zirconium alloys in that it is intended primarily for use at room temperature.

Magnesium-thorium-zirconium alloys are more difficult to cast than EZ33A because they are more susceptible to the formation of inclusions and defects as a result of gating turbulence. The tendency for inclusions to form in the magnesium-thorium-zirconium alloys is particularly marked in thin-wall parts that require rapid pouring rates. These alloys have adequate castability for production of complex parts of moderate-to-heavy wall thickness.

At 260 °C (500 °F) and slightly higher, HZ32A is equal to or better than HK31A in short-time and long-time creep strength at all extensions. The HK31A alloy has higher tensile, yield, and short-time creep strengths up to 370 °C (700 °F). However, HZ32A has greater strength stability at elevated temperatures, and it has much better foundry characteristics than does HK31A.

Magnesium-Silver Casting Alloys. The presence of silver improves the room-temperature strength of magnesium alloys. When rare-earth elements or thorium is present, along with the silver, elevated-temperature strength is also increased. The QE22A and EQ21A grades are high tensile strength and yield strength alloys with fairly good properties at temperatures up to 205 °C (400 °F). Alloy QH21A has similar properties to QE22A and EQ21 at room temperature, but it exhibits superior properties at temperatures from 205 °C (400 °F) up to 260 °C (500 °F). The alloys QE22A, EQ21A, and QH21A have good castability and weldability. They do require solution and aging heat treatments to achieve the higher mechanical properties. The QE22A and QH21A alloys are relatively expensive because of their silver contents; EQ21A, which has a lower silver content, is less expensive.

Alloys WE54 and WE43 have high tensile strengths and yield strengths, and they exhibit good properties at temperatures up to 300 °C (570 °F) and 250 °C (480 °F), respectively. The WE54 alloy retains its properties at high temperature for up to 1000 h, whereas WE43 retains its properties at high temperature in excess of 5000 h. Both WE54 and WE43 have good castability and weldability, but they require solution and aging heat treatments to optimize their mechanical properties. They are relatively expensive because of their yttrium content. Both alloys are corrosion resistant, with corrosion rates similar to those of the common aluminum-base casting alloys.

Wrought Alloys

Wrought magnesium alloys are produced as bars, billets, shapes, wire, sheet, plate and forgings.

Extruded bars and shapes are made of several types of magnesium alloys (Table 3). For normal strength requirements, one of the magnesium-aluminum-zinc (AZ) alloys is usually selected. The strength of these alloys increases as aluminum content increases. Alloy AZ31B is a widely used moderate-strength grade with good formability; it is used extensively for cathodic protection. Alloy AZ31C is a lower-purity commercial variation of AZ31B for light-weight structural applications that do not require maximum corrosion resistance. The M1A and ZM21A alloys can be extruded at higher speeds than AZ31B, but they have limited use because of their lower strength. Alloy AZ10A has a low aluminum content and thus is of lower strength than AZ31B, but it can be welded without subsequent stress relief. The AZ61A and AZ80A alloys can be artificially aged for additional strength (with a sacrifice in ductility); AZ80A is not available in hollow shapes. Alloy AZ21X1 is designed specially for use in battery applications.

Alloy ZK60A is used where high strength and good toughness are required. This alloy is heat treatable and is normally used in the artificially aged (T5) condition. ZK21A and ZK40A alloys are of lower strength and are more readily extrudable than ZK60A; they have had limited use in hollow tubular strength requirements.

Alloy ZC71 is a member of a new family of magnesium alloys containing neither aluminum nor zirconium. The alloy can be extruded at high rates and exhibits good strength properties. The corrosion resistance of ZC71 is similar to that of AZ91C, but it falls far short of that of AZ91E.

Alloy HM31A is of moderate strength. It is suitable for use in applications requiring good strength and creep resistance at temperatures in the range of 150 to 425 °C (300 to 800 °F).

Forgings are made of AZ31B, AZ61A, AZ80A, M1A, and ZK60A; the compositions and properties of these alloys are listed under extruded bars and shapes in Table 3. Alloy HM21A, which is listed under sheet and plate alloys in Table 3, is also a good forging alloy. Alloys M1A and AZ31B maybe used for hammer forgings (whereas the other alloy are almost always press forged); however, there has been a gradual decline in the use of the magnesium-manganese alloy M1A. The AZ80A alloy has greater strength than AZ61A and requires the slowest rate of deformation of the magnesium-aluminum-zinc alloys. Alloy ZK60A has essentially the same strength as AZ80A but with greater ductility. To develop maximum properties, both AZ80A and ZK60A are heat treated to the artificially aged (T5) condition; AZ80A may be given the T6 solution heat treatment, followed by artificial aging to provide maximum creep stability. Alloy HM21A is give the T5 temper. It is useful at elevated temperatures up to 370 to 425 °C (700 to 800 °F) for applications in which good creep resistance is needed.

Hydraulic and mechanical processes are both used for the forging of magnesium. A slow and controlled rate of one deformation is desirable because it facilitates control of the plastic flow of metal; therefore, hydraulic press forging is the most commonly used process. Magnesium, which has a hexagonal crystal structure, is more easily worked at elevated temperatures. Consequently, forging stock (ingot or billet) is heated to a temperature between 350 and 500 °C (650 and 950 °F) prior to forging. Forgeability ratings of four magnesium alloys are given in Table 6. Forgeability was measured by transverse ductility, assuming a web thickness of approximately 3 mm ($\frac{1}{8}$ in.) and a minimum draft angle of 1°. The ZK60A alloy is indicated as having slightly higher forgeability than the other three high-strength alloys.

Table 6 Forgeability of four magnesium alloys

Alloy	Transverse ductility, %[(a)]	Forging characteristics
ZK60A	7.0	Excellent on hydraulic or mechanical presses for small forgings; large forgings confined to hydraulic presses.

		Properties nearly equivalent to those of AZ80A
AZ80A	5.0	Forgings have maximum strength. Forging limited to hydraulic presses
HK31A	5.0	Readily forged if proper temperature is maintained. Recommended for elevated-temperature applications
HM21A	5.0	Rolled ring and die forgings. Recommended for elevated-temperature applications

(a) for a minimum web thickness of approximately 3 mm ($\frac{1}{8}$ in.) and a minimum draft of 1°

Sheet and plate are rolled magnesium-aluminum-zinc (AZ and photoengraving grade, or PE) and magnesium-thorium (HK and HM) alloys (Table 3).

Alloy AZ31B is the most widely used alloy for sheet and plate and is available in several grades and tempers. It can be used at temperatures up to 100 °C (200 °F). The HK31A and HM21A alloys are suitable for use at temperatures up to 315 and 345 °C (600 and 650 °F), respectively. However, HM21A has superior strength and creep resistance. For example, an air impeller manufactured from thick plate of alloy HK31A failed as a result of excessive creep. The same item manufactured from HM21A provided satisfactory performance and service life. Test coupons machined from the two materials gave the following stress values:

Alloy	**Stress for 0.1 % creep in 100 h**	
	MPa	**ksi**
At 205 °C (400 °F)		
HM21A	86.2	12.5
HK31A	41	6.0
At 260 °C (500 °F)		
HM21A	72.4	10.5
HK31A	28	4.0
At 315 °C (600 °F)		
HM21A	52	7.5
HK31A	14	2.0

Alloy PE is a special-quality sheet with excellent flatness, corrosion resistance, and etchability. It is in photoengraving.

Good formability is an important requirement for most sheet materials. The approximate formability of magnesium alloy sheet is indicated by its ability to withstand 90° bending over a mandrel without cracking. The minimum size of the mandrel without (minimum radius) over which the sheet can be bent without cracking depends on alloy composition and temper, material thickness, and temperature (Table 7). When correct temperatures and forming conditions are employed, all magnesium alloys can be deep drawn to about equal reduction.

Table 7 Recommended minimum radii for 90° bends in magnesium sheet

The numerical values for bend radii are given as multiples of sheet thickness.

Alloy and temper	Forming temperature[(a)]							
	20 °C (70 °F)	95 °C (200 °F)	150 °C (300 °F)	205 °C (400 °F)	260 °C (500 °F)	315 °C (600 °F)	370 °C (700 °F)	425 °C (800 °F)

(a) See Table 18 for maximum time at temperature.

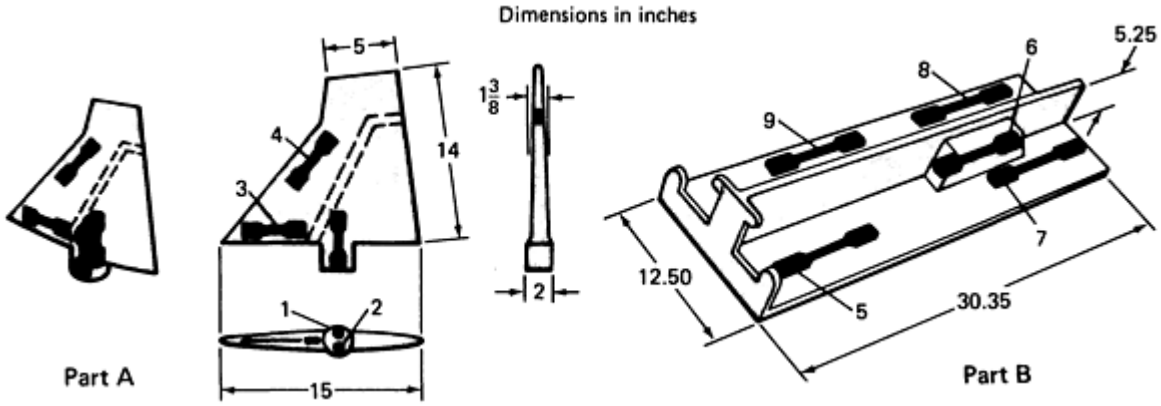
Metal-Matrix Composites. Magnesium serves as an excellent matrix for metal-matrix composites. It has an excellent affinity for bonding to reinforcing ceramic materials, which include continuous and discontinuous ceramic fibers along with ceramic particles. Magnesium composites can be manufactured by liquid metal infiltration processes, continuous casting, squeeze casting, diffusion bonding, powder metallurgy, and proprietary casting techniques.

Continuous fiber reinforced magnesium composites have excellent room- and elevated-temperature stiffness and strength. However, they are relatively expensive because of the high cost of the continuous reinforcements, which include alpha Al_2O_3, boron, graphite, SiC, and steel fibers. Magnesium alloys reinforced with continuous graphite fibers have the best combination of specific stiffness and thermal-deformation resistance of any common engineering material. Magnesium alloys reinforced with discontinuous alumina-silica, or mineral fibers are being investigated for use in commercial automobile pistons because their wear properties are superior to those of typical magnesium alloys. Magnesium-ceramic particle composites have shown excellent specific stiffness, strength, and increased abrasive wear resistance. These properties, along with the low cost of ceramic particles such as SiC, B_4C, and Al_2O_3, make magnesium-ceramic particle composites a competitive candidate for many commercial automotive applications. A more detailed explanation of reinforced magnesium alloys can be found in the article "Metal-Matrix Composites" in this Volume.

Mechanical Properties

Typical values for the mechanical and physical properties of magnesium alloys are given in the article "Properties of Magnesium Alloys" in this Volume. For castings, these values are obtained by testing separately cast specimens. Tensile strengths of investment mold and shell mold castings compare favorably with those of sand and permanent mold castings. Yield strength, tensile strength, and percentage elongation may vary with cooling rate and generally are lower than those of separately cast sand mold test bars.

Figure 1 shows the effect of specimen location on the tensile properties of specimens machined from two representative sand castings that have sections of varying thickness. Some specifications permit a 25% reduction in tensile strength and a 75% reduction in elongation for specimens machined from castings, as compared with requirements for separately cast bars.



Specimen location	Tensile strength		Yield strength		Elongation in 50 mm (2 in.), %
	MPa	ksi	MPa	ksi	
Part A					
1	202.4	29.35	116.5	16.90	2.8
2	199.6	28.95	123.1	17.85	2.8
3	227.5	33.00	133.1	19.30	2.5
4	265.4	38.50	141.0	20.45	4.0
Part B					
5	242.7	35.20	140.8	20.42	2.8
6	214.8	31.15	135.5	19.65	3.1
7	248.6	36.05	142.1	20.61	2.5
8	250.6	36.35	141.8	20.57	2.2

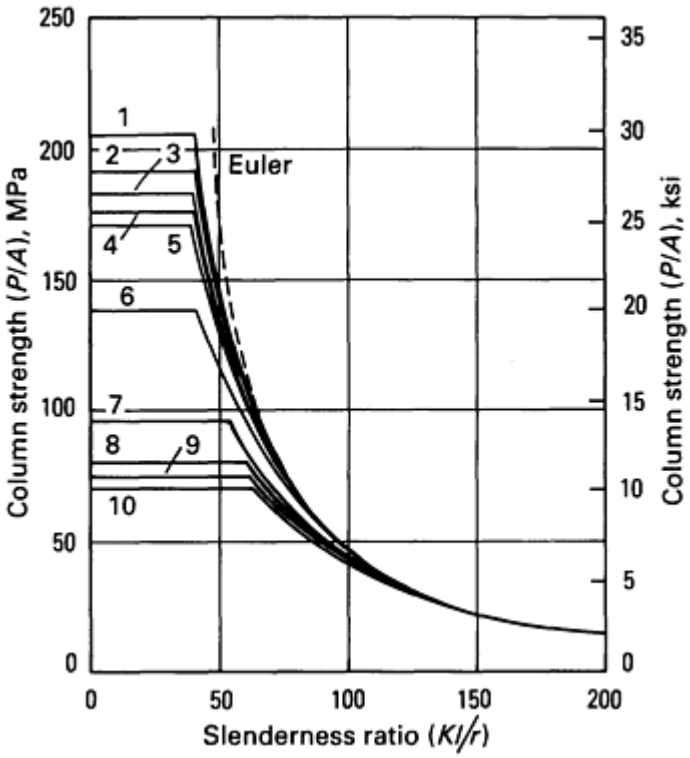
Fig. 1 Effect of specimen location on the tensile properties of two AZ91A-T6 production sand castings. Part A, average mechanical properties for parts made from 11 different heats. Specimens 1 and 2 were machined 13 mm (0.50 in.) in diameter; specimens 3 and 4, 6.4 × 13 mm (0.25 × 0.50 in.) flat. Part B, average mechanical properties for parts made from 16 heats. Castings weighed approximately 7 kg (15 lb), and all sections were 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.) thick, except specimen 6, which was taken from a section about 25 mm (1.0 in.) thick. Test specimens were 6.4 × 13 mm ($\frac{1}{4}$ × $\frac{1}{2}$ in.) flat, except number 6, which was 13 mm (0.50 in.) in diameter. Customer required a minimum of 176 MPa (25.5 ksi) tensile strength, 110 MPa (16.0 ksi) yield strength, and 1.0% elongation in 50 mm (2 in.).

Most magnesium alloys have ratios of tensile strength to density and tensile yield strength to density that are comparable to those of other common structural metals.

The direction, temperature, and speed at which an alloy is fabricated have a significant effect on the mechanical properties of wrought parts. For example, extrusions produced at higher temperatures and speeds have lower strength than those produced under normal operating conditions. Mechanical properties of forgings depend on the orientation of the tested specimen in relation to the flow patterns developed during forging.

Compressive Strength. Compressive yield strength is defined as the stress required to produce a deviation or offset of 0.2% from the modulus line. For castings, compressive yield strength is approximately equal to tensile yield strength. For wrought alloys, however, yield strength in compression may be considerably less than yield strength in tension. The ratio of yield strength in compression to yield strength in tension varies from about 0.4 for alloy M1A to an average value of about 0.7 for the other wrought magnesium alloys. Typical compressive yield strength values for various magnesium alloys are given in Table 3.

Maximum design stresses for magnesium alloy columns that are loaded axially and that have sufficient stability to prevent local failure may be determined, for columns in the long-column range, by using the Euler column formula. (A long column is one in which the length and cross section are such that the stress at which it will buckle does not exceed the elastic limit of the column material). Maximum design stresses for magnesium alloy columns in the short-column range depend on the strengths and the forms of the alloys being tested. (A short column is any column of such length and cross section that it fails under compressive loading by plastic yielding and/or crushing, rather than by buckling.) In practical application, the maximum design stress of a column is considered to be the minimum compressive yield stress of the material. Various formulas have been developed for determining the maximum design stresses for columns of intermediate length (those that fail by elastic buckling in combination with plastic yielding and/or crushing). Column strength curves for several magnesium extrusion alloys are shown in Fig. 2.



Alloy	Curve number	Least dimension of area range	
ZK60A-T5	1	<1290 mm^2	<2.000 $in.^2$
	2	1290-1935 mm^2	2.000-2.999 $in.^2$
	5	1935-3225 mm^2	3.000-4.999 $in.^2$

AZ80A-T5	2	6.35-38.09 mm	0.250-1.499 in.
	3	38.10-63.49 mm	1.500-2.499 in.
	4	63.50-127.00 mm	2.500-5.000 in.
ZK21A-F	6	<3226 mm^2	<5.000 $in.^2$
AZ61A-F	7	6.35-127.00 mm	0.250-5.000 in.
AZ31B-F	8	≤ 6.35 mm	≤ 0.250 in.
	9	6.35-63.49 mm	0.250-2.499 in.
	10	63.50-127.00 mm	2.500-5.000 in.

Bearing strength is the resistance to a stress applied by a pin in a hole; it is particularly important in the design of bolted and riveted joints. Bearing yield strength is defined as the stress required to produce an offset from the initial straight portion of the curve equal to 2% of the hole diameter. Bearing strength values listed in Table 3 were determined using specimens with an edge distance (from the center of the hole) of $2\frac{1}{2}$ times the pin diameter and width of 8 times the pin diameter. Increasing edge distance to more than about twice the pin diameter had little effect on bearing strength values. Sheet thicknesses in a wide range were tested, and the ratio of pin diameter to sheet thickness had no observable effect, except when bucking occured. A pin diameter not greater than four times the sheet thickness prevented buckling.

Shear strength is an important consideration in the design of joints in magnesium parts, such as threaded joints and spot welds. Values for castings and extrusions given in Table 3 were obtained by the conventional double-shear method, using solid rods. Values for sheet and AZ80A-T5 structural shapes were obtained by the punch method, using flat specimens.

Hardness and Wear Resistance. Magnesium alloys have sufficient hardness for all structural application except those involving severe abrasion. Hardness values are given in Table 3 and in the article "Properties of Magnesium Alloys" in this Volume. Although rather wide variations in hardness are observed in magnesium alloys, resistance of the alloys to abrasion varies by only about 15 to 20%. When subjected to wear by rubbing, by frequent removal of studs, or by heavy bearing loads, magnesium can be protected by inserts of steel, bronze, or nonmetallic materials; these materials can be attached as sleeves, liners, plates, or bushings. Such inserts may be attached mechanically by pressing, shrinking, riveting, bolting, or bonding; in castings, inserts may be cast in place.

Magnesium alloys perform satisfactorily as bearing materials for applications in which:

- Loads do not exceed 14 MPa (2 ksi)
- Shafts are hardened (350 to 600 HB)
- Lubrication is ample
- Speeds are low (5 m/s, or 1000 ft/min, max)

- Operating temperatures do not exceed 105 °C (220 °F)

Fatigue strength of magnesium alloys, as determined using laboratory test samples, covers a relatively wide scatter band, which is characteristic of other metals as well. The *S-N* curves have a gradual change in slope and become essentially parallel to the horizontal axis at 10 to 100 million cycles.

Fatigue strengths are higher for wrought products than for cast test bars. The fatigue strengths of several alloys are listed in the article "Properties of Magnesium Alloys" in this Volume. Increasing surface smoothness improves resistance to fatigue failure. For example, removing the relatively rough as-cast surfaces of castings by machining improves the fatigue properties of the castings (Fig. 3). Sharp notches, small radii, fretting, and corrosion are more likely to reduce fatigue life than are variations in chemical composition or heat treatment.

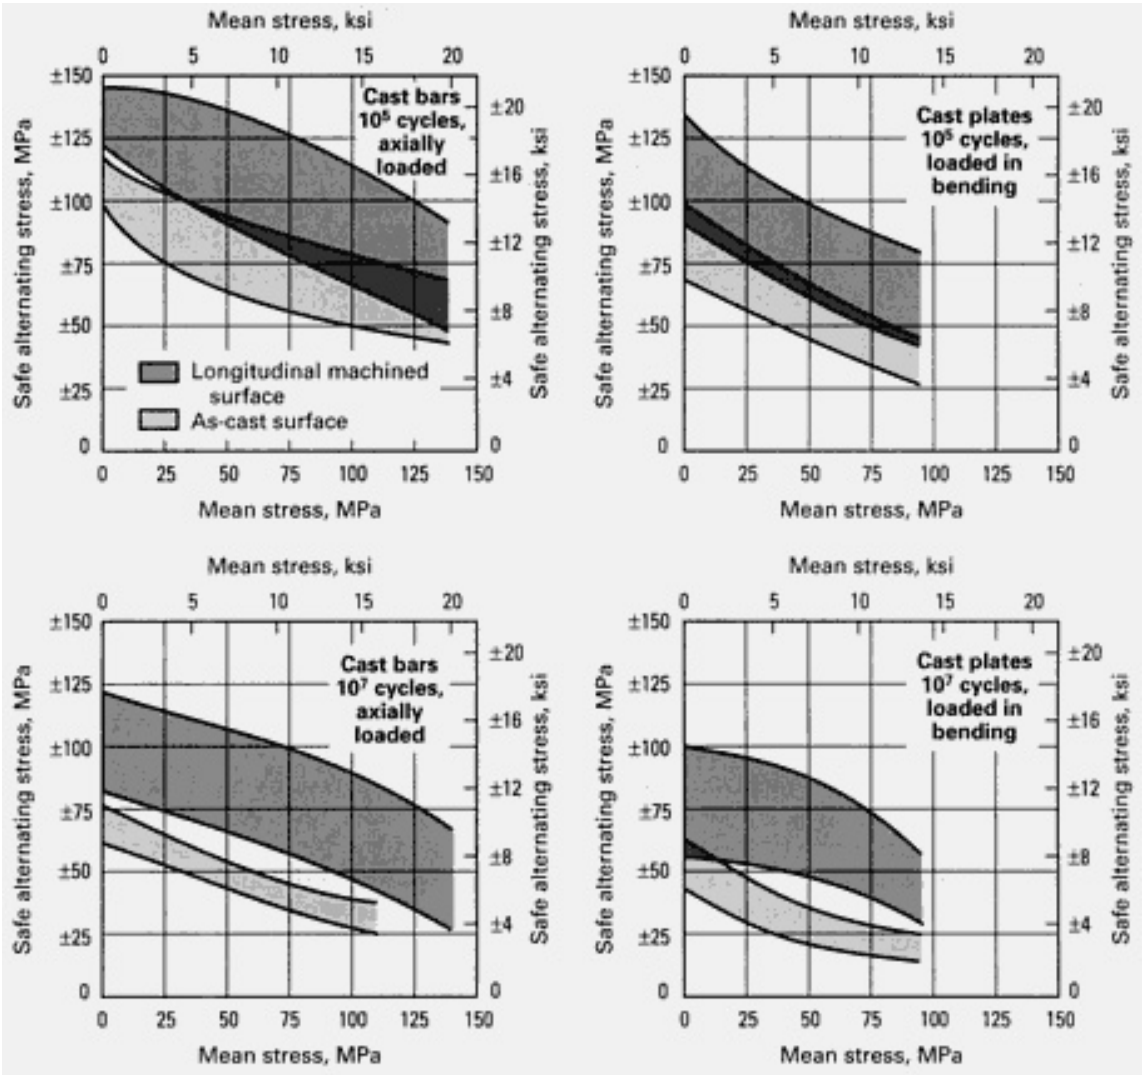

Fig. 3 Effect of surface type on the fatigue properties of cast magnesium-aluminum-zinc alloys

A specimen of alloy ZK60A-T5 (static yield strength, 290 MPa, or 42 ksi) with a machined 60° notch of 0.025 mm (0.001 in.) radius has a fatigue limit of 28 MPa (4 ksi) at 500 million cycles, compared with 110 MPa (16 ksi) for an unnotched specimen. This is a notch factor of about 0.25. For a shorter life of 100,000 cycles, the notch factor is about 0.48. As the severity of the notch decreases, its effect on fatigue limit decreases rapidly. For instance, a semicircular notch with radius of 1.2 mm (0.047 in.) reduces fatigue strength by only 20%, compared with 75% for the sharp V-notch cited above.

When the fatigue is the controlling factor in design, every effort should be made to decrease the severity of stress raisers. Use of generous fillets in reentrant corners and gradual changes of section greatly increase fatigue life. Situations in which the effects of one stress raiser overlap those of another should be eliminated. Further improvement in fatigue strength can be obtained by inducing stress patterns conducive to long life. Cold working the surfaces of critical regions by rolling or peening to achieve appreciable plastic deformation produces residual compressive surface stress and increases fatigue life.

Surface rolling of radii is especially beneficial to fatigue resistance because radii generally are the locations of higher-than-normal stresses. In surface rolling, the size and shape of the roller, as well as the feed and pressure, are controlled to obtain definite plastic deformation of the surface layers for an appreciable depth (0.25 to 0.38 mm, or 0.010 to 0.015 in.). In all surface working processes, caution must be exercised to avoid surface cracking, which decreases fatigue life. For example, if shot peening is used, the shot must be smooth and round. The use of broken shot or grit can result in surface cracks.

Damping capacity is the ability of a metal to elastically absorb vibrational energy and keep the vibrations from transmitting through the metal. Magnesium and magnesium alloys have excellent damping capacity, giving them the ability to decrease vibration and noise in many applications. These applications include vibration testing fixtures and mounting brackets for electronic equipment that is sensitive to vibrations. The percent damping capacity of magnesium alloys is compared with that of other metals in Table 8.

Table 8 Damping capacity of selected magnesium alloys and other metals

Alloy	Temper	Specific damping capacity, %, at

Note: Values for wrought alloys (Table 9(a)) are averages of two to four tests at room temperature (50 mm, or 2 in. gage length). Values of duplicate tests at low temperatures are also averages (25 mm, or 1 in. gage length). Values for cast alloys are averages of two to four tests on separately cast bars.

Elevated temperatures have adverse effects on ultimate and yield strengths, as demonstrated by the bearing strength data given for two magnesium alloys in Table 10. The effect of elevated temperatures on the mechanical properties of magnesium alloys is evaluated by considering:

- The strength as determined by bringing the test specimen up to temperature and testing immediately (short-time test)
- The strength at temperature after prolonged heating at elevated temperature
- The effect on room-temperature properties of heating at elevated temperature for short and long times
- The deformation produced by prolonged heating under load (creep test)

Data showing the effects of elevated temperature on the mechanical properties of several magnesium alloys are presented in Tables 11 and 12. Elevated-temperature properties, including isochronous stress-strain curves, are given in greater detail in the data compilations in the article "Properties of Magnesium Alloys" in this Volume.

(a) Stress to produce 0.2% creep strain in 1000 h for cast alloys and 100 h for wrought alloys.

(b) Tested at 150 °C (300 °F).

Designs of many parts for use at elevated temperatures under continuous load are based on maximum allowable deformation. The limiting creep-stress values given in Table 12 and based on 0.2% total extension. The isochronous curves in the data compilations cover a wide range of deformations. The alloys that contain thorium have the greatest

resistance to creep at 205 and 315 °C (400 and 600 °F), and the magnesium-aluminum-zinc alloys have the lowest resistance. The decrease in modulus of elasticity with increase in temperature, a characteristic of the magnesium-aluminum-zinc alloys, is considerably less for thorium-containing alloys.

Selection of Product Form

Selection of a particular product form for a structural application is based on mechanical property requirements and on cost, availability, and fabricability. Requirements for production and design may change under operating conditions or as need arises. A part originally machined from bar stock may subsequently be made by extrusion or forging. Assemblies built up by joining sheets and extrusions may be redesigned as castings with equivalent performance at lower cost.

Castings. Parts too intricate to fabricate economically by other methods can be produced as castings. Sand, permanent mold, and die castings are more widely used than investment and shell mold castings. The choice of casting method is determined primarily by the size, shape, quantity, cost, and desired mechanical properties of the casting. The cost of magnesium alloy castings is governed largely by ingot price, alloy castability, and required heat treatment. Ingot price increases with additions of rare-earth metals, zirconium, silver, yttrium, and thorium. Small changes in composition can affect the cost of heat treatment. Comparative costs for casting an aircraft engine part from three different magnesium alloys are given in Table 13.

Table 13 Comparison of costs for making a typical aircraft engine casting from three different magnesium alloys

Item	AZ91C	ZE41A	QE22A
Cores	$ 41.18	$ 41.18	$ 41.18
Molding	79.44	79.44	79.44

Nondestructive testing	94.68	94.68	94.68
Fixturing	8.80	8.80	8.80
Total cost per casting	**$386.37**	**$418.98**	**$610.56**

Magnesium alloys are cast by the permanent mold process when the number of parts required justifies the very high cost of equipment. The mechanical properties of sand and permanent mold castings are comparable, but the permanent mold process normally provides closer control of dimensions and produces better cast surfaces. Because of the slow solidification rate inherent in the processes, sand and permanent mold castings usually require a heat treatment to obtain the required mechanical properties. Temper designations are shown in Table 2.

The cost of castings is also influenced by such factors as required tolerances, mold and die costs, and machining costs. The quantity of a part to be produced is an important factor affecting cost and must be considered in seeking the most

economical method of production. For example, in making the part illustrated in Fig. 4, tooling costs would have made investment casting more expensive if only 30 pieces were produced; however, because more than 30 pieces were produced, investment casting was cheaper than machining from bar stock. Although rejection rates vary from one casting method to another (Fig. 5), they are high for all methods when tolerances are close.

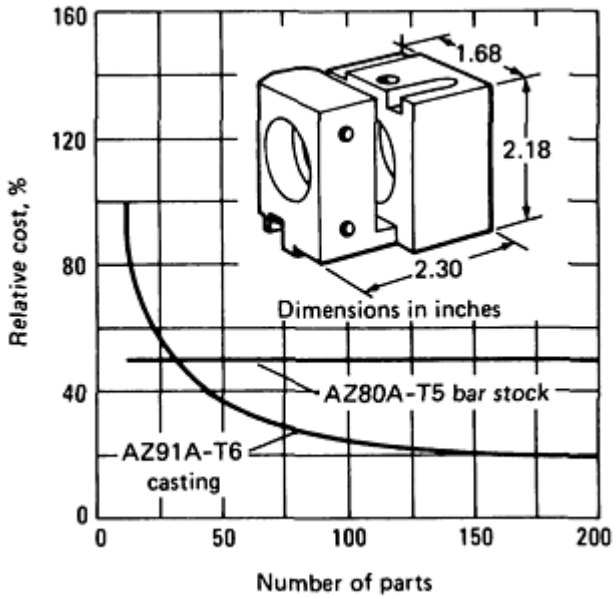

Fig. 4 Comparison of cost-quantity relationships for producing a part by investment casting and by machining from bar stock

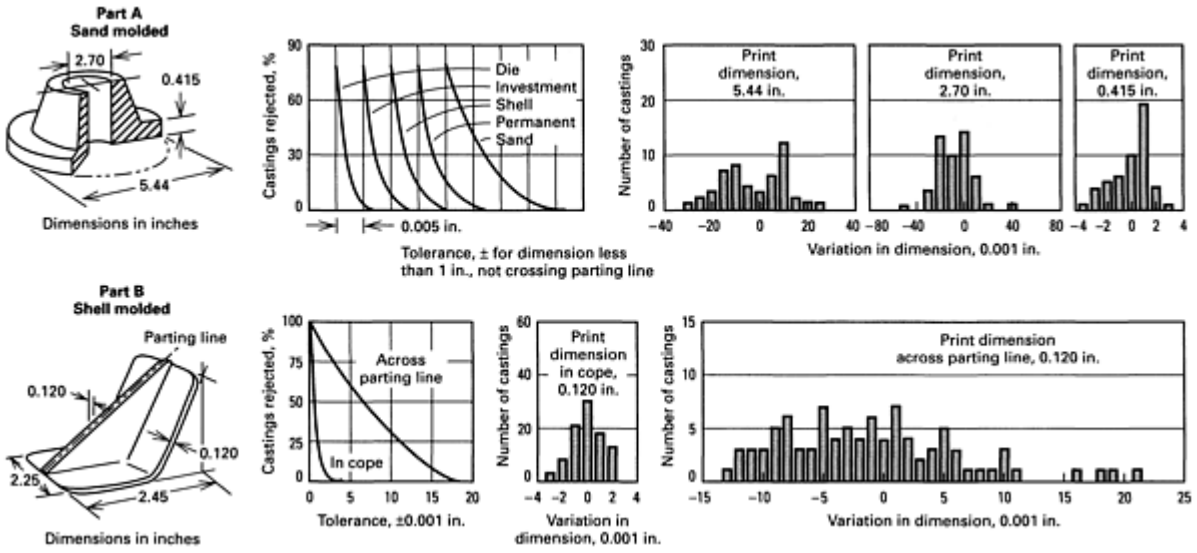

Fig. 5 Dimensional variations, tolerances, and rejection rates for two magnesium-aluminum-zinc alloy castings

Figure 6 illustrates a casting that was produced at lower cost by shell mold casting than by sand casting and machining when more than 700 castings were made. The sand mold casting required one extra machining operation to obtain a dimension that could be held within the tolerance of the shell mold.

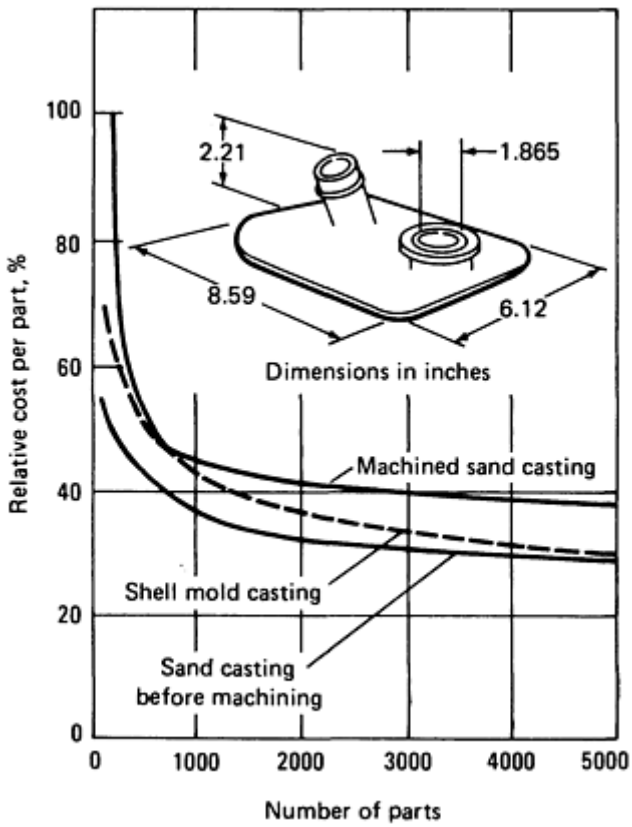

Fig. 6 Comparison of cost-quantity relationships for two methods of casting a magnesium-aluminum-zinc alloy part. The sand casting required an extra machining operation to meet a dimensional limit that could be held in the shell mold casting without machining. Thus, the curve for the machined sand casting should be used in comparing the total costs of the two casting methods.

Die castings made of magnesium alloys may be selected in preference to aluminum die castings of the same design because of the savings in weight. Magnesium die castings may also replace assembled steel parts, zinc die castings, and plastics. Service requirements and size may govern whether a magnesium alloy is selected for use in a die casting, but quantity is the most important factor because die castings are high-production items. The effects of both quantity and weight are shown in Fig. 7. Magnesium alloy die castings, like castings in general, are always priced and purchased on a per piece basis. The cost per pound varies, depending primarily on complexity of design, wall thickness, number of cavities in the mold, and quality level.

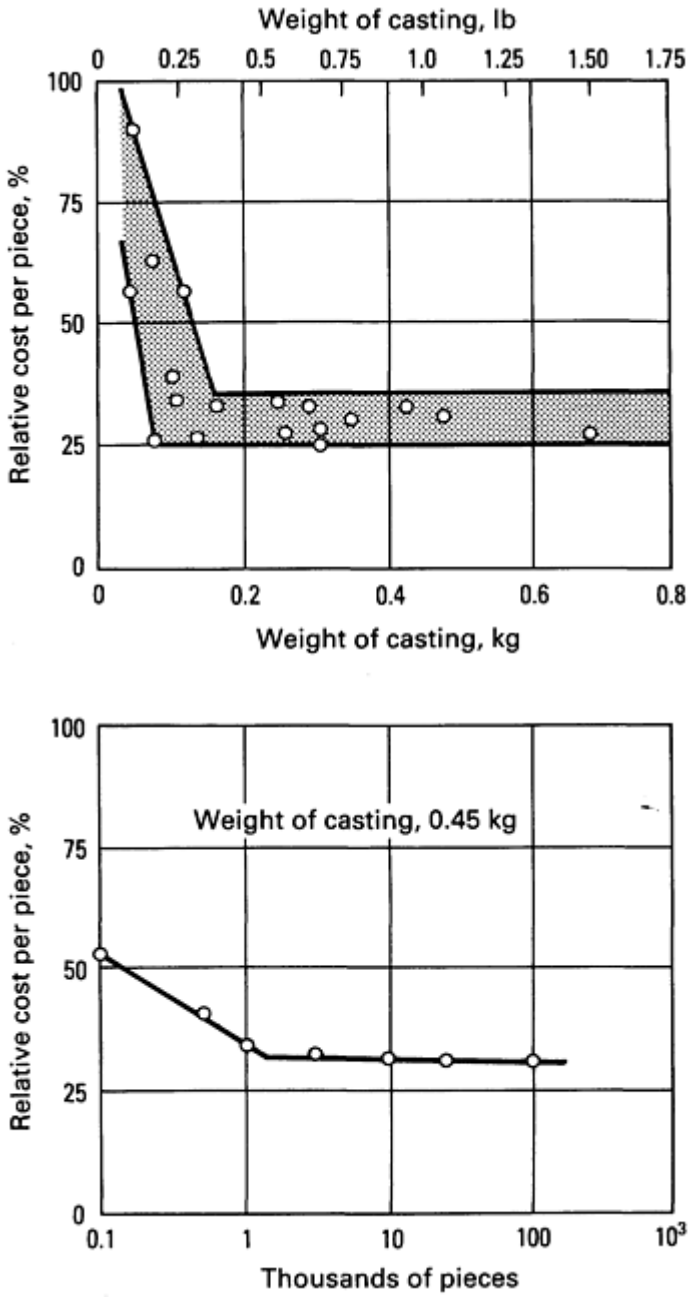

Fig. 7 Typical effects of weight and quantity on the cost of magnesium die castings. On a weight basis, the cost of die castings heavier than about 0.15 kg ($\frac{1}{3}$ lb) is fairly constant. For lighter castings, those weighing less than about 0.10 for 0.15 kg (4 or 5 oz), the cost per pound may vary by a factor of three or four, depending on design, wall thickness, and quality level.

Magnesium has several processing advantages over aluminum in die casting. The low heat content of magnesium produces rapid solidification of molten metal and short die holding times; therefore, production rates can be much higher for magnesium. This low heat content also reduces thermal fatigue and leads to longer die life when casting magnesium as opposed to aluminum. The low reactivity of magnesium alloys with iron allows the use of steel processing equipment and reduces die erosion, which again leads to longer die life. Depending on the application, magnesium can be cast in both hot and cold chamber die casting machines, whereas aluminum is most commonly processed only in cold chamber machines. Hot chamber machines can offer significantly increased production rates over cold chamber machines.

Extrusions. Magnesium alloys are extruded as round rods and as a variety of bars, tubes, and shapes. A wide variety of special shapes also can be extruded. Extrusion is selected as a means of producing certain shapes when:

- Several small extrusions or a combination of extrusions and sheet can be joined to form an assembly
- Shapes are desired that are uneconomical to machine from castings
- Pieces cut from extrusions can replace individually cast or forged parts

The extrusion process offers many design possibilities not economically attainable by other production methods. These include reentrant angles and undercuts, thin-wall tubing of large diameter, and almost unrestricted variations in section thickness. Probably the most important factor in determining whether a magnesium alloy shape will extrude well is good symmetry, preferably around both axes.

Very thin and wide sections with large circumscribing circles should be avoided. The optimum width-to-thickness (*w/t*) ratio for magnesium extrusions normally is less than 20. Parts with higher ratios can be extruded, but require more generous tolerances. A thick section tapering to a thin wedge must always be modified by rounding the edge, or the die may not fill properly. A thin leg attached to a thick body of an extrusion should be limited to a length not exceeding ten times the leg thickness. Semiclosed shapes requiring long, thin die tongues should be avoided. For best extrudability, the length of the tongue should not exceed three times its width, although it is possible to extrude lengths five times the width. Similarly, shapes requiring unbalanced die tongues do not constitute good extrusion design. Hollow shapes that contain unsymmetrical voids, or voids separated by sections of inadequate thickness, are undesirable. Sharp outside corners result in excessive stress concentration and die breakage and thus should be avoided. Inside corners should be filleted to reduce stress concentration in the part and to ensure complete filling of the die during extrusion. Regardless of the shape being extruded, it is difficult to hold distances between thin sections to close tolerances.

Many shapes can be extruded economically. Extrusion dies are relatively inexpensive, and dimensions can be held closely enough so that machining is often unnecessary. Part A in Fig. 8 is an example of a shape that lends itself to extrusion. However, because more metal had to be machined from this part as an extrusion than as a die casting, die casting proved to be cheaper. A slight design change in the bracket shown as part B in Fig. 8 permitted the part to be made more economically by extrusion than by casting.

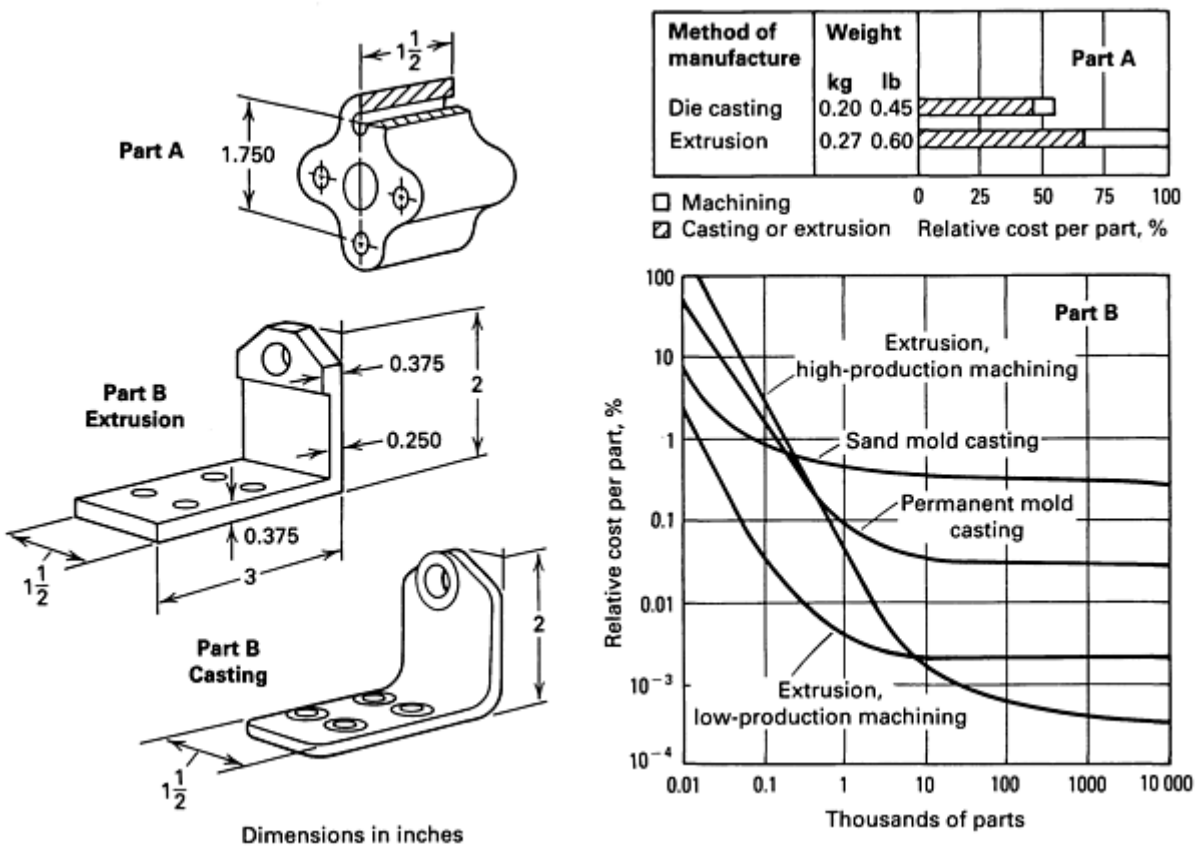

Fig. 8 Effect of manufacturing method on the cost of two magnesium alloy parts. Costs are based on AZ91B die

castings and AZ31B extrusions.

Impact extrusions are tubular parts of symmetrical shape. The impact type of hot extrusion is particularly applicable when:

- It is not practical to make the part by any other method, such as with parts requiring very thin walls, parts in which thin walls having high strength are essential or parts that must incorporate irregular profiles
- High production rates are required, where scrap loss from machining would be excessive if the part were made by other means, where strength requirements cannot be met by die castings, where the number of manufacturing operations or the number of parts in an assembly can be reduced by the use of impact extrusions, where portions of the part require zero draft, and/or where closer tolerances are required

In designing impact extrusions, the following factors should be taken into consideration:

- A wide variety of symmetrical shapes is possible
- Variations in wall thickness are possible (thin sidewall, thick bottom; thick sidewall, thin bottom)
- Ribs, flanges, bosses, and indentations can be incorporated
- Length-to-diameter ratios can range from 1.5:1 to 15:1. Ratios from 6:1 to 8:1 are considered good working ratios
- Reduction in area varies with the alloy being extruded and is limited by the size of available equipment. Parts with reduction in area up to 95% have been made. In general, extrusions of alloys M1A and AZ31B can have thinner walls than AZ61A, AZ80A, and ZK60A extrusions
- Sharp corner radii are possible in some areas of impact extrusions. This is not true of other product forms
- The average properties of impact extrusions are slightly higher than the typical properties of the hot-extruded stock from which the parts are made

Forgings. Magnesium forgings can be produced in the same variety of shapes and sizes as forgings of other metals. Maximum size is limited primarily by the size of available equipment. Tolerances can be held to the same values as in normal forging of other metals; they vary somewhat with forging size and design.

Forgings have the best combination of strength characteristics of all forms of magnesium. They are used where light weight coupled with rigidity and high strength are required. Magnesium forgings are sometimes used because of their pressure tightness, machinability, and lack of warpage rather than because of their high strength-to-weight ratio.

Forging is used for parts produced in quantities sufficient to amortize die costs and for parts requiring high strength and ductility; greater uniformity and soundness than can be obtained with castings. For small quantities, hand forgings may be used, but die forgings have better mechanical properties and are less expensive in larger quantities.

The ease with which magnesium can be worked greatly reduces the number of forging operations needed to produce finished parts. Many of the steps commonly required in forging brass, bronze, and steel (such as punching, planishing, drawing and ironing, sizing, and coining, and edging and rolling) are unnecessary in forging magnesium. Bending, blocking, and finishing are the principal steps used in the forging process. Recommended corner and fillet radii for magnesium forgings (Fig. 9) are given in Tables 14(a) and 14(b).

Table 14(a) Corner and fillet radii (in millimeters) for large magnesium forgings

Note: The values given for r_3 and r_4, the corner and fillet radii for I sections in magnesium forgings, apply when the *W/D* ratio is approximately 2 to 1. For *W/D* ratios greater than 2 to 1, the radii should be increased; for lower *W/D* ratios the radii may be decreased. In corner and fillet radii for channel sections, $r_7 = r_5 + t_1$.

For *W/D* ratios greater than 2 to 1, the radii should be increased; for lower *W/D* ratios the radii may be decreased. In corner and fillet radii for channel sections, $r_7 = r_5 + t_1$.

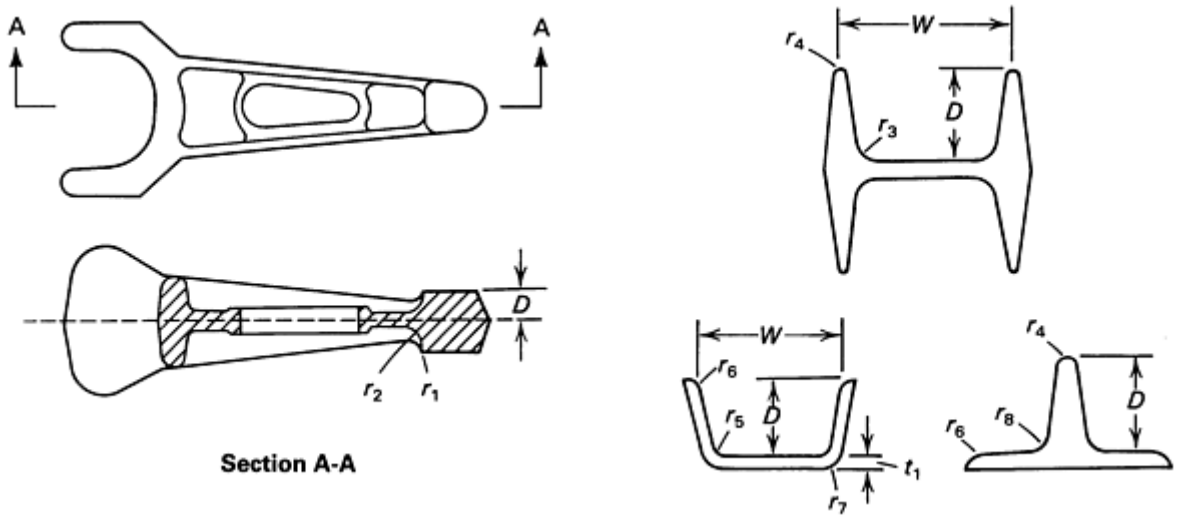

Fig. 9 Large magnesium forgings. Corner and fillet radii are given in Tables 14(a) and 14(b).

Die design and resulting metal flow cause variations in tensile properties at different sections of large forgings. An example involving aircraft wheels forged from magnesium alloys is illustrated in Fig. 10. Test specimens were taken at several locations in forgings made from alloy AZ80A-T5 and from alloy ZK60A in the T5 and T6 conditions.

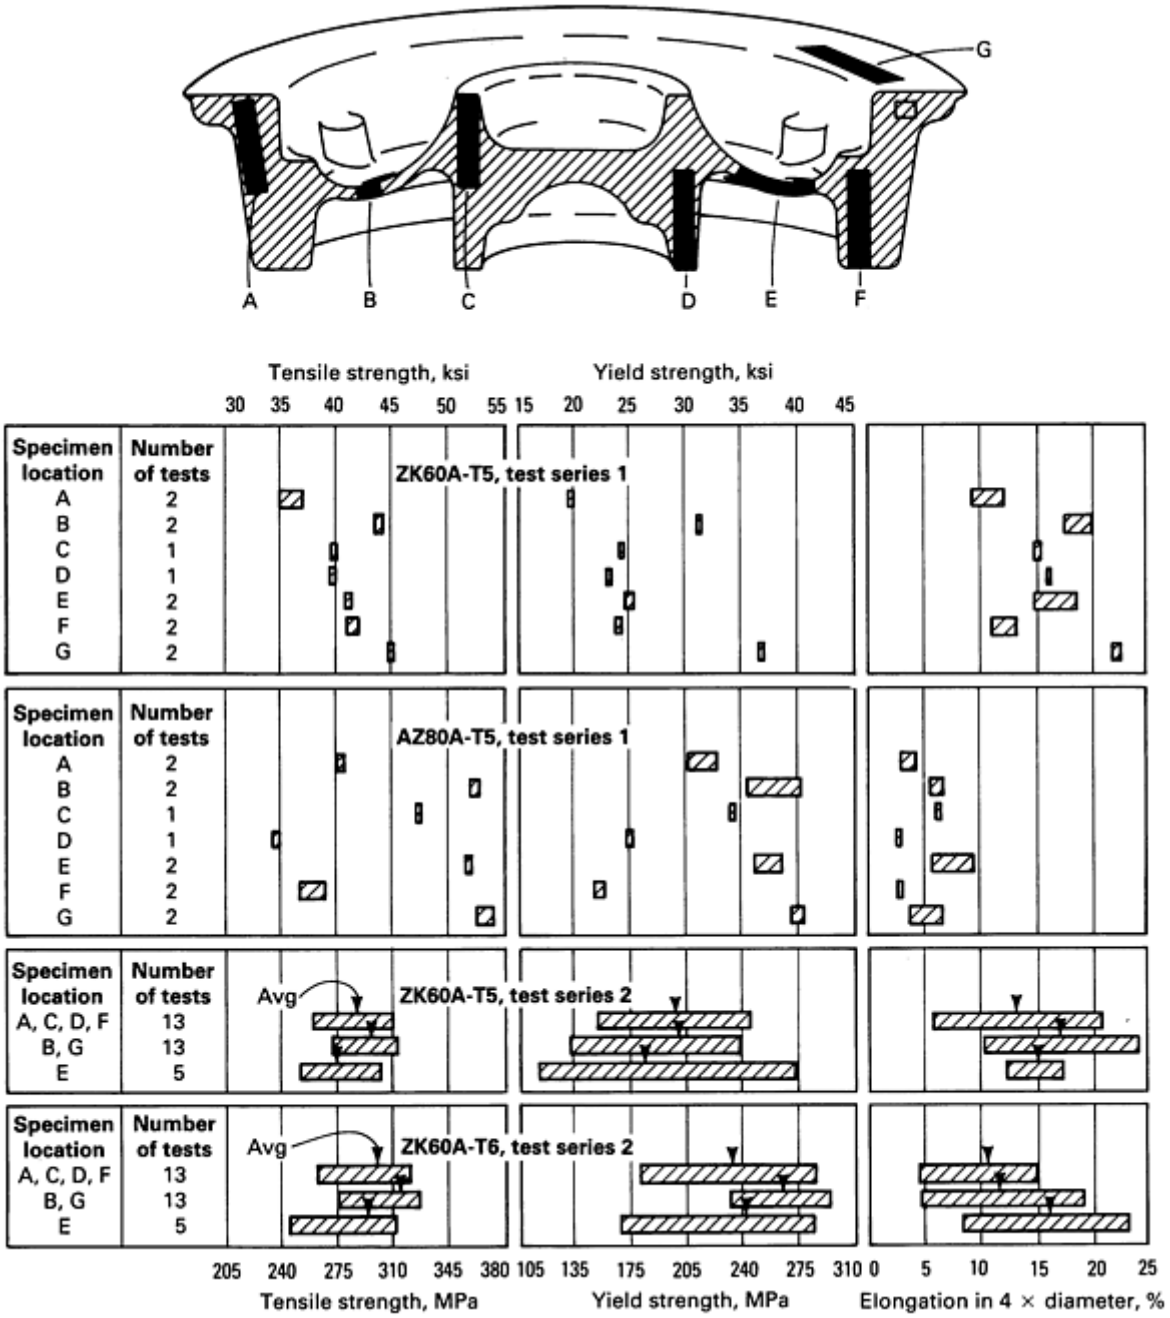

Fig. 10 Effect of alloy, heat treatment, and specimen location on mechanical properties of forged magnesium aircraft wheels

Mechanical properties of magnesium alloy forgings or castings, as determined by testing of separately cast or forged bars, are useful for evaluating certain characteristics on a comparative basis and serve as a means of control. However, test results for these bars may vary significantly from properties of specimens taken from various locations in production castings or forgings. The amount of this variation is affected by section thickness and direction of metal flow. The wide variations in properties between forged brackets of the same design made from two different heat-treated alloys are shown in Fig. 11, and a comparison of the properties of separately cast and forged test specimens with those of specimens cut from castings and forgings are presented in Fig. 12. Forgings made from magnesium-thorium alloys are considerably more expensive than those of magnesium-zinc-zirconium alloys. Comparing the costs of forging and casting requires careful analysis for each design and specification.

Inserts

Magnesium surfaces that are subjected to heavy bearing loads or severe wear require protection. Inserts that provide such protection to the surfaces of holes can be made of various materials and can be attached in numerous ways.

Cast-In Inserts. Inserts in magnesium may be fixed in place by casting the magnesium around them. Cast-in inserts for use in magnesium can be made of steel, brass, bronze, or other metals. Nonferrous inserts can be plated with chromium to prevent alloying with magnesium, although such plating is seldom used. Tinning of ferrous inserts prevents galvanic corrosion of the magnesium.

Cast-in inserts become securely fixed when the cast metal shrinks around them. The inserts is even more securely fixed if the outside of the insert is knurled or grooved. Care should be taken to ensure that stress concentrations are not set up by sharp corners or insufficient metal around the insert.

Shrinkage of the magnesium alloy around cast-in inserts can cause high residual stress in the metal surrounding the insert. This possibility can be significantly reduced by preheating the insert, although inserts with a wall thickness of 1.3 mm (0.050 in.) or less will preheat sufficiently from contact with the hot die and the molten magnesium. If these design and manufacturing conditions are not allowed, the high residual stresses may lead to failure of the part in service brought

about by stress-corrosion cracking. Safe design dimensions for cast-in steel inserts with a wall thickness greater than 1.3 mm (0.050 in.) are shown in Fig. 13.

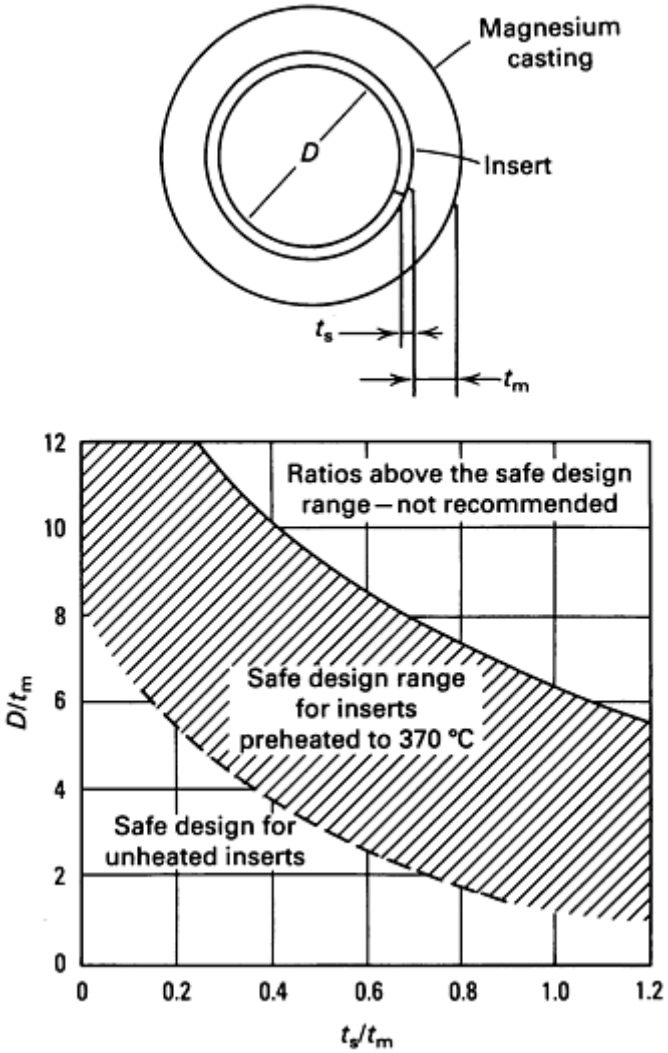

Fig. 13 Safe design dimensions for cast-in steel inserts in magnesium alloy castings. Values apply to inserts having a wall thickness (t_s) greater than 1.3 mm (0.050 in.)

In highly stressed castings, it may be desirable to cast in a pilot to which the insert can be attached, thus avoiding high shrink stresses around the insert. Cast-in inserts can also be used for providing design details not otherwise feasible, such as lubrication lines of steel or copper, or appendages that otherwise could not be attached conveniently. Cast-in inserts complicate manufacture of castings and should be used only if other methods are not feasible.

Press-Fit and Shrink-Fit Inserts. Because of the low modulus of elasticity of magnesium, greater interference must be used for press-fit or shrink-fit inserts in magnesium than for inserts in other metals in order to obtain sufficient gripping force. An interference of 0.5 to 1.0 mm/m (0.0005 to 0.001 in./in.) is usually satisfactory, but may be increased appreciably where high-torque loads are likely to be encountered. Table 15 presents recommended interferences for steel and bronze inserts in normal service at various temperatures. The values given serve only as a guide because service temperature, type of insert material, severity of service, thickness of insert, and sensitivity of the alloy to stress-corrosion cracking all influence the correct amount of interference. Differences in thermal expansion, yield strength, and modulus of elasticity must also be considered for service at elevated temperature.

Table 15 Approximate interferences suggested for press-fit and shrink-fit inserts in magnesium

152.4	6.0	6.4	0.25	0.0036	0.0053	0.0098	0.0147	0.0036	0.0043	0.0070	0.0098

Inserts are more easily assembled by shrinking than by pressing. It is relatively easy to heat a magnesium part and thus expand a hole in the part so that it is large enough to receive an insert. Where necessary, the insert may be cooled to facilitate insertion. On the other hand, assembly by pressing requires careful machining of both insert and hole, and proper lubrication. When large interferences are required, it is best to specify shrink-fit inserts because press-fits may score the magnesium.

Screwed-In Inserts. Various types of screwed-in (and other mechanically attached) inserts may also be used successfully in magnesium parts. When screwed-in inserts be chosen carefully in order to avoid stress concentrations and to provide sufficient engagement length for the thread.

Formability

Magnesium alloys, like other alloys with hexagonal crystal structures, are much more workable at elevated temperatures than at room temperature. Consequently, magnesium alloys are usually formed at elevated temperatures, and cold forming is used only for mild deformations around generous radii. The methods and equipment used in forming magnesium alloys are the same as those commonly employed in forming alloys of other metals, except for differences in tooling and technique that are required when forming is done at elevated temperatures.

Working of metals at elevated temperature has several advantages over cold working. Magnesium parts usually are drawn at elevated temperature in one operation without repeated annealing and redrawing, thus reducing the time involved for making the part and also eliminating the necessity of additional die equipment for extra stages. Hardened dies are unnecessary for most types of forming. Hot-formed parts can be made to closer dimensional tolerances than cold-formed parts because they experience less springback. Suggested maximum forming temperatures and times for various wrought magnesium alloys are given in Table 16.

Table 16 Maximum forming temperatures and times for wrought magnesium alloys

Alloy	Temperature		Time[(a)]
	°C	°F

19.05	0.750	1220, 1525	48, 60	1830	72	3.66	12	5.5	18

(a) Maximum length for maximum width. Size of a single piece is limited to 998 kg (2200 lb).

(b) Coiled sheet up to 610 mm (24 in.) wide can be produced in thicknesses down to 0.25 mm (0.10 in.).

(c) In steps of 6.35 mm (0.250 in.).

(d) In steps of 1.588 mm (0.0625 in.)

The ability to use increased section thickness without weight penalty is of particular importance in designs that employ magnesium sheet. Thick-sheet construction provides the rigidity necessary in a structure, without the need for costly assembly of ribs and similar reinforcing members.

Rolled magnesium alloy products can be worked by most conventional methods. For severe forming, sheet in the annealed (O temper) condition is preferred. However, sheet in the partially annealed (H24 temper) condition can be formed to a considerable extent. Because heat has significant effects on properties of hard-rolled magnesium, properties of the metal after exposure to elevated temperature must be considered in forming. The design curves shown in Fig. 14 give minimum values suitable for design use. Although the curves are based primarily on tests of sheet 1.63 mm (0.064 in.) thick or less, check tests indicate reasonable applicability for gages up to 6.35 mm (0.250 in.).

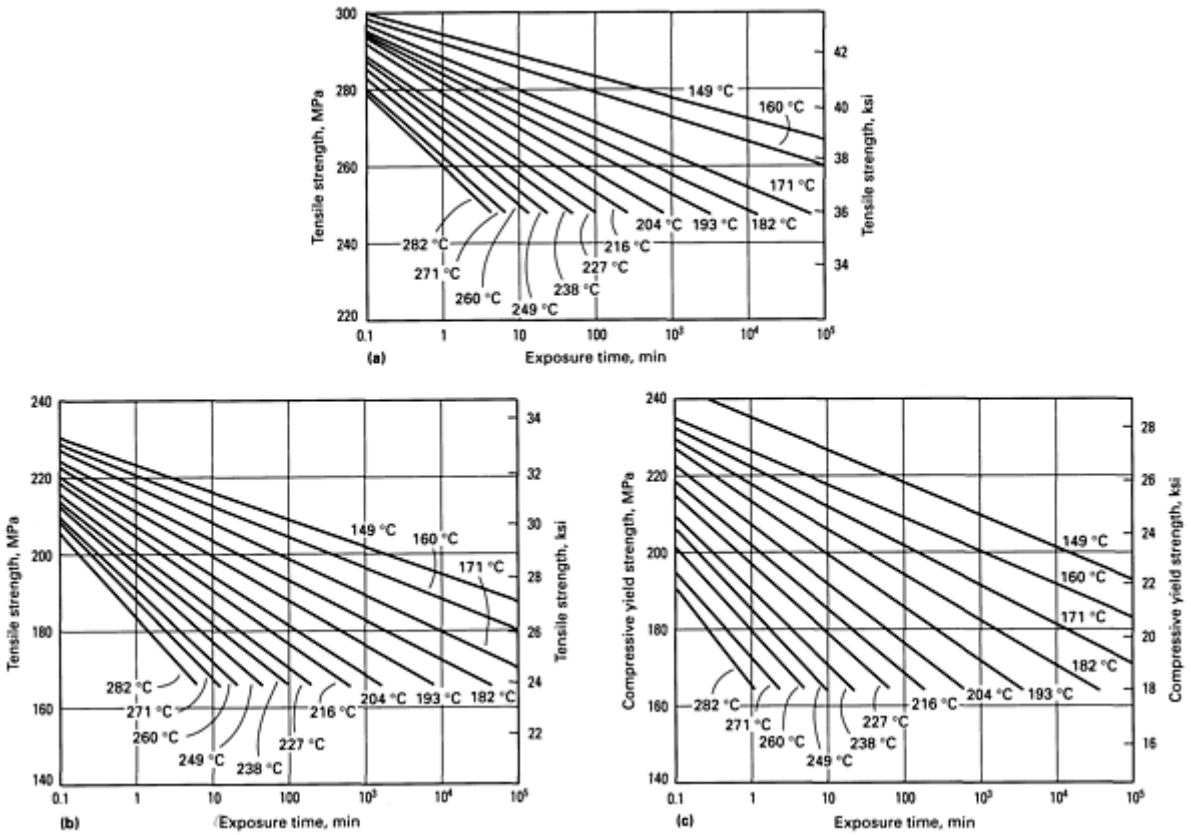

Fig. 14 Effect of exposure time at elevated temperature on the mechanical properties of AZ31B-H24 at room temperature. Data are based on sheet 1.63 mm (0.064 in.) thick. Check tests indicate reasonable applicability for thicknesses up to 6.35 mm (0.250 in.).

Figure 14 shows how the properties of AZ31B-H24 vary with exposure time at several temperatures. The curves have been extrapolated above the typical property levels of AZ31B-H24 sheet. Thus, if the value selected from a curve exceeds the actual property level of the material before exposure, the actual figure must be used.

Tests indicate that the effects of multiple exposures at elevated temperature are cumulative. Using Fig. 14 as an example, suppose that a part is held at 195 °C (380 °F) for 10 min; the resultant design compressive yield stress is 159 MPa (23.1 ksi). Then suppose the part is subsequently exposed for 300 min at 170 °C (340 °F). Because 200 min at 170 °C (340 °F) and 10 min at 195 °C (380 °F) both result in a minimum compressive yield stress of 159 MPa (23.1 ksi), they are equivalent exposures. The total equivalent exposure time at 170 °C (340 °F) then is 300 plus 200, or 500 min, which according to the data given in Fig. 14 results in a compressive yield stress of 155 MPa (22.5 ksi).

AZ31B-H24 sheet is commonly hot formed at temperatures below 160 °C (325 °F) to avoid annealing it to room-temperature property levels lower than the specified minimums. Annealing is a function of both time and temperature of exposure; thus, temperatures higher than 160 °C (325 °F) can be tolerated if exposure is carefully controlled. Table 18 shows the maximum permissible combination of time and temperature that will ensure that the specified minimum room-temperature properties of AZ31B-H24, HK31A-H24, and HM21A-T8 can be retained. This table is used for establishing limits of time and temperature for single exposures in normal forming operations. Whenever the sheet must endure multiple exposures, or whenever time of exposure at a given temperature must exceed the value indicated in Table 18, the data compilations in the article "Properties of Magnesium Alloys" in this Volume should be consulted.

Table 18 Maximum time at temperature to maintain properties of magnesium alloy sheet

Maximum time, min	Temperature	
	°C	°F
AZ31B-H24		
0.3	260	500
1	224	435
2	210	410
3	202	395
4	196	385
5	188	370
10	182	360
30	174	345
60	163	325
HK31A-H24		
15	343	650
5	371	700
3	385	725
3	399	750
HM21A-T8[(a)]		
60	399	750
10	427	800

Note: Annealed sheet will endure much higher temperatures than heat-treated sheet for short periods without significant reduction of properties at room temperature.

(a) Based on limited data obtained in laboratory tests

Deep Drawing. Magnesium alloys can be cold drawn to a maximum reduction of 15 to 25% in the annealed condition. The cold drawability limit of alloy AZ31B-O is about 20%. The drawability, or percentage reduction in blank diameter, is calculated by the formula:

$$Percentage\ reduction = \frac{D-d}{D} x100$$

where D is the blank diameter before drawing and d is the diameter of the punch.

The time and temperature for annealing AZ31B-O are 15 min at 260 °C (500 °F). Cold-drawn parts are stress relieved at 150 °C (300 °F) for 1 h after the final draw, to eliminate the danger of cracking from residual stresses.

Both hydraulic and mechanical presses can be used in drawing operations. Hydraulic presses are utilized most often because they can operate at slower, more uniform speeds, thus providing accurate control when intricate draws are made. Deep draws also require the use of a hydraulic press because mechanical presses are not capable of extremely long strokes. Mechanical presses can be used for moderate draws at higher production rates.

The technique for hot drawing of magnesium alloy sheet has been developed largely so that drawing can be completed in a single operation. Heating magnesium alloys increases their drawability to such an extent that most parts can be made in a single draw. The amount of possible reduction increases as temperature increases up to about 230 °C (450 °F) for alloy AZ31B. It is usual practice to draw annealed AZ31B sheet to reductions as high as 68% in a single draw. When heated, magnesium can be drawn to higher reduction in a single draw than other metals. Maximum single-draw reduction as a function of temperature is shown in Fig. 15. These values were determined for 1.63 mm (0.064 in.) sheet using a cupping die 38 mm ($1\frac{1}{2}$ in.) in diameter. There radii on the draw ring and punch were both 5*t*, and drawing speeds were 38 mm ($1\frac{1}{2}$ in.) and 500 mm (20 in.) per minute. The data in Fig. 15 show that the amount of reduction possible at a given temperature is also influenced by drawing speed.

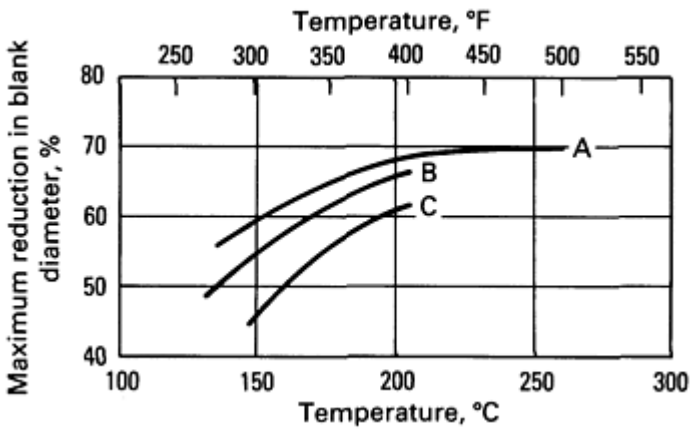

Fig. 15 Effect of temperature on the drawability of 1.63 mm (0.064 in.) AZ31B sheet. Cupping die diameter, 38 mm ($1\frac{1}{2}$ in.); radii on draw ring and punch, 5*t*. A, temper O; drawing speed, 38 mm ($1\frac{1}{2}$ in.)/min. B, temper

H24; drawing speed 38 mm (1$\frac{1}{2}$ in.)/min. C, temper H24; drawing speed, 500 mm (20 in.)/min

The possibilities inherent in two-step draws are illustrated by the following parts: In the first operation, 610 mm (24 in.) blanks of 0.64 mm (0.025 in.) annealed sheet were drawn to a cup 200 mm (8 in.) in diameter by 400 mm (16 in.) deep; they were redrawn to a cup 140 mm (5$\frac{1}{2}$ in.) in diameter by 585 mm (23 in.) deep. Starting with a rectangular blank of 1.3 mm (0.051 in.) AZ31B-O, 455 × 485 mm (18 × 19 in.), a rectangular box 110 × 275 × 165 mm (4$\frac{3}{8}$ × 10$\frac{3}{4}$ × 6$\frac{1}{2}$ in.) deep was drawn in the first operation. This box was then redrawn into a rectangular box 90 × 255 × 170 mm (3$\frac{1}{2}$ × 10 × 6$\frac{3}{4}$ in.) deep, having 5.6 mm ($\frac{7}{32}$ in.) corner radii.

For most parts, however, depth of draw is not a primary consideration, and usually no trouble is experienced in drawing to the depth required. More trouble is encountered in keeping the metal free from puckers in parts with rounded corners or contours. Temperatures above those required for maximum drawability often are necessary to eliminate these puckers. On unusual or difficult jobs, it may be necessary to vary the procedure to obtain minimum scrap.

Choice of die materials is influenced chiefly by the severity of the operation and the number of parts to be produced. For most applications, unhardened low-carbon steel boiler plate or cast iron is satisfactory. For runs of 10,000 parts or more, for maximum surface smoothness, or for close tolerances where no significant die wear can be tolerated, hardened tool steels are recommended. W1 or O1 tool steels are satisfactory for extremely long runs (one million parts). For the most severe draws, however, the more abrasion-resistant tool steels, such as A2 or D2, will probably be more satisfactory and more economical. For room-temperature drawing, it is usually desirable that die steels be heat treated to obtain near-maximum hardness in service. However, for elevated-temperature drawing, the maximum temperature to which the dies will be exposed in drawing must also be considered. In this situation, the dies must be tempered slightly above the maximum service temperature, even though some hardness may be sacrificed.

Dimensional allowances must be considered for pieces of the punch and die that will affect part size. For example, magnesium, aluminum, and zinc alloys can be used in the design of punches to minimize the difference in the coefficients of thermal expansion between magnesium and the punch. However, if mild steel or cast iron are used in the design of a punch, dimensional allowances must be given to account for the great difference in the coefficients of thermal expansion.

Parts with smooth bottoms are usually drawn with open dies or dies in which the punch does not bottom on the female, or bottom, plate. These parts are formed by the pull exerted on the blank by the pressure ring and the draw ring. Mating dies are used with magnesium only in forming parts having reentrant portions that cannot be made by other means.

Stretch Forming. Both magnesium sheet and magnesium extrusions can be stretch formed. The temper of the alloy has no effect on the techniques employed. Sheet is usually heated to 165 to 290 °C (325 to 550 °F) and slowly stretched to the desired contour. Annealed sheet can be stretched at room temperature to a limited extent. However, the formabilities of alloys of any temper are so much greater at elevated temperatures than at room temperature that elevated-temperature forming is preferred for most operations. The percentage of differential stretching (*P*) during stretch forming is expressed:

$$P = \frac{L - S}{S} * 100$$

where *L* is the longest stretched length in the part and *S* is the shortest comparable length parallel to the longest stretched length. *L* and *S* are assumed to be of equal length before stretching.

Hot stretch forming results in minimum springback; the little springback that may occur is controlled by adding about 1% to the total stretch. Contour and springback control are good for positive contour radii curvature up to 6 m (20 ft).

For differential stretching of sheet over dies of low curvature, the maximum practical limit is about 15%. A 12% maximum is considered more desirable, however, because it permits enough overstretch for springback control.

Wrinkling is often a problem in the stretch forming of magnesium sheet, particularly in making asymmetrical parts of low curvature. The best way to control wrinkling is to build the proper restraints in the dies.

Dies can be made of a variety of materials, including magnesium alloys, aluminum alloys, zinc alloys, iron, or steel. One aircraft company has reported the use of dies made of concrete cast over a wire mesh and heated by electrical resistance. Zinc alloy blocks should not be used above 230 °C (450 °F). Grippers should not have sharp serrated edges, which tear magnesium alloys; the use of emery paper between the grips and the magnesium sheet helps to reduce the possibility of tearing.

Heat control is important, and proper arrangement of heating units provides correct heat distribution. In addition to electrical-resistance heating, infrared radiant heating units can be employed. Thermostatic control is essential and should be used on all heaters. The resistance heaters can be placed at various points where critical forming occurs. It is important that heating be sufficient to induce plastic flow, yet not great enough to cause excessive elongation and rupture of the part.

Die temperature varies with the material being formed. AZ31B-O sheet is usually formed at 290 °C (550 °F) without loss of mechanical properties. Hard-rolled AZ31B-H24 can withstand a temperature of 165 °C (325 °F) for 1 h and higher temperatures for shorter periods. The maximum time at temperature to maintain original properties is given in Table 18. Extruded magnesium alloys can be heated to 315 °C (600 °F) in most instances. For most contours, only heating of the die is necessary because the sheet will pick up heat quickly from the hot die. More complicated parts may require additional heating of the sheet by radiant heat or thermal blankets. Thick material may require the same treatment.

Lubricants are normally recommended; colloidal graphite is the best for high-temperature forming. Lower-temperature operation (≤260 °C, or 500 °F) may permit the use of heat-resisting waxes and greases, or a dry-film stearate-type lubricant instead of colloidal graphite. Some shops have used heat-resisting synthetic rubber or fiberglass cloth between the magnesium sheet and the forming block.

Annealed magnesium sheet can be shrunk satisfactorily at room temperature. The amount of shrinkage possible can be greatly increased by heating. Standard shrinking machines are employed.

Extrusion Formability. Production bending of extrusions can be done on standard angle rolls, in mating dies, in stretch-forming machines, or in other specialized bending equipment. If the forming is severe, extrusions are heated to approximately 260 to 345 °C (500 to 650 °F) and formed hot.

Some bend radii data for flat extruded magnesium strip, as well as maximum forming temperatures and times, are given in Table 19. Bending of more complex extrusions is more difficult, and the bend radii required must be established for a given shape. The minimum bend radii for round magnesium tubing varies with the ratio of outer diameter to wall thickness (Table 20).

Table 19 Suggested limits for bending flat magnesium alloy extrusions

As established for 2.29 × 22.2 mm (0.090 × 0.875 in.) extruded flat strip. Numerical values for bend radii are given as multiples of extrusion thickness.

Joining of Magnesium Alloys

Welding. Magnesium alloys can be readily welded by gas metal arc welding and by resistance spot welding. Rods of approximately the same composition as the base metal are generally satisfactory. With alloys HM21A and HM31A, EZ33A rods give higher joint efficiencies (Table 21).

Table 21 Weldability of magnesium alloys

(a) Percentage elongation across the weld over a 50 mm (2 in.) gage length from tension tests

Butt and fillet joints are preferred in magnesium because they are the easiest to make by arc welding, and they provide more consistent results than other types of joints. Lap joints are used sometimes, but they are generally less satisfactory than butt joints for load-carrying applications.

Arc welded joints in annealed magnesium alloy sheet and plate have room-temperature tensile strengths less than 10% lower than those of the base metal (joint efficiencies, of greater than 90%). Tensile strengths of arc welds in hard-rolled material, however, are significantly lower than those of the base metal (joint efficiencies of only 60 to 85%) as a result of the annealing effect of welding. Consequently, room-temperature strengths of arc welded joints in magnesium alloy sheet and plate are about the same regardless of the temper of the base metal.

Joint efficiencies also are affected by service temperatures. For example, arc welds in HK31A-H24 sheet exhibit joint efficiencies of 75 to 80% at room temperature, but these increase to nearly 100% at 260 °C (500 °F). Joint efficiencies of arc welds in HM21A-T8 sheet range from about 80% at room temperature to 100% at 200 °C (400 °F). HM31-T5 extrusions exhibit joint efficiencies of 75 to 85% from room temperature to about 370 °C (700 °F), and 100% at 425 °C (800 °F) and above. There are no appreciable differences in properties between welds made with alternating current and those made with direct current.

Stress Relieving. Arc welds in some magnesium alloys--specifically the magnesium-aluminum-zinc series and alloys containing more than 1% Al--are subject to stress-corrosion cracking, and thermal treatment must be used to remove the residual stresses that cause this condition. This treatment consists of placing the parts in a jig or clamping plate and heating them at the temperatures indicated in Table 22 for the specified times. After heating, the parts are cooled in still air. The use of jigs is sometimes necessary so that relief of stresses does not result in warpage of the assembly.

(a) Postweld stress relief is required to prevent possible stress-corrosion cracking in this alloy. Postweld heat treatment of other alloys is used primarily for straightening or for stress relieving prior to machining.

(b) When extrusions are welded to sheet, distortion may be minimized by using a lower stress-relieving temperature and a longer time. For example, 60 min at 150 °C (300 °F) instead of 15 min at 260 °C (500 °F).

(c) ZK60 has limited weldability.

(d) These stress-relief schedules for casting alloys will not develop maximum joint strength. For maximum strength, use the postweld heat treatments shown in Table 23.

(e) No stress relief is necessary after welding this alloy.

The other types of magnesium alloys, including those containing manganese, rare earths, thorium, zinc, or zirconium, are not sensitive to stress corrosion and normally do not require stress relief after welding.

Repaired castings are generally heat treated again after welding. All alloys which require full (T6) heat treatment are best welded in the solution-treated (T4) condition. After welding, a short solution treatment followed by the normal aging treatment is necessary. The postweld heat treatment of magnesium casting alloys depends on the desired final temper of the castings (Table 23). However, if complete solution heat treatment is not desired, welded castings should always be stress relieved as described in Table 22.

Table 23 Weld preheat and postweld heat treatment of magnesium castings

Alloy	Metal temper before welding[a]	Desired temper after welding[a]	Weld preheat[b]	Postweld heat treatment (time after reaching temperature)[c]

ZK61A	T4 or T6	T6	None to 315 °C (600 °F)	2-5 h at 500 °C (930 °F)[(d)] + 48 h at 130 °C (265 °F)

(a) Temper T4, solution heat treated; T6, solution heat treated and aged; T5, artificially aged; F, as-cast.

(b) Heavy and unrestrained sections usually need no preheat; thin and restrained sections may need to be preheated to indicated temperatures to avoid weld cracking.

(c) Temperatures listed are maximum allowable; furnace controls should be set so that temperature does not cycle above indicated maximum.

(d) SO_2 or CO_2 atmosphere recommended when heating temperature exceeds 370 °C (700 °F).

(e) Optional postweld heat treatment serves to induce greater stress relief.

Spot welds in magnesium have good static strength, but their fatigue strength is lower than for either riveted or adhesive-bonded joints. Spot-welded assemblies are used mainly for low-stress applications and are not recommended where joints are subject to vibration. Typical shear strengths of spot welds in three alloys are given in Table 24. Shear strengths of welds AZ61A and HK31A are about the same as those in AZ31B.

Seam welds of the continuous or intermittent types have strength properties comparable to those of spot welds. Shear strengths of about 19.2 to 40.2 kg/linear mm (1075 to 2250 lb/linear in.) of welded seam can be obtained in AZ31B sheet from 1 to 3 mm (0.040 to 0.12 in.) thick.

The cost of weldments is less likely to vary significantly with quantity than the cost of other methods of fabrication. Therefore, weldments are used most often where quantities are small or where fabrication of specific designs is impractical or impossible by other methods. For a dozen parts of the design shown in Fig. 16, sand castings cost twice as much as weldments; at about 35 pieces, the tooling cost for casting was absorbed, and casting was more economical for larger lots.

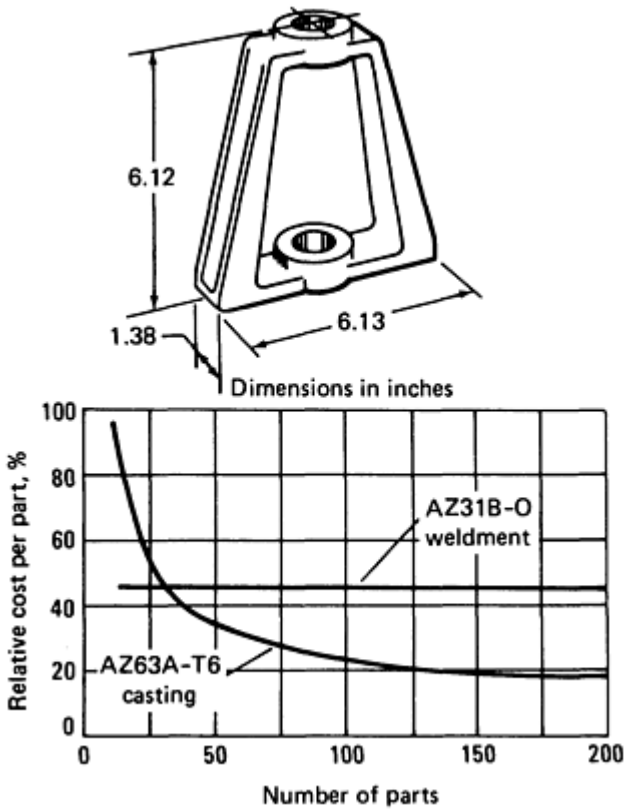

Fig. 16 Effect of quantity on the cost of magnesium alloy sand castings compared with the same parts made as weldments

For the electronic mounting base shown in Fig. 17, the die casting was superior to the weldment in mechanical properties, although properties of both were above minimum requirements. Die castings were less expensive than weldments in quantities of 5000 (including cost of tooling); in quantities of 100, weldments were less expensive.

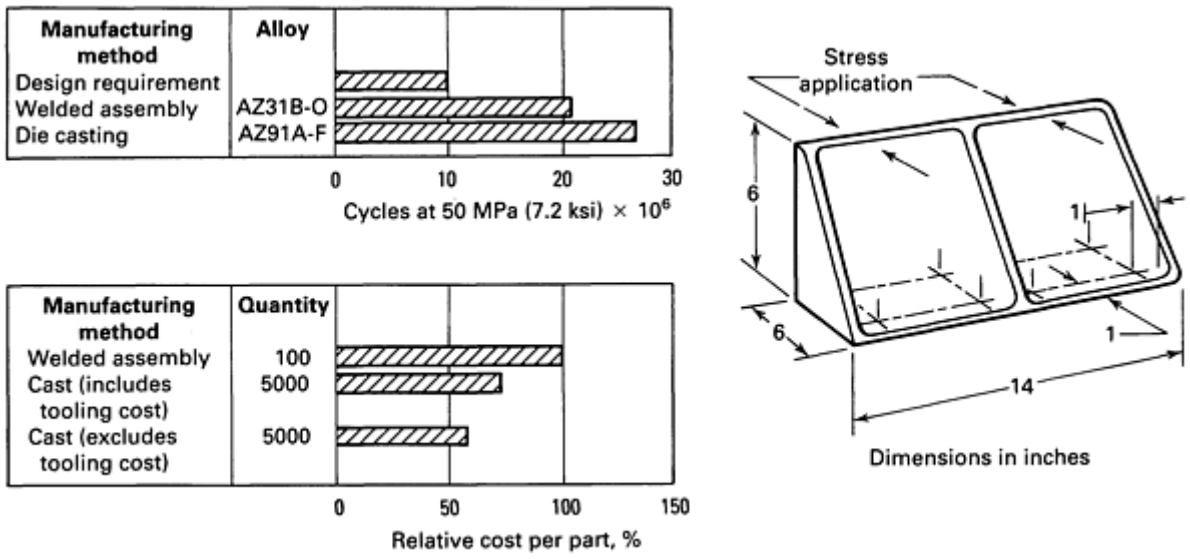

Fig. 17 Comparison of a magnesium alloy electronic mounting base as manufactured by welding and by casting. Weight of part, 1.25 kg (2.75 lb)

Adhesive bonding of magnesium has become an important fabrication technique. The fatigue characteristics of adhesive-bonded lap joints are better than those of other types of joints. The probability of stress concentration failure in adhesive-bonded joints is minimal. Adhesive bonding permits the use of thinner materials than can be effectively riveted. The adhesive fills the spaces between the contacting surfaces and thus acts as an insulator between any dissimilar metals in the joint. It also permits manufacture of assemblies having surfaces smoother than those associated with riveting.

Adhesive bonding has been limited almost exclusively to lap joints. A few general factors should be considered when designing adhesive-bonded joints:

- Joint strengths vary with the lap width, metal thickness, direction in which loads are applied, and type of adhesive used
- The joint should be designed so that it provides a sufficiently large bonded area
- The adhesive layer should be uniform in thickness
- The adhesive layer should be as thin as possible, yet applied in sufficient quantity so that no joints are starved
- Joints should be designed so that pressure and heat can be readily applied
- The curing temperatures of the common structural adhesives are below the temperatures at which the properties of hard-rolled magnesium sheet are affected, and thus they do not significantly reduce the properties of magnesium alloys in the annealed (O) condition

The effect of lap width on the shear strength of joints bonded with phenolic rubber-base resin adhesive is shown in Fig. 18(a). The effect of temperature on the shear strength of adhesive-bonded joints in magnesium and aluminum is shown in Fig. 18(b).

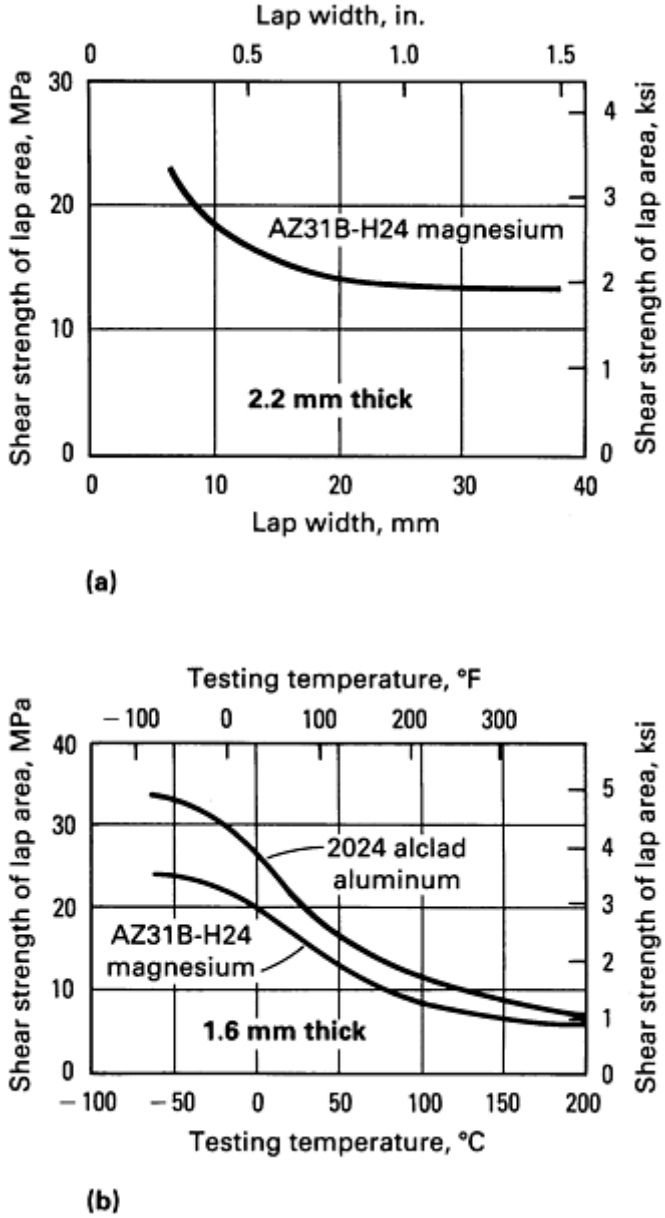

Fig. 18 Effect of (a) lap width and (b) temperature on the shear strength of joints bonded with a phenolic rubber-base resin adhesive

The characteristics and properties of some adhesives used with magnesium are given in Table 26. These adhesives cannot be utilized in assemblies operating above 80 °C (180 °F) because of low shear strength.

Table 26 Characteristics of adhesives used for bonding magnesium

These adhesives are for service at temperatures up to 82 °C (180 °F).

(a) Known to meet USAF specifications

Riveting. Essentially the same procedures employed in riveting other materials are used in riveting magnesium alloys. Standard procedures are used for drilling and countersinking holes. Both dimpling and machine countersinking are used in flush riveting. With machine countersinking, it is desirable to have a cylindrical land with a minimum depth of 0.38 mm (0.015 in.) at the bottom of the hole. Thus, machine countersinking is limited to sheet thick enough to permit lands of this depth with a given size of rivet. Dimpling of magnesium alloy sheet is a hot-forming operation; to prevent reduction of properties during dimpling, the sheet must not be heated to excessively high temperatures or for long periods.

Only aluminum rivets should be used if galvanic incompatibility is to be minimized, and those up to 8 mm ($\frac{5}{16}$ in.) in diameter can be driven cold. The ease of driving rivets of alloy 5056 will vary with the temper. Quarter-hard temper (5056-H32) is satisfactory for all normal riveting.

Machinability

Magnesium and its alloys can be machined at extremely high speeds using greater depths of cut and higher rates of feed than can be used in machining other structural metals. There are no significant differences in machinability among magnesium alloys. Therefore, a specific magnesium alloy rarely, if ever, is selected in place of another magnesium alloy solely on the basis of machinability.

Because of the free-cutting characteristic of magnesium, chips produced in machining are well broken. Dimensional tolerances of about ±0.1 mm (a few thousandths of an inch) can be obtained using standard operations.

The power required to remove a given amount of metal is lower for magnesium than for any other commonly machined metal. Based on the volume of metal removed per minute, the comparative power requirements of various metals are:

Metal	Relative power
Magnesium alloys	1.0
Aluminum alloys	1.8
Brass	2.3
Cast iron	3.5
Low-carbon steel	6.3
Nickel alloys	10.0

Tool wear is also reduced when machining magnesium because of the high thermal conductivity of the metal, which allows rapid dissipation of heat, and the low cutting pressures required. Ordinary carbon steel tools can be used in machining magnesium, but high-speed tools and carbide-tipped tools can be used for high production rate jobs.

An outstanding machining characteristic of magnesium alloys is their ability to acquire an extremely fine finish. Often, it is unnecessary to grind and polish magnesium to obtain a smooth finished surface. Surface smoothness readings of about 0.1 μm (3 to 5 μin.) have been reported for machined magnesium and are attainable at both high and low speeds, with or without cutting fluids.

Cutting Fluids (Coolants). In the machining of magnesium alloys, cutting fluids provide far smaller reductions in friction than they provide in the machining of other metals; thus, they are of little use in improving surface finish and tool life. Most machining of magnesium alloys is done dry, but cutting fluids sometimes are used for cooling the work.

Although less heat is generated during machining of magnesium alloys than during machining of other metals, higher cutting speeds and the low heat capacity and relatively high thermal expansion characteristics of magnesium may make it necessary to dissipate the small amount of heat that is generated. Heat generation can be minimized by the use of correct tooling and machining techniques, but cutting fluids are sometimes needed to reduce the possibilities of distortion of the work and ignition of fine chips. Because they are used primarily to dissipate heat, cutting fluids are referred to as coolants when used in the machining of magnesium alloys.

Numerous mineral oil cutting fluids of relatively low viscosity are satisfactory for use as coolants in the machining of magnesium. Suitable coolants represent a compromise between cooling power and flash point. Additives designed to increase wetting power are usually beneficial. Only mineral oils should be used as coolants; animal and vegetable oils are not recommended.

Water-soluble oils, oil-water emulsions, or water solutions of any kind should not be used on magnesium. Water reduces the scrap value of magnesium turnings and introduces potential fire hazards during shipment and storage of machine shop scrap.

Safe Practice. The possibility of chips or turnings catching fire must be considered when magnesium is to be machined. Chips must be heated close to their melting point before ignition can occur. Roughing cuts and medium finishing cuts produce chips too large to be readily ignited during machining. Fine finishing cuts, however, produce fine

chips that can be ignited by a spark. Stopping the feed and letting the tool dwell before disengagement, and letting the tool or tool holder rub on the work, produce extremely fine chips and should be avoided.

Factors that increase the probability of chip ignition are:

- Extremely fine feeds
- Dull or chipped tools
- Improperly designed tools
- Improper machining techniques
- Sparks caused by tools hitting iron or steel inserts

Feeds less than 0.02 mm (0.001 in.) per revolution and cutting speeds higher than 5 m/s (1000 ft/min) increase the risk of fire. Even under the most adverse conditions--with dull tools and fine feeds--chip fires are very unlikely at cutting speeds below 3.5 m/s (700 ft/min).

Any fire hazard connected with machining of magnesium is easy to control, and large quantities of magnesium are machined without difficulty. Following these rules will reduce the fire hazard:

- Keep all cutting tools sharp and ground with adequate relief and clearance angles
- Use heavy feeds to produce thick chips
- Use mineral oil coolants (15 to 19 L/min, or 4 to 5 gal/min) whenever possible; when not possible, avoid fine cuts
- Do not allow chips to accumulate on machines or on the clothing of operators. Remove dust and chips at frequent intervals and store in clean, plainly labeled, covered metal cans
- Keep an adequate supply of a recommended magnesium fire extinguisher within reach of operators

If dry chips are ignited, they will burn with a brilliant white light, but the fire will not flare up unless disturbed. Burning chips should be extinguished as follows:

- Scatter a generous layer of clean, dry cast iron chips or metal extinguishing powder over the burning magnesium
- Cover actively burning fires on combustible surfaces like wood floors with a layer of the extinguishant, then shovel the entire mass into an iron container or onto a piece of iron plate
- Do not use water or any of the common liquid or foam-type extinguishers, which intensify magnesium chip fires

Distortion of magnesium parts during machining occurs rarely and usually can be attributed to excessive heating or improper chucking or clamping.

Heating of the work is increased by use of dull or improperly designed tools, extremely high machining feeds and speeds, or very fine cuts. Because magnesium has a relatively high coefficient of thermal expansion, such excessive heating results in substantial increases in dimensions--particularly in thin sections, where heating causes relatively large increases in temperature. Use of sharp, properly designed tools; mineral oil coolants; and relatively coarse feeds and depths of cut reduces excessive heating. Wide variations in room temperature during machining can also cause sufficient dimensional change to affect machining tolerances.

Clamping should always be done on heavier sections of magnesium castings, and clamping pressures should not be high enough to cause distortion. Special care should be taken with light parts that could be distorted easily by the chuck or by use of heavy cuts.

Distortion of magnesium parts is seldom caused by stresses during casting, forging, or extruding, but it may result from stresses caused by straightening or welding. Such stresses can be relieved prior to machining by heating at 260 °C (500

°F) for 2 h and slowly cooling. However, such treatment causes some loss of strength in AZ31B-H24 sheet products. If distortion of part is observed after rough machining, the cutting tool should be inspected to ensure that it is sharp and properly ground. If so, the size of cut should be decreased. With complex parts or parts machined to extremely close tolerances, it may be advisable to stress relieve or, if time permits, to store parts for 2 or 3 days between rough machining and finishing.

Design and Weight Reduction

By substituting magnesium alloys for heavier metals such as steel and aluminum alloys, many structural parts can be substantially reduced in weight with little or no redesign. This is possible because manufacturing limitations make many parts heavier than necessary. For example, for successful filling of the mold, a casting may require a minimum wall thickness greater than that dictated by service requirements and the strength of the metal used. Similarly, forgings and extrusions sometimes must be made thicker than necessary, and the light weight of magnesium can be used to advantage. In many instances, a casting, forging, or extrusion for which magnesium is substituted for a heavier metal can have adequate strength with no increase in wall thickness.

In other parts, substitution of magnesium may require greater wall thickness, and substantial redesign may be necessary in order to realize maximum weight savings. Because strength and stiffness in bending of many structural sections increase approximately as the square and cube of the section depth, respectively, it is possible to obtain large increases in strength and stiffness with moderate increases in depth and cross-sectional area. When such increases in depth are permissible, it usually is economical to redesign the part for magnesium. The greater bulk of the redesigned part reduces local instability, and although the saving in weight is less than maximum, the reduction in instability allows design simplification and thus reduces manufacturing costs.

The room-temperature thickness, strength, stiffness, and weight of magnesium alloys are compared with those of aluminum alloys and steel in Table 27. Bending strength is defined as the product of yield strength and section modulus.

Table 27 Relative bending strength, stiffness, and weight of selected structural metals

Material	Thickness	Bending strength	Stiffness	Weight
For equal thickness				
1025 steel	100	100.0	100.0	100.0

For equal weight				
1025 steel	100	100	100	100
6061-T6 aluminum sheet and extrusions	290	817	841	100
AZ31B magnesium extrusions	444	930	1962	100
ZK60A-T5 magnesium extrusions	444	1753	1962	100
AZ31B-H24 magnesium sheet	444	1451	1962	100

Note: Comparison made at room temperature for rectangular beams of constant width with the following minimum yield strengths: 1025 steel, 250 MPa (36 ksi); 6061-T6 aluminum, 240 MPa (35 ksi); magnesium alloys, average of minimum tensile yield and compressive yield strengths. All comparisons expressed in percent

Bending. Rectangular steel, aluminum, and magnesium sections of equal thickness have rigidities in the ratio of their moduli of elasticity. The magnesium section weighs about 63% as much as the aluminum section and about 22% as much as the steel section.

The rigidity in bending of a rectangular section is proportional both to the cube of its depth and to its modulus of elasticity. If the section thicknesses of a magnesium section, an aluminum section, and a steel section are adjusted until their rigidities are equal, the magnesium section will weigh about 71% of the aluminum and about 40% of the steel. If the section thickness of the magnesium is increased to about twice that of the steel, the magnesium will be more than 70% more rigid than the steel and less than 50% as heavy. Magnesium supporting its own weight shows no more deflection than other metals under the same conditions.

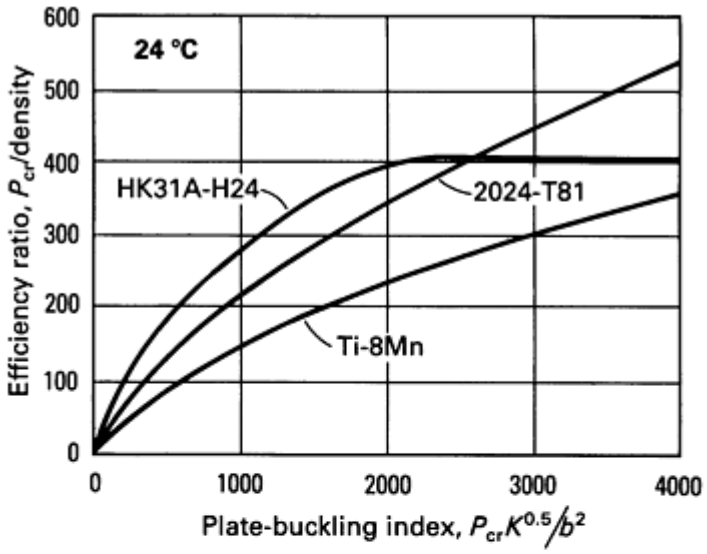
At high temperatures, the difference between short-time ultimate and yield strengths of certain magnesium alloys decreases significantly. Creep properties that depend on time must also be considered in evaluating materials for long-time operation at elevated temperature. Creep-strength values of several magnesium alloys are given in the data compilations in the article "Properties of Magnesium Alloys" in this Volume.

Plate Buckling. Structures subjected to compressive loads may be limited in efficiency (load carried versus weight of structure) by buckling at relatively low stresses.

A structural index is a valuable aid to designers in the selection of optimum materials for plate structures that are critical in compression loading. A structural index is nondimensional; that is, equivalent designs give the same value of structural index regardless of the size of the actual part. The plate-buckling index is computed from the maximum edge load (P_{cr}) that will not cause crippling, the width (b) of the plate and a factor, K, determined by the amount of restraint or clamping along the unloaded edges for a simply supported edge, $K = 4.0$). The formula is:

$$Index = \frac{P_{cr} k^{0,5}}{b^2}$$

Using this index, the efficiency of various structural materials can be directly compared for given conditions of loading and structural configuration. For example, the efficiencies of three materials at room temperature and at 260 °C (500 °F) for plate-buckling indexes up to 4000 are shown in Fig. 19. Comparisons are based on typical properties after short-time exposure at temperature.



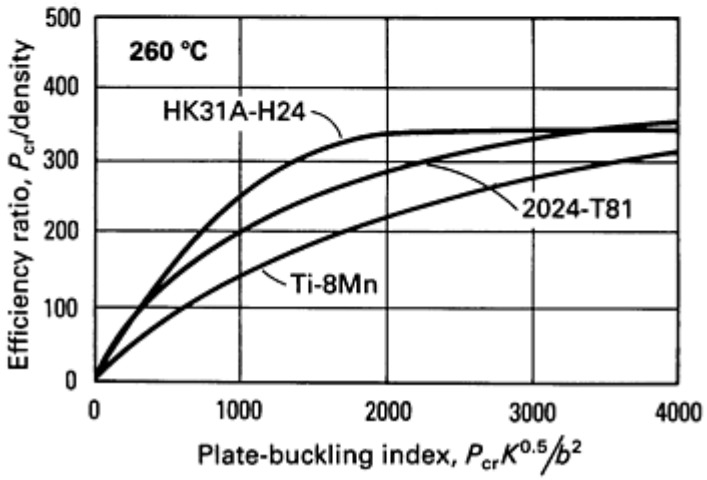


Fig. 19 Effect of plate-buckling index and temperature on the structural efficiency of magnesium, aluminum, and titanium alloys. See text for discussion.

A low value of plate-buckling index means either that the critical edge load is low or that the plate is wide, corresponding in either instance to a more lightly stressed structure. As the index value increases, it represents a transition to narrower plates and/or heavier edge loads and, at high values, corresponds to a condition of pure prismatic compression.

The ratio of working stress to density is an inverse measure of structural weight--the higher the ratio, the lighter the structure. Figure 19 shows the expected advantage in efficiency of the lowest-density magnesium alloy HK31A-H24 over the higher-density aluminum and titanium alloys. This advantage fades as the index increases, and the stress condition moves from elastic buckling toward prismatic compression. Comparison of the two charts shows that the range over which the magnesium alloy is the most efficient of the three alloys (magnesium, aluminum, and titanium) is higher at 260 °C (500 °F) than at room temperature.

Wrought Magnesium Alloys

AZ10A

Specifications

UNS. M11100

Government. Extruded rods, bars, and shapes: QQ-M-31

Chemical Composition

Composition limits. 1.0 to 1.5 Al, 0.2 to 0.6 Zn, 0.2 Mn min, 0.1 Si max, 0.1 Cu max, 0.005 Ni max, 0.005 Fe max, 0.04 Ca max, bal Mg

Applications

Typical uses. Low-cost extrusion alloy with moderate mechanical properties and high elongation. Used in as-extruded (F) temper

Mechanical Properties

Tensile properties. See Table 1.

Table 1 Typical mechanical properties of AZ10A at room temperature

Size and shape	Tensile strength		Yield strength		Elongation, %	Compressive yield strength	
	MPa	ksi	MPa	ksi		MPa	ksi
Solid shapes with least dimension up to 6.4 mm (0.025 in.)	240	35	145	21	10	69	10

Shear strength. See Table 2.

Compressive yield strength. See Table 2.

Bearing properties. See Table 2.

Hardness: See Table 2.

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Impact Strength. Forgings and extruded bar, rod, and solid shapes: Charpy V-notch, 4.3 J (3.2 ft · lbf)

Directional properties. See Table 4.

Table 4 Typical directional properties of AZ31B

Condition	Tensile strength		Yield strength		Elongation %[(a)]
	MPa	ksi	MPa	ksi	
Parallel to rolling direction					
Annealed	255	37	150	22	21
Hard rolled	290	42	220	32	15
Perpendicular to rolling direction					
Annealed	270	39	170	25	19
Hard rolled	295	43	235	34	19

(a) In 50 mm (2 in.)

Mass Characteristics

Density: 1.77 g/cm^3 (0.064 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 630 °C (1170 °F)

Solidus temperature. 605 °C (1120 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F)

Specific heat versus temperature. $C_p = 0.2441 + 0.000105T - 2783T^{-2}$

Latent heat of fusion. 330 to 347 kJ/kg (142 to 149 Btu/lb)

Thermal conductivity. 96 W/m · K (56 Btu/ft · h · °F) at 100 to 300 °C (212 to 572 °F)

Electrical Properties

Electrical conductivity. 18.5% IACS

Electrical resistivity. 92 nΩ · m at 20 °C (68 °F)

Electrolytic solution potential. 1.59 V versus saturated calomel electrode

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AZ61A or AZ92A rod (AZ61A preferred), excellent; stress relief required. Resistance welding, excellent

Recrystallization temperature. Recrystallizes after 1 h at 205 °C (400 °F) following 15% cold work

Annealing temperature. 345 °C (650 °F)

Hot-working temperature. 230 to 425 °C (450 to 800 °F)

AZ61A

Specifications

AMS. Extrusions: 4350. Forgings: 4358

ASTM. Extrusions: B 107. Forgings: B 91

SAE. J466. Former SAE alloy numbers: 520 (extrusions) and 531 (forgings)

UNS number. M11610

Government. Extruded bar, rod, and shapes: QQ-M-31B. Extruded tubing: WW-T-825A. Forgings: QQ-M-40B

Foreign. Elektron AZ61 (extruded bar, sections, and tubing). British: extruded bar, sections, and tubing, BS 3373 MAG121; forgings, BS 3372 MAG121. German: DIN 9715 3.5612; castings, DIN 1729 3.5612. French: AFNOR G-A6Z1

Chemical Composition

Composition limits. 5.8 to 7.2 Al, 0.15 Mn min, 0.40 to 1.5 Zn. 0.10 Si max, 0.05 Cu max, 0.005 Ni max, 0.005 Fe max, 0.30 max other (total), bal Mg

Consequence of exceeding impurity limits. Excessive Cu, Ni, or Fe degrades corrosion resistance.

Applications

Typical uses. General-purpose extrusions with good properties and moderate costs, and forgings with good mechanical properties; used in the as-fabricated (F) temper. This alloy is used in sheet form for battery applications only.

Mechanical Properties

Tensile properties. See Tables 5 and 6.

Table 5 Typical room-temperature mechanical properties of AZ61A-F

Form and condition	Tensile strength		Tensile yield strength[a]		Elongation, %[b]	Hardness		Shear strength		Compressive yield strength[a]		Ultimate bearing strength[d]		Bearing yield strength[d]

Shear strength. See Table 5.

Compressive yield strength. See Table 5.

Bearing properties. See Table 5.

Hardness. See Table 5.

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Impact strength. Charpy V-notch: forgings, 3 J (2.2 ft · lbf); extruded rod, bar, and shapes, 4.1 J (3.0 ft · lbf)

Mass Characteristics

Density: 1.8 g/cm^3 (0.065 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 620 °C (1145 °F)

Solidus temperature. 525 °C (975 °F)

Incipient melting temperature. 418 °C (785 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F) at 20 °C (68 °F)

Specific heat. 1.05 kJ/kg · K (0.25 Btu/lb · °F) at 25 °C (78 °F)

Latent heat of fusion. 373 kJ/kg (160 Btu/lb)

Thermal conductivity. 80 W/m · K (46 Btu/ft · h · °F)

Electrical Properties

Electrical conductivity. 11.6% IACS at 20 °C (68 °F)

Electrical resistivity. 125 nΩ·m at 20 °C (68 °F)

Electrolytic solution potential. 1.58 V versus saturated calomel electrode

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AZ16A or AZ92A rod (AZ61A preferred), good; stress relief required. Resistance welding, excellent

Recrystallization temperature. Recrystallizes after 1 h at 288 °C (550 °F) following 20% cold work

Annealing temperature. 345 °C (650 °F)

Hot-working temperature. 230 to 400 ° (450 to 750 °F)

Hot-shortness temperature. 415 °C (780 °F)

AZ80A

Specifications

AMS. Forgings: 4360

ASTM. Extruded rod, bar, and shapes: B 107. Forgings: B 91

SAE. J466. Former SAE alloy numbers: 523 (extrusions) and 532 (forgings)

UNS number. M11800

Government. Extruded bar, rod, and shapes: QQ-M-31B. Extruded tubing: WW-T-825. Forgings: QQ-M-40B

Chemical Composition

Composition limits. 7.8 to 9.2 Al, 0.20 to 0.80 Zn, 0.12 Mn min, 0.10 Si max, 0.05 Cu max, 0.005 Ni max, 0.005 Fe max, 0.30 max other (total), bal Mg

Consequence of exceeding impurity limits. Excessive Si, Cu, Ni, or Fe degrades corrosion resistance.

Applications

Typical uses. Extruded products and press forgings. This alloy can be heat treated.

Mechanical Properties

Tensile properties. See Tables 7 and 8.

Electrical resistivity. At 20 °C (68 °F): H24 temper, 52 nΩ · m; O temper, 50 nΩ · m

Fabrication Characteristics

Weldability. Gas-shielded arc welding with EZ33A rod, excellent; resistance welding, very good

Annealing temperature. 455 °C (850 °F)

Hot-working temperature. 455 to 595 °C (850 to 1100 °F)

HM31A

Specifications

AMS. AS-extruded: 4388. Extruded and aged: 4389

SAE. J466

UNS number. M13312

Government. MIL-M-8916

Chemical Composition

Composition limits. 2.5 to 3.5 Th, 1.2 Mn min, 0.30 max other (total), bal Mg

Applications

Typical uses. Weldable alloy developed primarily for elevated-temperature structural service in the form of extruded bar, rod, shapes, and tubing. Exposure to temperatures up to 315 °C (600 °F) for 1000 h causes virtually no change in short-time room- and elevated-temperature properties. Superior elastic modulus, particularly at elevated temperatures. Although certain extruded sections develop optimum properties in the as-extruded (F) temper, other sections require aging to the T5 temper.

Mechanical Properties

Tensile properties. See Table 13 and Fig. 7.

Table 13 Typical tensile and compressive properties of HM31A extrusions up to 2600 mm^2 (4 in.^{2}) in area

Testing temperature		Tensile strength		Tensile yield strength		Compressive yield strength		Elongation in 50 mm (2 in.), %

Compressive yield strength. See Table 13.

Bearing properties. As 21 °C (70 °F): ultimate bearing strength, 480 MPa (70 ksi); bearing yield strength, 345 MPa (50 ksi)

Poisson's ratio. 0.35

Elastic modulus. Tension: 45 GPa (6.5×10^6 psi) at 21 °C (70 °F); 42 GPa (6.1×10^6 psi) at 150 °C (300 °F); 40 GPa (5.9×10^6 psi) at 200 °C (400 °F); 39 GPa (5.6×10^6 psi) at 315 °C (600 °F). Shear: 17 GPa (2.4×10^6 psi) at 21 °C (70 °F)

Creep characteristics. See Table 14.

Table 14 Typical creep properties of HM31A extrusions

Testing temperature		Stress to produce, in 100 h, extension of					
		0.1% (creep)		0.2% (total)		0.5% (total)	
°C	°F	MPa	ksi	MPa	ksi	MPa	ksi

200	400	110	16	83	12	115	17
260	500	76	11	69	10	83	12
315	600	41	6	41	6	48	7

Mass Characteristics

Density. 1.8 g/cm^3 (0.065 lb/in.^{3})

Thermal Properties

Liquidus temperature. 650 °C (1200 °F)

Solidus temperature. 605 °C (1120 °F)

Incipient melting temperature. 482 °C (900 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14.5 μin./in. · °F) at 20 to 93 °C (68 to 200 °F); 28 μm/m · K (15.6 μin./in. · °F) at 20 to 316 °C (68 to 600 °F); 30 μm/m · K (16.8 μin./in. · °F) at 20 to 540 °C (68 to 1000 °F)

Specific heat versus temperature. $C_p = 0.0982 + 0.0002894T + 53000T^{-2}$

Latent heat of fusion. 331 kJ/kg (143 Btu/lb)

Thermal conductivity. 104 W/m · K (60 Btu/ft · h · °F)

Electrical Properties

Electrical conductivity. F temper at 20 °C (68 °F): volumetric, 26% IACS; mass, 135% IACS

Electrical resistivity. F temper: 66 nΩ · m at 20 °C (68 °F); 79 nΩ · m at 93 °C (200 °F); 97 nΩ · m at 200 °C (400 °F); 115 nΩ · m at 315 °C (600 °F)

Temperature coefficient of electrical resistivity. 0.18 nΩ · m per K

Fabrication Characteristics

Weldability. Gas-shielded arc welding with EZ33A rod, excellent; no stress relief is necessary. Resistance welding, very good

Recrystallization temperature. Recrystallizes after 1 h at 400 °C (750 °F) following 50% cold work

Hot-working temperature. 370 to 540 °C (700 to 1000 °F)

M1A

Specifications

ASTM. Extruded rod, bar, shapes, and tubing: B 107

SAE. J466. Former SAE alloy numbers: 522 (extrusions) and 533 (forgings)

UNS number. M15100

Government. Extruded bar, rod, and shapes: QQ-M-31. Extruded tubing: WW-T-825. Forgings: QQ-M-40. Sheet and plate: QQ-M-54

Foreign. Elektron AM503. British: BS 3370 MAG101. German: DIN 9715 3.5200

Chemical Composition

Composition limits. 1.2 Mn min, 0.30 Ca max, 0.05 Cu max, 0.01 Ni max, 0.10 Si max, 0.30 max others (total), bal Mg

Consequence of exceeding impurity limits. Excessive Si tends to precipitate Mn. Excessive Cu or Ni degrades corrosion resistance in salt water.

Applications

Typical uses. Wrought products with moderate mechanical properties as well as excellent weldability, corrosion resistance, and hot formability; not heat treatable

Mechanical Properties

Tensile properties. See Tables 15 and 16.

Table 15 Typical room-temperature mechanical properties of M1A

Product form	Tensile strength		Tensile yield strength[a]		Elongation, %[b]	Hardness		Shear strength		Compressive yield strength[a]		Ultimate bearing strength[d]		Bearing yield strength[d]

Shear strength. See Table 15.

Compressive properties. See Table 15.

Bearing properties. See Table 15.

Hardness. See Table 15.

Directional properties. See Table 17.

Table 17 Typical directional properties of M1A sheet

Condition	Tensile strength		Yield strength		Elongation, %
	MPa	ksi	MPa	ksi	
Parallel to rolling direction					
Annealed	230	33	125	18	17
Hard rolled	250	36	180	26	7
Perpendicular to rolling direction					
Annealed	220	32	115	17	17
Hard rolled	255	37	185	27	13

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Mass Characteristics

Density. 1.77 g/cm^3 (0.064 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 649 °C (1200 °F)

Solidus temperature. 648 °C (1198 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 1.05 kJ/kg · K (0.25 Btu/lb · °F)

Latent heat of fusion. 373 kJ/kg (160 Btu/lb)

Thermal conductivity. 138 W/m · K (79.8 Btu/ft · h · °F)

Electrical Properties

Electrical conductivity. 34.5% IACS at 20 °C (68 °F)

Electrical resistivity. 50 nΩ · m at 20 °C (68 °F)

Electrolytic solution potential. 1.64 V versus saturated calomel electrode

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AZ61A, AZ92A, or M1A rod (AZ61A preferred), excellent; stress relief not required but may be used. Resistance welding, good. Oxyacetylene welding, if necessary, can be done with M1A rod, magnesium flux, and neutral flame.

Recrystallization temperature. Recrystallizes after 1 h at 260 °C (500 °F) following 20% cold work

Annealing temperature. 370 °C (700 °F)

Hot-working temperature. 295 to 540 °C (560 to 1000 °F)

PE

Chemical Composition

Composition limits. 2.5 to 4.0 Al, 0.08 Mn max, 0.7 to 1.6 Zn, 0.05 Si max, 0.05 Cu max, 0.005 Ni max, 0.005 Fe max, 0.04 Ca max, 0.03 max other impurities (total), bal Mg

Consequence of exceeding impurity limits. Poor etch quality

Applications

Typical uses. Photoengraving

Mass Characteristics

Density. 1.76 g/cm^3 (0.064 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 632 °C (1170 °F)

Solidus temperature. 605 °C (1120 °F)

Incipient melting temperature. 532 °C (990 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F)

Specific heat. 1047 J/kg · K (0.25 Btu/lb · °F) at 20 °C (68 °F)

Latent heat of fusion. 330 to 347 kJ/kg (142 to 149 Btu/lb)

Fabrication Characteristics

Annealing temperature. 345 °C (650 °F)

Hot-working temperature. 230 to 425 °C (450 to 800 °F)

Hot-shortness temperature. 345 °C (650 °F)

ZC71

Specifications

ASTM. Extrusions: B 107

UNS number. M16710

Chemical Composition

Composition limits. 6.0 to 7.0 Zn. 1.0 to 1.5 Cu, 0.5 to 1.0 Mn, 0.20 Si max, 0.010 Ni max, 0.30 max other (total), bal Mg

Applications

Typical uses. Medium-cost extrusion alloy with good mechanical properties and high elongation. Used in the solution-heat-treated and artificially aged (T6) condition

Mechanical Properties

Tensile properties. See Table 18.

Table 18 Typical and minimum tensile properties of magnesium alloy ZC71

Specimen	Condition	0.2% yield strength		Tensile strength		Elongation, %
		MPa	ksi	MPa	ksi	
Round bar with 13-125 mm ($\frac{1}{2}$-5 in.) diameter	ZCM 711-F (as extruded)	158	23	240	35	7

	T6 condition	315-335	45.7-48.6	340-360	49.3-52.2	5-7

Elastic modulus. Tension, 44.2 GPa (6.4×10^6 psi) at 20 °C (68 °F)

Hardness. 70 to 80 HB

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 635 °C (1175 °F)

Solidus temperature. 455 °C (850 °F)

Thermal conductivity. 122 W/m · K (70.5 Btu · ft · °F) at 20 °C (68 °F)

Electrical Properties

Electrical resistivity. 54 nΩ · at 20 °C (68 °F)

Fabrication Characteristics

Weldability. Gas-shielded arc welding with weld rod of same base metal composition

ZK21A

Specifications

AMS. Extruded tubes, bars, rods, and shapes: 4387

UNS. M16210

Government. Extrusions: MIL-M-46039

Chemical Composition

Composition limits. 2.0 to 2.6 Zn, 0.45 to 0.8 Zr, 0.3 max impurities (total), bal Mg

Applications

Typical uses. Moderate-strength extrusion alloy with good weldability. Stress relief is not required. Used in as-extruded (F) temper

Mechanical Properties

Tensile properties. See Table 19.

Table 19 Minimum mechanical properties at room temperature of ZK21A-F extrusions

Form	Tensile strength		Yield strength		Compressive yield strength		Elongation, %
	MPa	ksi	MPa	ksi	MPa	ksi	

Rods, bars, and shapes	260	38	195	28	135	20	4
Tubing	235	34	180	26	97	14	4

Compressive properties. See Table 19.

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AZ61A or AZ92A rod, satisfactory. Resistance welding, satisfactory

ZK40A

Specifications

ASTM. Extrusions: B 107

UNS. M16400

Foreign. Canadian, CSA HG.5 ZK40A

Chemical Composition

Composition limits. 3.5 to 4.5 Zn, 0.45 Zr min, 0.30 max other (total), bal Mg

Applications

Typical uses. High yield strength extrusion alloy, available in as-extruded (F) and artificially aged (T5) tempers. Not as sensitive to stress concentration at thread roots as other high-strength alloys. Can be heat treated. Can replace ZK60A, especially for diamond drill rod, and is more readily extruded

Mechanical Properties

Tensile properties. See Table 20.

Table 20 Minimum mechanical properties of ZK40A-T5 at room temperature

Form	Tensile strength		Yield strength		Elongation, %	Compressive yield strength	
	MPa	ksi	MPa	ksi		MPa	ksi
Extruded bars and shapes	275	40	255	37	4	140	20

(a) 0.2% offset.

(b) 500 kg load, 10 mm ball

Shear strength. See Table 21.

Compressive yield strength. See Table 21.

Bearing properties. See Table 21.

Hardness. See Table 21.

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 635 °C (1175 °F)

Solidus temperature. 520 °C (970 °F)

Incipient melting temperature. 518 °C (965 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F) at 20 °C (68 °F)

Specific heat versus temperature. $C_p = 0.1233 + 0.0002566T + 3939T^{-2}$

Latent heat of fusion. 300 to 355 kJ/kg (129 to 144 Btu/lb)

Thermal conductivity. F temper, 117 W/m · K (68 Btu/ft · h · °F) at 20 °C (68 °F); T5 temper, 121 W/m · K (70 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. At 20 °C (68 °F): F temper, 29% IACS; T5 temper, 30% IACS

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AZ92A welding rod is possible but not recommended because these alloys are prone to hot-shortness cracking; when welds free of cracks are obtained, they exhibit high weld efficiencies. Resistance welding, excellent.

Aging temperature. 150 °C (300 °F) for 24 h in the air, followed by air cooling

Hot-working temperature. 315 to 400 °C (600 to 750 °F)

Hot-shortness temperature. Cast, 315 °C (600 °F); wrought, 510 °C (950 °F)

AM60A, AM60B

Specifications

ASTM. Die castings: B 94

UNS numbers. AM60A: M10600. AM60B: M10603

Foreign. German: DIN 1729 3.5662

Chemical Composition

Composition limits of AM60A. 5.5 to 6.5 Al, 0.13 Mn min, 0.50 Si max, 0.35 Cu max, 0.22 Zn max, 0.03 Ni max, bal Mg

Composition limits of AM60B. 5.5 to 6.5 Al, 0.25 Mn min, 0.10 Si max, 0.22 Zn max, 0.005 Fe max, 0.010 Cu max, 0.002 Ni max, 0.003 max other (total), bal Mg. If the Mn content is less than 0.25% or the Fe content in AM60B exceeds 0.005%, then the Fe-Mn ratio will not exceed 0.010, and corrosion resistance will rapidly decrease.

Consequence of exceeding impurity limits. Corrosion resistance decreases with increasing Fe, Cu, or Ni content.

Applications

Typical uses. Die casting alloy used in as-cast (F) temper for production of automotive wheels and other parts requiring good elongation and toughness combined with reasonable yield and tensile properties

Mechanical Properties

Tensile properties. F temper: tensile strength, 220 MPa (32 ksi); yield strength, 130 MPa (19 ksi); elongation, 6% in 50 mm (2 in.)

Compressive yield strength. F temper: 130 MPa (19 ksi)

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi)

Mass Characteristics

Density. 1.8 g/cm^3 (0.065 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 615 °C (1140 °F)

Solidus temperature. 540 °C (1005 °F)

Coefficient of linear thermal expansion. 25.6 μm/m · K (14.2 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 62 W/m · K (36 Btu/ft · h · °F) at 20 °C (68 °F)

Fabrication Characteristics

Casting temperature. 650 to 695 °C (1200 to 1280 °F)

Weldability. Not weldable

Corrosion Resistance

ASTM B 177 salt spray test. AM60B: <0.13 mg/cm^2/day (<20 mils/yr)

AM100A

Specifications

AMS. Permanent mold castings: 4483. Investment castings: 4455

ASTM. Sand castings: B 80. Ingot for sand, permanent mold, and die castings: B 93. Permanent mold castings: B 199. Investment castings: B 403

SAE. J465. Former SAE alloy number: 502

UNS number. M10100

Government. Permanent mold castings: QQ-M-55

Chemical Composition

Composition limits. 9.3 to 10.7 Al, 0.10 Mn min, 0.30 Zn max, 0.30 Si max, 0.10 Cu max, 0.01 Ni max, 0.30 max other (total), bal Mg

Consequence of exceeding impurity limits. Corrosion resistance decreases with increasing amounts of Cu, Ni, and Fe. Increased amounts of Zn decrease pressure tightness. More than 0.5% Si decreases elongation.

Applications

Typical uses. Pressure-tight sand and permanent mold castings with good combinations of tensile strength, yield strength, and elongation

Mechanical Properties

Tensile properties. See Tables 22 and 23, and Fig. 8.

Table 22 Typical mechanical properties of AM100A sand castings at room temperature

Temper	Tensile strength		Tensile or compressive yield strength[(a)]		Elongation in 50 mm (2 in.), %	Hardness		Shear strength	
	MPa	ksi	MPa	ksi		HB	HRE	MPa	ksi

Compressive yield strength. See Table 22.

Hardness. At room temperature: See Table 22. At -78 °C (-108 °F): F temper, 63 HB or 75 HRE; T4 temper, 60 HB or 73 HRE; T6 temper, 85 HB or 90 HRE

Bearing properties. Ultimate bearing strength: T4 temper, 475 MPa (69 ksi); T61 temper, 560 MPa (81 ksi). Bearing yield strength: T4 temper, 310 MPa (45 ksi); T61 temper, 470 MPa (68 ksi)

Poisson's ratio. 0.35

Impact strength. Charpy V-notch. At 20 °C (68 °F): F temper, 0.8 J (0.6 ft · lbf); T4 temper, 2.7 J (2.0 ft · lbf); T61 temper, 0.9 J (0.7 ft · lbf). At -78 °C (-108 °F): F temper, 1.1 J (0.8 ft · lbf); T4 temper, 3.4 J (2.5 ft · lbf); T6 temper, 1.1 J (0.8 ft · lbf)

Fatigue strength. R.R. Moore type test. At 5×10^8 cycles: F and T61 tempers, 70 MPa (10 ksi); T4 temper, 75 MPa (11 ksi)

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 595 °C (1100 °F)

Solidus temperature. 463 °C (865 °F)

Incipient melting temperature. 430 °C (810 °F)

Coefficient of linear thermal expansion. 25 μm/m · K (14 μin./in. · °F) at 18 to 100 °C (65 to 212 °F)

Specific heat. 1.05 kJ/kg · K (0.25 Btu/lb · °F) at 25 °C (77 °F)

Thermal conductivity. 73 W/m · K (42 Btu/ft · h · °F) at 100 to 300 °C (212 to 572 °F)

Latent heat of fusion. 372 kJ/kg (160 Btu/lb)

Electrical Properties

Electrical conductivity. F temper, 11.5% IACS; T4 temper, 9.9% IACS; T6 temper, 12.3% IACS

Electrical resistivity. F temper, 150 nΩ · m; T4 temper, 175 nΩ · m; T6 temper, 140 nΩ · m; at 20 °C (68 °F)

Electrolytic solution potential. 1.57 V versus saturated calomel electrode

Hydrogen overvoltage. 0.27 V for extrusions; 0.06 V for castings

Fabrication Characteristics

Weldability. Gas-shielded arc welding with AM100A rod, very good

Casting temperatures. Sand castings, 735 to 845 °C (1350 to 1550 °F); permanent mold castings, 650 to 815 °C (1200 to 1500 °F); ingot, 650 to 705 °C (1200 to 1300 °F)

AS41A, AS41XB

Specifications

ASTM. Die castings: AS41A, B 94

UNS numbers. AS41A, M10410

Foreign. German: DIN 1729 3.5470

Chemical Composition

Composition limits of AS41A. 3.5 to 5.0 Al, 0.50 to 1.5 Si, 0.20 to 0.50 Mn, 0.12 Zn max, 0.06 Cu max, 0.03 Ni max, 0.30 max other (total), bal Mg

Composition limits of AS41XB. 3.5 to 5.0 Al, 0.50 to 1.50 Si, 0.35 Mn min, 0.12 Zn max, 0.0035 Fe max, 0.020 Cu max, 0.002 Ni max, bal Mg

Consequence of exceeding impurity limits. Corrosion resistance decreases with increasing Fe, Cu, or Ni content. If the Mn content is less than 0.35% or the Fe content in AS41XB exceeds 0.0035%, then the Fe-Mn ratio will not exceed 0.010, and corrosion resistance will rapidly decrease.

Applications

Typical uses. Die castings used in the as-cast condition (F temper), with creep resistance superior to that of AZ91A, AZ91B, AZ91D, or AM60A up to 175 °C (350 °F), and with good tensile strength, tensile yield strength, and elongation

Mechanical Properties

Tensile properties. F temper: tensile strength, 210 MPa (31 ksi); yield strength, 140 MPa (20 ksi); elongation, 6% in 50 mm (2 in.)

Compressive yield strength. F temper, 140 MPa (20 ksi)

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi)

Mass Characteristics

Density. 1.77 g/cm^3 (0.064 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 620 °C (1150 °F)

Solidus temperature. 565 °C (1050 °F)

Coefficient of linear thermal expansion. 26.1 μm/m · K (14.5 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 1.0 kJ/kg · K (0.24 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 68 W/m · K (40 Btu/ft · h · °F) at 20 °C (68 °F)

Fabrication Characteristics

Casting temperature. 660 to 695 °C (1220 to 1280 °F)

Weldability. Not weldable

Corrosion Resistance

ASTM B 117 salt spray test. AS41XB: <0.25 mg/cm^2/day (<20 mils/yr)

AZ63A

Specifications

AMS. Sand castings: F temper, 4420; T4 temper, 4422; T5 temper, 4424

ASTM. Ingot: B 93. Sand Castings: B 80

SAE. J465. Former SAE alloy number: 50

UNS number. M11630

Government : Sand castings: QQ-M-56. Permanent mold castings: QQ-M-55

Chemical Composition

Composition limits. 5.3 to 6.7 Al, 2.5 to 3.5 Zn, 0.15 Mn min, 0.30 Si max, 0.25 Cu max, 0.01 Ni max, 0.30 other (total), bal Mg

Consequence of exceeding impurity limits. Excessive Si causes brittleness. Excessive Cu degrades mechanical properties and corrosion resistance. Excessive Ni degrades corrosion resistance.

Applications

Typical uses. Sand castings with good strength, ductility, and toughness

Mechanical Properties

Tensile properties. Tensile strength: F and T5 tempers, 200 MPa (29 ksi); T4, T6, and T7 tempers, 275 MPa (40 ksi). Yield strength: F and T4 tempers, 97 MPa (14 ksi); T5 temper, 105 MPa (15 ksi); T6 temper, 130 MPa (19 ksi); T7 temper, 115 MPa (17 ksi). Elongation in 50 mm (2 in.): F and T7 tempers, 6%, T4 temper, 12%; T5 temper, 4%; T6 temper, 5%. See also Fig. 9.

UNS numbers. AZ91A: M11910. AZ91B: M11912. AZ91C: M11914. AZ91D: M11916. AZ91E: M11921

Government. Die castings: AZ91A, QQ-M-38. Permanent mold castings: AZ91C, QQ-M-55 and MIL-M-46062. Sand castings: AZ91C, QQ-M-56, and MIL-M-46062

Foreign. Elektron AZ91, British: BS 2970 MAG3. French: AIR 3380 G-AZ91. German: DIN 1729 3.5912

Chemical Composition

Composition limits of AZ91A. 8.3 to 9.7 Al, 0.13 Mn min, 0.35 to 1.0 Zn, 0.50 Si max, 0.10 Cu max, 0.03 Ni max, 0.30 max other, bal Mg

Composition limits of AZ91B. 8.3 to 9.7 Al, 0.13 Mn min, 0.35 to 1.0 Zn, 0.50 Si max, 0.35 Cu max, 0.03 Ni max, 0.30 max other, bal Mg

Composition limits of AZ91C. 8.1 to 9.3 Al, 0.13 Mn min, 0.40 to 1.0 Zn, 0.30 Si max, 0.10 Cu max, 0.01 Ni max, 0.3 max other (total), bal Mg

Composition limits of AZ91D. 8.3 to 9.7 Al, 0.15 Mn min, 0.35 to 1.0 Zn, 0.10 Si max, 0.005 Fe max, 0.030 Cu max, 0.002 Ni max, 0.02 max other (each), bal Mg

Composition limits of AZ91E. 8.1 to 9.3 Al, 0.17 to 0.35 Mn, 0.4 to 1.0 Zn, 0.20 Si max, 0.005 Fe max, 0.015 Cu max, 0.0010 Ni max, 0.01 max other (each), 0.30 max other (total)

Consequence of exceeding impurity limits. Corrosion resistance decreases with increasing Fe, Cu, or Ni content. More than 0.5% Si decreases elongation. If Fe content exceeds 0.005% in AZ91D or AZ91E, the permissible Fe-Mn ratio will not exceed 0.032, and corrosion resistance will rapidly decrease.

Applications

Typical uses. AZ91A, AZ91B, and AZ91D, which have the same nominal composition except for iron, copper, and nickel contents, are die casting alloys used in the as-cast condition (F temper). AZ91D is a high-purity alloy which has excellent corrosion resistance; it is the most commonly used magnesium die casting alloy. AZ91A and AZ91B can be made from secondary metal, reducing the cost of the alloy; they must be used when maximum corrosion resistance is not required. AZ91E is a high-purity alloy with excellent corrosion resistance used in pressure-tight sand and permanent mold castings with high tensile strength and moderate yield strength. AZ91C is used in sand and permanent mold castings when maximum corrosion resistance is not required.

Corrosion Resistance

ASTM B 117 salt spray test. AZ91D: <0.13 mg/cm^2/day (<10 mils/yr). AZ91E-T6: <0.63 mg/cm^2/day (<50 mils/yr)

Mechanical Properties

Tensile properties. See Tables 27 and 28, and Fig. 11, 12, and 13.

T6 temper					
93	200	260	38	7	160
150	300	170	25	40	160
200	400	115	17	43	160
260	500	76	12	47	40

(a) Tested after prolonged heating at testing temperature.

(b) Prior to testing

Shear strength. F temper, 125 MPa (18 ksi); T4 and T5 tempers, 140 MPa (20 ksi); T6 temper, 145 MPa (21 ksi); T7 temper, 150 MPa (22 ksi)

Compressive yield strength. F and T4 tempers, 97 MPa (14 ksi); T5 temper, 115 MPa (17 ksi); T6 temper, 150 MPa (22 ksi); T7 temper, 145 MPa (21 ksi)

Bearing properties. Ultimate bearing strength: F and T5 tempers, 345 MPa (50 ksi); T4 temper, 470 MPa (68 ksi); T6 temper, 550 MPa (80 ksi). Bearing yield strength: F, T4, and T5 tempers, 315 MPa (46 ksi); T6 temper, 450 MPa (65 ksi)

Hardness. F temper: 65 HB or 76 HRE. T4 temper: 63 HB or 75 HRE. T5 temper: 69 HB or 80 HRE. T6 temper: 81 HB or 88 HRE. T7 temper: 78 HB or 86 HRE

Poisson's ratio. 0.35

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi); shear, 17 GPa (2.4×10^6 psi)

Impact strength. Charpy V-notch: F temper, 0.7 J (0.5 ft · lbf); T4 temper, 2.7 J (2.0 ft · lbf); T6 temper, 1.1 J (0.8 ft · lbf)

Fatigue strength. R.R. Moore type test. At 5×10^8 cycles: F and T6 tempers, 83 MPa (12 ksi); T4 and T7 tempers, 90 MPa (13 ksi); T5 temper, 76 MPa (11 ksi)

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 595 °C (1100 °F)

Solidus temperature. 445 °C (830 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14 μin./in. · °F) at 18 to 100 °C (65 to 212 °F)

Incipient melting temperature. 410 °C (770 °F)

Specific heat. 1.05 kJ/kg · K (0.25 Btu/lb · °F) at 25 °C (78 °F)

Latent heat of fusion. 373 kJ/kg (160 Btu/lb)

Thermal conductivity. 72 W/m · K (41.8 Btu/ft · h · °F) at 100 to 300 °C (212 to 572 °F)

Electrical Properties

Electrical conductivity. At 20 °C (68 °F): F temper, 12.3% IACS; T4 temper, 10.5% IACS; T6 temper, 12.3% IACS

Electrical resistivity. At 20 °C (68 °F): F temper, 140 nΩ · m; T4 temper, 165 nΩ · m; T6 temper, 140 nΩ · m

Electrolytic solution potential. 1.56 V versus saturated calomel electrode

Hydrogen overvoltage. As-cast, 0.3 V

Fabrication Characteristics

Casting temperature. Sand castings, 705 to 845 °C (1300 to 1550 °F); permanent mold castings, 650 to 815 °C (1200 to 1500 °F)

Weldability. Gas-shielded arc welding with AZ92A rod, good; stress relief required

EQ21

Specifications

AMS. 4417

ASTM. Sand castings: B 80. Permanent mold castings: B 199. Investment castings: B 403

UNS number. M16330

Government. Sand and permanent mold castings: MIL-M-46062

Foreign. British: BS 2970 MAG13

Chemical Composition

Composition limits. 1.3 to 1.7 Ag, 1.75 to 2.5 Nd-rich rare earths, 0.4 to 1.0 Zr, 0.05 to 0.10 Cu, 0.01 Ni max, 0.3 max other (total), bal Mg

Consequence of exceeding impurity limits. Zr content below 0.5% may result in somewhat coarser as-cast grains and lower mechanical properties.

Applications

Typical uses. Sand and permanent mold castings used in the solution-treated and artificially aged condition (T6 temper), with high yield strengths up to 200 °C (390 °F). Castings have excellent short-time elevated-temperature mechanical properties and are pressure tight and weldable.

Mechanical Properties

Tensile properties. T6 temper: tensile strength, 235 MPa (34 ksi); yield strength, 170 MPa (25 ksi); elongation, 2% in 50 mm (2 in.)

Tensile properties versus temperature. See Table 31 and Fig. 15 and 16.

Table 31 Typical tensile properties of EQ21A sand castings at various temperatures

Testing temperature	Tensile strength	Yield strength

°C	°F	MPa	ksi	MPa	ksi
20	68	261	37.8	195	28.3
100	212	230	33.4	189	27.4
200	390	191	27.7	170	24.6
300	570	132	19.1	117	17.0

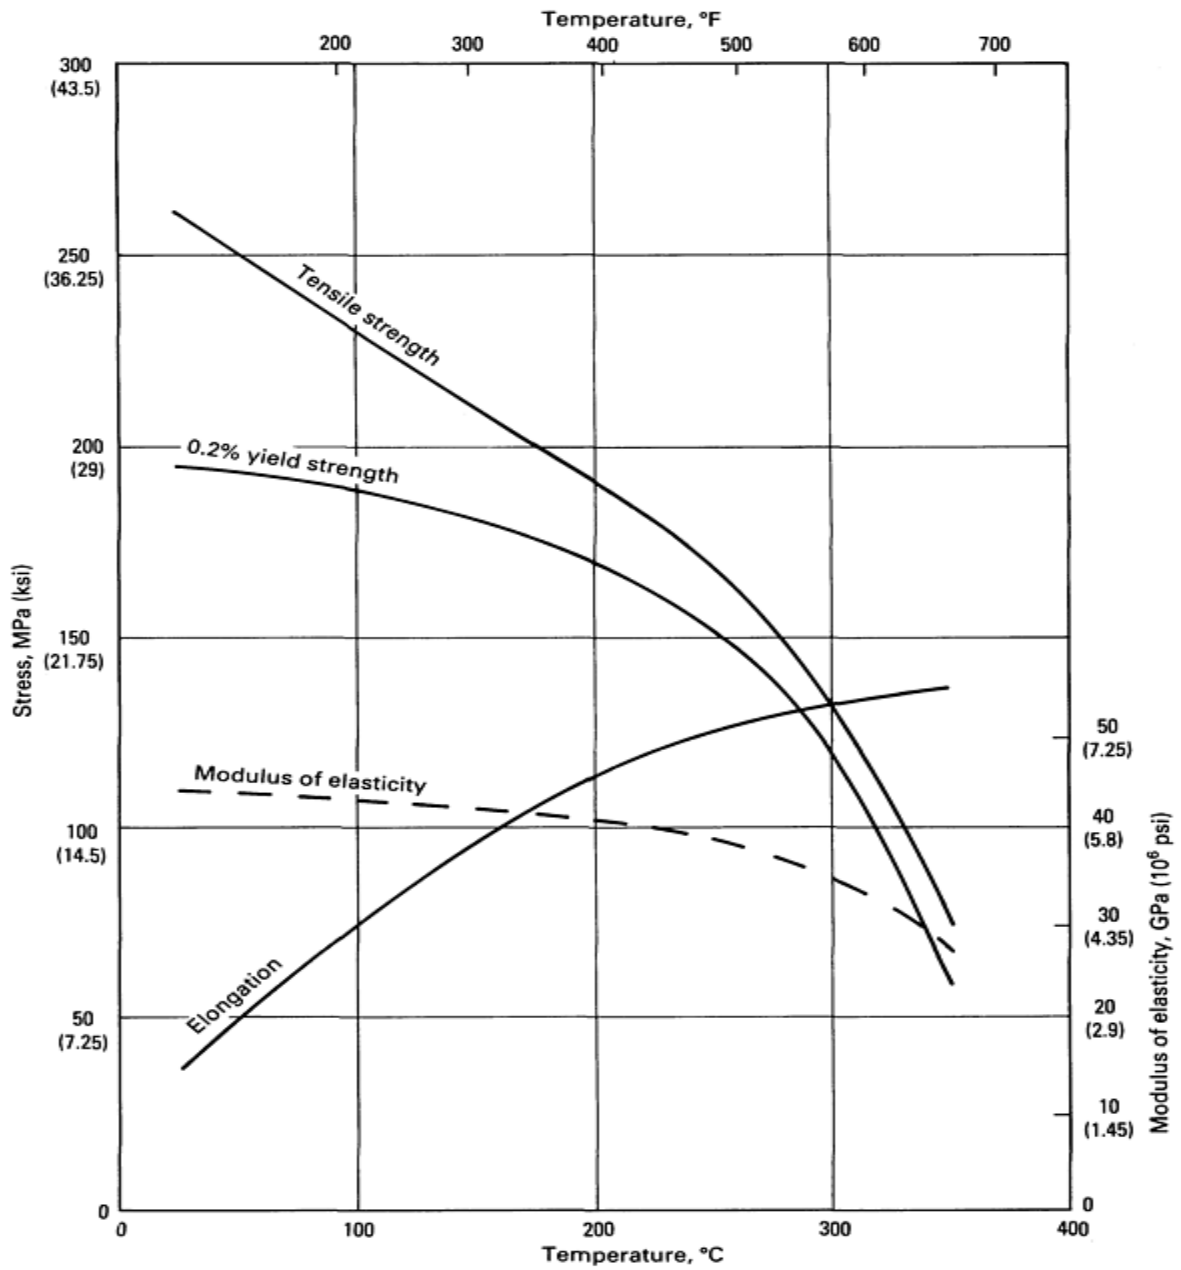

Fig. 15 Effect of temperature on the strength of EQ21A-T6 sand castings

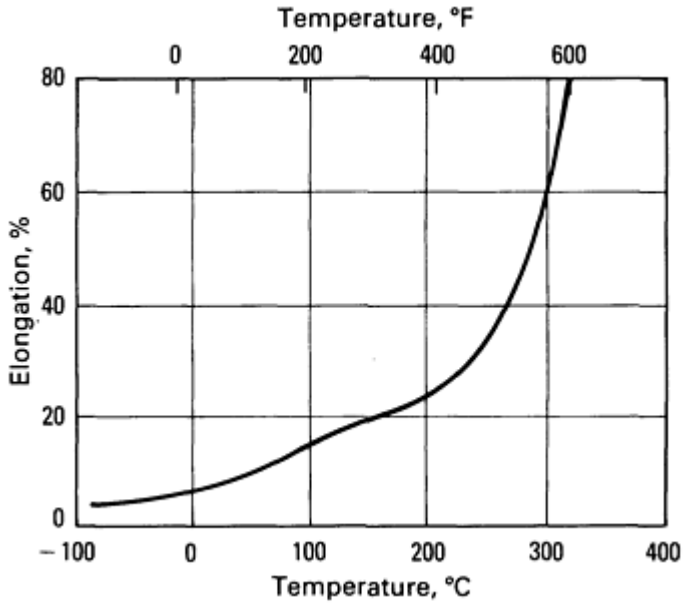

Fig. 16 Effect of temperature on the elongation of EQ21A-T6 sand castings

Compressive properties. T6 temper: compressive strength, 345 MPa (50 ksi); compressive yield strength, 195 MPa (28 ksi)

Elastic modulus. Tension, 45 GPa (6.5×10^6 psi) (See also Fig. 17); shear, 17 GPa (6.4×10^6 psi)

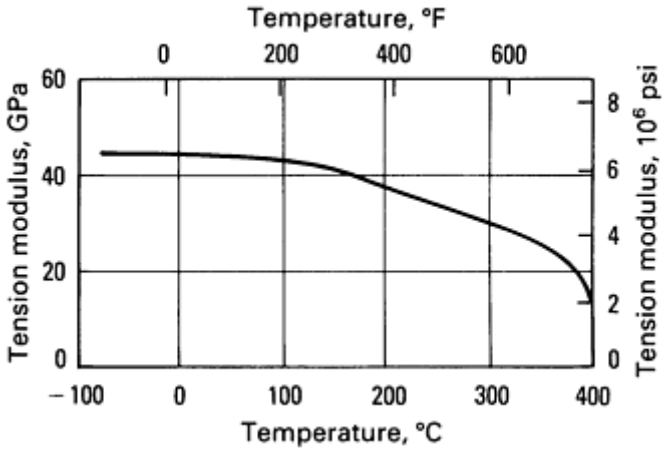

Fig. 17 Effect of temperature on the elastic modulus of EQ21-T6 sand castings

Creep characteristics. See Table 32.

Mass Characteristics

Density. 1.8 g/cm^3 (0.065 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 650 °C (1205 °F)

Solidus temperature. 590 °C (1090 °F)

Incipient melting temperature. 627 to 632 °C (1160 to 1170 °F) in circulating air

Specific heat versus temperature. $C_p = 1374 + 0.0002306T + 3370T^{-2}$

Latent heat of fusion. 318 to 335 kJ/kg (137 to 144 Btu/lb)

Thermal conductivity. At 20 °C (68 °F); T6 temper, 92 W/m · K (53 Btu/ft · h · °F); H24 temper, 113 W/m · K (65 Btu/ft · h · °F); O temper,105 W/m · K (61 Btu/ft · h · °F)

Thermal conductivity versus temperature. See Table 37.

Table 37 Thermal conductivity of HK31A-T6 sand castings at various temperatures

Temperature		Thermal conductivity	
°C	°F	W/m · K	Btu/ft · h · °F
20	68	92	53

38	100	92	53
93	200	100	58
150	300	105	61
200	400	109	63
260	500	113	65

Electrical Properties

Electrical conductivity. T6 temper, 22% IACS at 20 °C (68 °F)

Electrical resistivity. At 20 °C (68 °F): T6 temper, 77 nΩ · m; H24 temper, 61 nΩ · m; O temper, 60 Ω· m

Fabrication Characteristics

Casting temperature. Sand and permanent mold castings, 750 to 820 °C (1380 to 1510 °F)

Weldability. Gas-shielded arc welding with EZ33A or HK31A rod (EZ33A preferred), very good, stress relief required for sand castings

HZ32A

Specifications

AMS. Sand castings: 4447

ASTM. Sand castings: B 80

UNS number. M13320

Government. Sand castings: QQ-M-56, MIL-M-46062

Foreign. Elektron ZT1. British: BS 2970 MAG8. German: DIN 1729 3.5105

Chemical Composition

Composition limits. 1.7 to 2.5 Zn, 2.5 to 4.0 Th, 0.10 rare earths max, 0.50 to 1.0 Zr, 0.10 Cu max, 0.01 Ni max, 0.30 max other (total), bal Mg

Consequence of exceeding impurity limits. More than 0.1% rare earths causes a loss in creep resistance.

Applications

Typical uses. Sand castings used in the artificially aged condition (T5 temper), with moderate strength and an optimum combination of properties for medium- and long-time exposure at temperatures above 260 °C (500 °F). Castings are pressure tight, and under long-time exposure can withstand higher stresses and higher temperatures than any other commercially available magnesium alloy.

Mechanical Properties

Tensile properties. T5 temper: tensile strength, 185 MPa (27 ksi); yield strength, 90 MPa (13 ksi); elongation in 50 mm (2 in.), 4%. See also Fig. 25.

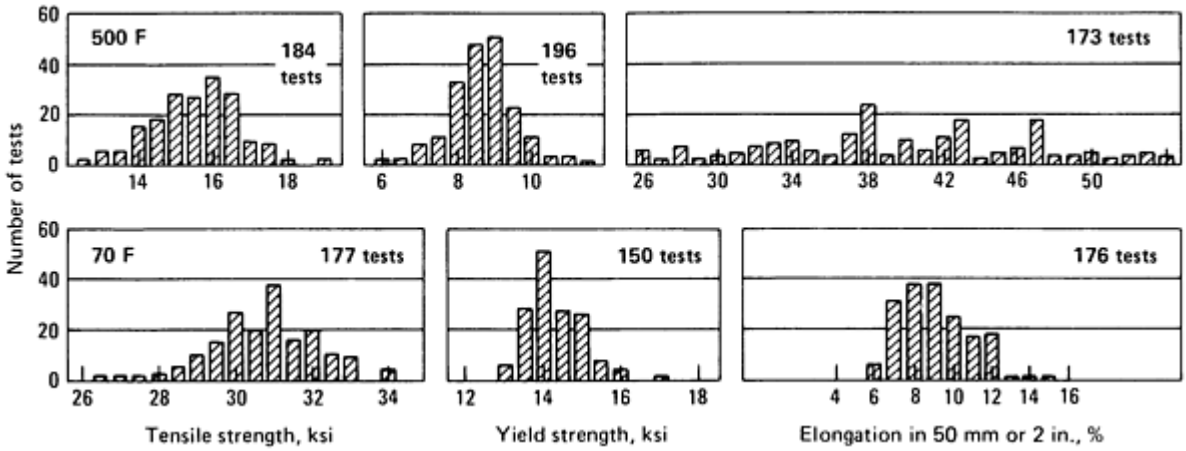

Fig. 25 Distribution of tensile properties for separately sand cast test bars of HZ32A-T5

Fabrication Characteristics

Casting temperature. Sand castings, 750 to 820 °C (1380 to 1510 °F)

Weldability. Gas-shielded arc welding with HZ32A or EZ33A welding rod, fair; heavy-section castings required stress relief after welding.

K1A

Specifications

ASTM. Sand castings: B 80

UNS number. M18010

Chemical Composition

Composition limits. 0.40 to 1.0 Zr, 0.30 max other (total), bal Mg

Applications

Typical uses. K1A is used in the as-cast condition (F temper) for its high damping capacity. It has slightly better mechanical properties as die cast than as sand cast.

Mechanical Properties

Tensile properties. Sand castings, F temper: tensile strength, 180 MPa (26 ksi); yield strength, 55 MPa (8 ksi); elongation, 19%. Die castings, F temper; tensile strength, 165 MPa (24 ksi); yield strength, 83 MPa (12 ksi); elongation, 8%

Tensile properties versus temperature. See Table 39.

Table 39 Typical tensile properties of K1A-F sand castings at elevated temperatures

Testing temperature		Tensile strength		Tensile yield strength		Elongation, %
°C	°F	MPa	ksi	MPa	ksi	
93	200	115	17	48	7	30
200	400	55	8	34	5	71
315	600	28	4	14	2	78

Shear strength. Sand castings, F temper: 55 MPa (8 ksi)

Bearing properties. Sand castings, F temper: ultimate bearing strength, 317 MPa (46 ksi); bearing yield strength, 125 MPa (18 ksi)

Mass Characteristics

Density. 1.74 g/cm^3 (0.063 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 650 °C (1200 °F)

Solidus temperature. 650 °C (1200 °F)

Coefficient of linear thermal expansion. 27 μm/m · K (15 μin./in. · °F) at 21 to 200 °C (70 to 400 °F)

Thermal conductivity. 122 W/m · K (71 Btu/ft · h · °F) at 20 °C (68 °F)

Latent heat of fusion. 343 to 360 kJ/kg (148 to 155 Btu/lb)

Electrical Properties

Electrical resistivity. 57 nΩ · m

Fabrication Characteristics

Casting temperature. Sand castings, 750 to 820 °C (1380 to 1510 °F)

Weldability. Can be readily welded and soldered

QE22A

Specifications

AMS. Sand castings: 4418C

ASTM. Sand castings: B 80. Permanent mold castings: B 199. Investment castings: B 403

UNS number. M18220

Government. Sand castings: QQ-M-56B. Sand and permanent mold castings: MIL-M-46062B. Permanent mold castings: QQ-M-55

Foreign. Elektron MSR-B. British: DTD 5055. French: MSR-B AECMA MG-C-51. German: DIN 1729 3.5164

Chemical Composition

Composition limits. 2.0 to 3.0 Ag, 1.75 to 2.5 Nd-rich rare earths, 0.4 to 1.0 Zr, 0.1 Cu max, 0.01 Ni max, 0.3 max other (total), bal Mg

Consequence of exceeding impurity limits. Zr content below 0.5% may result in somewhat coarser as-cast grains and lower-mechanical properties.

Applications

Typical uses. Sand and permanent mold castings used in the solution-treated and artificially aged condition (T6 temper), with high yield strengths at temperatures up to 200 °C (390 °F). Castings have excellent short-time elevated-temperature mechanical properties and are pressure tight and weldable.

Mechanical Properties

Tensile properties. T6 temper: tensile strength, 260 MPa (38 ksi); yield strength, 195 MPa (28 ksi); elongation, 3% in 50 mm (2 in.)

Tensile properties versus temperature. See Table 40 and Fig. 28 and 29.

Table 40 Typical tensile properties of QE22A sand castings at various temperatures

Testing temperature		Tensile strength		Yield strength	
°C	°F	MPa	ksi	MPa	ksi

WE43

Specifications

ASTM. Sand castings: B 80. Permanent mold castings: B 93. Investment castings: B 199

UNS number. M18430

Chemical Composition

Composition limits. 3.7 to 4.3 Y, 2.4 to 4.4 rare earths, 0.4 to 1.0 Zr, 0.15 Mn max, 0.2 Zn max, 0.03 Cu max, 0.01 Si max, 0.005 Ni max, 0.2 Li max, bal Mg. Rare earths consist of 2.0 to 2.5% Nd with the remainder comprising heavy rare earths (HRE), principally Tb, Er, Dy, and Gd. The HRE fraction is directly related to the Y content of the alloy (that is, Y is present in a nominal 80Y-20HRE mixture).

Consequence of exceeding impurity limits. Zr content below 0.5% may result in somewhat coarser as-cast grains and lower mechanical properties.

Applications

Typical uses. Sand castings used in the solution-heat-treated and artificially aged condition (T6). Castings retain properties at elevated temperatures (≤250 °C, or 480 °F) for extended periods of time (>5000 h), and they are pressure tight and weldable.

Mechanical Properties

Tensile properties. T6 temper: tensile strength, 250 MPa (36.3 ksi); yield strength, 162 MPa (23.5 ksi), elongation, 2%

Tensile properties versus temperature. See Table 43 and Fig. 36.

Table 43 Elevated-temperature properties taken from specimens of sand cast 25 mm (1 in.) thick plate of WE43 magnesium alloy

ZE41A

Specifications

ASTM. Sand castings: B 80

UNS number. M16410

Foreign. Elektron RZ5. British: BS 2970 MAG5. German: DIN 1729 3.5101. French: AIR 3380 RZ5

Chemical Composition

Composition limits. 3.5 to 5.0 Zn, 0.75 to 1.75 rare earths (as mischmetal), 0.40 to 1.0 Zr, 0.15 Mn max, 0.10 Cu max, 0.01 Ni max, 0.30 max other (total), bal Mg

Consequence of exceeding impurity limits. Content of less than 0.6% soluble Zr may increase grain size and thus reduce mechanical properties; weldability also may decrease.

Typical uses. Sand castings used in the artificially aged condition (T5 temper), with better castability than ZK51A and good strength up to 93 °C (200 °F). Useful in pressure-tight applications. Can be welded. Stress relieved at 345 °C (650 °F)

Mechanical Properties

Tensile properties. T5 temper: tensile strength, 205 MPa (30 ksi); yield strength, 140 MPa (20 ksi); elongation, 3.5%

Tensile properties versus temperature. See Table 46 and Fig. 41.

Applications

1000	6	0.84	7	1.0	10	1.4	12	1.7

(a) Total extension equals initial extension plus creep extension.

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Solidification shrinkage. 4.2%

Volume change during cooling. 5% contraction from 600 to 20 °C (1110 to 68 °F)

Thermal Properties

Liquidus temperature. 640 °C (1185 °F)

Solidus temperature. 560 °C (1040 °F)

Nonequilibrium solidus temperature. 550 °C (1020 °F)

Coefficient of linear thermal expansion. 26 μm/m · K (14.5 μin./in. · °F) at 20 °C (68 °F)

Specific heat. 1.02 kJ/kg · K (0.244 Btu/lb · °F) at 20 °C (68 °F)

Latent heat of fusion. 318 kJ/kg (137 Btu/lb)

Thermal conductivity. 110 W/m · K (63 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. 28% IACS at 20 °C (68 °F)

Electrical resistivity. 62 nΩ · m at 20 °C (68 °F). Temperature coefficient, 0.16 nΩ · m per K at 20 °C (68 °F)

Fabrication Characteristics

Casting temperature. Sand castings, 750 to 820 °C (1380 to 1510 °F)

Weldability. Gas-shielded arc welding with EZ33A or ZK51A rod (EZ33A preferred), limited, preheating not necessary, but may be used; postweld heat treatment required

ZK61A

Specifications

ASTM. Sand castings: B 80

SAE. J465. Former SAE alloy number: 513

UNS number. M16610

Government. Sand castings: QQ-M-56B

Chemical Composition

Composition limits. 5.5 to 6.5 Zn, 0.6 to 1.0 Zr, 0.10 Cu max, 0.01 Ni max, 0.30 max other (total), bal Mg

Applications

Typical uses. Simple, highly stressed castings of uniform cross section. High in cost. Intricate castings subject to microporosity and cracking due to shrinkage. Not readily welded. Sometimes used in the artificially aged condition (T5 temper) but usually in the solution-heat treated and artificially aged condition (T6 temper) to develop properties fully

Mechanical Properties

Tensile properties. T6 temper: tensile strength, 310 MPa (45 ksi); yield strength, 195 MPa (28 ksi); elongation in 50 mm (2 in.), 10%

Fatigue properties. At least equal to those of the Mg-Al-Zn alloys

Mass Characteristics

Density. 1.83 g/cm^3 (0.066 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 635 °C (1175 °F)

Solidus temperature. 530 °C (985 °F)

Coefficient of linear thermal expansion. 27.0 μm/m · K (15.0 μin./in. · °F) at 20 to 200 °C (68 to 390 °F)

Fabrication Characteristics

Weldability. Not readily weldable. Addition of Th or rare earths decreases porosity and improves weldability.

Casting temperature. Sand castings, 705 to 815 °C (1300 to 1500 °F)

Tin and Tin Alloys

Revised by William B. Hampshire, Tin Research Institute, Inc.

Introduction

TIN was one of the first metals known to man. Throughout ancient history, various cultures recognized the virtues of tin in coatings, alloys, and compounds, and the use of the metal increased with advancing technology. Today, tin is an important metal in industry even though the annual tonnage used is much smaller than those of many other metals. One reason for the small tonnage is that, in most applications, only very small amounts of tin are used at a time.

Tin Production and Consumption

Tin is produced from both primary and secondary sources. Secondary tin is produced from recycled materials (see the article "Recycling of Nonferrous Alloys" in this Volume). Figure 1 shows the consumption of primary and secondary tin in the United States during recent years. Figure 2 shows 1988 data for the relative consumption of tin in the United States by application.

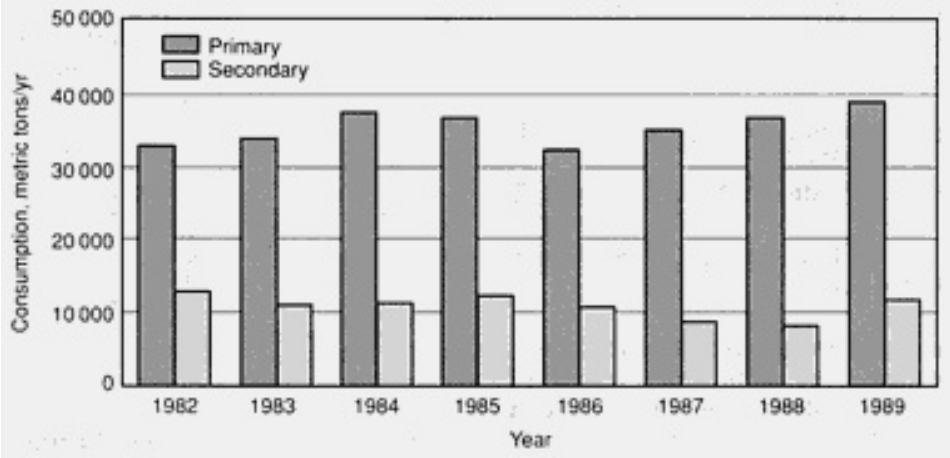

Fig. 1 U.S. consumption of primary and secondary tin in recent years

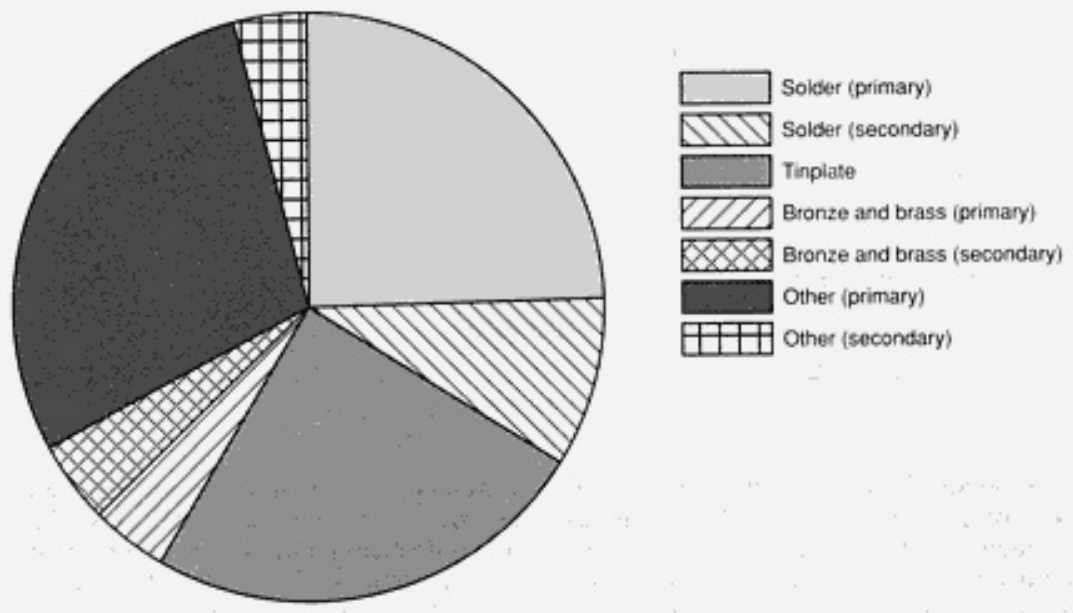

Fig. 2 Relative consumption of tin in the United States by application. 1988 data. Source: U.S. Bureau of Mines

Primary Production. Tin ore generally is centered in areas far distant from centers of consumption. The leading tin-producing countries (excluding the USSR and China) are, in descending order, Brazil, Indonesia, Malaysia, Thailand, Bolivia, and Australia (1988 totals). These countries supply over 85% of total world production.

Cassiterite, a naturally occurring oxide of tin, is by far the most economically important tin mineral. The bulk of the world's tin ore is obtained from low-grade placer deposits of cassiterite derived from primary ore bodies or from veins associated with granites or rocks of granitic composition.

Primary ore deposits can contain very low percentages of tin (0.01%, for example), and thus large amounts of soil or rock must be worked to provide recoverable amounts of tin minerals. Unlike ores of other metals, cassiterite is very resistant to chemical and mechanical weathering, but extended erosion of primary lodes by air and water has resulted in deposition of the ore as eluvial and alluvial deposits.

Underground lode deposits of tin ores are worked by sinking shafts and driving adits, and the rock is broken from the working face by drilling and blasting. Cassiterite is recovered from eluvial and alluvial deposits by dredging, gravel pumping, and hydraulicking. In open-pit mining, a much less widely employed mining method, mechanical and manual methods are used to move tin-bearing materials. After ball mill concentration of the ore, a final culling is provided at dressing stations.

The final concentrates, which contain 70 to 77% tin, are then sent to the smelter, where they are mixed with anthracite and limestone. This charge is heated in a reverberatory furnace to about 1400 °C (2550 °F) to reduce the tin oxide to impure tin metal, which is again heated in huge cast iron melting pots to refine the metal. Steam or compressed air is introduced into the molten metal, and this treatment, plus addition of controlled amounts of other elements that combine with the impurities, results in tin of high purity (99.75 to 99.85%). This high-purity tin often is treated again by liquating or electrolytic refining, which provides tin with a purity level approaching 99.99%.

After the tin is refined, it is cast into ingots weighing 12 to 25 kg (26 to 56 lb) or bars in weights of 1 kg (2 lb) and upwards. Tin normally is sold by brand name, and the choice of brand is determined largely by the amounts of impurities that can be tolerated in each end product. High-purity brands of tin may contain small amounts of lead, antimony, copper, arsenic, iron, bismuth, nickel, cobalt, and silver. Total impurities in commercially pure tin rarely exceed 0.25%.

Tin in Coatings

Tinplate. The largest single application of tin worldwide is in the manufacture of tinplate (steel sheet coated with tin), which accounts for about 40% of total world tin consumption. Since 1940, the traditional hot dip method of making tinplate has been largely replaced by electrodeposition of tin on continuous strips of rolled steel. Electrolytic tinplate can be produced with either equal or unequal amounts of tin on the two surfaces of the steel base metal. Nominal coating thicknesses for equally coated tinplate range from 0.38 to 1.5 μm (15 to 60 μin.) on each surface. The thicker coating on tinplate with unequal coatings (differential tinplate) rarely exceeds 2.0 μm (80 μin.). Tinplate is produced in thicknesses from 0.15 to 0.60 mm (0.006 to 0.024 in.).

Over 90% of world production of tinplate is used for containers (tin cans). Traditional tinplate cans are made of three pieces of tin-coated steel: two ends and a body with a soldered side seam. Innovations in can manufacture have produced two-piece cans made by drawing and ironing. Tinplate cans find their most important use in the packaging of food products, beer, and soft drinks, but they are also used for holding paint, motor oil, disinfectants, detergents, and polishes. Other applications of tinplate include signs, filters, batteries, toys, and gaskets, and containers for pharmaceuticals, cosmetics, fuels, tobacco, and numerous other commodities.

Electroplating accounts for one of the major uses of tin and tin chemicals. Tin is used in anodes, and tin chemicals are used in formulating various electrolytes and for coating a variety of substrates. Tin electroplating can be performed in either acid or alkaline solutions. Sodium or potassium stannates form the bases of alkaline tinplating electrolytes that are very efficient and capable of producing high-quality deposits. Advantages of these alkaline stannate baths are that they are not corrosive to steel and that they do not require additional agents. Acid electrotinning solutions operate at higher current densities and higher plating rates and require additions of organic compounds.

A number of alloy coatings can be electroplated from mixed stannate-cyanide baths, including coatings of tin-zinc and tin-cadmium alloys and a wide range of tin-copper alloys (bronzes). The bronzes range in tin content from 7 to 98%. Red bronze deposits contain up to 20% tin; high-tin bronzes, called speculum, usually contain about 40% tin.

Tin-nickel and tin-lead electrodeposits are plated from acid electrolytes and are important coatings for printed circuits and electronic components. Tin-cobalt plate is used in applications requiring an attractive finish and good corrosion resistance.

Two ternary alloy electrodeposits are used by industry. These are the copper-tin-lead for bearing surfaces and the copper-tin-zinc alloy for coatings in certain electronic applications.

Hot Dip Coatings. Coating steel with lead-tin alloys produces a material called terneplate (see the article "Lead and Lead Alloys" in this Volume). Terneplate is easily formed and easily soldered. It is used as a roofing and weather-sealing material and in the construction of automotive gasoline tanks, signs, radiator header tanks, brackets, chassis and covers for electronic equipment, and sheathing for cable and pipe.

Hot dip tin coatings are used both on wire for component leads and on food-handling and food-processing equipment. In addition, hot dip tin coatings are used to provide the bonding layer for the babbitting of bearing shells.

Pure Tin

Commercial tin is considered to be pure when it contains a minimum of 99.8% Sn. Of the various types of commercially pure tin, about 80 to 90% is a high-purity commercial tin known as Grade A tin as specified in ASTM B 339. According to this specification, Grade A tin must have a minimum tin purity of 99.85% Sn and maximum residual impurities of 0.04% Sb, 0.05% As, 0.030% Bi, 0.001% Cd, 0.04% Cu, 0.015% Fe, 0.05% Pb, 0.01% S, 0.005% Zn, and 0.01% (Ni + Co). Other specifications for commercially pure tin include:

- U.S. government specification QQT-371, Grade A (99.75% Sn)
- British specification BS 3252, Grade T (99.8% Sn)
- German specification DIN 1704, Grade A2 (99.75% Sn)

Table 1 summarizes selected physical, thermal, electrical, and optical properties of pure tin. Further information is contained in the article "Properties of Pure Metals" in this Volume. General applications of Grade A tin include tinplate foil, collapsible tubes, block tin products, and pewter.

Table 1 Physical, thermal, electrical, and optical properties of commercially pure tin

Property	Value
Physical properties	
Atomic number	50
Atomic weight	118.69
Crystal structure	α phase or β phase
Density, g/cm^3 ($lb/in.^3$)	
α phase at 1 °C (33.8 °F)	5.765 (0.2083)
β phase at 20 °C (68 °F)	7.168 (0.2590)
Liquid surface tension at 400-800 °C (750-1470 °F), mN/m	$700-0.17 \times T + (25 + 0.015 \times T)$[(a)]
Hardness, HB	
At 20 °C (68 °F)	3.9
At 60 °C (140 °F)	3.0
At 100 °C (212 °F)	2.3
Modulus of elasticity, GPa (10^6 psi)	
Cast (coarse grain)	41.6 (6.03)
Self-annealed (fine grain)	44.3 (6.43)

Mechanical Properties. Typical tensile properties of commercially pure tin are given in Table 2. Hardness and elasticity values are given in Table 1.

Table 2 Tensile properties of commercially pure tin

Temperature		Yield strength		Elongation in 25 mm (1 in.), %	Reduction in area, %
°C	°F	MPa	ksi		
Strained at 0.2 mm/m · min (0.0002 in/in. · min)					
-200	-328	36.2	5.25	6	6
-160	-256	90.3	13.10	15	10

-120	-184	87.6	12.71	60	97
-80	-112	38.9	5.64	89	100
-40	-40	20.1	2.92	86	100
0	32	12.5	1.81	64	100
23	73	11.0	1.60	57	100
Strained at 0.4 mm/m · min (0.0004 in./in. · min)					
15	59	14.5	2.10	75	. . .
50	122	12.4	1.80	85	. . .
100	212	11.0	1.60	55	. . .
150	302	7.6	1.10	55	. . .
200	392	4.5	0.65	45	. . .

Note: It is uncertain if the inconsistencies among these data are due to differences in purity or the difference in straining rate.

Creep Characteristics. Like lead, tin is subject to creep deformation and rupture even at room temperature. Consequently, tensile strength may not be an important design criterion because creep rupture can occur at stresses even below the yield strengths in Table 2. For example, one series of tests on a commercially pure tin resulted in the following creep characteristics at room temperature:

Initial stress		**Time, days**	**Extension, %**
MPa	**psi**		
1.083	157.0	551	3.5
1.351	196.0	551	7
2.256	327.1	173*	101

2.772	402.1	79[*]	132
3.227	468.1	21[*]	119
4.214	611.2	4.6	105
7.069	1025.2	0.5[*]	78

Fatigue Strength. Rotating-cantilever fatigue tests on a commercially pure tin resulted in fatigue strength levels of 2.9 MPa (430 psi) for 10^7 cycles at 15 °C (59 °F) and 2.6 MPa (380 psi) for 10^8 cycles at 100 °C (212 °F). Because creep deformation of tin occurs at room temperature, fatigue strengths may be influenced by creep-fatigue interaction and thus may depend on the frequency and/or waveform of stress cycling.

Impact Strength. Charpy V-notch tests on commercially pure tin at various temperatures resulted in the following impact strengths:

Temperature		**Charpy V-notch impact energy**	
°C	**°F**	**J**	**ft · lbf**
-80	-112	3.7	2.75
-60	-76	11.5	8.5
-15	5	28.5	21.0
0	32	44.1	32.5
150	302	22.7	16.75
190	374	20.3	15.0
215	419	2.7	2.0

Specific Damping Capacity. Tests on bars vibrating at audio frequencies in the free-free mode produced these results:

Temperature		Logarithmic decrement	
°C	°F	Polycrystalline	Single crystals
25	77	0.022	0.0010

Chemical Properties and Corrosion Behavior. Tin reacts with both strong acids and strong alkalies, but it is relatively resistant to near-neutral solutions. Oxygen greatly accelerates corrosion in aqueous solutions. In general, with mineral acids the rate of attack increases with the temperature and concentration. Dilute solutions of weak alkalies have little effect on tin, but strong alkalies are corrosive even in cold dilute solutions. Salts with an acid reaction at tack tin in the presence of oxidizers or air. Tin resists demineralized waters but is slightly attacked near the water line by hard tap waters. The corrosion resistance of tin in specific environments is summarized in Table 3. Additional information on the corrosion of tin is given in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Table 3 Resistance of tin to specific corroding agents

Corrosive agent	Resistance	Remarks
Acid, acetic	Slight attack	Increased by air
Acid, butyric	Resistant	. . .
Acid, citric	Moderate attack	At water line
Acids, fatty	Moderate attack	. . .
Acid, hydrochloric	Severe attack	In presence of air
Acid, hydrofluoric	Severe attack	In presence of air
Acid, lactic	Moderate attack	Increased by air
Acid, nitric	Severe attack	. . .

Acid, oxalic	Moderate attack	[a]
Acid, phosphoric	Resistant	. . .
Acid, salts	Severe attack	Air present
Acid, sulfuric	Severe attack	[b]
Acid, tartaric	Slight attack	. . .
Air	Resistant	. . .
Ammonia	Resistant	. . .
Bromine	Severe attack	. . .
Carbon tetrachloride	Resistant	. . .
Chlorine	Severe attack	. . .
Iodine	Severe attack	. . .
Milk	Resistant	. . .
Motor fuel	Resistant	. . .
Petroleum products	Resistant	. . .
Potassium hydroxide	Severe attack	Increased by air
Sodium carbonate	Slight attack	. . .
Sodium hydroxide	Severe attack	Increased by air
Water, distilled	Resistant	. . .
Water, sea	Slight attack	. . .

(a) Most corrosive of common organic acids.

(b) Increased with concentration and in the presence of air

Applications of Unalloyed Tin. There are only a few applications where tin is used unalloyed with other metals. Unalloyed tin is the most practical lining material for handling-purity water in distillation plants because it is chemically inert to pure water and will not contaminate the water in any way.

In the manufacture of plate glass, the molten glass is fed from the furnace onto the surface of a molten tin bath, which is protected from oxidation by an atmosphere that contains nitrogen and some hydrogen. The natural forces of surface tension and gravity within the bath ordinarily produce plate glass about 6 mm ($\frac{1}{8}$ in.) thick, but the thickness of the glass can be varied by adjusting the speed at which the molten glass is drawn from the float bath and the temperature of the tin. With this process, glass ribbons are formed with flat and parallel surfaces. The surfaces of the glass are so smooth that surface polishing is not required.

Powder Applications. Much of the supply of tin powders is used in making sintered bronze or sintered iron parts. However, tin powders are also increasingly employed in making paste solders and creams used in the plumbing and electronic manufacturing industries. Tin and tin alloy powders find minor uses in sprayed coatings for food-handling equipment, metallizing of nonconductors, and bearing repairs. Tin particles can also be used in food can lacquers to decrease the dissolution of iron and any exposed lead-base solder by the food product.

Additions of 2% tin powder and 3% copper powder aid the sintering of iron compacts. The tin provides a low-melting-point phase, which in turn provides diffusion paths for the iron. Iron-tin-copper compacts sintered at 950 °C (1740 °F) have mechanical properties comparable to those of iron-copper powder metallurgy parts containing 7 to 10% Cu sintered at 1150 °C (2100 °F). In addition, closer control of finished dimensions is afforded by the iron-tin-copper mixture, and this control results in improved quality and cost effectiveness.

Sintered compacts made from mixtures of iron and tin-lead solder powders are suitable for certain low-stress engineering applications. Warm compressing of these compacts (at 450 °C, or 840 °F) provides cohesion of the iron solder mixtures but does not recrystallize the iron powder; therefore, any work hardening obtained during compaction is retained. Different properties can be obtained in the pressed-and-sintered compacts by varying the pressing conditions and the relative amounts of the iron and solder powders.

Tin in Chemicals

The manufacture of inorganic and organic chemicals containing tin constitutes one of the major uses of metallic tin. The use of tin compounds has grown so rapidly over the past quarter century that the tin chemicals industry has been transformed from one based mainly on recovered secondary tin to one that consumes significant amounts of primary ingot tin.

Tin chemicals are used for such widely diversified applications as electrolyte solutions for depositing tin and its alloys; pigments and opacifiers for ceramics and glazes; catalysts and stabilizers for plastics; pesticides, fungicides, and antifouling agents in agricultural products, paints, and adhesives; and corrosion-inhibiting additives for lubricating oils.

Solders

Solders account for the largest use of tin in the United States (Fig. 2). Tin is an important constituent in solders because it wets and adheres to many common base metals at temperatures considerably below their melting points. Tin is alloyed with lead to produce solders with melting points lower than those of either tin or lead (see the article "Lead and Lead Alloys" in this Volume). Small amounts of various metals, notably antimony and silver, are added to tin-lead solders to increase their strength. These solders can be used for joints subjected to high or even subzero service temperatures.

Solder compositions and the applications of joining by soldering are many and varied (Table 4). Commercially pure tin is used for soldering side seams of cans for special food products and aerosol sprays. The electronics and electrical industries employ solders containing 40 to 70% Sn that provide strong and reliable joints under a variety of environmental conditions. High-tin solders are used for joining parts of electrical apparatuses because their electrical conductivity is higher than that of high-lead solders. High-tin solders are also used where lead may be a hazard, for example, in contact with food-stuffs or in potable-water plumbing applications.

Table 4 Applications, specifications, and nominal compositions of selected tin-base solder materials

Common name	Specifications				Nominal composition, %	Liquidus temperature		Solidus temperature		Typical applications
	ASTM	Government	British	German		°C	°F	°C	°F	
Commercially pure tin	B 339, Grade A	QQ-T-371, Grade A	BS 3252, Grade T	DIN 1704, Grade A2	(a)	. . .	. . .	. . .	. . .	Soldering sideseams of cans for foods or aerosols

(a) See the section "Pure Tin" in this article for minimum tin contents.

General-purpose solders (50Sn-50Pb and 40Sn-60Pb) are used for light engineering applications, plumbing, and sheet metal work. Lower-tin solders (20 to 35% Sn, balance Pb) are used in joining cable and in the production of automobile radiators and heat exchangers. Some solders are used to fill crevices at seams and welds in automotive bodies, thereby providing smooth joints and contours.

Tin-zinc solders are used to join aluminum. Tin-antimony and tin-silver solders are employed in applications requiring joints with high creep resistance, and in applications requiring a lead-free solder composition, such as potable-water plumbing. Also, tin solders that contain 5% Sb (or 5% Ag) are suitable for use at higher temperatures than are the tin-lead solders. Further information on solders is provided in Ref 1 and in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Impurities in solders can affect wetting properties, flow within the joint, melting temperature of the solder, strength capabilities of joints, and oxidation characteristics of the solder alloys. The most common impurity elements and their principal levels and effects are discussed below.

Aluminum. Traces of aluminum in a tin-lead solder bath can seriously affect soldering qualities. More than 0.005% Al can cause grittiness, lack of adhesion, and surface oxidation of the solder alloy. A deterioration in the surface brightness of a molten bath sometimes is an indication of the presence of aluminum.

Antimony is slightly detrimental to wetting properties, but it can be used as an intentional additional for strengthening. As an impurity, antimony tends to reduce the effective spread of a solder alloy. High-lead solder specifications usually require a maximum limit of 0.5% Sb. The general rule is that antimony should not exceed 6% of the tin content, although in some applications this rule can be invalid. In various high-lead solders (such as Sn40B, Sn30B, Sn35B, Sn25B, and Sn20B in ASTM B 32), the presence of antimony is used to ensure that a transformation from βtin to α tin does not take place. Such a transformation would result in a volume change and a drastic loss in solder strength.

Arsenic. A progressive deterioration in the quality of the solder is observed with increases in arsenic content. As little as 0.005% As induces some dewetting, and dewetting becomes more severe as the percentage of arsenic is increased to 0.02%. Arsenic levels should be kept within this range. At the maximum allowable level of 0.03%, arsenic can cause dewetting problems when soldering brass.

Bismuth. Low levels of bismuth in the solder alloy generally do not cause any difficulties, although some discoloration of soldered surfaces occurs at levels above 0.5%.

Cadmium. A progressive decrease in wetting capability occurs with additions of cadmium to tin-lead solders. While there is no significant change in the molten appearance, small amounts of cadmium can increase the risk of bridging and icicle formation in printed circuits. For this reason, and for health reasons, cadmium levels should be kept to a minimum.

Copper. Although copper levels above about 0.25% can cause grittiness of solder, for the most part, the role of copper as a solder contaminant appears to be variable and related to the particular product. A molten tin-lead solder bath is capable of dissolving copper at a high rate, and the level of copper in the bath can easily reach 0.3%. Copper in liquid solder does not appear to have any deleterious effect upon the wetting rate or joint formation. Excess copper settles to the bottom of a solder bath as an intermetallic compound sludge. New solder alloy allows a maximum copper content of 0.08%.

Iron and nickel are not naturally present in solder alloy. The presence of iron-tin compounds in tin-lead solders can be identified as a grittiness. Generally, iron is limited to a maximum of 0.02% in new solder. There are no specification limits for nickel, but levels as low as 0.02% can produce some reduction in wetting characteristics. Iron levels above about 0.1% cause grittiness of solder.

Phosphorous and Sulfur. Phosphorous at a level of 0.01% is capable or producing dewetting and some grittiness. At higher levels, surface oxidation occurs, and some identifiable problems such as grittiness and dewetting become readily discernible. Sulfur causes grittiness in solders at a very low level and should be held to 0.001%. Discrete particles of tin-sulfide can be formed. Both of these elements are detrimental to good soldering.

Zinc. The ASTM new solder alloy specification states that zinc content must be kept to a maximum of 0.005% in tin-lead solders. At this maximum limit, even with new solders in a molten bath, some surface oxidation can be observed, and oxide skins may form, encouraging icicles and bridging. Up to 0.01% Zn has been identified as the cause of dewetting on copper surfaces. Excessive zinc causes oxidation of solder to be more noticeable.

The combined effects of the above impurity elements can be significant. Excessive contamination in solder baths or dip pots generally can be identified through surface oxidation, changes in the product quality, and the appearance of grittiness or frostiness in joints made in this bath. A general sluggishness of the solder also may indicate excessive impurities. In addition to analysis, experience with solder bath operation is helpful in determining the point at which the material should be renewed for good solder joint production. The ASTM solder specifications, which specify maximum allowable impurity concentrations, are useful when purchasing solder for general use (Table 5). In particular applications, specific contaminants or a combination of elements may be detrimental to a particular soldered product. On occasion, determining a revised or limited specification for solder materials is required.

Table 5 Impurity limits in ASTM specifications for the tin-base solders listed in Table 4

Common name	Nominal composition, %	Impurity limits, %[(a)]											
		Sb	Ag	Al	As	Bi	Cd	Cu	Fe	Pb	S	Zn	Other

Impurities of a metallic and nonmetallic nature can be found in raw materials and in the scrap solder that is sometimes used by reclaimers. Reclaimed solder is used in many industrial applications where impurities may not be detrimental. However, correct selection of solder grade is important for economical production. Manufacturing problems can result from inappropriate solder selection, from the use of solder baths for longer periods than contamination build-up will

tolerate, or from processing methods that rapidly contaminate a solder bath. Determination of suitable specifications, of allowable impurities in new materials, and of allowable impurities in the solder bath through its deterioration to the point at which it is discarded should be included in any soldering quality control program.

Electrical and mechanical property data for selected tin-base solders are given in Table 6. The effects of elevated temperatures on the tensile strength and elongation of 60-40 solder are listed in Table 7.

Table 6 Electrical and mechanical properties of selected tin-base solders

Antimonial-tin solder (95Sn-5Sb)
Tensile properties. Cast: typical tensile strength, 40.7 MPa (5.9 ksi); elongation in 100 mm (4 in.), 38%. Soldered copper joint: typical tensile strength, 97.9 MPa (14.2 ksi)
Shear strength. Cast, 41.4 MPa (6.0 ksi). Soldered copper joint, 76.5 MPa (11.1 ksi)
Impact strength. Cast (Izod test), 27 J (20 ft · lbf)
Electrical conductivity. Volumetric, 11.9% IACS at 20 °C (68 °F)
Electrical resistivity. 145 nΩ · m at 25 °C (77 °F)
Tin-silver solder (95Sn-5Ag)
Tensile properties. Sheet, 1.02 mm (0.040 in.) thick, aged 14 days at room temperature: typical tensile strength, 31.7 MPa (4.6 ksi); yield strength, 24.8 MPa (3.6 ksi); elongation in 50 mm (2 in.), 49%. Soldered copper joint: typical tensile strength, 96.5 MPa (14 ksi)
Shear strength. Soldered copper joint, 73.1 MPa (10.6 ksi)
Electrical conductivity. Volumetric, 16.6% IACS at 20 °C (68 °F)
Electrical resistivity. 104 nΩ · m at 0 °C (32 °F)
Temperature coefficient of electrical resistivity. 0-100 °C (32-212 °F), 42.3 pΩ · m/K
70-30 soft solder (70Sn-30Pb)
Tensile properties. Cast: typical tensile strength, 46.9 MPa (6.8 ksi)
Hardness. 12 HB
Electrical conductivity. Volumetric, 11.8% IACS
Electrical resistivity. 146 nΩ · m

Eutectic solder (63Sn-37Pb)
Tensile properties. Cast: typical tensile strength, 51.7 MPa (7.5 ksi); elongation in 100 mm (4 in.), 32%. Soldered copper joint: typical tensile strength, 200 MPa (2g ksi)
Shear strength. Cast, 42.7 MPa (6.2 ksi); soldered copper joint, 55.2 MPa (8 ksi)
Hardness. Cast, 14 HB
Impact strength. Cast (Izod test), 20 J (15 ft · lbf)
Creep characteristics. Minimum creep rate: at room temperature and 2.3 MPa (335 psi), 0.1 mm/m (100 μin./in.) per day; at 80 °C (176 °F) and 467 MPa (68 psi), 0.1 mm/m (100 μin./in.) per day
Dynamic viscosity. 1.33 mPa · s (0.0133 poise) at 280 °C (536 °F)
Liquid surface tension. 0.490 N/m at 280 °C (536 °F)
Electrical conductivity. Volumetric, 11.9% IACS
Electrical resistivity. 145 nΩ · m
60-40 soft solder (60Sn-40Pb)
Tensile properties. Bulk solder at room temperature (measurements depend greatly on conditions of casting and testing): mean tensile strength, 52.5 MPa (7.61 ksi); elongation, 30-60%.
Shear strength. Mean, 37.1 MPa (5.38 ksi) (depends greatly on conditions of casting and testing)
Hardness. 16 HV (depends on casting conditions)
Elastic modulus. Tension (bulk solder), 30.0 GPa (4.35×10^6 psi)
Creep-rupture characteristics. Limiting creep stress, 2.2-3.0 MPa (320-430 psi) for a strain rate of 10^{-4} m/m per day at room temperature. Rupture life: 1000 h under stress of 4.5 MPa (650 psi) at 26 °C (79 °F); 1000 h under stress of 1.4 MPa (200 psi) at 80 °C (176 °F)
Dynamic liquid viscosity. Estimated, 2.0 mPa · s (0.020 poise) at the liquidus temperature
Liquid surface tension. Estimated: 468 mN/m at 330 °C (626 °F), 461 mN/m at 430 °C (806 °F)
Electrical conductivity. Volumetric, 11.5% IACS

Electrical resistivity. 149.9 nΩ · m
Thermoelectric potential. Same as pure tin when measured against copper
Temperature of superconductivity. 7.05 K. Critical field, 83.2 mT at 1.3 K

Table 7 Effect of temperature on properties of 60-40 solder cast at 300 °C (570 °F) in steel molds (specimens not machined)

Temperature		Tensile strength		Elongation, %
°C	°F	MPa	ksi	
Cast in 150 °C (300 °F) molds				
19	66	56.4	8.18	60[(a)]
50	122	45.4	6.58	80[(a)]
75	167	41.7	6.05	90[(a)]

125	257	19.3	2.80	180[(a)]
150	302	12.4	1.80	180[(a)]
Cast in 200 °C (390 °F) molds				
0	32	59	8.6	50[(b)]
-40	-40	76	11.0	50[(b)]
-80	-112	97	14.1	55[(b)]
-120	-184	119	17.3	30[(b)]
-160	-256	112	16.2	10[(b)]
-200	-328	109	15.8	5[(b)]

(a) In 22.5 mm (0.89 in.).

(b) In 25.4 mm (1.00 in.)

When measuring the tensile properties of bulk solder, the results depend greatly on the casting and testing conditions. For example, eutectic and near-eutectic 60-40 solder compositions were examined for superplasticity. It was found that the strain rate sensitivity *m* has a value of about 0.4 at a strain rate of 10^{-4} m/m · s, increasing to a relative maximum of about 0.5 at a strain rate of 10^{-3} mm/m · 2, then decreasing to a value near 0.2 at a strain rate of 10^{-1} m/m · s.

Thermal Properties. Solidus and liquidus points of various solder compositions are given in Table 4 and in the article "Lead and Lead Alloys" in this Volume. Other thermal properties include:

Solder	Linear thermal expansion at 15-110 °C (60-230 °F), 10^{-6}/K	Thermal conductivity at 0-180 °C (32-355 °F), W/m · K
70Sn-30Pb	21.6	. . .
63Sn-37Pb	24.7	50
60Sn-40Pb	24	. . .

The 60-40 solder has a specific heat of 176 J/kg · K (0.042 Btu/lb · °F) and an estimated heat of fusion of 37 J/g (16 Btu/lb).

Pewter

Pewter is a tin-base white metal containing antimony and copper. Originally, pewter was defined as an alloy of tin and lead, but to avoid toxicity and dullness of finish, lead is excluded from modern pewter. These modern compositions contain 1 to 8% Sb and 0.25 to 3.0% Cu. Pewter casting alloys usually are lower in copper than pewters used for spinning hollowware and thus have greater fluidity at casting temperatures.

Modern pewter consists of a cored solid solution of antimony in tin within which are distributed fine crystals of η (Cu_6Sn_5) phase. Pewter is malleable and ductile, and it is easily spun or formed into intricate designs and shapes. Pewter parts do not require annealing during fabrication. Much of the costume jewelry produced today is made of pewter alloys centrifugally cast in rubber or silicone molds. Typical pewter products include coffee and tea services, trays, steins, mugs, candy dishes, jewelry, bowls, plates, vases, candlesticks, compotes, decanters, and cordial cups.

Chemical Composition. Although a wide range of compositions has been called pewter, the usual modern alloys contain 90 to 95% Sn and 1 to 3% Cu, with the balance consisting of antimony. Some pewterlike materials are sand cast or spun aluminum alloys, which are traditionally not considered to be pewter. Although some pewter contains lead as an

alloying constituent, a considerable portion of lead is undesirable for applications in which the material may be in contact with food or beverages. In addition, lead may impart a dullness to the ware.

Composition limits of modern pewter are shown in Table 8.

Table 8 Chemical composition limits for modern pewter

Physical Properties. Typical tensile properties and hardnesses of pewter are given in Table 9. The effect of processing variables on the mechanical properties of pewter is covered in Table 10. In addition to those properties given in Table 9, pewter has:

- *An elastic modulus* of 53 GPa (7.7×10^6 psi)
- *A density* of 7.28 g/cm^3 (0.263 lb/in.^{3})
- *A liquidus temperature* of 295 °C (563 °F)
- *A solidus temperature* of 244 °C (471 °F)

Table 9 Typical mechanical properties of pewter

Form and condition	Section thickness		Tensile strength		Elongation in 50 mm (2 in.), %	Hardness, HB
	mm	in.	MPa	ksi		
Chill cast[(a)]	19.05	0.750	. . .	. . .	. . .	23.8

Source: Ref 2

(a) About 150-200 °C (302-392 °F).

Chemical Properties and Corrosion Resistance. Pewter tarnishes in soft water, with the production of a visible film of interference-tint thickness. It does not tarnish in hard water, but localized attack can occur at the water line and sometimes elsewhere if a chalky deposit is formed from the water. Pewter is attacked by dilute hydrochloric and citric acids in the presence of air.

Fabrication Characteristics. Pewter has good solderability. Casting temperatures of pewter range from 315 to 330 °C (600 to 625 °F).

Pewter can be formed by rolling, hammering, spinning, or drawing. The earing of pewter sheet can be reduced by an intermediate cross-rolling operation or heat treatment; rolling can then be continued down to final thickness.

Bearing Alloys

The primary consideration in the selection of a bearing alloy is that the material must have a low coefficient of friction. Bearing alloys also must maintain a balance between softness and strength. Aluminum-tin bearing alloys, for example, provide an excellent compromise between the requirement for high fatigue strength and the need for good surface properties such as softness, seizure resistance, and embeddability. Tin-base bearing alloys are specified in ASTM B 23, AMS 4800, and U.S. Government specification QQ-M-161.

Compositions. Table 11 lists the chemical compositions of various tin-base bearing alloys specified in ASTM and SAE standards. Tin has a low coefficient of friction and thus meets the primary requirement of a bearing material. Tin is structurally a weak metal; therefore, when it is used in bearing applications it is alloyed with copper and antimony for increased hardness, tensile strength, and fatigue resistance. Normally, the quantity of lead in these alloys, called tin-base babbitts, is limited to 0.35 to 0.5% to avoid formation of the tin-lead eutectic, which would significantly reduce strength properties at operating temperatures.

Table 11 Compositions of tin-base bearing alloys

Designation	Nominal composition, %									
	Sn[(a)]	Sb	Pb max[(b)]	Cu	Fe max	As max	Bi max	Zn max	Al max	Total other max

(a) Desired minimum in ASTM alloys; specified minimum in SAE alloys.

(b) Maximum unless a range is specified.

(c) Total named elements, 99.80%

The presence of zinc in tin-base bearing metals generally is not favored. Arsenic increases resistance to deformation at all temperatures; zinc has a similar effect at 38 °C (100 °F), but causes little or no change at room temperature. Zinc has a marked effect on the microstructures of some of these alloys. Small quantities of aluminum (even less than 1%) will modify their microstructures. Bismuth is objectionable because, in combination with tin, it forms a eutectic that melts at 137 °C (279 °F). At temperatures above this eutectic, alloy strength is appreciably decreased.

In high-tin alloys, such as ASTM grades 1, 2, and 3, and SAE 11 and 12, lead content is limited to 0.50% or less because of the deleterious effect of higher percentages on the strength of these alloys at temperatures of 150 °C (300 °F) and above. Lead and tin form a eutectic that melts at 183 °C (361 °F). At higher temperatures, bearings become fragile as a result of the formation of a liquid phase within them.

Lead-base bearing alloys, called lead-base babbitts, contain up to 10% Sn and 12 to 18% Sb. In general, these alloys are inferior in strength to tin-base babbitts, and this must be equated with their lower cost. Segregation of the constituents of these alloys may provide some difficulties during centrifugal casting of linings. During casting, careful selection of rotational speed in relation to bearing size is necessary. Additions of cerium, arsenic, or nickel also assist in controlling segregation of these alloys. Lead-base babbitt alloys are discussed in more detail in the article "Lead and Lead Alloys" in this Volume.

Intermediate Lead-Tin Babbitt Alloys. In addition to the tin-base and lead-base babbitts, there is a series of intermediate lead-tin bearing alloys. These alloys have tin and lead contents between 20 and 65%; in addition, they contain various amounts of antimony and copper. Increasing the tin content of these alloys provides higher hardness and greater ease of casting. These alloys are less prone to segregation during melting than lead-base babbitts. Cast intermediate bearing alloys, however, exhibit lower strength values than either tin-base or lead-base babbitts.

Aluminum-tin bearing alloys represent an excellent compromise between the requirement for high fatigue strength and the need for good surface properties such as softness, seizure resistance, and embeddability. Aluminum-tin bearing alloys are usually employed in conjunction with hardened-steel or ductile-iron crankshafts, and they allow significantly higher loading than tin- or lead-base bearing alloys.

Low-tin aluminum-base alloys (5 to 7% Sn) containing small amounts of strengthening elements, such as copper and nickel, are often used for connecting-rod and thrust bearings in high-duty engines. Strict dimensional tolerances must be adhered to, and oil contamination should be avoided. Alloys containing 20 to 40% Sn and a balance of aluminum show excellent resistance to corrosion by products of oil breakdown; they also exhibit good embeddability, particularly in dusty environments. The higher-tin alloys have adequate strength and better surface properties, which make them useful for crosshead bearings in high-power marine diesel engines.

Properties of Tin-Base Bearing Alloys. The mechanical properties of selected tin-base bearing alloys are shown in Tables 12 and 13. The mechanical-property values obtained from massive cast specimens are dependent on temperature. Also, hardness and compression tests are sensitive to the duration of the load because of the plastic nature of these materials. Bulk properties may be of some value in initial screening of materials, but they do not accurately predict the behavior that the material will exhibit when it is in the form of a thin layer bonded to a strong backing, which is the manner in which the babbitts are normally used. The relationship that exists between bearing life and the thickness of the babbitt is shown in Fig. 3, which also shows the marked influence of operating temperature.

Table 12 Physical properties and compressive strengths of selected tin-base bearing alloys

Designation	Specific gravity	Compressive yield strength[a][b]				Compressive ultimate strength[a][c]				Hardness, HB[d]		Solidus temperature		Liquidus temperature		Pouring temperature

Lead-tin babbitt from Table II	7.53	38.3	5.55	14.8	2.15	111.4	16.15	47.6	6.9	24[e]	12	184	363	306	583	. . .	. . .
ASTM B 102, Alloy PY1815A (die cast)	7.75	34	5	14	2.1	103	15	46	6.7	23	10	181	358	296	565	. . .	. . .

(a) The compression test specimens were cylinders 38 mm (1 $\frac{1}{2}$ in.) long and 13 mm ($\frac{1}{2}$ in.) in diameter, machined from chill castings 50 mm (2 in.) long and 20 mm ($\frac{3}{4}$ in.) in diameter.

(b) Values for yield point were taken from stress-strain curves at a deformation of 0.125% reduction of gage length.

(c) Values for ultimate strength were taken as the unit load necessary to produce a deformation of 25% of the length of the specimen.

(d) Tests were made on the bottom face of parallel machined specimens cast at room temperature in a steel mold 50 mm (2 in.) in diameter by 16 mm ($\frac{5}{8}$ in.). deep. The Brinell hardness values listed are the averages of three impressions on each alloy, using a 10 mm ball and applying a 500 kg load for 30 s.

(e) Chill cast hardness of 27 HB

Table 13 Mechanical properties of selected tin-base babbitt alloys

(b) Izod impact energy of 0.9 J (0.7 ft · lbf) at 200 °C (390 °F).

(c) Fatigue strength for 2×10^7 cycles, R.R. Moore-type test.

(d) Tensile strength of 45 MPa (6.5 ksi) at 100 °C (212 °F) and 20 MPa (2.9 ksi) at 175 °C (345 °F).

(e) Gage length equals 4 $\sqrt{Area}$.

(f) Cast from 315 °C (600 °F) into mold at 150 °C (300 °F).

(g) Cast from 400 °C (750 °F) into a mold at 100 °C (212 °F)

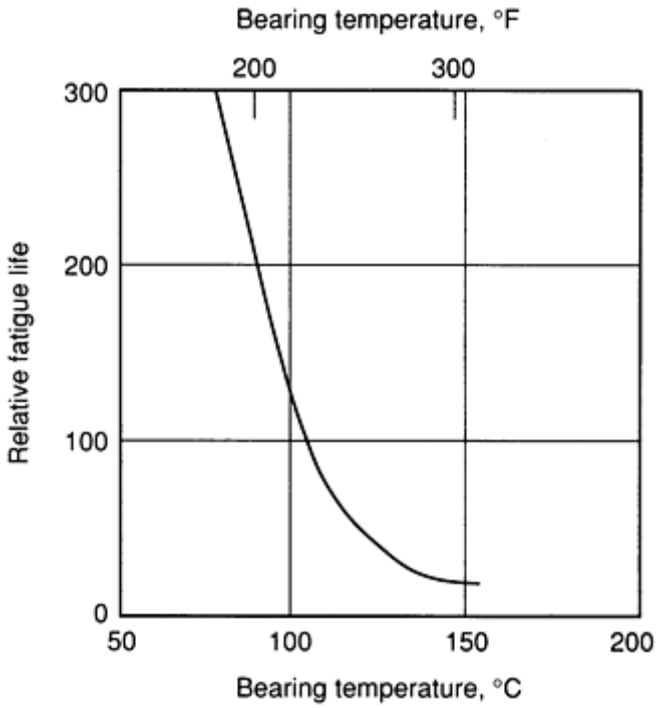

Fig. 3 Variation of bearing life with temperature for SAE 12 bimetal bearings. Thickness of alloy lining, 0.05 to 0.13 mm (0.002 to 0.005 in.); bearing load, 14 MPa (2000 psi)

Compared with other bearing materials, tin alloys have low resistance to fatigue, but their strength is sufficient to warrant their use under low-load conditions. These alloys are easy to bond and handle, and they have excellent antiseizure qualities. In addition, they are much more resistant to corrosion than lead-base bearing alloys.

Microstructures. Tin-base bearing alloys vary in microstructure in accordance with their composition. Alloys that contain about 0.5 to 8% Cu and less than about 8% Sb are characterized by a solid-solution matrix in which needles of a copper-rich constituent and fine, rounded particles of precipitated SbSn are distributed. The proportion of the copper-rich constituent increases with copper content. SAE 12 (ASTM Grade 2) has a structure of this type in which the needles often assume a characteristic hexagonal starlike pattern. Alloys that contain about 0.5 to 8% Cu and more than about 8% Sb exhibit primary cuboids of SbSn and needles of the copper-rich constituent in the solid-solution matrix. In alloys with about 8% Sb and about 0.5 to 8% Cu, rapid cooling suppresses formation of the SbSn cuboids; this is particularly true of alloys containing lower percentages of copper.

Other Tin-Base Alloys

Alloys for Organ Pipes. Tin-lead alloys are used in the manufacture of organ pipes. These materials are commonly called spotted metal because they develop large nucleated crystals, or spots, when solidified as strip on casting tables. The

pipes that produce the diapason tones of organs generally are made of alloys with tin contents varying from 20 to 90% according to the tone required. Broad tones generally are produced by alloys rich in lead; as tin content increases, the tone becomes brighter. Cold-rolled tin-copper-antimony alloys (95% Sn) also have been used successfully in the manufacture of pipes, and the adoption of these alloys has improved the efficiency and speed of fabrication of finished pipes. This composition provides for a bright appearance that is more tarnish resistant than the tin-lead alloys.

Type metals are cast alloys containing various proportions of lead, antimony, and tin. They do not readily segregate on solidification from the melt, buy they are subject to porosity in the central regions of type characters and slugs because air in molds escapes with difficulty. When these alloys are used, good fill of the mold should be ensured by rapid injection, and the temperature of the metal should be high enough to avoid premature solidification and entrapment of gases. Further information on type metals is given in the article "Lead and Lead Alloys" in this Volume.

Tin-base casting alloys are included in ASTM specification B 102, Alloy CY44A in this specification is similar to Alloy 1 in ASTM B 23 for sleeve bearings (Tables 11 and 12). Composition limits of the die casting version (Alloy CY44A in ASTM B 102) are 90 to 92% Sn, 4 to 5% Sb, 4 to 5% Cu, 0.35% Pb max, 0.08% Fe max, 0.08% As max, 0.01% Zn max, and 0.01% Al max.

Alloy PY1815A in ASTM B 102 is another alloy used for die castings and sleeve bearings. This alloy which has nominal contents of 82% Sn, 13% Sb, and 5% Cu, is included in Tables 11 and 12 with the other tin-base bearing alloys.

Alloy YC135A in ASTM B 102 has nominal composition contents of 65% Sn, 18% Pb, 15% Sb, and 2% Cu and is typically used for die castings. This alloy has a typical tensile strength of 69 MPa (10 ksi), an elongation value of 1% in 50 mm (2 in.), and a hardness of 29 HB. Alloy YC135A has creep-rupture strengths of about 17 MPa (2.5 ksi) for 1 year and 13 MPa (1.875 ksi) for a 10-year life.

White metal (92Sn-8Sb) is a tin-base alloy used for jewelry. Typical mechanical properties of white metal are listed in Tables 14 and 15. During cold rolling, the alloy hardens at first, and maximum hardness is reached at a reduction of about 40 to 45%. Further working causes progressive softening until, at about 80% reduction, the hardness approaches that of the cast alloy; annealing at 200 to 225 °C (392 to 437 °F) causes the severely worked alloy to harden slightly.

Table 14 Mechanical properties of white metal

Form and condition	Section size		Tensile strength		Elongation, %
	mm	in.	MPa	ksi	
Chill cast, tested 2 months after casting[a]	50 × 13	2 × 1/2	50	7.2	. . .
Chill cast, annealed at 225 °C (437 °F)[b]	50 × 13	2 × 1/2	45	6.5	50

Table 15 Creep-rupture characteristics of white metal

Tests conducted at room temperature (9 to 27 °C, or 48 to 81 °F) on rolled material 2.5 mm (0.1 in.) thick

Stress		Time to fracture, days	Final extension, %
MPa	ksi		
9.7	1.4	19	66
8.3	1.2	54	54
7.6	1.1	71	37
6.9	1.0	155	42
6.2	0.9	198	49
5.5	0.8	360	98
4.1	0.6	339[(a)]	4.12[(a)]

(a) Specimen did not fracture.

The solidus temperature of white metal is 246 °C (475 °F). White metal has a volumetric electrical conductivity of about 11.1% IACS and an electrical resistivity of about 155 nΩ · m at 25 °C (77 °F).

Fusible alloys are any of the more than 100 white metal alloys that melt at relatively low temperatures. Most commercial fusible alloys contain bismuth, lead, tin, cadmium, indium, and antimony, and special alloys of this class may

also contain significant amounts of zinc, silver, thallium, or gallium. Further information on fusible alloys is contained in the article "Indium and Bismuth" in this Volume.

Many of the fusible alloys used in industrial applications are based on eutectic compositions. These alloys find important uses in automatic safety devices such as fire sprinklers, boiler plugs, and furnace controls. Under ambient temperature, these alloys have sufficient strength to hold parts together, but at a specific elevated temperature the fusible-alloy link will melt, thus disconnecting the parts. Examples of tin-base eutectic fusible alloys are:

Alloy composition, %	Melting temperature	
	°C	°F
51.2 Sn, 30.6 Pb, 18.2 Cd	142	288
67.75 Sn, 32.25 Cd	177	351
61.86 Sn, 38.14 Pb	183	362
91 Sn, 9.0 Zn	199	390

Collapsible tubes and tin foil are forms of tin metal that are still in use, although they are not as common as they once were. Collapsible tubes of tin are used for certain pharmaceutical products and for some premium artist paints. Tin foil is used for packaging some premium products and for wine bottle capsules. Two common tin alloys for these types of applications are described below.

Hard tin (99.6Sn-0.4Cu) is used for collapsible tubes and foils. Hard tin is resistant to attack by foodstuffs, medicinal products, cosmetics, and artist's colors. The luquidus temperature of hard tin is 230 °C (446 °F); the solidus temperature is 227 °C (441 °F).

Typical tensile strengths of 2.5 mm (0.1 in.) thick strip hard tin in various conditions are:

- 23 MPa (3.3 ksi) for strip annealed for 3 h at 100 °C (212 °F)
- 21 MPa (3.1 ksi) for strip annealed for 3 h at 200 °C (390 °F)
- 28 MPa (4.0 ksi) for cold-rolled strip (80% reduction)

Bursting of a tube 25 mm (1 in.) in diameter and 0.1 mm (0.004 in.) in wall thickness occurred with an internal pressure of 320 kPa (46 psi). In a bend test, a flattened impact-extruded collapsible tube 0.1 mm (0.004 in.) in wall thickness survived 21 bends over 90° jaws (1 kg load).

Tin foil (92Sn-8Zn) is used for food packaging. Its suitability for this application is indicated by, for example, immersion and bottle-capping tests with milk that showed that this alloy is only slightly soluble and has no effect on the milk (Ref 3).

Typical tensile properties of tin foil include a tensile strength of 60 MPa (8.7 ksi), a yield strength of 41 MPa (6.0 ksi), and an elongation of 40%. The solidus temperature is about 200 °C (390 °F).

Other Alloys Containing Tin

Battery Grid Alloys. Lead-calcium-tin alloys have been developed for storage-battery grids, largely as replacements for antimonial-lead alloys. The use of ternary lead-base alloys containing up to 1.3% Sn has substantially reduced gassing, and thus batteries with grids made of these alloys do not require periodic water additions during their working life. Two chief methods of grid manufacture are casting and fabrication of wrought alloys; fabrication of wrought alloys includes punching, roll forging, and expanded-metal processes.

Copper Alloys. Copper-tin bronzes were some of the first alloys used by man, and these alloys continue to be used for structural and decorative purposes. True bronzes contain tin in amounts up to 10% as well as very small amounts of phosphorus. Quaternary bronzes containing 5% Sn, 5% Zn, 5% Pb, and a balance of copper are used for general-purpose castings for applications requiring reasonable strength and soundness, such as gears, pumps, and automotive fittings. Special copper-base alloys with 20 to 24% Sn have historically been used for cast bells of excellent tonal quality. Spinodal copper-nickel-tin alloys containing 2 to 8.5% Sn have excellent elastic properties and have replaced tin-free copper-nickel alloys in some spring and electrical-contact applications. In addition to these uses in copper-base alloys, small quantities of tin (0.75 to 1.0%) are added to copper-zinc alloys (brasses) for increased corrosion resistance. Cast leaded brasses may contain up to 4% Sn.

Dental alloys for making amalgams contain silver, tin, mercury, and some copper and zinc. The copper increases hardness and strength, and the zinc acts as a scavenger during alloy manufacture, protecting major constituents from oxidation. Most of the dental alloys presently available contain 25 to 27% Sn and consist mainly of the intermetallic compound Ag_3Sn. When porcelain veneers are added to gold alloys for high-grade dental restoration, 1% Sn is added to the gold alloy to ensure bonding with the porcelain.

Cast Irons. The presence of about 0.1% Sn in flake or ductile iron castings ensures a completely pearlitic structure, and this pearlite is retained even at elevated temperatures. Commercially pure tin is added to the cast iron in the form of shot, bars, or cast pieces; in cupola melting, the tin is commonly added to the ladle or to the cupola spout during tapping. Tin is also added to special mixing chambers along with suitable inoculant materials in the production of ductile iron castings. Because the mixing chambers are an integral part of the mold, this technique allows one-step treatment of the molten metal as it enters the mold, and it prevents fading (that is, the loss of effectiveness of inoculating additions before the metal is cast). In addition, the mixing chamber provides immediate dissolution of the tin in the iron and ensures uniform distribution in the casting.

Titanium Alloys. Tin strengthens titanium alloys by forming solid solutions. Titanium can exist in the low-temperature α-phase or the higher temperature β phase, which remains stable up to the melting point. In titanium alloys, relative amounts of α-and β phases present at the service temperature have profound effects on properties. Aluminum additions raise the transformation temperature and stabilize the α-phase, but they can cause embrittlement in amounts greater than 7%. However, with tin additions, increased strength without embrittlement can be obtained in aluminum-stabilized α-titanium alloys. Optimum strength and workability can be obtained with 5% Al and 2.5% Sn; in addition, this alloy has the advantage of being weldable. Alpha-beta titanium alloys contain aluminum as an α-stabilizer and combinations of β stabilizers (such as chromium, iron, molybdenum, manganese, or vanadium), as well as tin and zirconium as substitutional solid-solution strengthening elements. Such alloys have good strength and creep resistance at elevated temperatures. Strength and forming properties of many of these alloys can be optimized by various heat treatments.

Zirconium alloys are similar to titanium alloys in that the elements they contain can be divided into two classes: α-stabilizers, which raise the transformation temperature, and β-stabilizers, which lower it. Tin and aluminum are α-stabilizers in zirconium alloys and enhance high-temperature strength. A commercial series of corrosion-resistant zirconium alloys containing 0.15 to 2.5% Sn has been developed for nuclear service.

Zinc and Zinc Alloys

Robert J. Barnhurst, Noranda Technology Centre

Introduction

ZINC AND ZINC ALLOYS for decorative and functional applications are described in this article. Zinc and zinc alloys are used in the form of coatings, castings, rolled sheets, drawn wire, forgings, and extrusions. Other uses of zinc are as a major constituent in brasses (see the articles on copper-base alloys in this Volume) and as a sacrificial anode for marine environments.

In its purer form, zinc is available as slabs, ingots, shot, powder, and dust; combined with oxygen, it is available as zinc oxide powder. Slab zinc is produced in three grades (Table 1). Impurity limits are very important when zinc is used for alloying purposes. Exceeding impurity limits can result in poor mechanical and corrosion properties. Pure zinc shot is used primarily for additions to electrogalvanizing baths, and zinc powder and dust are used in batteries and in enhanced corrosion-resistant paints. Zinc oxide is used as a pigment in primers and finish paint, as a reducing agent in chemical processes, and as a common additive in the production of rubber products.

Table 1 Grades and compositions of slab zinc (ASTM B 6)

Grade	UNS number	Composition, %							
		Pb	Fe max	Cd max	Al max	Cu max	Sn max	Total nonzinc max	Zn min by difference
Special high grade	Z13001	0.003 max	0.003	0.003	0.002	0.002	0.001	0.010	99.990
High grade	Z15001	0.03 max	0.02	0.02	0.01	. . .	. . .	0.10	99.90

Zinc Products

Coating of steel constitutes the largest single use of zinc, but it is used in large tonnages in zinc alloy castings, as zinc dust and oxide (for zinc-rich organic and inorganic coatings), and in wrought zinc products. This section will review the various zinc product forms as well as provide references to articles in other *ASM Handbook* volumes that contain more detailed information. The mechanical and physical properties of both wrought and cast alloys are described in the section "Properties of Zinc Alloys" in this article.

Zinc Coatings

The use of zinc as a coating to protect steel and iron from corrosion is the largest single application for the metal worldwide. Metallic zinc coatings are applied to steels:

- From a molten metal bath (hot dip galvanizing)
- By electrochemical means (electrogalvanizing)
- From a spray of molten metal (metallizing)
- In the form of zinc powder by chemical/mechanical means (mechanical galvanizing)

Zinc coatings are applied to many different types of products, ranging in size from small fasteners to continuous strip to large structural shapes and assemblies.

Hot Dip Galvanizing. The hot dip galvanizing industry is currently the largest consumer of zinc in the coatings field. It is divided into two segments:

- Production of continuously galvanized steel strip.
- Galvanizing of structural shapes and products after fabrication

Galvanized products can be joined by conventional techniques such as welding and bolting.

Conventional strip galvanizing makes use of an alloy with a nominal content of 0.20% Al and a balance of zinc. The coating thickness is generally less than 25 μm (0.001 in.), or approximately 175 g/m^2 (0.573 oz/ft^2) of steel surface (one-side total). The coating is characterized by excellent adhesion and formability. These attributes, along with good weldability by conventional welding techniques, make strip galvanizing particularly attractive for automobile manufacturing. Galvanized strip is also used in the building industry, where significant tonnages are used in prepainted condition. The appliance industry is also a large consumer of both painted and unpainted galvanized strip. Some galvanized strip is subjected to a heat treatment known as galvannealing that converts the coating to an iron-zinc alloy. Galvannealing has been used for building products for a number of years and, more recently, for automotive parts. In recent years, new strip coatings with improved corrosion resistance, namely Galfan (5% Al) and Galvalume (55% Al), have been introduced. Galfan has been incorporated into ASTM B 750 (Table 2) and Galvalume into ASTM A 792. Additional information on strip galvanizing is available in the article "Precoated Steel Sheet" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook* and in the articles "Hot Dip Coatings," "Organic Coatings and Linings," and "Corrosion of Zinc" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Table 2 Zn-5Al-MM alloy ingot chemical requirements for hot dip coatings (Galfan, or UNS Z38510) per ASTM B 750

Element	Composition, %

Zinc	bal

Note: For purposes of acceptance and rejection, the observed value or calculated value obtained from analysis should be rounded to the nearest unit in the last right-hand place of figures used in expressing the specified limit, in accordance with the rounding procedure prescribed in Section 3 of ASTM E 29. By agreement between purchaser and supplier, analysis may be required and limits established for elements or compounds not specified in the table of chemical composition. Zn-5Al-MM alloy ingot for hot dip coatings may contain antimony, copper, and magnesium in amounts of up to 0.002, 0.1, and 0.05%, respectively. No harmful effects have ever been noted from the presence of these elements up to these concentrations; therefore, analyses are not required for these elements. Magnesium may be specified by the buyer up to 0.1% max. Zirconium and titanium may each be specified by the buyer up to 0.02% max.

(a) Aluminum may be specified by the buyer up to 7.2% max.

(b) Lead and cadmium and to a lesser extent, tin and antimony are known to cause intergranular corrosion in zinc-aluminum alloys. Therefore, it is important to maintain the levels of these elements below the limits specified.

(c) Except antimony, copper, magnesium, zirconium, and titanium

After-Fabrication Galvanizing. An aluminum-free grade of zinc that contains up to 1 wt% Pb and a balance of zinc is used for after-fabrication galvanizing. Most specifications cell for a minimum coating thickness in the range of 85 to 100 μm (0.0034 to 0.004 in.), or 500 to 600 g/m^2 (1.6 to 2.0 oz/ft^2). Coating thickness is controlled by immersion time, which in turn is governed by the substrate thickness; it can be much higher with some reactive grades of steel containing even small amounts of silicon (silicon-killed steels). Proprietary galvanizing processes that use small additions of aluminum (Polygalva) or nickel (Technigalva) in concentrations of 0.04 and 0.08 wt%, respectively, have been developed in attempts to control coating thickness.

Traditional markets for after-fabrication coatings include electric utility and microwave transmission towers; highway-related products such as guard rails, signs, and lighting standards; structural applications in the industrial sector (for example, chemical, petrochemical, agricultural, and pulp and paper industries); drainage products; pipe for potable drinking water; heat exchangers; and reinforcing bar for concrete structures.

Electrogalvanizing. Strip-applied electrogalvanized coatings are becoming increasingly important for automotive applications. These coatings are applied at high-speed, high-current-density electroplating lines. Pure zinc as well as zinc-nickel and zinc-iron coatings are produced. The coatings are generally more uniform, smoother, and thinner than hot dip coatings. Corrosion resistance, coating-to-steel adhesion, formability, weldability, and paintability are critical properties for automotive applications of electrogalvanized steel.

Metallizing, also known as thermal spraying, is used in applications where heavy coatings are specified for corrosion protection. The process is amenable to field applications and is used in refurbishing existing structures. Very long service lives are possible with composite systems, often with the use of thinner coatings (plus suitable organic paint coats) than those that are required with conventional metallizing alloys.

In a typical metallizing procedure, either pure zinc (special high grade) or Zn-15Al is sprayed onto the steel surface to be protected. The zinc alloy is provided either in dust form or as rods that are atomized by a flame or electric arc and then propelled onto the substrate by a high-speed gas jet. Additional information is available in the article "Thermal Spray Coatings" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Mechanical galvanizing is a batch process that is carried out in rotating drums. During processing, the workpiece is tumbled in a mixture of zinc dust, chemicals, and glass beads, and the coating is impacted onto the surface of the workpiece by the tumbling action. It is used for coating fasteners fabricated from specialty spring or case-hardened steels, or both materials, because the properties of such fasteners might be adversely affected by the high temperature of a hot dip bath. Mechanical galvanizing is also used for applications where relatively heavy coating weights are specified.

Zinc Alloy Castings

Zinc alloys are used extensively in both gravity and pressure die castings. When used as general casting alloys, zinc alloys can be cast using such processes as high-pressure die casting, low-pressure die casting, sand casting, permanent mold casting (iron, graphite, or plaster molds), spin casting (silicone rubber molds), investment (lost-wax) casting, continuous or semicontinuous casting, and centrifugal casting. A newer process involves semisolid casting, of which several techniques can be employed. A detailed treatment of casting processes for zinc alloys is included in the article "Zinc and Zinc Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Corrosion is of no concern for most applications. However, for castings under moderate-to-severe corrosive attack, some loss of properties is to be expected. Long-term aging also may cause some small loss of properties; the effects will vary from alloy to alloy and depend upon the casting method used.

Pressure Die Castings. Zinc alloys have been used for die casting for over 60 years. Until recently, all zinc alloys were based on a hypoeutectic composition, that is, they contained less aluminum (close to 4.0% Al) than the eutectic chemistry of 5.0% Al. Recently, a family of hypereutectic zinc-aluminum alloys with higher aluminum contents (>5.0% Al), have become widely used as die casting alloys. These alloys were originally designed as gravity casting alloys (see the section "Gravity Castings" in this article). They possess higher strength than the hypoeutectic zinc alloys. The compositions of current die casting alloys are included in Tables 3 and 4.

Table 3 Nominal compositions of common zinc alloy die castings and zinc alloy ingot for die casting

Alloy[a]			Composition, %

				4.3							

Note: For purposes of acceptance and rejection, the observed value or calculated value obtained from analysis should be rounded to the nearest unit in the last right-hand place of figures used in expressing the specified limit, in accordance with the rounding procedure prescribed in ASTM E 29.

(a) ASTM alloy designations were established in accordance with ASTM B 275. UNS designations were established in accordance with ASTM E 527. The last digit of a UNS number differentiates between alloys of similar composition. UNS designations for ingot and casting versions of an alloy were not assigned in the same sequence for all alloys.

(b) Zinc alloy die castings may contain nickel, chromium, silicon, and manganese in amounts of 0.02, 0.02, 0.035, and 0.06%, respectively. No harmful effects have ever been noted from the presence of these elements in these concentrations; therefore, analyses are not required for these elements.

(c) Zinc alloy ingot for die casting may contain nickel, chromium, silicon, and manganese in amounts of up to 0.02, 0.02, 0.035 and 0.05%, respectively. No harmful effects have ever been noted from the presence of these elements up to these concentrations; therefore, analyses are not required for these elements, except that nickel analysis is required for Z33522.

(d) For the majority of commercial applications, a copper content in the range of 0.25-0.75% will not adversely affect the serviceability of die castings and should not serve as a basis for rejection.

(e) Magnesium may be as low as 0.015% provided that the lead, cadmium, and tin do not exceed 0.003, 0.003, and 0.002% respectively.

Table 4 Nominal compositions of zinc-aluminum foundry and die casting alloys directly poured to produce castings and in ingot form for remelting to produce castings

Alloy		**Composition, %**

ZA-27	Z35840	25.5-28.0	2.0-2.5	0.012-0.020	bal	0.072	0.005	0.005	0.002

(a) UNS alloy designations have been established in accordance with ASTM E 527.

(b) Determined arithmetically by difference.

(c) Zinc-aluminum ingot for foundry and pressure die casting may contain chromium, manganese, or nickel in amounts of up to 0.01% each or 0.03% total. No harmful effects have ever been noted from the presence of these elements in these concentrations; therefore, analyses are not required for these elements.

Zinc casting alloys have dendritic/eutectic microstructures. The hypoeutectic alloys solidify with zinc-rich (η) dendrites, whereas the hypereutectic alloys solidify with aluminum-rich dendrites. The ZA-8 and ZA-12 alloys solidify with cored β dendrites, whereas ZA-27 solidifies with α-dendrites. The microstructure of zinc alloys are discussed in detail in the article "Zinc and Zinc Alloys" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

It is critically important that all zinc-aluminum casting alloys be carefully handled to prevent excessive pickup of harmful impurity elements such as lead, cadmium, tin, and iron, among others. Cross contamination caused by melting the alloys in furnaces used for casting copper and aluminum alloys or iron is particularly troublesome because these alloys contain elements harmful to zinc alloys. Purity concerns have led producers in many countries (those belonging to the European Economic Community, for example) to require that only 100% virgin material be used in the production of zinc foundry alloys. This requirement does not apply in North America, but alloyed ingots obtained from external suppliers are expected to meet strict impurity limits. A maximum 50% remelt of foundry returns to the melting furnace is acceptable during the making of castings.

Zinc alloys have low melting points, require relatively low heat input, do not require fluxing or protective atmospheres, and are nonpolluting; the last is a particularly important advantage. The rapid chilling rate inherent in zinc die castings results in minor property and dimensional changes with time, particularly if the casting is quenched from the die rather than air cooled. Although this is rarely a problem, a stabilizing heat treatment can be applied prior to service if rigid dimensional tolerances are to be met. The higher the heat treatment temperature, the shorter the stabilizing time required; 100 °C (212 °F) is a practical limit to prevent blistering of the casting or other problems. A common treatment consists of 3 to 6 h at 100 °C (212 °F), followed by air cooling. The time extends to 10 to 20 h for a treatment temperature of 70 °C (158 °F).

Because of their high fluidity, zinc alloys can be cast in much thinner walls than other die castings alloys, and they can be die cast to tighter dimensional tolerances. Zinc alloys allow the use of very low draft angles; in some cases, a zero draft angle is possible.

Alloy No. 2 has the highest tensile strength, creep strength, and hardness of all alloys in the hypoeutectic Zamak series of die casting alloys. The high copper content (3.0% Cu) causes some dimensional instability and leads to a net expansion of approximately 0.0014% after 20 years. It also causes some loss of impact strength and ductility. Alloy No. 2 has good bearing properties.

Alloy No. 3 is the most widely used zinc die casting alloy in the United States. It provides the best overall combination of strength, castability, dimensional stability, ease of finishing, and cost.

Alloy No. 5 produces castings that are both harder and stronger than those made from alloy No. 3. However, these properties improvements come at the expense of ductility, and postforming operations such as riveting, swaging, or crimping must be done with additional care. The creep resistance of alloy No. 5 is second only to that of alloy No. 2 among the hypoeutectic zinc-aluminum alloys.

Alloy No. 7 is essentially a high-purity version of alloy No. 3. Because of its lower magnesium content, alloy No. 7 has even better castability than alloy No. 3, enabling excellent reproduction of surface detail in castings. Alloy No. 7 has the highest ductility among the hypoeutectic alloys.

Alloy ZA-8 is the only member of the hypereutectic alloys that can be hot chamber die cast along with the hypoeutectic alloys. It is equivalent to alloy No. 2 in many respects, but ZA-8 has higher tensile, fatigue, and creep strengths, is more dimensionally stable, and has lower density. Alloy ZA-8 castings can be readily finished, thereby combining their high structural strength with excellent appearance.

Alloy ZA-12 has very good castability in cold chamber die casting machines. It is lower in density than all other zinc alloys except ZA-27, and it is frequently specified for castings that must combine casting quality with optimum performance. The plating quality of ZA-12 is lower than that of ZA-8, but it has excellent bearing and wear properties.

Alloy ZA-27 is the lightest, hardest, and strongest of all the zinc alloys, but it has relatively low ductility and impact strength when pressure die cast. Because of the wide freezing range of ZA-27, casting quality can suffer unless care is taken. The secondary creep strength of ZA-27 is better than that of all other zinc alloys except for the now rarely used ILZRO (International Lead-Zinc Research Organization) 16; however, ZA-8 has better primary creep strength. Alloy ZA-27 demonstrate the highest sound and vibration damping properties of all the zinc casting alloys; as a group, zinc alloys have a damping resistance equal to that of cast irons at elevated temperatures.

Alloy ILZRO 16 was developed specifically for optimum creep resistance, particularly at elevated temperatures. It does have the highest creep resistance of all zinc alloys, but it is difficult to manufacture and suffers from melt instability; for these reasons, ZA-8 often is used in its place.

It should be noted that the strength performance of zinc alloys drops significantly with increases in temperature. At 100 °C (212 °F), tensile and yield strengths are typically 65 to 75% of those at room temperature, and creep strength is similarly reduced.

Gravity Castings. With the exceptions of forming die alloys, slush casting alloys, and specialty alloys developed and used for bearings, no general-purpose gravity casting zinc alloys existed until the 1960s. In the 1960s and 1970s, a new family of hypereutectic zinc-aluminum alloys was developed. Alloy ILZRO-12 (now ZA-12) was the first to appear, beginning in 1962; ZA-8 and ZA-27 were quickly added. Alloy ZA-12 was developed first as a prototyping alloy for alloy No. 3 pressure die castings. Alloy ZA-27 was developed specifically as a sand casting alloy, and ZA-8 was turned into a permanent mold casting alloy. All three alloys are now used more extensively in pressure die castings.

The performance of the ZA alloys when they are gravity cast varies markedly from that of the same alloys when they are pressure die cast. The compositions of the gravity casting alloys are given in Table 4. The same requirements concerning impurities, melt cross contamination, and general handling described for the die casting alloys apply equally to the gravity casting alloys. As with the die casting alloys, microstructural changes with time can alter the properties and dimensions of cast parts. However, property changes are normally very small over the normal life span of a component, and dimensional changes, except in ZA-27, are negligible. A stabilizing heat treatment of 12 h at 250 °C (482 °F), followed by furnace cooling, effectively eliminates three-fourths of the dimensional changes that occur upon long-term aging.

Alloy ZA-8 is used mostly with ferrous permanent molds casting, but it is also used with graphite molds. Alloy ZA-8 can also be sand cast if needed, although sand casting is not used extensively for this alloy. With the exception of creep resistance, the strength of a permanent mold casting is lower than that of a pressure die casting due to the coarser microstructure of the former. The plating quality of ZA-8 is excellent, and its surface detail reproducibility is better than that of all other ZA alloys.

Alloy ZA-12 is more versatile than ZA-8 because it can be either sand cast or permanent mold cast. Its strength properties are high, and its ductility and impact strength properties are acceptable. It is clearly the alloy of choice for graphite mold casting. The bearing and damping properties of ZA-12 are both very high. Alloy ZA-12 can be readily semicontinuous cast in solid and hollow rounds for machining bushings and industrial bearings.

Alloy ZA-27 develops its optimum properties when it is sand cast. However, care should be taken when producing heavy-section castings to ensure maximum soundness and minimal underside shrinkage. Underside shrinkage, caused by gravity segregation of the aluminum-rich phase during solidification, causes a roughening on the drag surface of the casting as zinc liquid is drawn up into the casting. Both a reduction in underside shrinkage and a sound casting can be

ensured when chills are used to promote directional solidification and to increase the solidification rate. The addition of rare earth elements has also been reported to reduce underside shrinkage.

In a sound gravity casting, ZA-27 produces ductility and impact strength properties much higher than those found in many die castings. Alloy ZA-27 has excellent bearing and wear properties, and it demonstrates the best damping resistance of any zinc alloy. Although it is very rarely required, a simple heat treatment of 3 h at 320 °C (608 °F), followed by furnace cooling, can increase the ductility and impact strength of ZA-27 castings. Dimensional stability is enhanced by a stabilizing heat treatment of 12 h at 250 °C (482 °F), followed by furnace cooling.

Kirksite alloy is used as a forming die alloy, and is capable of being sand cast to shape rapidly. It has an almost identical composition to the No. 2 die casting alloy. It is mainly used in the construction of cast two-piece dies for forming sheet metal parts such as components for use in the transportation and aerospace industries. Kayem 1 and Kayem 2 are similar alloys used extensively in Europe. Cast-to-size molds made of Kirksite are being used for plastic injection molding for both short-run prototyping and production operations. Two die forming die alloys are included in ASTM B 793 (Table 5).

Table 5 Nominal compositions of zinc casting alloys used for sheet metal forming dies and for slush casting alloys in ingot form

Alloy		Composition, %							
Common designation	**UNS number**	**Al**	**Cd max**	**Cu**	**Fe max**	**Pb max**	**Mg**	**Sn max**	**Zn**
Forming die alloys (ASTM B 793)									
Alloy A	Z35543	3.5-4.5	0.005	2.5-3.5	0.100	0.007	0.02-0.10	0.005	bal
Alloy B	Z35542	3.9-4.3	0.003	2.5-2.9	0.075	0.003	0.02-0.05	0.001	bal
Slush casting alloys (ASTM B 792)									
Alloy A	Z34510	4.50-5.00	0.005	0.2-0.3	0.100	0.007	. . .	0.005	bal
Alloy B	Z30500	5.25-5.75	0.005	0.1 max	0.100	0.007	. . .	0.005	bal

Slush casting alloys are used extensively for the production of hollow castings such as table lamp bases. The molten alloy is poured into the mold until it is full or nearly full, and then the mold is inverted, allowing the unsolidified metal (slush) to run out. The solidified shell that is left is then removed. The thickness of the shell depends on the time interval between pouring and inverting the mold, the melt and mold temperatures, and the mold material. Two slush casting alloys are currently available (Table 5).

Specialty Alloys. Main Metal alloy and Alzen alloy are still used in Europe for the production of continuously cast bearing stock. They are also used for sliding elements, hydraulic components, worm wheels, roller bearing cages, and several other products. A series of Cosmal alloys, specifically formulated for applications requiring high damping, have been developed in Japan.

Cast Product Applications. Zinc is used extensively in the transportation industry for parts such as carburetors, fuel pump bodies, wiper parts, speedometer frames, grilles, horns, shift levers, load-bearing transmission cases, heater components, brake parts, radio bodies, electronic heat sinks, lamp and instrument bezels, steering wheel hubs, alternator brackets, exterior and interior hardware, instrument panels, and body moldings. Zinc castings are also extensively used in general hardware and electronic and electrical fittings of all kinds, including parts for domestic appliances (for example,

washing machines, vacuum cleaners, mixers, and so on), oil burners, motor housings, locks, and clocks. Zinc castings are frequently and increasingly being specified for hardware used in the computer industry, in business machines (photocopiers, facsimile machines, cash registers, and typewriters), and in such items as recording machines, projectors, vending machines, cameras, gasoline pumps, many hand tools, and machinery such as larger drill presses and lathes. The ZA alloys are increasingly being specified for bearings and bushings in low-speed high-load applications.

Finishing and Secondary Operations for Zinc Alloy Castings. Many of the finishes applied to other types of metal products can be applied to zinc die castings and gravity castings. Suitable finishing treatments include:

- Mechanical buffing, polishing, brushing, and tumbling
- Plating with materials such as copper, nickel, silver and black nickel, chromium, electroless nickel, and brass
- Chemical finishing such as chromating, enameling, lacquering, painting, varnishing, anodizing, and vacuum aluminizing
- Plastic (powder coat) finishing

Phosphating of the cast surface is generally recommended to provide good adhesion for subsequent paint or powder coatings. Additional information on surface preparation techniques and coatings for zinc is available in the article "Surface Engineering of Zinc Alloys" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Although zinc alloys have good natural corrosion resistance (provided that impurity limits are not exceeded), chromating and anodizing provide added corrosion protection in moderate-to-severe corrosive environments. The white rust that can form on zinc castings stored in damp environments is effectively prevented or delayed by chromating the surface. Detailed information is available in the article "Corrosion of Zinc" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

All zinc casting alloys have excellent machining properties, with long tool life, low cutting forces, good surface finish, low tool wear, and small chip formation. Common machining operations performed on these alloys include drilling, tapping, reaming, broaching, routing, turning, milling, die threading, and sawing. Detailed information is available in the article "Machining of Zinc Alloy Die Castings" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Zinc alloy castings can be conveniently joined by soldering or brazing, or by certain welding techniques using zinc-base fillers. Cadmium-, tin-, or lead-base solders are not recommended because they can promote intergranular corrosion problems unless the castings are plated with heavy coatings of nickel or copper prior to soldering. Newer zinc-base solders are becoming available. Detailed information about these joining techniques is available in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Adhesive bonding or mechanical fasteners are also excellent methods for joining castings. Zinc castings can be riveted, staked, and crimped. Threaded fasteners, including self-tapping screws, should not be overtightened but rather tightened to recommended torques. Up to 40% loss of torque should be incorporated into the design for parts operating at elevated temperatures of 50 °C (122 °F) or higher. Significant torque loss can be avoided by using special fasteners, including cone (spring or Belleville) or star washers of the correct size. Joining two or more parts can be accomplished by die casting a joint to properly align and join the parts.

Additional Properties of Zinc Castings. In addition to their excellent physical and mechanical properties, zinc alloys offer:

- Good corrosion resistance
- Excellent vibration- and sound-damping properties that increase exponentially with temperature (because of these damping characteristics, zinc alloys can be designated HIDAMETS, or high-damping metals
- Excellent bearing and wear properties
- Spark (incendivity) resistance (with the exception of the high-aluminum ZA-27 alloy)

Wrought Zinc and Zinc Alloys

Zinc in pure form or with small alloying additions is used in three main types of wrought products: flat-rolled products, wire-drawn products, and extruded and forged products. Wrought zinc is readily machined, joined, and finished.

Flat-Rolled Products. Zinc is usually cast into 25 to 100 mm (1.0 to 4.0 in.) thick flat slabs that are suitable for rolling; these slabs are preheated and then rough and finish rolled. Schedules for finish rolling of zinc strip vary and depend on the product required. Strip is produced in various widths up to 2 m (79 in.) and in thicknesses down to 0.1 mm (0.004 in.). Foil in thicknesses of 0.025 mm (0.001 in.) or less is produced in special mills. For a bright surface combined with high ductility, finish rolling is performed at 120 to 150 °C (250 to 300 °F).

Rolled zinc can be readily formed into many different shapes by bending, spinning, deep drawing, roll forming, coining, and impact extrusion. Joining is easily achieved by soldering and resistance welding. When alloyed with copper and titanium, zinc sheet is very creep resistant and can be used in functional applications; examples include architectural applications such as in roofing and siding. Rolled zinc is produced in seven basic alloys and also as pure zinc (Table 6). Variations in chemistry and rolling conditions produce a variety of properties.

Table 6 Nominal compositions of rolled zinc alloys per ASTM B 69

Alloy		Composition, %						
Common designation	**UNS number**	**Cu**	**Pb**	**Cd**	**Fe max**	**Al max**	**Other max**	**Zn**

Superplastic zinc, which contains 21 to 23% Al and a small amount of copper (0.4 to 0.6%), can be easily formed into complex shapes and displays the characteristics of plastics or molten glass at temperatures of 250 to 270 °C (480 to 520 °F). The very fine grain size produced by processing at 275 to 375 °C (525 to 705 °F) followed by quenching and aging gives superplastic zinc its unique properties. Different grades of superplastic zinc, such as air-cooled or surface-cooled varieties, have different levels of strength. When superplastic zinc is reheated to above 275 °C (527 °F) and slowly cooled to room temperature, the superplastic properties disappear. Detailed information about superplasticity is available in the article "Sheet Formability Testing" in *Mechanical Testing,* Volume 8 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Wire-Drawn Products. Zinc is easily rolled or extruded into rod and then drawn into wire. The manufacture of zinc alloy wire is normally continuous and follows casting, rolling, and drawing operations. Special finishes or lubricants are sometimes applied following drawing. Wire sizes vary from 1.0 to 6.35 mm (0.004 to 0.25 in.)

Zinc alloy wire is widely used in thermal spraying, or metallizing, where the wire is melted and sprayed onto a substrate using a special gun. This process is used primarily for the corrosion protection of steel (see the section "Zinc Coatings" in this article). In addition to pure zinc, zinc alloys containing 15% Al are used in thermal spraying because the zinc-aluminum alloy provides increased corrosion protection. In addition to its thermal spraying applications, zinc alloy wire is used in nail and screw production and in zinc-base solders.

Extruded and Forged Products. Two zinc forging alloys are currently in commercial use; one has a zinc-aluminum base, and the other contains copper and titanium. Korloy 2573 (Zn-14.5Al-0.02Mg-0.75Cu) has high impact strength at low temperatures. The titanium-containing alloy, Korloy 3130 (Zn-1.0Cu-0.1Ti), is a more general-purpose alloy and has better creep strength. Both alloys have excellent machining, joining, and finishing characteristics, although machining of the titanium-containing alloy is best performed with carbide-tipped tooling.

Zinc alloys are generally capable of bearing extruded but require higher pressures and lower speeds than other nonferrous metals. Alloy ZA-27 has been fabricated from continuously cast billets into extruded stock for bushings. The tensile properties of the extruded ZA-27 are improved over those of the cast stock, especially elongation. Extruding offers near-net-shape capability with minimal or no machining. Temperatures of the order of 250 to 300 °C (480 to 570 °F) are required to extruded zinc alloys.

Wrought Product Applications. In addition to the use of wrought zinc in roofing and flashing, rolled zinc is drawn into many different products, including dry-cell battery cans, batter cups, handrails, eyelets, meter cases, buckles, ferrules, gaskets, and electrical components such as lamp parts. Examples of typical end uses for the various grades of wrought zinc are given in Table 7.

Table 7 Typical applications of wrought zinc and zinc alloys

Alloy	Applications
Pure zinc	Deep-drawn hardware, expanded metal
Zn-Cu	Building construction materials, deep-drawn hardware, coinage
Zn-Cu-Ti	Roofing, gutters, and downspouts; building construction materials; deep-drawn hardware; address plates; solar collectors
Zn-Pb-Cd-Fe	Building construction materials, dry-cell battery cans, deep-drawn hardware, address plates, electrical components
Zn-Al (superplastic zinc)	Shaped components such as typewriter casings, computer panels, and covers

Properties of Zinc Alloys

AG40A
Zn-4Al-0.04Mg

Commercial Names

Trade name. No. 3 die casting alloy

Previous trade name. Zamak 3

Foreign. Mazak 3

Specifications

ASTM. B 86: alloy AG40A (die castings). B 240: alloy AG40A (ingot)

SAE. J468, alloy 903

UNS. Z33521 (ingot), Z33520 (castings)

U.S. Government. QQ-Z-363

Foreign. AFNOR-ZA4G; BS 1004A; CSA HZ-3 (ingot), HZ-11 (castings); DIN-1743; JIS H 2201 class 1 (ingot), H 5301 ZDC 2 (castings); SAA-AS1881

Chemical Composition

Composition limits. ASTM B 86: 3.5 to 4.3 Al, 0.020 to 0.05 Mg, 0.25 Cu max, 0.100 Fe max, 0.005 Pb max, 0.004 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloys becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking.

Applications

Typical uses. Die castings such as automotive parts, household appliances and fixtures, office and computer equipment, building hardware

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 283 MPa (41 ksi); elongation, 10% in 50 mm (2 in). gage length. Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Table 8 Effect of temperature on the mechanical properties of zinc-alloy and zinc-aluminum alloy castings

Alloy designation	Temperature		Tensile strength[a]		Impact energy[b]		Fracture toughness (average K_{Ic})			
							Pressure die cast		Sand cast

(b) As-cast, unnotched 6.35 mm (0.25 in.) square specimen.

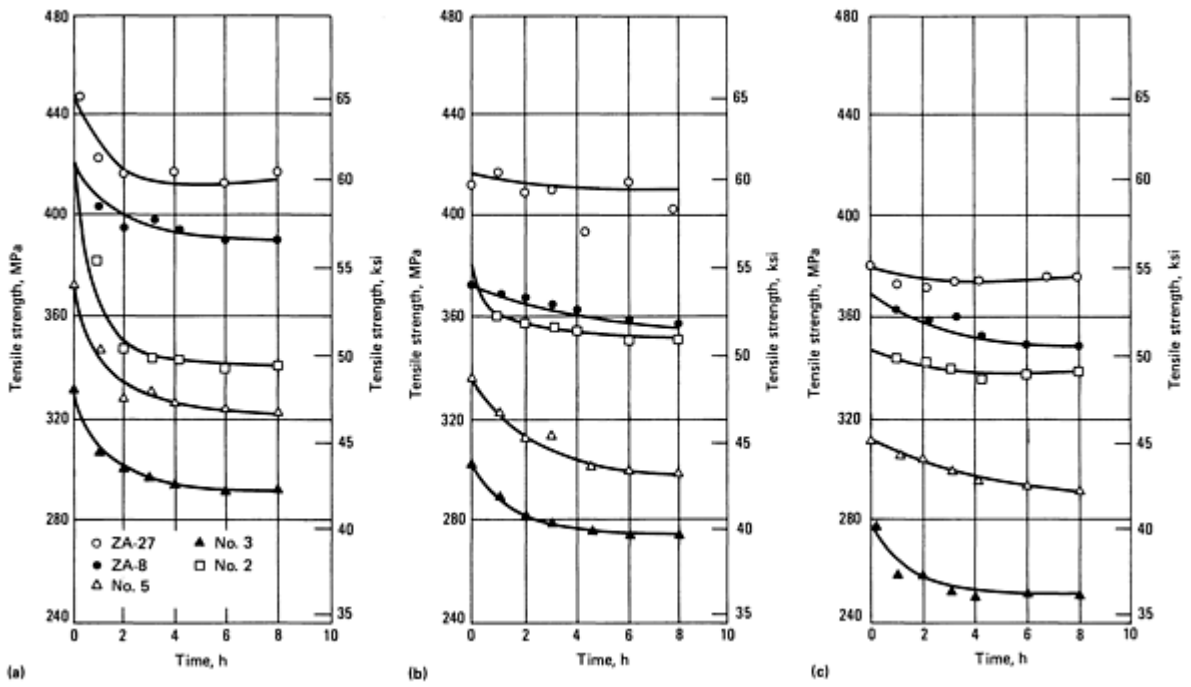

Fig. 1 Effect of aging time on the tensile strengths of five zinc alloys. Aging temperature, 100 °C (212 °F). (a) 0.76 mm (0.030 in.) casting wall thickness. (b) 1.52 mm (0.060 in.) casting wall thickness. (c) 2.54 mm (0.100 in.) casting wall thickness. Source: Noranda Technology Centre

Shear strength. 214 MPa (31.0 ksi)

Compressive strength. 414 MPa (60.0 ksi)

Hardness. 82 HB (500 kg load, 10 mm hardened steel ball, 30-s duration)

Impact strength. Charpy, unnotched 6.35 mm (0.25 in.) square bar: 58 J (43 ft · lbf). See Table 8.

Fracture toughness. Pressure die cast, 12.3 MPa $\sqrt{m}$ (11.2 ksi $\sqrt{in}$) at 24 °C (75 °F). See Table 8.

Fatigue strength. Reverse bending, 48 MPa (7.0 ksi) at 5×10^8 cycles

Creep strength. Stress to give 1% secondary creep extension in 10^5 h, per ASME boiler code: 21 MPa (3.0 ksi) at 20 °C (68 °F). See Fig. 2.

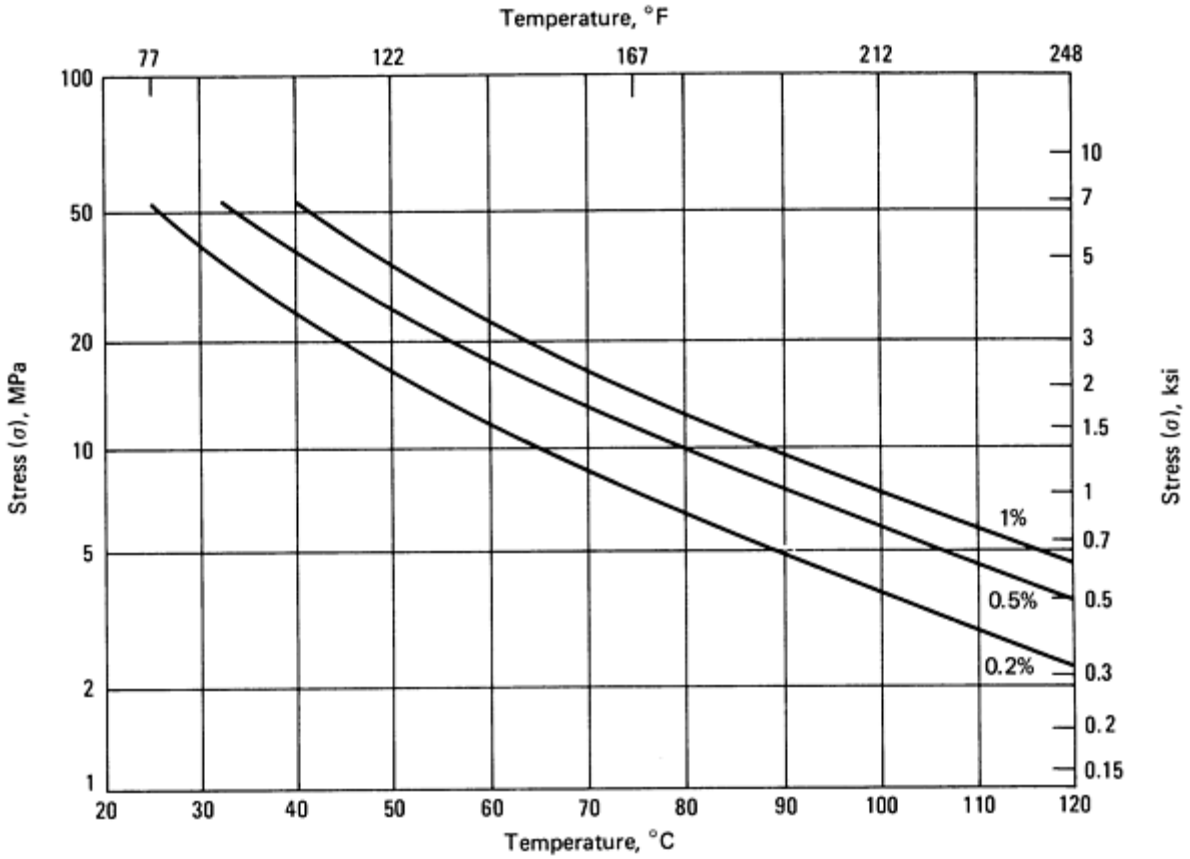

Fig. 2 Elongation of zinc alloy No. 3 at various combinations of stress and temperature for a service life of 3×10^3 h. Source: AM&S Europe Ltd.

Mass Characteristics

Density. 6.6 g/cm^3 (0.24 lb in.^{3}) at 21 °C (70 °F)

Volume change on freezing. 1.17% shrinkage

Thermal Properties

Liquidus temperature. 387 °C (728 °F)

Solidus temperature. 381 °C (718 °F)

Coefficient of linear thermal expansion. 27.4 μm/m · K (15.2 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 0.419 kJ/kg · K (0.10 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 113.0 W/m · K (784 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 27% IACS at 20 °C (68 °F)

Electrical resistivity. 6.4 μΩ· cm (2.52 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Other Properties

Damping. Q^{-1} (× 10^3) at 100 Hz, 3.6 at 20 °C (68 °F), 6.4 at 100 °C (212 °F). See Table 9.

Table 9 Damping properties of selected zinc alloys at 20 °C (68 °F) and 100 °C (212 °F)

Alloy	$Q^{-1} \times 10^{3}$[a]											
	10 Hz		50 Hz		100 Hz		500 Hz		10^3 Hz		5×10^3 Hz

(a) Specific damping capacity = $200\pi\ Q^{-1}$.

(b) As die cast.

(c) Cold-rolled superplastic zinc sheet.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, tungsten inert-gas (TIG) or metal inert-gas (MIG) welding. Solder with lead-tin solder over nickel-plated surface; acidulated zinc chloride flux. Oxyacetylene weld with alloy No. 3, no flux, soft flame. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 395 to 425 °C (740 to 800 °F)

Precautions in melting. Stir well after melt-down and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper die design are necessary to ensure sound castings and high strength and ductility.

AC41A
Zn-4Al-1Cu-0.05Mg

Commercial Names

Trade name. No.5 die casting alloy

Previous trade name. Zamak 5

Foreign. Mazak 5

Specifications

ASTM. B 86: alloy AC41A (die castings). B 240: alloy AC41A (ingot)

SAE. J468, alloy 925

UNS. Z35530 (ingot), Z35531 (castings)

Government. QQ-Z-363

Foreign. AFNOR-ZA4UIG; BS 1004A; CSA HZ-3 (ingot), HZ-11 (castings); DIN-1743; JIS H 2201 class 2 (ingot), H 5301 ZDC 1 (castings); SAA-AS1881

Chemical Composition

Composition limits. ASTM B 86: 3.5 to 4.3 Al, 0.75 to 1.25 Cu, 0.030 to 0.08 Mg, 0.100 Fe max, 0.005 Pb max, 0.004 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking.

Applications

Typical uses. Die castings such as automotive parts, household appliances and fixtures, office and computer equipment, building hardware

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 328 MPa (47.6 ksi), elongation, 7% in 50 mm (2 in.) gage length. Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Shear Strength. 262 MPa (38.0 ksi)

Compressive strength. 600 MPa (87.0 ksi)

Hardness. 91 HB (500 kg load, 10 mm hardened steel ball, 30-s duration)

Impact strength. Charpy, unnotched 6.35 mm (0.25 in.) square bar: 65 J (48 ft · lbf). See Table 8.

Fatigue strength. Reverse bending, 56.5 MPa (8.20 ksi) at 5×10^8 cycles

Mass Characteristics

Density. 6.7 g/cm^3 (0.24 lb/in.^{3}) at 21 °C (70 °F)

Volume change on freezing. 1.17% shrinkage

Thermal Properties

Liquidus temperature. 386 °C (727 °F)

Solidus temperature. 380 °C (717 °F)

Coefficient of linear thermal expansion. 27.4 μm/m · K (15.2 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 0.419 kJ/kg · K (0.10 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 109.0 W/m · K (755 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 26% IACS at 20 °C (68 °F)

Electrical resistivity. 6.5 μΩ· cm (2.56 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Solder with lead-tin solder over nickel-plated surface; acidulated zinc chloride flux. Oxyacetylene weld with alloy No. 3, no flux, soft flame. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 395 to 425 °C (740 to 800 °F)

Precautions in melting. Stir well after melt-down and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper die design are necessary to ensure sound castings and high strength and ductility.

AG40B
Zn-4Al-0.015Mg

Commercial Names

Trade name. No. 7 die casting alloy

Previous trade name. Zamak 7

Foreign. Mazak 7

Specifications

ASTM. B 86: alloy AG40B (die castings). B 240: alloy AG40B (ingot)

UNS. Z33522 (ingot), Z33523 (castings)

Chemical composition

Composition limits. ASTM B 86: 3.5 to 4.3 Al, 0.25 Cu max, 0.005-0.020 Mg, 0.075 Fe max, 0.003 Pb max, 0.002 Cd max, 0.001 Sn max, 0.005-0.020 Ni, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking.

Applications

Typical uses. Die castings such as automotive parts, household appliances and fixtures, office and computer equipment, building hardware

Mechanical Properties

Tensile properties. Die cast specimen, 63.5 mm (0.25 in.) in diameter: tensile strength, 283 MPa (41.0 ksi); elongation, 13% in 50 mm (2 in.) gage length. Tensile and other mechanical properties are affected by operating temperature and time (see Table 8).

Shear strength. 214 MPa (31.0 ksi)

Compressive strength. 414 MPa (60.0 ksi)

Hardness. 80 HB (500 kg load, 10 mm hardened steel ball, 30-s duration)

Impact strength. Charpy, unnotched 6.35 mm (0.25 in.) square bar; 58 J (43 ft · lbf). See Table 8.

Fatigue strength. Reverse bending, 47 MPa (6.80 ksi) at 5×10^8 cycles

Mass Characteristics

Density. 6.6 g/cm^3 (0.24 lb/in.^{3}) at 21 °C (70 °F)

Volume change on freezing. 1.17% shrinkage

Thermal Properties

Liquidus temperature. 387 °C (728 °F)

Solidus temperature. 381 °C (718 °F)

Coefficient of linear thermal expansion. 27.4 μm/m · K (15.2 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 0.419 kJ/kg · K (0.10 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 113.0 W/m · K (784 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 27% IACS at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Solder with lead-tin solder over nickel-plated surface; acidulated zinc chloride flux. Oxyacetylene weld with alloy No. 3, no flux, soft flame. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 395 to 425 °C (740 to 800 °F)

Precautions in melting. Stir well after meltdown and alloy a 15-mm holding period. Skim surface dross.

Precautions in casting. Strict adherence to chemical composition limits and proper die design are necessary to ensure sound castings and high strength and ductility.

AC43A
Zn-4Al-2.5Cu-0.04Mg

Commercial Names

Trade name. No. 2 die casting alloy

Previous trade name. Zamak 2

Foreign. Mazak 2

Specifications

ASTM. B 86: alloy AC43A (die castings). B 240: alloy AC43A (ingot)

SAE. Alloy 921

UNS. Z35540 (ingot), Z35541 (castings)

Foreign. AFNOR-ZA4U3G; BS 1004; DIN-1743

Chemical Composition

Composition limits. ASTM B 86; 3.5 to 4.3 Al, 2.5 to 3.0 Cu, 0.020 to 0.05 Mg, 0.100 Fe max, 0.005 Pb max, 0.004 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking.

Applications

Typical uses. die castings such as automotive parts, household appliances and fixtures, office and computer equipment, building hardware

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 358 MPa (52.0 ksi); elongation, 7% in 50 mm (2 in.) gage length. Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Shear strength. 317 MPa (46.0 ksi)

Compressive strength. 641 MPa (93.0 ksi)

Hardness. 100 HB (500 kg load, 10 mm hardened steel ball, 30-s duration)

Impact strength. Charpy, unnotched 6.35 mm (0.25 in.) square bar: 47 J (35 ft · lbf). See Table 8.

Fatigue strength. Reverse bending, 59 MPa (8.50 ksi) at 5×10^8 cycles

Mass Characteristics

Density. 6.6 g/cm^3 (0.24 lb/in.^{3}) at 20 °C (70 °F)

Volume change on freezing. 1.25% shrinkage

Thermal Properties

Liquidus temperature. 390 °C (734 °F)

Solidus temperature. 379 °C (715 °F)

Coefficient of linear thermal expansion. 27.8 μm/m · K (15.4 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 0.419 kJ/kg · K (0.10 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 105.0 W/m · K (726 Btu/ft · in./ft^2 · h · °F

Electrical Properties

Electrical conductivity. 25% IACS at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Solder with lead-tin solder over nickel-plated surface; acidulated zinc chloride flux. Oxyacetylene weld with alloy No. 3, no flux soft flame. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 395 to 425 °C (740 to 800 °F)

Precautions in melting. Stir well after meltdown and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper die design are necessary to ensure sound castings and high strength and ductility.

ZA-8
Zn-8Al-1Cu-0.02Mg

Commercial Names

Trade name. ZA-8, zinc foundry alloy

Specifications

ASTM. B 791 (castings), B 669 (ingot)

UNS. Z35635 (ingot), Z35636 (castings)

Foreign. BS DD 139 (casting)

Chemical Composition

Composition limits. ASTM B 669 (ingot): 8.2 o 8.8 Al, 0.8 to 1.3 Cu, 0.020 to 0.030 Mg, 0.065 Fe max, 0.005 Pb max, 0.005 Cd max, 0.002 Sn max, bal Zn. ASTM B 791 (castings): 8.0 to 8.8 Al, 0.8 to 1.3 Cu, 0.015 to 0.030 Mg, 0.075 Fe max, 0.006 Pb max, 0.006 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking.

Applications

Typical uses. For pressure die castings and gravity castings, wherever high strength is required. Automobiles, general hardware, agricultural equipment, electronic and electrical fittings, domestic and garden appliances, computer hardware, business machines, recording machines, radios, and hand tools.

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 374 MPa (54.2 ksi); yield strength (0.2% offset), 290 MPa (42.1 ksi); elongation, 8% in 50 mm (2 in.) gage length. Permanent mold cast specimen, 12.7 mm (0.5 in.) in diameter: tensile strength, 240 MPa (34.8 ksi); yield strength (0.02% offset), 208 MPa (30.2 ksi); elongation, 1.3% in 50 mm (2 in.). Elastic modulus, all processes: 85.5 GPa (12.4×10^6 psi). Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Shear strength. Die cast, 275 MPa (39.9 ksi); permanent mold cast, 242 MPa (35.1 ksi)

Compressive strength. 0.1% offset: die cast, 252 MPa (36.5 ksi); permanent mold cast, 210 MPa (30.5 ksi)

Hardness. 500 kg load, 10 mm ball, 30-s duration: die cast, 103 HB; permanent mold cast, 87 HB

Impact strength. Charpy, unnotched: die cast 6.35 mm (0.25 in.) square bar, 42 J (31 ft · lbf); permanent mold cast 10.0 mm (0.394 in.) square bar, 20 J (15 ft · lbf). See Table 8.

Fracture toughness. Pressure die cast, 12.6 MPa $\sqrt{m}$ (11.5 ksi $\sqrt{in}$) at 24 °C (75 °F). See Table 9.

Fatigue strength. Reverse bending at 5×10^8 cycles: die cast, 103 MPa (15.0 ksi); permanent mold cast, 52 MPa (7.5 ksi)

Creep strength. Stress to give 1% secondary creep extension in 10^5 h, per ASME boiler code: 70 MPa (10.1 ksi) at 20 °C (68 °F). See Fig. 3.

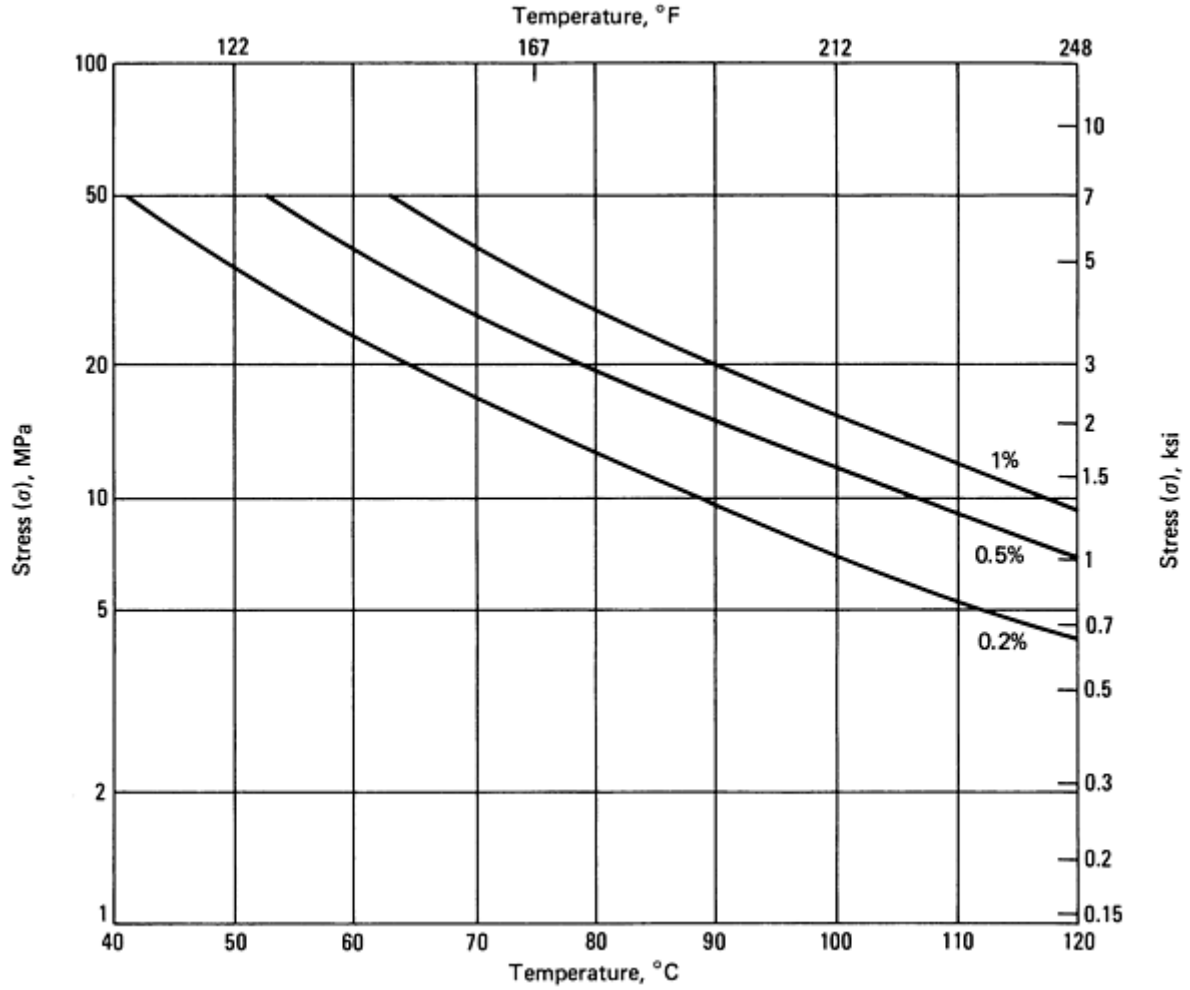

Fig. 3 Elongation of pressure die cast zinc alloy ZA-8 at various combinations of stress and temperature for a service life of 3 × 10^3 h. Source: AM&S Europe Ltd.

Mass Characteristics

Density. 6.30 g/cm^3 (0.227 lb/$in.^3$) at 21 °C (70 °F)

Volume change on freezing. 1% shrinkage

Thermal Properties

Liquidus temperature. 404 °C (759 °F)

Solidus temperature. 375 °C (707 °F)

Coefficient of linear thermal expansion. 23.2 μm/m · K (12.9 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Latent heat of fusion. 112 kJ/kg (48 Btu/lb)

Specific heat. 0.435 kJ/kg · K (0.104 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 115 W/m · K (795 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 27.7% IACS at 20 °C (68 °F)

Electrical resistivity. 6.2 μΩ· cm (2.44 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and hypoeutectic zinc-aluminum alloys and can be safely used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Other Properties

Damping. Q^{-1} ($\times 10^3$) at Hz: pressure die cast, 5.2 at 20 °C (68 °F), 8.8 at 100 °C (212 °F). See Table 9.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 435 to 460 °C (815 to 860 °F)

Precautions in melting. Stir well after meltdown and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper pattern or die design are necessary to ensure sound castings and high strength and ductility.

ZA-12
Zn-11Al-1Cu-0.025Mg

Commercial Names

Trade name. ZA-12, zinc foundry alloy

Previous trade name. ILZRO 12

Specifications

ASTM. B 791 (castings), B 669 (ingot)

UNS. Z35630 (ingot), Z35631 (castings)

Foreign. BS DD 139 (castings); SAA-AS1881

Chemical Composition

Composition limits. ASTM B 669 (ingot): 10.8 to 11.5 Al, 0.5 to 1.2 Cu, 0.020 to 0.030 Mg, 0.065 Fe max, 0.005 Pb max, 0.005 Cd max, 0.002 Sn max, bal Zn. ASTM B 791 (castings): 10.5 to 11.5 Al, 0.5 to 1.2 Cu, 0.015 to 0.030 Mg, 0.075 Fe max, 0.006 Pb max, 0.006 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking. High iron causes excessive tool wear.

Applications

Typical uses. For pressure die castings and gravity castings, wherever high strength is required. Automobiles, general hardware, agricultural equipment, electronic and electrical fittings, domestic and garden appliances, computer hardware, business machines, recording machines, radios, and hand tools. This alloy is used in bearings and bushings for high-load low-speed applications.

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 404 MPa (58.5 ksi); yield strength (0.2% offset), 320 MPa (46.4 ksi); elongation, 5% in 50 mm (2 in.) gage length. Permanent mold cast specimen, 12.7 mm (0.5 in.) in diameter: tensile strength, 328 MPa (47.5 ksi); yield strength (0.02% offset), 268 MPa (38.9 ksi); elongation, 2.2% in 50 mm (2 in.). Sand cast specimen, 12.7 mm (0.5 in.) in diameter: tensile strength, 299 MPa (43.4 ksi); elongation, 1.5% in 50 mm (2 in.). Elastic modulus, all processes: 82.7 GPa (12.0×10^6 psi). Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Shear strength. Die cast, 296 MPa (42.9 ksi); sand cast, 253 MPa (36.7 ksi)

Compressive strength. 0.1% offset: die cast, 269 MPa (39.0 ksi); permanent mold cast, 234 MPa (34.0 ksi); sand cast, 230 MPa (33.3 ksi)

Hardness. 500 kg load, 10 mm hardened steel ball, 30-s duration: die cast, 100 HB; permanent mold, 89 HB; sand cast, 94 HB

Impact strength. Charpy, unnotched. Die cast, 6.35 mm (0.25 in.) square bar: 29 J (21 ft · lbf); permanent mold, machined 10.0 mm (0.394 in.) square bar: 20 J (15 ft · lbf); sand cast, machined 10.0 mm (0.394 in.) square bar: 26 J (19 ft · lbf). See Table 8.

Fracture toughness. At 24 °C (75 °F): sand cast, 14.5 MPa $\sqrt{m}$ (13.2 ksi $\sqrt{in}$); pressure die cast, 14.4 MPa $\sqrt{m}$ (13.1 ksi $\sqrt{in}$). See Table 8.

Fatigue strength. Reverse bending at 5×10^8 cycles: die cast, 117 MPa (17.0 ksi); sand cast, 103 MPa (15.0 ksi)

Creep strength. Stress to give 1% secondary creep extension in 10^5 h, per ASME boiler code: 69 MPa (10.0 ksi) at 20 °C (68 °F)

Mass Characteristics

Density. 6.03 g/cm^3 (0.218 lb/in.^{3}) at 21 °C (70 °F)

Volume change on freezing. 1.3% shrinkage

Thermal Properties

Liquidus temperature. 432 °C (810 °F)

Solidus temperature. 377 °C (710 °F)

Coefficient of linear thermal expansion. 24.1 μm/m · K (13.4 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Latent heat of fusion. 118 kJ/kg (52 Btu/lb)

Specific heat. 0.450 kJ/kg · K (0.107 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 116 W/m · K (805 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 28.3% IACS at 20 °C (68 °F)

Electrical resistivity. 6.1 μΩ· cm (2.4 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and hypoeutectic zinc-aluminum alloys, and it can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Other Properties

Damping. Q^{-1} (× 10^3) at 100 Hz, pressure die cast: 5.1 at 20 °C (68 °F); 9.8 at 100 °C (212 °F). See Table 9.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Recommended casting temperature range. 460 to 490 °C (860 to 915 °F)

Precautions in melting. Stir well after meltdown and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper pattern or die design are necessary to ensure sound castings and high strength and ductility. Not recommended for hot chamber die casting unless shot end components and pot are made with special materials

---

ZA-27
Zn-27Al-2Cu-0.015Mg

Commercial Names

Trade name. ZA-27, zinc foundry alloy

Specifications

ASTM. B 791 (castings), B 669 (ingot)

UNS. Z35840 (ingot), Z35841 (castings)

Foreign. BS DD 139 (castings); SAA-AS1881

Chemical Composition

Composition limits. ASTM B 669 (ingot): 25.5 to 28.0 Al, 2.0 to 2.5 Cu, 0.012 to 0.020 Mg, 0.072 Fe max, 0.005 Pb max, 0.005 Cd max, 0.002 Sn max, bal Zn. ASTM B 791 (castings): 25.0 to 28.0 Al, 2.0 to 2.5 Cu, 0.01 to 0.02 Mg, 0.075 Fe max, 0.006 Pb max, 0.006 Cd max, 0.003 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes subject to intergranular corrosive attack and fails prematurely by warping and cracking. High iron causes excessive tool wear.

Applications

Typical uses. For pressure die castings and gravity castings, wherever very high strength is required. In automobile engine mounts and drive trains, general hardware, agricultural equipment, domestic and garden appliances, and heavy-duty hand and work tools. This

alloy is extensively used in bearings and bushings for high-load low-speed applications.

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 426 MPa (61.8 ksi); yield strength (0.2% offset), 371 MPa (53.8 ksi); elongation, 2.5% in 50 mm (2 in.) gage length. Permanent mold cast specimen, 12.7 mm (0.5 in.) in diameter: tensile strength, 424 MPa (61.5 ksi), elongation, 2% in 50 mm (2 in.). Sand cast specimen, 12.7 mm (0.5 in.) in diameter: tensile strength, 421 MPa (61.0 ksi); elongation, 4.5% in 50 mm (2 in.). Elastic modulus, all processes: 77.9 GPa (11.3 × 10^6 psi). Tensile and other mechanical properties are affected by operating temperature and time (see Table 8 and Fig. 1).

Shear strength. Die cast, 325 MPa (47.1 ksi); sand cast, 292 MPa (42.3 ksi)

Compressive strength. 0.1% offset: die cast, 359 MPa (52.1 ksi); sand cast, 330 MPa (47.8 ksi)

Hardness. 500 kg load, 10 mm hardened steel ball, 30-s duration: die cast, 119 HB; permanent mold, 113 HB; sand cast, 90 HB

Impact strength. Charpy, unnotched. Die cast, 6.35 mm (0.25 in.) square bar: 12 J (9 ft · lbf); sand cast, machined 10.0 mm (0.394 in.) square bar: 48 J (35 ft · lbf). See Table 8.

Fracture toughness. At 24 °C (75 °F): sand cast, 23.7 MPa $\sqrt{m}$ (21.6 ksi $\sqrt{in}$); pressure die cast, 20.2 MPa $\sqrt{m}$ (18.4 ksi $\sqrt{in}$). See Table 8.

Fatigue strength. Reverse bending at 5 × 10^8 cycles: die cast, 117 MPa (17.0 ksi); sand cast, 172 MPa (25.0 ksi)

Creep strength. Stress to give 1% secondary creep extension in 10^5 h, per ASME boiler code: pressure die cast, 69 MPa (10.0 ksi) at 20 °C (68 °F); sand cast, 76 MPa (11.0 ksi); sand cast and homogenized (320 °C, or 608 °F, furnace cooled), 95 MPa (13.8 ksi). See Fig. 4.

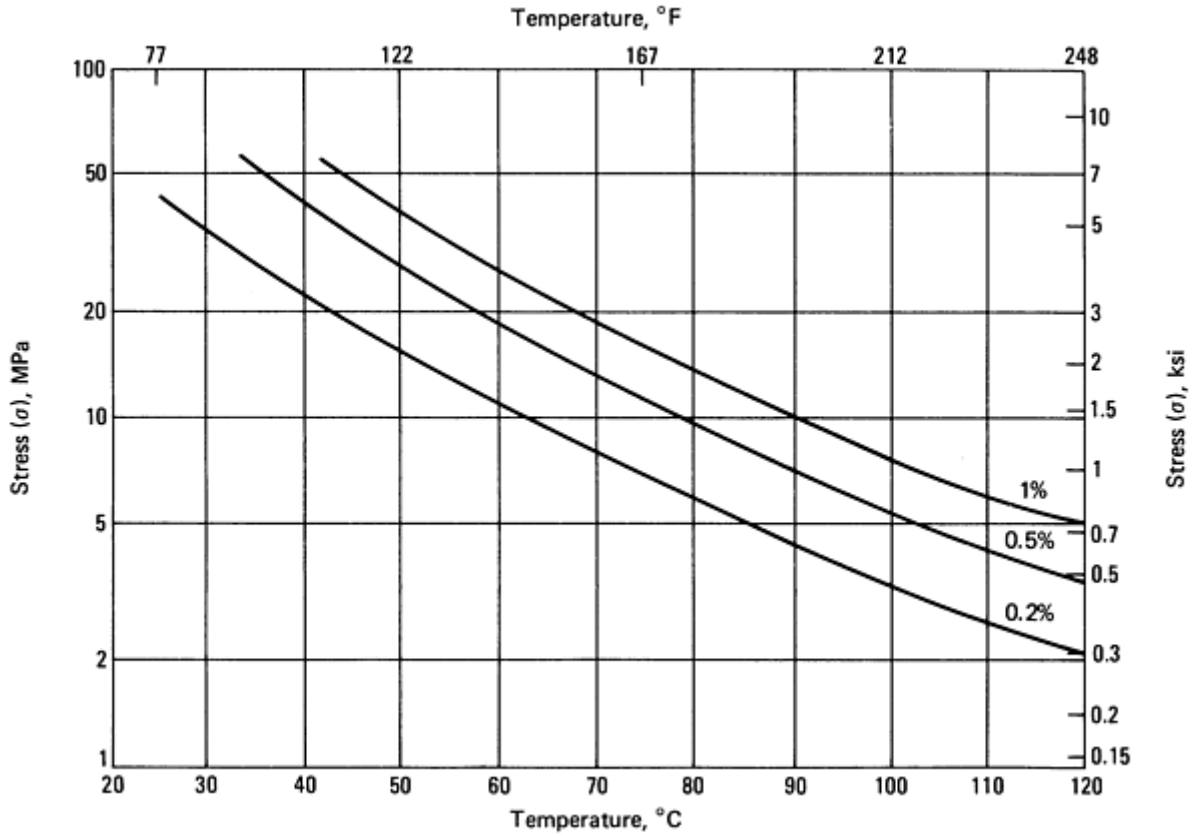

Fig. 4 Elongation of pressure die cast zinc alloy ZA-27 at various combinations of stress and temperature for a service life of 3 × 10^3 h. Source: AM&S Europe Ltd.

Mass Characteristics

Density. 5.00 g/cm^3 (0.181 lb/$in.^3$) at 21 °C (70 °F)

Volume change on freezing. 1.3% shrinkage

Thermal Properties

Liquidus temperature. 484 °C (903 °F)

Solidus temperature. 375 °C (708 °F)

Coefficient of linear thermal expansion. 26.0 μm/m · K (14.4 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Latent heat of fusion. 128 kJ/kg (55 Btu/lb)

Specific heat. 0.525 kJ/kg · K (0.125 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 125.5 W/m · K (870 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 29.7% IACS at 20 °C (68 °F)

Electrical resistivity. 5.8 μΩ· cm (2.3 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and hypoeutectic zinc-aluminum alloys, and it can safely be used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Other Properties

Damping. Q^{-1} (× 10^3) at 100 Hz: pressure die cast, 5.0 at 20 °C (68 °F); 10.9 at 100 °C (212 °F). See Table 9.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Recommended casting temperature range: 515 to 545 °C (960 to 1015 °F)

Precautions in melting. Stir well after meltdown and allow a 15-min holding period. Skim surface dross. Avoid high melt temperatures to prevent magnesium loss.

Precautions in casting. Strict adherence to chemical composition limits and proper pattern or die design are necessary to ensure sound castings and high strength and ductility. Alloy cannot be hot chamber cast without special shot end and pot materials.

ILZRO 16
Zn-1.25Cu-0.2Ti-0.15Cr

Commercial Names

Trade name. ILZRO 16

Chemical Composition

Composition limits. 1.0 to 1.5 Cu, 0.15 to 0.25 Ti, 0.10 to 0.20 Cr, 0.01 to 0.04 Al, 0.02 Mg max, 0.04 Fe max, 0.005 Pb max, 0.004 Cd max, 0.003 Sn max. bal Zn

Applications

Typical uses. Sustained high-load bearing components for elevated-temperature service

Mechanical Properties

Tensile properties. Die cast specimen, 6.35 mm (0.25 in.) in diameter: tensile strength, 230 MPa (33.5 ksi); yield strength (0.2% offset), 140 MPa (20.5 ksi); elongation, 6% in 50 mm (2 in.) gage length. Elastic modulus, 97.0 GPa (14.0 × 10^6 psi)

Hardness. 500 kg load, 10 mm hardened steel ball, 30-s duration: die cast, 76 HB; permanent mold, 113 HB; sand cast, 90 HB

Impact strength. Charpy, unnotched. Die cast, 6.35 mm (0.25 in.) square bar: 25 J (18 ft · lbf)

Creep strength. Stress to give 1% secondary creep extension in 10^3 h, per ASME boiler code: 95 MPa (13.8 ksi) at 20 ° C (68 °F), 28 MPa (4.0 ksi) at 100 °C (212 °F). See Fig. 5

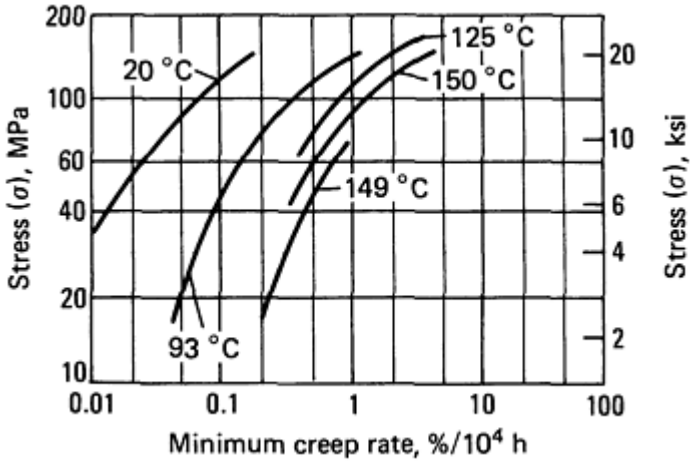

Fig. 5 Tensile creep properties of zinc alloy ILZRO 16 at various temperatures. (0.1%/10^4 h) = (1%/10^5 h). Source: *Engineering Properties of Zinc Alloys,* International Lead-Zinc Research Organization, 1989

Mass Characteristics

Density. 7.1 g/cm^3 (0.256 lb/in.^{3}) at 21 °C (70 °F)

Thermal Properties

Liquidus temperature. 416 °C (781 °F)

Solidus temperature. 418 °C (785 °F)

Coefficient of linear thermal expansion. 27.0 μm/m · K (15.0 μin./in. · °F) at 20 to 100 °C (68 to 212 °F)

Specific heat. 0.402 kJ/kg · K (0.096 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 104.7 W/m · K (726 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical resistivity. 8.4 μΩ· cm (3.3 μΩ· in.) at 20 °C (68 °F)

Fabrication Characteristics

Recommended casting temperature range. 460 to 470 °C (860 to 880 °F)

Precautions in melting. Use refractory crucibles. Stir well after meltdown.

Precautions in casting. Strict adherence to chemical composition limits and proper pattern or die design are necessary to ensure sound castings and high strength. Alloy cannot be hot chamber die cast without special shot end and pot materials.

Slush Casting Alloy Zn-4.75Al-0.25Cu

Commercial Names

Trade name. Slush casting Alloy A

Specifications

ASTM. B 792 (ingot)

UNS. Z34510 (ingot)

Chemical Composition

Composition limits. ASTM B 792 (ingot): 4.5 to 5.0 Al, 0.2 to 0.3 Cu, 0.10 Fe max, 0.007 Pb max, 0.005 Cd max, 0.005 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. For all slush and permanent mold castings, chiefly in the manufacture of lightning fixtures and statues

Mechanical Properties

Tensile properties. Chill cast specimen, 12.7 mm (0.50 in.) in diameter tensile strength, 193 MPa (28.0 ksi); elongation, 1.0% in 50 mm (2 in.) gage length

Impact strength. Charpy, unnotched: chill cast 6.35 mm (0.25 in.) square bar, 4 J (3.0 ft · lbf)

Thermal Properties

Liquidus temperature. Approximately 390 °C (734 °F)

Solidus temperature. 380 °C (716 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can be safely used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Precautions in casting. Avoid contamination with lead, tin, or cadmium.

Slush Casting Alloy Zn-4.75Al-0.25Cu

Commercial Names

Trade name. Slush casting Alloy A

Specifications

ASTM. B 792 (ingot)

UNS. Z34510 (ingot)

Chemical Composition

Composition limits. ASTM B 792 (ingot): 4.5 to 5.0 Al, 0.2 to 0.3 Cu, 0.10 Fe max, 0.007 Pb max, 0.005 Cd max, 0.005 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. For all slush and permanent mold castings, chiefly in the manufacture of lightning fixtures and statues

Mechanical Properties

Tensile properties. Chill cast specimen, 12.7 mm (0.50 in.) in diameter tensile strength, 193 MPa (28.0 ksi); elongation, 1.0% in 50 mm (2 in.) gage length

Impact strength. Charpy, unnotched: chill cast 6.35 mm (0.25 in.) square bar, 4 J (3.0 ft · lbf)

Thermal Properties

Liquidus temperature. Approximately 390 °C (734 °F)

Solidus temperature. 380 °C (716 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc and can be safely used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners, adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Precautions in casting. Avoid contamination with lead, tin, or cadmium.

Slush Casting Alloy
Zn-5.5Al

Commercial Names

Trade name. Slush casting Alloy B, unbreakable metal

Specifications

ASTM. B 792 (ingot)

UNS. Z30500 (ingot)

Chemical Composition

Composition limits. ASTM B 792 (ingot): 5.25 to 5.75 Al, 0.1 Cu max. 0.10 Fe max, 0.007 Pb max, 0.005 Cd max, 0.005 Sn max, bal Zn

Consequence of exceeding impurity limits. Alloys becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. For all slush and permanent mold castings, chiefly in the manufacture of lighting fixtures and statues

Mechanical Properties

Tensile properties. Chill cast specimen, 12.7 mm (0.50 in.) in diameter: tensile strength, 172 MPa (12.0 ksi); elongation, 1.0% in 50 mm (2 in.) gage length

Impact strength. Charpy, unnotched: chill cast 6.35 mm (0.25 in.) square bar, 1.4 J (1.0 ft · lbf)

Thermal Properties

Liquidus temperature. Approximately 395 °C (745 °F)

Solidus temperature. 380 °C (716 °F)

Chemical Properties

General corrosion behavior. This alloy has better resistance than pure zinc, and can be safety used wherever zinc, zinc-coated iron, or zinc-coated steel has been used successfully in the past.

Fabrication Characteristics

Joining. Mechanical fasteners adhesives, TIG or MIG welding. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Precautions in casting. Avoid contamination with lead, tin, or cadmium.

Commercial Rolled Zinc
Zn-0.08Pb

Commercial Names

Previous trade name. Deep-drawing zinc

Specifications

ASTM. B 69

UNS. Z21210

Chemical Composition

Composition limits. ASTM B 69: 0.10 Pb max, 0.012 Fw max, 0.005 CD max, 0.001 Cu max, 0.001 Al max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Generally drawn, formed, or spun articles requiring some rigidity, such as drawn battery cans and formed eyelets and grommets

Precautions in use. Deforms under light continuous load, particularly at elevated temperatures

Mechanical Properties

In wrought materials, properties often are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 134 MPa

(19.4 ksi) (longitudinal to 159 MPa (23.0 ksi) (transverse).

Tensile properties. Hot-rolled specimen: tensile strength, 134 to 159 MPa (19.5 to 23.0 ksi); elongation, 65 to 50%. Cold-rolled specimen: tensile strength, 145 to 186 MPa (21.0 to 27.0 ksi); elongation, 50 to 40%

Hardness. Hot-rolled, 42 HB

Fatigue strength. Rotating beam, hot-rolled strip: 17 MPa (2.5 ksi) at 10^8 cycles

Mass Characteristics

Density. 7.14 g/cm^3 (0.258 lb/in.^{3}) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 32.5 μm/m · K (18.05 μin./in. · °F) (longitudinal) to 23.0 μm/m · K (12.7 μin./in. · °F) (transverse).

Melting point. 419 °C (786 °F)

Coefficient of linear thermal expansion. 32.5 to 23 μm/m · K (18.05 to 12.7 μin./in.) · °F) at 20 to 40 °C (68 to 105 °F)

Specific heat. 0.395 kJ/kg · K (0.094 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 108 W/m · K (749 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 28.4% IACS at 20 °C (68 °F)

Electrical resistivity. 6.2 μΩ· cm (2.4 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to drawing, bending, roll forming, spinning, swaging, and impact extrusion

Precautions in forming. Keep temperature above 21 °C (70 °F). Use pure soapy water or noncorrosive mineral oil as lubricant.

Precautions in finishing. Air-dried coatings are preferred over baked finishes because many enamels must be baked at temperatures high enough to change the mechanical properties of the rolled zinc.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Hot-working temperature. 120 to 275 °C (250 to 525 °F). Hot shortness occurs at 300 to 420 to °C (570 to 785 °F).

Commercial Rolled Zinc
Zn-0.06Pb-0.06Cd

Specifications

ASTM. B 69

UNS. Z21220

Chemical Composition

Composition limits. ASTM B 69: 0.05 to 0.10 Pb, 0.012 Fe max, 0.05 to 0.08 Cd, 0.005 Cu max, 0.001 Al max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Generally drawn, formed, or spun articles requiring some rigidity, such as drawn battery cans and formed eyelets and grommets

Precautions in use. Deforms under light continuous load, particularly at elevated temperatures

Mechanical Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic

are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 150 MPa (21.8 ksi) (longitudinal) to 170 MPa (24.7 ksi) (transverse).

Tensile properties. Hot-rolled specimen: tensile strength, 145 to 173 MPa (21.0 to 25.0 ksi); elongation, 52 to 30%. Cold-rolled specimen: tensile strength, 152 to 201 MPa (22.0 to 29.0 ksi); elongation, 40 to 30%

Hardness. Hot rolled: 43 HB

Fatigue strength. Rotating beam, hot-rolled strip: 26 MPa (3.8 ksi) at 10^8 cycles

Shear strength. Approximately 124 to 138 MPa (18.0 to 20.0 ksi)

Mass Characteristics

Density. 7.14 g/cm^3 (0.258 lb/in.^{3}) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 32.5 μm/m · K (18.1 μin./in. · °F) (longitudinal) to 23.0 μm/m · K (12.7 μin./in. · °F) (transverse).

Melting point. 419 °C (786 °F)

Coefficient of linear thermal expansion. 32.5 to 23 μm/m · K (18.05 to 12.7 μin./in. · °F) at 20 to 40 °C (68 to 105 °F)

Specific heat. 0.395 kJ/kg · K (0.094 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 108 W/m · K (749 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 32% IACS at 20 °C (68 °F)

Electrical resistivity. 6.06 μΩ· cm (2.4 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to drawing, bending, roll forming, spinning, swaging, and impact extrusion

Precautions in forming. Keep temperature above 21 °C (70 °F). Use pure soapy water or noncorrosive mineral oil as lubricant.

Precautions in finishing. Air-dried coatings are preferred over baked finishes because many enamels must be baked at temperatures high enough to change the mechanical properties of the rolled zinc.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Hot-working temperature. 120 to 275 °C (250 to 525 °F). Hot shortness occurs at 300 to 420 °C (570 to 785 °F).

Copper-Hardened Rolled Zinc
Zn-1.0Cu

Specifications

ASTM. B 69

UNS. Z44330

Chemical Composition

Composition limits. ASTM B 69: 0.85 to 1.25 Cu, 0.10 Pb max, 0.012 Fe max, 0.005 Cd max, 0.001 Al max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Weather stripping, nameplates, ferrules, and drawn, formed, or spun articles requiring stiffness

Precautions in use. Deforms under heavy continuous load, particularly at elevated temperatures

Mechanical Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 170 MPa (24.7 ksi) (longitudinal to 210 MPa (30.5 ksi) (transverse).

Tensile properties. Hot-rolled specimen: tensile strength, 170 to 210 MPa (24.7 to 30.5 ksi); elongation, 50 to 35%. Cold-rolled specimen: tensile strength, 210 to 280 MPa (30.5 to 40.6 ksi); elongation, 40 to 25%

Hardness. Hot rolled, 52 HB; cold rolled, 60 HB

Fatigue strength. Rotating beam, hot-rolled strip: 28 MPa (4.1 ksi) at 10^8 cycles

Shear strength. 138 to 152 MPa (20.0 to 22.0 ksi)

Mass Characteristics

Density. 7.17 g/cm^3 (0.259 lb/in.^{3}) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 32.5 μm/m · K (18.1 μin./in · °F) (longitudinal) to 23.0 μm/m · K (12.9 μin./in · °F) (transverse).

Liquidus temperature. 422 °C (792 °F)

Solidus temperature. 419 °C (786 °F)

Coefficient of linear thermal expansion. 34.7 to 21.1 μm/m · K (19.3 to 11.7 μin./in. · °F) at 20 to 40 °C (68 to 105 °F)

Specific heat 0.402 kJ/kg · K (0.096 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 104.7 W/m · K (726 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. Approximately 28% IACS at 20 °C (68 °F)

Electrical resistivity. Approximately 6.2 μΩ· cm (2.45 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to drawing, bending, roll forming, spinning, and swaging

Precautions in forming. Keep temperature above 21 °C (70 °F). Use pure soapy water or noncorrosive mineral oil as lubricant.

Precautions in finishing. Air-dried coatings are preferred over baked finishes because many enamels must be baked at temperatures high enough to change the mechanical properties of the rolled zinc.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Hot-working temperature. 175 to 300 °C (345 to 570 °F). Hot shortness occurs at 300 to 420 °C (570 to 785 °F).

Rolled Zinc Alloy Zn-1.0Cu-0.010 Mg

Specifications

ASTM. B 69

UNS. Z45330

Chemical Composition

Composition limits. ASTM B 69: 0.85 to 1.25 Cu, 0.006 to 0.016 Mg, 0.15 Pb max, 0.012 Fe max, 0.04 Cd max 0.001 Al max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Corrugated roofing and flat, drawn, or mildly formed articles requiring maximum stiffness

Precautions in use. Deforms under heavy continuous load, particularly at elevated temperatures

Mechanical Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 200 MPa (29.0 ksi) (longitudinal) to 276 MPa (40.0 ksi) (transverse).

Tensile properties. Hot-rolled specimen: tensile strength, 200 to 276 MPa (29.0 to 40.0 ksi); elongation, 20 to 10%. Cold-rolled specimen: tensile strength, 248 to 317 MPa (36.0 to 46.0 ksi); elongation, 25 to 10%

Hardness. Hot rolled, 61 HB; cold rolled, 80 HB

Fatigue strength. Rotating beam, hot-rolled strip: 47 MPa (6.8 ksi) at 10^8 cycles

Mass Characteristics

Density. 7.17 g/cm^3 (0.259 lb/in.^{3}) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 34.8 μm/m · K (19.3 μin./in. · °F) (longitudinal) to 21.1 μm/m · K (11.7 μin./in. · °F) (transverse).

Liquidus temperature. 422 °C (792 °F)

Solidus temperature. 419 °C (786 °F)

Coefficient of linear thermal expansion. 34.8 to 21.1 μm/m · K (19.3 to 11.7 μin./in. · °F) at 20 to 40 °C (68 to 105 °F)

Specific heat. 0.401 kJ/kg · K (0.096 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 105 W/m · K (728 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. Approximately 27% IACS at 20 °C (68 °F)

Electrical resistivity. Approximately 63 μΩ· cm (2.5 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloys has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to drawing, bending, and roll forming

Precautions in forming. Keep temperature above 21 °C (70 °F). Use pure soapy water or noncorrosive mineral oil as lubricant.

Precautions in finishing. Air-dried coatings are preferred over baked finishes because many enamels must be baked at temperatures high enough to change the mechanical properties of the rolled zinc.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Annealing temperature. 175 °C (345 °F)

Hot-working temperature. 175 to 300 °C (345 to 570 °F). Hot shortness occurs at 300 to 420 °C (570 to 785 °F).

Zn-Cu-Ti Alloy
Zn-0.8Cu-0.15Ti

Specifications

ASTM. B 69

UNS. Z41320

Chemical Composition

Composition limits. ASTM B 69: 0.50 to 1.50 Cu, 0.12 to 0.50 Ti, 0.10 Pb max, 0.012 Fe max, 0.05 Cd max, 0.001 Al max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular

corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Corrugated roofing, leaders and gutters, and formed articles requiring maximum creep resistance

Precautions in use. Creep resistance decreases with increasing temperature of use. Should be heat treated after cold working for maximum creep resistance

Mechanical Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 221 MPa (32.0 ksi) (longitudinal) to 290 MPa (42.0 ksi) (transverse).

Tensile properties. Hot-rolled specimen: tensile strength, 221 to 290 MPa (32.0 to 42.0 ksi); yield strength (0.2% offset), 125 to 177 MPa (18.1 to 25.7 ksi); elastic modulus, 63.5 to 88.0 GPa (9.2 to 12.8 × 10^6 psi); elongation, 38 to 21%. Cold-rolled specimen: tensile strength, 200 to 260 MPa (29.0 to 37.7 ksi); elongation, 60 to 44%

Shear strength. 138 to 152 MPa (20.0 to 22.0 ksi)

Hardness. Hot rolled, 61 HB; cold rolled, 80 HB

Fatigue strength. Rotating beam, hot-rolled strip: 47 MPa (6.8 ksi) at 10^8 cycles

Mass Characteristics

Density. 7.17 g/cm^3 (0.259 lb/$in.^3$) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 24.0 μm/m · K (13.3 μin/in. · °F) (longitudinal) to 19.4 μm/m · K (10.8 μin./in. · °F) (transverse).

Liquidus temperature. 422 °C (792 °F)

Solidus temperature. 419 °C (786 °F)

Coefficient of linear thermal expansion. 24.0 to 19.4 μm/m · K (13.3 to 10.8 μin./in. · °F) at 20 to 40 °C (68 to 105 °F)

Specific heat. 0.402 kJ/kg · K (0.096 Btu/lb · °F) at 20 to 100 °C (68 to 212 °F)

Thermal conductivity. 105 W/m · K (727 Btu · in./ft^2 · h · °F)

Electrical Properties

Electrical conductivity. 27% IACS at 20 °C (68 °F)

Electrical resistivity. 6.24 μΩ· cm (2.5 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to drawing, bending, and roll forming

Precautions in forming. Keep temperature above 21 °C (70 °F). Use pure soapy water or noncorrosive mineral oil as lubricant.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Annealing temperature. High creep resistance can be restored after cold working by annealing for 45 min at 250 °C (480 °F).

Hot-working temperature. 150 to 300 °C (300 to 570 °F). Hot shortness occurs at 300 to 420 °C (570 to 785 °F).

Superplastic Zinc
Zn-22Al

Commercial Names

Trade names. Super Z300, Formetal 22 Alloy, Korloy 2684

Chemical Composition

Composition limits. 21 to 23 Al, 0.40 to 0.60 Cu, 0.008 to 0.012 Mg, 0.01 Pb max, 0.002 Fe max, 0.01 Cd max, 0.001 Sn max, bal Zn

Consequence of exceeding impurity limits. Iron or cadmium increases hardness and reduces ductility. Alloy becomes hot short, subject to intergranular corrosive attack, and fails prematurely by warping and cracking.

Applications

Typical uses. Supplied as sheet for thermal forming. Especially useful for low-volume applications where tooling costs must be kept low. Used for electronic enclosures, cabinets and panels, business machine parts, and medical and other laboratory instruments and tools

Precautions in use. Subject to creep if highly stressed, particularly at elevated temperature

Mechanical Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, tensile strength, 310 MPa (45.0 ksi) (longitudinal) to 380 MPa (55.1 ksi) (transverse).

Tensile properties. As-rolled: tensile strength, 310 to 380 MPa (45.0 to 55.0 ksi); yield strength (0.2% offset), 255 to 297 MPa 37.0 to 43.0 ksi); elongation, 27 to 25%. Annealed at 315 °C (600 °F), air cooled: tensile strength, 400 to 441 MPa (58 to 64.0 ksi); yield strength (0.2% offset), 352 to 386 MPa (51.0 to 56.0 ksi); elongation, 11 to 9 %. Elastic modulus, 68 to 93 GPa (9.9 to 13.5 × 10^6 psi)

Hardness. As-rolled. 70 to 79 HRB; annealed, 84 to 85 HRB

Creep strength. Stress for 1% extension in 10^5 h at 20 °C (68 °F): as-rolled, 20 to 25 MPa (3.0 to 3.6 ksi); annealed, 40 to 69 MPa (5.8 to 10.0 ksi)

Impact strength. Rolled and annealed: 9.5 to 27 J (7 to 20 ft · lbf) at 20 °C (68 °F), depending on direction of testing

Damping. Q^{-1} (× 10^3) at 100 Hz: cold rolled, 7.8 at 20 °C (68 °F); 27.8 at 100 °C (212 °F). See Table 9.

Mass Characteristics

Density. 5.20 g/cm^3 (0.188 lb/$in.^3$) at 21 °C (70 °F)

Thermal Properties

Some properties are anisotropic (dependent on direction). Those properties that are strongly anisotropic are given in longitudinal and transverse direction (relative to rolling direction), respectively; for example, coefficient of thermal expansion, 22.0 μm/m · K (12.2 μin/in. · °F) (longitudinal) to 21.5 μm/m · K (11.9 μin./in. · °F) (transverse).

Coefficient of linear thermal expansion. At 20 to 40 °C (68 to 105 °F). As-rolled, 22.0 to 21.5 μm/m · K (12.2 to 11.9 μin./in. · °F); annealed, 26.6 to 26.8 μm/m · K (14.8 to 14.9 μin./in. · °F)

Electrical Properties

Electrical conductivity. At 20 °C (68 °F). As rolled, 32% IACS; annealed, 28% IACS

Electrical resistivity. 6.0 μΩ· cm (2.4 μΩ· in.) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. This alloy has excellent resistance to atmospheric corrosion.

Fabrication Characteristics

Forming methods. Suited to deep drawing, compressing molding, bending, stretch forming, and roll forming

Hot-working temperature. 250 to 270 °C (480 to 520 °F)

Annealing temperature. When superplastic zinc is reheated to above 275 °C (527 °F) and slowly cooled to room temperature, the superplastic properties disappear.

Joining. Mechanical fasteners, adhesives. Lead-tin or zinc-cadmium soft solder. Resistance welding pulsation technique can be used.

Lead and Lead Alloys

Revised by Anthony W. Worcester and John T. O'Reilly, The Doe Run Company

Introduction

LEAD was one of the first metals known to man. Probably the oldest lead artifact is a figure made about 3000 BC, which was found in the temple of Osiris near Abydos. All civilizations, beginning with the ancient Egyptians, Assyrians, and Babylonians, have used lead for many ornamental and structural purposes. Many magnificent buildings erected in the 15th and 16th centuries still stand under their original lead roofs.

Pipe was one of the earliest applications of lead. The Romans produced 15 standard sizes of water pipe in regular 3 m (10 ft) lengths. In the old Roman baths at Bath, England, the lead pipe installed by the Romans 1900 years ago is still in use. The Romans made their pipe by folding heavy sheets of cast lead and fusing the seams together. Presently, battery applications constitute more than 80% of lead alloy use.

Lead Processing

Sources of Lead. Although there are at least 60 known lead-containing minerals, by far the most important as a source of primary lead is galena (PbS). Recycling of scrap lead (from batteries, lead sheet, and cable sheathing) is also a major source, providing more than half of the lead used in the United States. Antimonial lead, soft lead, and lead-calcium alloys are produced from recycled lead. Considerable tonnages of scrap solder and bearing metals are recovered and used again. Lead recycling is discussed in more detail in the section "Recycling of Lead" in the article "Recycling of Nonferrous Alloys" in this Volume.

Galena is generally associated with substantial amounts of zinc and copper minerals and is not normally mined independently. Whenever possible, galena is separated from other minerals through comminution followed by differential flotation. Sometimes, however, the mineral particles are so small and so tightly locked together that separation by flotation is not efficient. In such instances, bulk concentrates containing lead, zinc, and copper are produced. These concentrates are then separated by the Imperial Smelting Process or at the facilities of an integrated polymetallic smelter.

The major lead mining centers of the world are, in alphabetical order, Australia, Canada, Mexico, Peru, the Soviet Union, and the United States. Total annual world production of lead from ores is about 3.5×10^6 Mg (3.8×10^6 tons).

Smelting and Refining. Concentrates leaving the flotation mills contain at least 40% Pb; they generally contain about 70%. The concentrates are sintered to remove sulfur, convert the lead to oxides, and agglomerate the fine flotation product, which is not physically desirable in a blast furnace. The roasted sinter is charged into the top of a blast furnace along with suitable fluxes and coke; the resulting impure lead-base bullion, containing copper, silver, gold, and various impurities, is shipped to the refinery for further treatment before the metal is suitable for industrial use.

In the initial refining, copper is removed by cooling the bullion and the addition of sulfur (or sulfur in combination with pyrite) to the molten furnace bullion (usually in the smelter). The resulting copper-rich drosses are re-treated in a reverberatory furnace to produce a high-copper matte, which is further treated elsewhere to recover the copper.

In the next step, antimony, tin, and arsenic are removed, usually by the Harris process. In this process, additions of sodium hydroxide and sodium nitrate react with the antimony, tin, and arsenic to form sodium salts, which are then removed and treated to recover the metals. Alternatively, the antimony, tin, and arsenic can be oxidized by air and/or oxygen blowing (usually in a continuous softener reverberatory furnace) and later recovered from the resulting oxide dross or slag.

Precious metals are removed next. In the Parkes process, zinc is added to form intermetallic compounds with the precious metals. These compounds are skimmed from the molten bullion and further processed to recover the gold and silver. Residual zinc generally is removed by the vacuum dezincing process. In electrolytic practice, the drossed lead bullion is cast into anodes, which are placed in electrolytic cells. Lead dissolves from the anode and is deposited on the cathode. Precious metals, along with antimony, arsenic, tin, bismuth, and other nonferrous elements, remain on the anode as a slimy residue. This residue is further treated to recover its metallic values.

Bismuth, if present, can be removed either by electrolytic refining or by the Betterton-Kroll process, in which a calcium-magnesium alloy is added to the molten lead. The calcium and magnesium selectively react with the bismuth to form a floating intermetallic dross.

The purity of commercial lead refined by these processes varies with ore composition and processing conditions. Final purification, using caustic or nitre, attains a purity of greater than or equal to 99.99%. Pig lead generally is cast into bars weighing roughly 30 to 45 kg (60 to 100 lb), although blocks weighing about 900 kg (1 ton) have become increasingly popular in recent years, particularly among large users.

Compositions and Grades

Table 1 lists the United Numbering System (UNS) designations for various pure lead grades and lead-base alloys. The designations are grouped according to general nominal chemical contents.

Table 1 UNS categories and nominal compositions of various lead grades and lead-base alloys

Lead alloy type[(a)]	**UNS designations**
Pure leads (UNS L50000-L50099)	
Zone-refined lead (99.9999% Pb min)	L50001
Refined soft lead (99.999% Pb min)	L50005
Refined soft lead (99.99% Pb min)	L50011, L50012, L50013, L50014
Corroding lead (99.94% Pb min)	L50042
Common lead (99.94% Pb min)	L50045
Lead-silver alloys (UNS L50100-L50199)	
Cable-sheathing alloy (0.2% Ag, 99.8% Pb)	L50101
Electrowinning alloys (0.5-1.0% Ag, 99.5-99% Pb)	L50110, L50115, L50120
Electrowinning alloy (1.0% Ag, 1.0% As, 98% Pb)	L50122
Cathodic protection anode alloy (2.0% Ag, 98% Pb)	L50140
Solder alloys (1.0-1.5% Ag, 1.0 Sn, bal Pb)	L50121, L50131
Solder alloys (1.5-2.5% Ag, with no tin)	L50132, L50150, L50151
Solder alloy (1.5% Ag, 5.0% Sn, 93.5% Pb)	L50134

Solder alloy (2.5% Ag, 2.0% Sn, 95.5% Pb)	L50152
Solder alloy (5.0% Ag, 95% Pb)	L50170
Solder alloys (5.0% Ag, with 5% Sn or 5% In)	L50171, L50172
Solder alloy (5.5% Ag)	L50180
Lead-arsenic alloys (UNS L50300-L50399)	
Arsenical lead cable-sheathing alloy (0.15% As, 0.10% Bi, 0.10% Sn, 99.6% Pb)	L50310
Lead-barium alloys (UNS L50500-L50599)	
Lead-barium alloy (0.05% Ba, 99.9% Pb)	L50510
Lead-tin-barium alloys (0.05-0.10% Ba, 1.0-2.0% Sn, 97.9-99% Pb)	L50520-L50522, L50530, L50535
Frary metal (0.4-1.2% Ba, 0.5-0.8% Ca, 97.2-98.8% Pb)	L50540-L50543
Lead-calcium alloys (UNS L50700-L50899)	
Lead-calcium alloys (99.9% Pb, 0.008-0.03% Ca)	L50710, L50720
Cable-sheathing alloys (0.025% Ca, 99.7-99.9% Pb, 0.0-0.025% Sn)	L50712, L50713
Lead-copper-calcium alloy (99.9% Pb, 0.06% Cu, 0.03% Ca)	L50722
Electrowinning anode alloy (0.5% Ag, 99.4% Pb, 0.05% Ca)	L50730
Battery grid alloy (99.9% Pb, 0.06% Ca)	L50735
Battery grid alloys (0.065% Ca, 0.2-1.5% Sn, 99.7-98.4% Pb)	L50736, L50737, L50740, L50745, L50750, L50755
Battery grid alloys (0.07% Ca, 0.0-0.7% Sn, 99.2-99.9% Pb)	L50760, L50765
Battery grid alloys (0.10% Ca, 0.0-1.0% Sn, 98.9-99.9% Pb)	L50770, L50775, L50780, L50790
Battery grid alloys (0.12% Ca, 0.3% Sn, 99.6% Pb)	L50795, L50800
Bearing metal (0.02% Al, 0.04% Li, 0.7% Ca, 0.6% Na, 98.7% Pb)	L50810

Lead-strontium alloy (2% Sr, 98% Pb)	L55290

(a) Unless otherwise specified as a minimum (min) or balance (bal), the listed compositions represent nominal values (or the range of nominal values when several alloy designations are grouped together).

(b) See Table 3 for compositions of specific lead-antimony alloys.

(c) See Table 4 for compositions of specific lead-tin alloys.

Grades of Lead. Composition limits of the four grades of pig lead covered in ASTM B 29 (1979) are given in Table 2. These grades are pure lead (also called corroding lead) and common lead (both containing 99.94% min lead), and chemical lead and acid-copper lead (both containing 99.90% min lead). Lead of higher specified purity (99.99%) is also available in commercial quantities.

Table 2 ASTM B 29 present and proposed pig lead composition specifications

Lead type	Composition, %[a]									
	Ag	Bi	Cd	Cu	Fe	Ni	Pb	Te	Zn	Other
Pure lead (UNS L50042)[b]										
Present specification	0.0015[c]	0.050	NR	0.0015[c]	0.002	NR	99.94	NR	0.001	[d]

							min			
Proposed specification	0.0025	0.030 or 0.025	0.0010	0.0010	0.001 or NR	0.0002	99.96	0.00005	0.0005	(e)
Common lead (UNS L50045)[(f)]										
Present specification	0.005	0.05[(g)]	NR	0.0015	0.002	NR	99.94 min	NR	0.001	(d)
Proposed specification	0.005	0.05	0.001	0.0015	0.002 or NR	0.001	99.94 min	. . .	0.001	(h)
Chemical lead[(i)] (UNS L51120)	0.002-0.020	0.005	NR	0.040-0.080	0.002	NR	99.90 min	NR	0.001	(d)
Acid-copper lead[(j)] (UNS L51121)	0.002	0.025	NR	0.40-0.080	0.002	NR	99.90 min	NR	0.001	(d)

(a) Compositions are maximums unless a range or minimum (min) is specified; by agreement between the purchaser and the supplier, analyses may be required and limits established for elements (or compounds) not specified here. NR, not required.

(b) Corroding lead is a designation used in the trade to describe lead that has been refined to a high degree of purity.

(c) Silver plus copper, 0.0025% max total.

(d) Arsenic plus antimony plus tin, 0.002% max total.

(e) Arsenic, antimony, and tin each at 0.0005% max.

(f) Common lead is fully refined desilverized lead.

(g) By agreement between the purchaser and the supplier, bismuth levels up to 0.150% may be allowed.

(h) Arsenic, antimony, and tin each at 0.001% max.

(i) Chemical lead designates the undesilverized lead produced from southeastern Missouri ores.

(j) Copper-bearing lead is made by adding copper to fully refined lead.

Specifications other than ASTM B 29 for grades of pig lead include federal specification QQ-L-171, German standard DIN 1719, British specification BS 334, Canadian Standard CSA-HP2, and Australian Standard 1812.

Corroding Lead. Most lead produced in the United States is pure (or corroding) lead (99.94% min Pb). Corroding lead, which exhibits the outstanding corrosion resistance typical of lead and its alloys, is namednot for a characteristic of the metal but rather for a process in which it was formerly used. Corroding lead is used in making pigments, lead oxides, and a wide variety of other lead chemicals. The required high purity is necessary to avoid problems, such as unwanted colors in white lead pigment, caused by impurities during and after processing.

Chemical Lead. Refined lead with a residual copper content of 0.04 to 0.08% and a residual silver content of 0.002 to 0.02% is particularly desirable in the chemical industries and thus is called chemical lead. Most chemical lead produced in the United States is refined from the lead ores of southeastern Missouri, which contain small amounts of copper and silver. The copper content significantly improves corrosion resistance and mechanical strength, making chemical lead the next most frequently used gradeafter corroding lead. The silver content also improves corrosion resistance in some applications.

Copper-bearing lead provides corrosion protection comparable to that of chemical lead in most applications that require high corrosion resistance. This grade is made by adding copper to fully refined lead. It differs from chemical lead primarily in its higher allowed bismuth content.

Common lead, which contains higher amounts of silver and bismuth than does corroding lead, is used for battery oxide and general alloying.

Lead-Base Alloys. Because lead is very soft and ductile, it is normally used commercially as lead alloys. Antimony, tin, arsenic, and calcium are the most common alloying elements.

Antimony generally is used to give greater hardness and strength, as in storage battery grids; sheet, pipe, and castings. Antimony contents of lead-antimony alloys can range from 0.5 to 25%, but they are usually 2 to 5%. Table 3 lists the compositions of various lead-antimony alloys.

(a) Nominal compositions unless otherwise specified. bal, balance.

Within the past decade, lead-calcium alloys have replaced lead-antimony alloys in a number of applications, in particular, storage battery grids and casting applications. These alloys contain 0.03 to 0.15% Ca (see, for example, some of the lead-calcium alloys in Table 1). More recently, aluminum has been added to calcium-lead and calcium-tin-lead alloys as a stabilizer for calcium.

Adding tin to lead or lead alloys increases hardness and strength, but lead-tin alloys are more commonly used for their good melting, casting, and wetting properties, as in type metals and solders. Tin gives the alloy the ability to wet and bond with metals such as steel and copper; unalloyed lead has poor wetting characteristics. Tin combined with lead and bismuth or cadmium forms the principal ingredient of many low-melting alloys. Table 4 lists the compositions of various lead-tin alloys.

1. *Properties of Lead and Lead Alloys,* Lead Industries Association, 1984

Properties of Lead

The properties of lead that make it useful in a wide variety of applications are density, malleability, lubricity, flexibility, electrical conductivity, and coefficient of thermal expansion, all of which are quite high; and elastic modulus, elastic limit, strength, hardness, and melting point, all of which are quite low. Lead also has good resistance to corrosion under a wide variety of conditions. Lead is easily alloyed with many other metals and casts with little difficulty.

Pouring temperature and rate of cooling markedly influence the microstructures and properties of lead alloys. High pouring temperatures and low cooling rates, such as those that result from the use of overly hot molds, promote segregation and the formation of a coarse structure. A coarse structure can cause brittleness, low compressive strength, and low hardness.

Density. The high density of lead (11.35 g/cm^3, at room temperature) makes it very effective in shielding against x-rays and gamma radiation (Fig. 1). In very large installations, it is often used for lining concrete structures to greatly reduce the thickness of concrete that otherwise would be required.

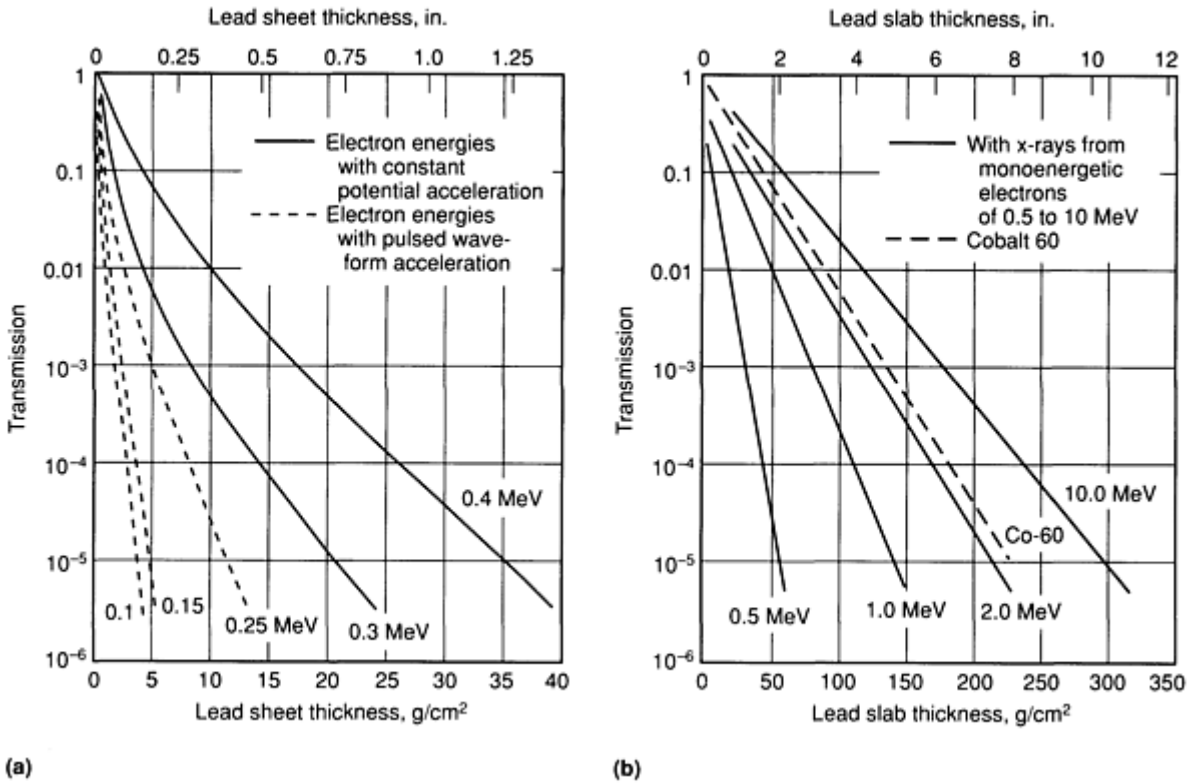

Fig. 1 Broad-beam transmission of x-rays through (a) lead sheet and (b) lead slab. The energy designations (in MeV) on each curve refer to the energy of electrons impinging upon a thick x-ray producing target. The curves represent transmission as a dose-equivalent index ratio, and the bottom scale indicates the required mass thickness (g/cm^2), which is useful in selecting a material when weight is a factor. Transmission of cobalt-60 gamma rays is included for comparison. Source: Adapted from Ref 2

The combination of high density, high limpness (low stiffness), and high damping capacity (Fig. 2) makes lead an excellent material for deadening sound and for isolating equipment and structures from mechanical vibrations.

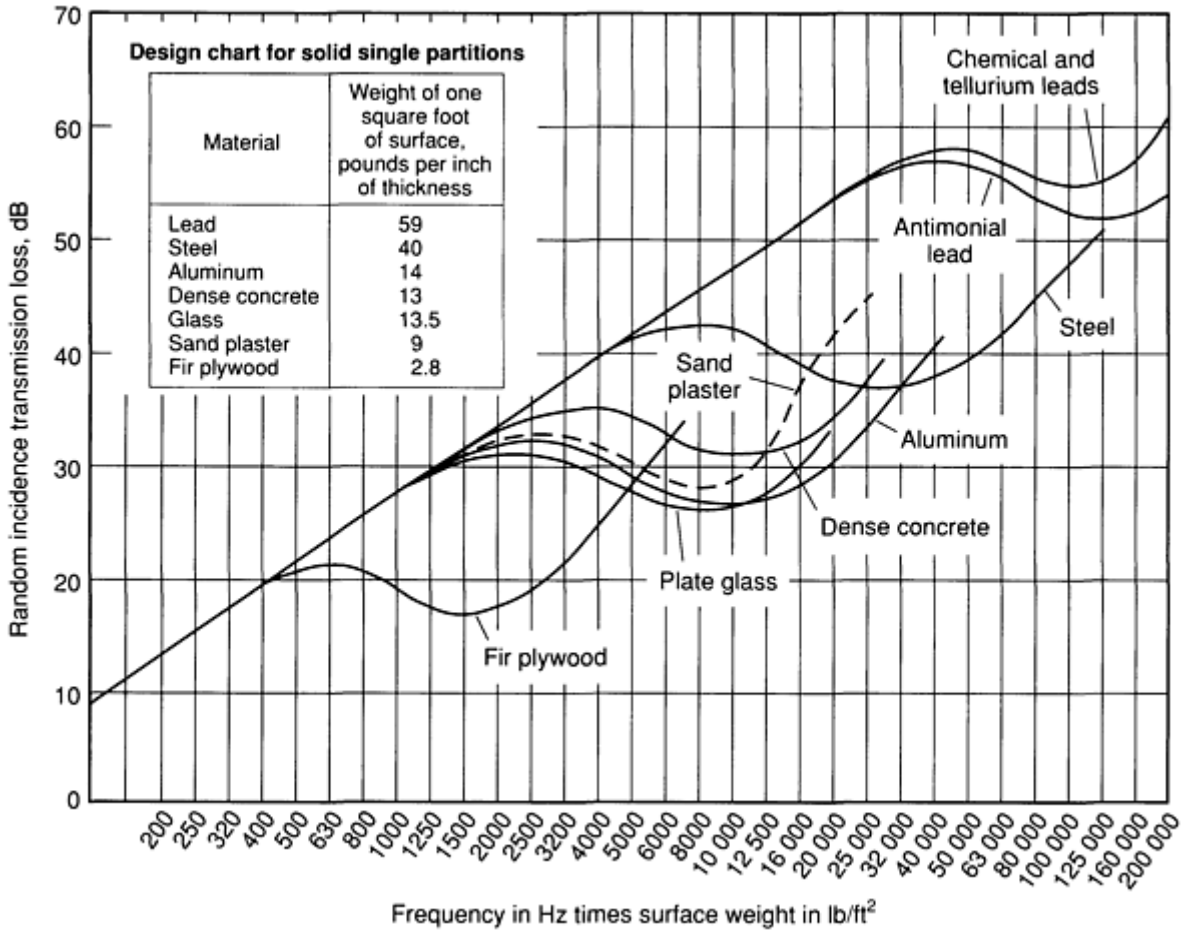

Fig. 2 Damping capacity of lead compared with that of other materials. Source: Ref 3

Because of its high density, lead generally is excluded from use in applications where light weight is important. However, even when light weight is desirable, the high density of lead sometimes can be used to advantage. For example, the use of lead in aircraft counterweights often reduces the total weight, because the high density of lead allows more mass to be concentrated at the point of greatest effect. In addition, lead has a low melting point and is relatively easy to cast; thus it is possible to fit lead weights into irregular and out-of-the-way spaces.

Malleability, softness, and lubricity are three related properties that account for the extensive use of lead in many applications. For example, high malleability is largely responsible for the use of lead as a caulking material, enabling it to fill caulked joints completely. The softness and self-lubricating properties of lead account in substantial part for its use in bearing alloys, gaskets, and washers. As a coating on wire or sheet metal, lead acts as a drawing lubricant, and in the form of powder, it imparts lubricity of antiseize compounds and engine bearings. The malleability of lead is used to greatest advantage in the manufacture of foil; lead foil often is rolled as thin as 0.01 mm (0.0005 in.).

On the other hand, the softness of lead requires that care be taken in designing for many applications. For example, excessive stream velocity in lead pipes can result in severe erosion if proper precautions are not taken in system design.

Strength. The low tensile strength (Table 5) and low creep strength (Table 6) of lead must always be considered when designing lead components. The principal limitation on the use of lead as a structural material is not its low tensile strength but its susceptibility to creep. Lead continuously deforms at low stresses (Fig. 3), and this deformation ultimately results in failure at stresses far below the ultimate tensile strength.

Table 5 Typical room-temperature tensile properties of selected lead alloys

UNS designation	Typical product forms or name	Condition	Tensile strength		Yield strength at 0.2% offset		Elongation, %[(a)]	Hardness

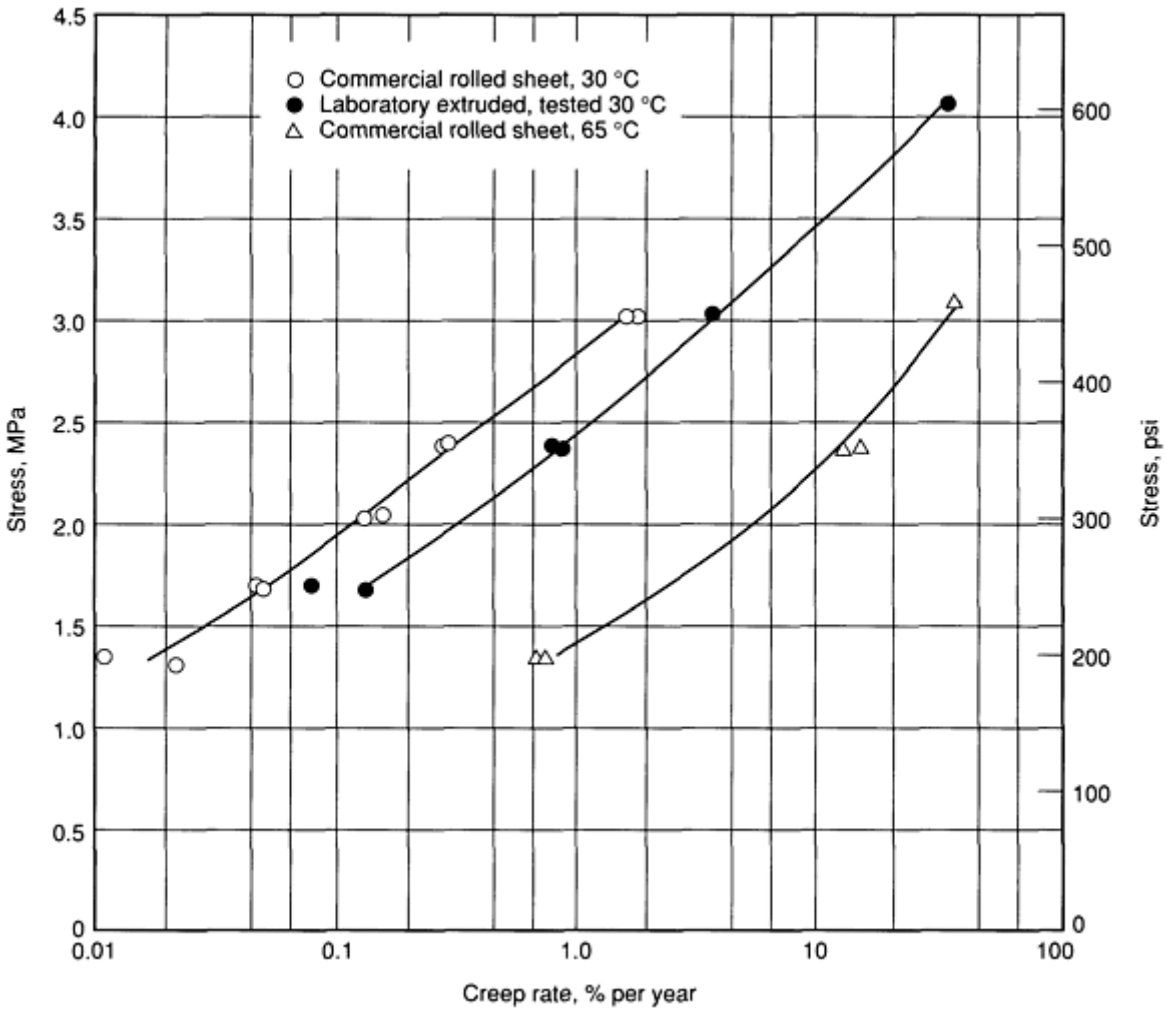

Fig. 3 Creep rate of chemical lead (+99.90% Pb). Test specimens were 19 by 32 mm ($\frac{3}{4}$ by $\frac{1}{8}$ in.) with a 250 mm (10 in.) gage length. Length of specimen parallel to the direction of rolling or extrusion

The low strength of lead does not necessarily preclude its use. Lead products can be designed to be self-supporting, or inserts or supports of other materials can be provided. Alloying with other metals, notably calcium or antimony, is a common method of strengthening lead for many applications. In general, consideration should always be given to supporting lead structures by lead-covered steel straps. When lead is used as a lining in a structure made of a stronger material, the lining can be supported by bonding it to the structure. With the development of improved bonding and adhesive techniques, composites of lead with other materials can be made. Composites have improved strength yet also retain the desirable properties of lead.

Thermal Expansion. The relatively high coefficient of thermal expansion of lead (29.3 μm/m/K, or 16.3 μin./in./°F, for pure lead) is another important design parameter. In lead roofing and flashing, thermal expansion must always be considered. It is provided for by using small sheets and loose-locking each sheet to the next, thus minimizing both individual and cumulative expansion. In pipelines subject to wide variations in temperature, allowance must be made for free expansion. The excellent flexibility of lead can be used to advantage in designing such systems.

Fatigue Properties. Because lead and lead-base alloys are susceptible to creep even at room temperature, the fatigue properties of lead-base alloys can be affected by creep-fatigue interaction. The effect of creep on fatigue life is manifested by frequency effects (Fig. 4). Lower cyclic frequencies are associated with a reduction in fatigue life.

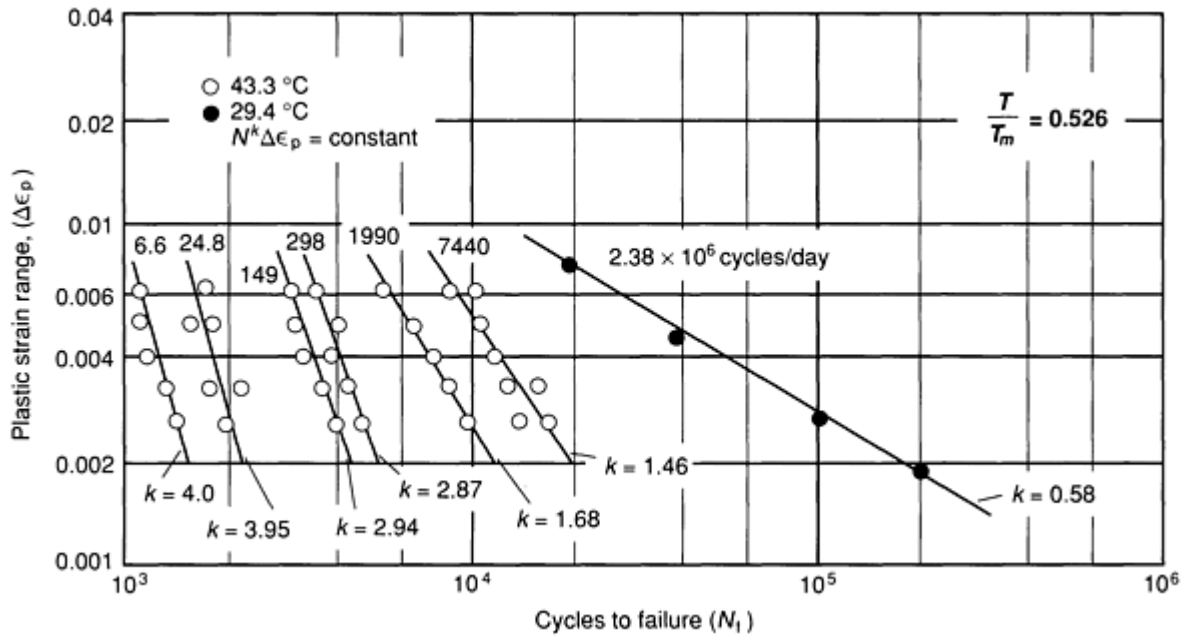

Fig. 4 Effect of frequency of cycling on the low-cycle fatigue behavior of lead

Stress limits for a fatigue life of 10^7 cycles generally range from about 3 MPa (0.435 ksi) for corroding lead (UNS L50042) to about 30 MPa (4.35 ksi) for lead babbitt (ASTM B 23, 1983) in the chill cast condition. Typical fatigue strengths in bending for two cable-sheathing lead alloys are shown in Fig. 5.

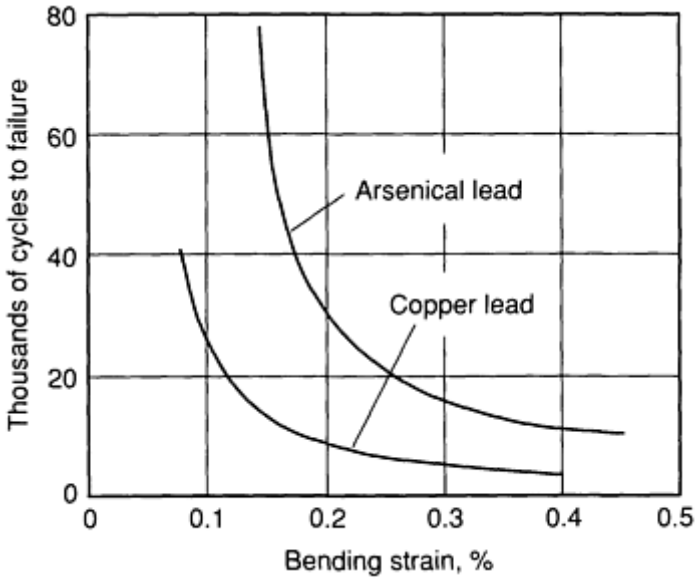

Fig. 5 Fatigue strengths of two cable-sheathing lead alloys in bending. Bending was at 25 °C (77 °F), one cycle per minute.

Corrosion Resistance. Lead is highly resistant to corrosion by the atmosphere, by waters, and by a wide range of chemicals in common use. Where resistance to corrosion must be combined with long service life, the limitations imposed by the mechanical properties of lead must be carefully considered in the final design. A general description of the resistance of chemical lead to specific corroding agents is given in Table 7. For a detailed description of the corrosion resistance of lead and lead alloys, see the article "Corrosion of Lead and Lead Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Table 7 Resistance of chemical lead to specific corroding agents

Corrosive agent	Resistance
Acetone	Resistant
Acetylene	Resistant
Acid, acetic[(a)]	Moderate general attack
Acid chromic	Resistant
Acid, citric	Moderate general attack
Acid, hydrochloric[(b)]	Moderate general attack
Acid, hydrofluoric	Resistant
Acids, mixed[(c)]	Resistant

Acid, nitric[d]	Severe general attack
Acid, phosphoric[e]	Resistant
Acid, sulfuric[f]	Resistant
Acid, sulfurous	Resistant
Acid, tartaric	Moderate general attack
Air	Resistant
Alcohol, ethyl	Resistant
Alcohol, methyl	Resistant
Aluminum sulfate	Resistant
Ammonia[g]	Resistant
Ammonium azide	Resistant
Ammonium chloride[h]	Resistant
Ammonium hydroxide	Resistant
Ammonium phosphate	Resistant
Benzol	Resistant
Bromine[i]	Resistant
Carbon dioxide	Resistant
Carbon tetrachloride[j]	Resistant
Chlorine[k]	Resistant
Dyestuffs	Generally Resistant
Formaldehyde	Moderate general attack

Magnesium chloride	Severe general attack
Magnesium sulfate	Resistant
Motor fuel	Resistant
Nickel sulfate	Resistant
Oxygen	Resistant
Phenols	Resistant
Photographic solutions	Generally resistant
Sodium carbonate	Resistant
Sodium chloride[l]	Resistant
Sodium hydroxide[m]	Resistant
Sodium sulfate[n]	Resistant
Sulfur dioxide[o]	Resistant
Water, chlorinated	Resistant
Water, sea	Resistant

(a) Used to handle acetic anhydride and glacial acetic acid.

(b) Use generally not recommended.

(c) At ordinary temperatures with 30% H_2O.

(d) Used at normal temperatures above 80% concentration.

(e) Up to 80% concentration at 200 °C (390 °F).

(f) Up to 96% concentration at room temperature, or 85% concentration at 220 °C (430 °F).

(g) Unless sodium or potassium is dissolved in it.

(h) Up to 10% concentration at ordinary temperatures.

(i) When cold and free from acid.

(j) At ordinary temperatures.

(k) Moist to 110 °C (230 °F), or dry.

(l) Dilute solutions at ordinary temperatures.

(m) Up to 26% concentration and 80 °C (175 °F).

(n) Up to 10% concentration boiling.

(o) Moist up to 200 °C (390 °F), or dry

Extrusion Characteristics. Lead and lead-base alloys exhibit high ductility and are easy to extrude. The addition of alloying elements increases the force required for extruding, but the process is carried out with little difficulty using billets heated to a maximum temperature of about 230 °C (450 °F). Principal applications include pipes, wire, tubes, munitions, and sheathing for cable. Molten lead is used in continuous extruders for cable sheathing and hose curing. Vertical extrusion presses are sometimes used to produce protective sheathings of lead on electrical conductors. Arsenical lead used for sheathing (UNS L50310) has a typical extrusion temperature of about 200 to 230 °C (400 to 450 °F).

Casting temperatures for various lead alloys are:

- 420 to 445 °C (790 to 830 °F) for chemical lead (UNS L51120)
- 400 °C (750 °F) for arsenical lead (UNS L50310)
- 425 to 500 °C (800 to 930 °F) for 1% Sb lead (UNS L52605), 4% Sb lead (UNS L52901), 6% Sb lead (UNS L53105), and 8% Sb lead (UNS L53230)
- 325 to 400 °C (617 to 750 °F) for lead babbitt alloys 7 and 13 in ASTM B 23 (UNS alloys L53581 and L53346, respectively)
- 480 to 540 °C (900 to 1000 °F) for lead babbitt alloy 15 in ASTM B 23 (UNS L53620)
- 340 to 425 °C (645 to 800 °F) for lead babbitt alloy 8 in ASTM B 23 (UNS L53565)

The recrystallization temperature for lead is below 0 °C (32 °F).

Products and Applications

The most significant applications of lead and lead alloys are lead-acid storage batteries (in the grid plates, posts, and connector straps), ammunition, cable sheathing, and building construction materials (such as sheet, pipe, solder, and wool for caulking). Other important applications include counterweights, battery clamps and other cast products such as: bearings, ballast, gaskets, type metal, terneplate, and foil. Lead in various forms and combinations is finding increased application as a material for controlling sound and mechanical vibrations. Also, in many forms it is important as shielding against x-rays and, in the nuclear industry, gamma rays. In addition, lead is used as an alloying element in steel and in copper alloys to improve machinability and other characteristics, and it is used in fusible (low-melting) alloys for fire sprinkler systems.

Although most lead is used in metallic form, substantial amounts are used in the form of lead compounds. These include tetraethyl and tetramethyl lead (used as antiknock compounds in gasoline), litharge (PbO), and various corrosion-inhibiting lead pigments such as red lead (Pb_3O_4), lead chromates, lead silicochromates, and lead silicates. Litharge is used in paste mixtures for grid plates of lead-acid storage batteries, in cements, glasses, and ceramics, and as a starting material for preparation of many other lead compounds.

Red lead has long been one of the most important rust-inhibiting pigments used in primers and undercoats for the protection of steel structures. Commercially important white corrosion-inhibiting pigments are basic lead carbonate, dibasic lead phosphite, dibasic lead phosphosilicate, and basic lead silicate. The most important colored pigments are tribasic lead chromosilicate, basic lead silicochromate, and normal lead silicochromate. The color of tribasic lead chromosilicate varies from red to orange, whereas the color of lead silicochromate is generally yellow. Lead silicochromate is used in yellow paint for marking pavement.

Battery Grids. The largest use of lead is in the manufacture of lead-acid storage batteries. These batteries consist of a series of grid plates made from either cast or wrought calcium lead or antimonial lead that is pasted with a mixture of lead oxides and immersed in sulfuric acid.

The length of the active life of a battery depends on the resistance of the lead alloy grids to corrosion under repeated cycling (charge and discharge) in the sulfuric acid. Automotive positive battery plates are usually made from antimony-lead alloys containing 1.5 to 3% antimony and other elements such as tin, arsenic, copper, sulfur, and selenium. Other automotive battery grids are made from lead-calcium-tin-aluminum alloys. The exact composition used varies with the manufacturer. Table 8 lists some typical compositions of lead alloys used for battery applications. Hybrid automotive batteries are made from 1 to 2% Sb-Pb alloys for the positive grid and lead-calcium alloys (0.04 to 0.15% Ca) for the negative grid. Battery grid alloys may also include 0.1 to 0.8% Sn (Table 8). In addition, some lead-calcium alloys contain 0.01 to 0.03% Al. Industrial batteries usually are made from alloys containing 5 to 8% Sb and various other elements. For all of these alloys, long battery life requires close control of impurities. Large standby stationary batteries can be made with grids of relatively pure lead of special design. This type of battery normally contains lead calcium.

Type metals, a class of metals used in the printing industry, generally consist of lead-antimony and tin alloys. Small amounts of copper are added to increase hardness for some applications. Compositions of type metals in present commercial use are given in Table 9. The lead base provides low cost, a low melting point, and ease of casting--properties that are desirable for all type metals. Additions of antimony harden the alloy, make it more resistant to compressive impact and wear, lower the casting temperature, and minimize contraction during freezing. Tin adds fluidity, improves castability, reduces brittleness, and imparts a finer structure--a characteristic that helps type reproduce fine detail.

Electrotype metal contains the lowest percentages of tin and antimony (see Table 9) because it is used as a backing metal only and is not required to resist wear. Unlike electrotype metal, stereotype metal ordinarily is used directly for printing; therefore, it must be harder and more wear resistant than electrotype metal, necessitating higher contents of tin and antimony. For greater resistance to wear, stereotypes can be lightly electroplated with chromium or nickel.

Linotype, or slug-casting metal, is used for high-speed composition of newspaper type. For this purpose, a low melting point and short temperature range during solidification are of greatest importance. The ternary eutectic alloy containing 84% Pb, 4% Sn, and 12% Sb, or an alloy of similar composition, is favored for linotype.

Like linotype metal, monotype metal is machine die cast. In monotype casting, only one type character is cast at a time. A rapid cooling rate is therefore possible, permitting the use of harder alloys of higher melting range than can be used for linotype metal, which is die cast an entire line at a time.

Foundry type metal is used exclusively to cast type for hand composition. The cast type is used over and over again instead of being melted before reuse, as is the case for other type metals. If not used to print directly, foundry type metal is subjected to heavy pressure in forming molds for electrotypes, stereotypes, and other duplicate plates. Such service requires the hardest,most wear-resistant alloy that is practical to use. Small additions of copper as a hardener are feasible for foundry type.

Because type metals other than foundry type are remelted and recast repeatedly, there is always a possibility of contamination by unwanted metals, as well as by oxide and dross formed during the melting and handling of the molten metal. Copper, zinc, nickel, aluminum, and arsenic are the principal metallic impurities that can impair the castability of type metals. Iron is also present in very small amounts, principally because of the action of molten tin on the steel equipment used in melting and casting. Iron usually is not considered a harmful impurity, except that it increases the amount of dross.

Cable Sheathing. Lead sheathing extruded around electrical power and communication cables gives the most durable protection against moisture and corrosion damage, and provides mechanical protection of the insulation. Chemical lead, 1% antimonial lead, and arsenical lead are most commonly employed for this purpose. The additional stiffness imparted to lead by antimony is advantageous for overhead cables. The additional resistance to bending and creep imparted by arsenic is desirable in applications involving severe vibration. Lead alloyed with 0.03% Ca or with tellurium has also been used with satisfactory results.

Lead-sheathed cables used underground or under water are usually protected against mechanical damage to the sheathing. Sheathing on underground cable generally is protected from contact with the ground by wood, cement, clay, or fiber. Where scoring of the sheathing or a severely corrosive environment is likely to be encountered, a polyethylene or neoprene jacket is applied over the lead. Underwater lead-sheathed cables are protected with asphalt-impregnated jute and galvanized steel wire.

Sheet. Lead sheet is a construction material of major importance in chemical and related industries because lead resists attack by a wide range of chemicals (for example, see Table 7, which describes the corrosion properties of chemical lead). Lead sheet is also used in building construction for roofing and flashing, shower pans, flooring, x-ray and gamma-ray protection, and vibration damping and soundproofing. Sheet for use in chemical industries and building construction is made from either pure lead or 6% antimonial lead. Calcium-lead and calcium-lead-tin alloys are also suitable for many of these applications.

Lead sheet is rolled in widths up to 3.6 m (11 $\frac{3}{4}$ ft) and in any thickness desired. Thickness often is designated by weight per unit area; lead weighs approximately 5 kg/m^2 (1 lb/ft^2) for each 0.4 mm ($\frac{1}{64}$ in.) of thickness. This approximation, however, should be used with care for thicknesses exceeding 6 mm ($\frac{1}{4}$ in.); lead sheet 13 mm ($\frac{1}{2}$ in.) thick weighs 145 kg/m^2 (30 lb/ft^2).

Roofing and flashing for general purposes are made of 3 lb lead sheet 1.2 mm ($\frac{3}{64}$ in.) thick. Flashing installed in contact with fresh cement, mortar, or concrete should be coated with black asphalt.

Pans placed beneath the concrete flooring of shower and bath stalls are made of at least 4 lb lead sheet. They should be coated on both sides with asphalt or covered with tar paper. As flooring, lead sheet offers a corrosion-resistant surface; it also is non-sparking, which is required for some specialized applications. Because of its excellent absorption characteristics, lead sheet is widely used as radiation shielding for medical and industrial installations.

Lead sheet is used in many applications where its vibration-damping characteristics are advantageous. For example, vibration-damping pads of lead sheet and steel are placed under the column footings of buildings to prevent the transmission of underground vibrations, such as those that originate from subway and railroad trains. The lead serves as a moistureproof envelope in addition to absorbing vibration. Hangers for rigid pipes often are lined with lead, which acts as

a vibration and movement absorber. The soundproof abilities of lead sheet are discussed in the section "Sound Control Materials" in this article.

Pipe. Seamless pipe made from lead and lead alloys is readily fabricated by extrusion. Because of its corrosion resistance and flexibility, lead pipe finds many uses in the chemical industry and in plumbing and water distribution systems. Pipe for these applications is made from either chemical lead or 6% antimonial lead. Sizes range from fine tubing to pipes 300 mm (12 in.) or more in diameter, with almost any wall thickness.

In the chemical industry, horizontal runs of exposed lead pipe are usually supported continuously in troughs or sheet metal shells. Unbounded lead-lined steel pipe can sometimes be used as a simple solution to the problem of pipe support. Lengths of pipe can also be fabricated with welded-on lead hanger bars; hanger hooks can be attached through the hanger bars. Vertical runs are supported at intervals of approximately 460 mm (18 in.). Lengths of pipe are joined by welding or by bolting through welded-on flanges. Expansion bends are provided for pipe that will operate at elevated or fluctuating temperatures.

Heating and cooling coils are important uses of lead pipe in the chemical industry. They usually are in the form of helixes or return-bend banks of coils. Lead spacer supports are welded between turns at about 460 mm (18 in.) intervals.

For lead pipe used in the chemical industry, the appropriate wall thickness depends on operating pressures and allowances for corrosion and abrasion. Pipe 40 mm ($1\frac{1}{2}$ in.) in diameter with 13 mm ($\frac{1}{2}$ in.) walls is commonly used with steam pressures up to 310 kPa (45 psi). For nonpressure service, pipes up to 50 mm (2 in.) in diameter are usually no lighter than the class known as B or M weight, and the minimum wall thickness of larger pipes generally is 6 mm ($\frac{1}{4}$ in.). For pressurized lead pipe, safe working pressure is calculated using the formula:

$$P = \frac{2st}{D}$$

where P is the working pressure, S is the maximum allowable fiber stress, t is the wall thickness, and D is the inside diameter of the pipe. For chemical lead, the maximum allowable fiber stress ranges from 1400 kPa (200 psi) at room temperature to 550 kPa (80 psi) at 150 °C (300 °F). Proper design of steam lines allows for condensate drainage, thus eliminating water hammer damage.

When optimum strength is essential, lead-lined steel pipe can be used, or coils can be made of copper tubing completely covered with an adherent layer of lead.

Lead pipes and traps have had a long history of use in water and waste service because of the excellent corrosion resistance of lead and its ability to adjust to ground settlement without damage. Joints in service pipes have been successfully made by wiping, by welding, by cupping and soldering, and through the use of compression-type couplings. Service pipe should be laid with goosenecks to allow for settlement, and a cast iron sleeve should be provided where the pipe passes through foundation walls. Where electrolysis, free lime, or cinder fill is encountered, lead pipe should be suitably protected.

Solders in the tin-lead system are the most widely used of all joining materials. The low melting range of tin-lead solders (Fig. 6) makes them ideal for joining most metals by convenient heating methods with little or no damage to heat-sensitive parts. Tin-lead solder alloys can be obtained with melting temperatures as low as 182 °C (360 °F) and as high as 315 °C (600 °F). Except for the pure metals and the eutectic solder with 63% Sn and 37% Pb, all tin-lead solder alloys melt within a temperature range that varies according to the alloy composition.

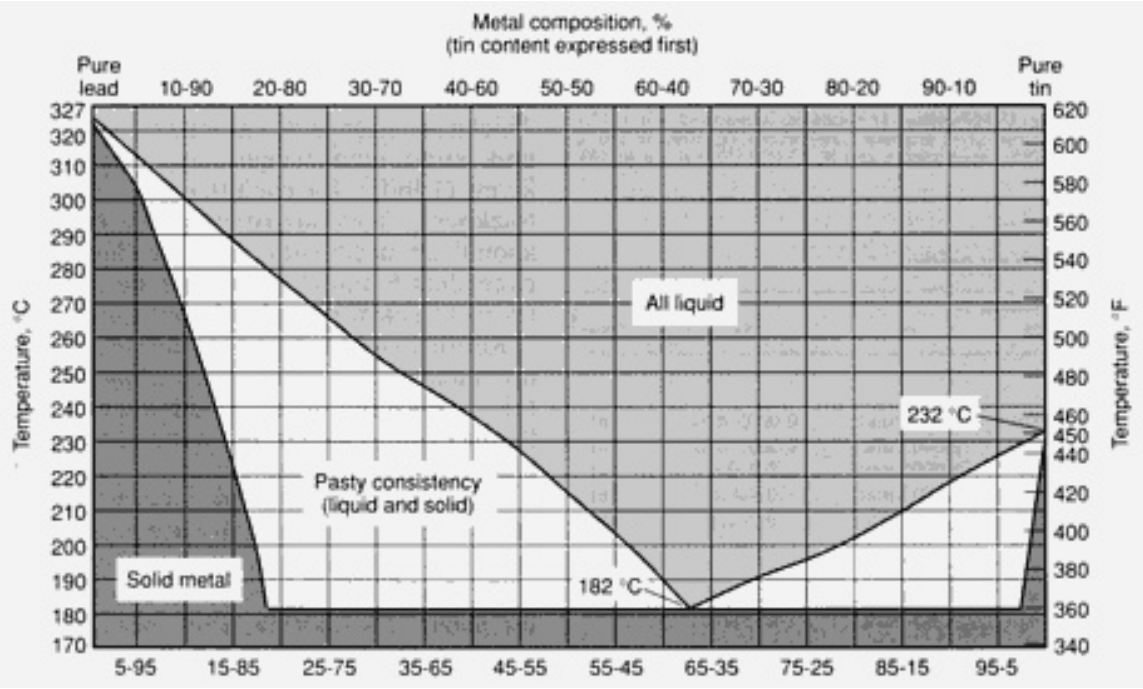

Fig. 6 Tin-lead phase diagram. Source: Lead Industries Association, Inc.

Industrial solder alloys include a wide variety of material combinations, from 100% Pb to 100% Sn, as demanded by the particular application. Table 10 gives the melting characteristics of some common tin-lead solders and their typical applications. The solders containing less than 5% Sn are used for sealing precoated containers, for coating and joining metals, and for applications where the service temperatures exceed 120 °C (250 °F). At those temperatures, the solder functions primarily as a seal. The 10/90, 15/85, and 20/80 solders are used for sealing cellular automobile radiators and for filling seams and dents in automobile bodies. The general-purpose solders are 40/60 and 50/50. They typically are used for soldering automobile radiator cores; electrical, and electronic connections; and roofing seams and heating units. Plumber's wiping solder used to be used on water pipe but is no longer permitted, for health reasons.

Table 10 Tin-lead solders

Composition, %		Solidus temperature		Liquidus temperature		Pasty range		Uses
Tin	Lead	°C	°F	°C	°F	Δ°C	Δ°F	
2	98	316	601	322	611	6	10	Side seams for can manufacturing
5	95	305	581	312	594	7	13	Coating and joining metals
10	90	268	514	302	576	34	62	Sealing cellular automobile radiators, filling seams or dents
15	85	227	440	288	550	61	110	Sealing cellular automobile radiators, filling seams or dents
20	80	183	361	277	531	94	170	Coating and joining metals, or filling dents or seams in automobile bodies

25	75	183	361	266	511	83	150	Machine and torch soldering
30	70	183	361	255	491	72	130	
35	65	183	361	247	477	64	116	General-purpose and wiping solder
40	60	183	361	238	460	55	99	Wiping solder for joining lead pipes and cable sheaths; also for automobile radiator cores and heating units
45	55	183	361	227	441	44	80	Automobile radiator cores and roofing seams
50	50	183	361	216	421	33	60	Most popular general-purpose solder
60	40	183	361	190	374	7	13	Primarily for electronic soldering applications where low soldering temperatures are required
63	37	183	361	183	361	0	0	Lowest-melting (eutectic) solder for electronic applications

Other solders contain additional alloy additions, such as antimony or silver. For the electronics industry, silver is added to tin-lead solders to reduce the dissolution of silver from silver alloy coatings. Silver can also be added to improve creep resistance. Tin-silver-lead alloys exhibit good tensile, creep, and shear strengths. Some are used for higher-temperature bonds in sequential soldering operations. Fatigue properties are increased by the addition of silver to the solder. Lead solder with 1% Sn and 1.5% Ag is used in cryogenic equipment because it does not embrittle at low temperatures.

Lead-base bearing alloys, which are called lead-base babbitt metals, vary widely in composition but can be categorized into two group:

- Alloys of lead, tin, antimony, and, in many instances, arsenic
- Alloys of lead, calcium, tin, and one or more of the alkaline earth metals

Many alloys of the first group have been used for centuries as type metals. They most likely were chosen for use as bearing materials because of the properties they were known to possess. The advantages of arsenic additions in this type of bearing alloy have been generally recognized since 1938. Alloys of the second type were developed early in the 20th century.

Pouring temperature and rate of cooling markedly influence the microstructures and properties of lead alloys, particularly when they are used in the form of heavy liners for railway journals. High pouring temperatures and low cooling rates, such as those that result from the use of overly hot mandrels, promote segregation and the formation of a coarse structure. A coarse structure can cause brittleness, low compressive strength, and low hardness. Therefore, low pouring temperatures (325 to 345 °C, or 620 to 650 °F) are usually recommended. Because these alloys remain relatively fluid almost to the point of complete solidification (about 240 °C, or 465 °F, for most compositions), they are easy to manipulate and can be handled with no great loss of metal from the formation of dross.

Typical compositions of lead-base bearing alloys covered by ASTM specifications, and the corresponding SAE, designations, are listed in Table 11 along with compositions of selected proprietary alloys. Additional information on the mechanical properties of some of these alloys is given in Table 12.

Table 11 Nominal compositions of lead-base babbitt alloys

(a) The compression test specimens were cylinders 38 mm (1.5 in.) long × 13 mm (0.5 in.) in diameter that were machined from chill castings 50 mm (2 in.) long × 19 mm (0.75 in.) in diameter.

(b) Values were taken from stress-strain curves at a deformation of 0.125% reduction of gage length.

(c) Values were taken as the unit load necessary to produce a deformation of 25% of the length of the specimen.

(d) Test were made on the bottom face of parallel-machined specimens that had been cast at room temperature in a steel mold. 50 mm (2 in.) in diameter × 16 mm (0.625 in.) deep. Values listed are the averages of three impressions on each alloy, using a 10 mm ball and applying a 500 kg load for 30 s.

In the absence of arsenic, the microstructures of these alloys comprise cuboid primary crystals of SbSn or of antimony embedded in a ternary mixture of Pb-Sb-SbSn in which lead forms the matrix. The number of these cuboids per unit volume of alloy increases as antimony content increases. If antimony content is more than about 15%, the total amount of the hard constituents increases to such an extent that the alloys become too brittle to be useful as bearing materials.

Arsenic is added to lead babbits to improve their mechanical properties, particularly at elevated temperatures. All lead babbitts are subject to softening or loss of strength during prolonged exposure to the temperatures (95 to 150 °C, 200 to 300 °F) at which they serve as bearings in internal-combustion engines. The addition of arsenic minimizes such softening. Under suitable casting conditions, the arsenical lead babbitts--for example, SAE 15 (ASTM grade 15)--develop remarkably fine and uniform structures. They also have better fatigue strength than arsenic-free alloys.

Arsenical babbitts give satisfactory service in many applications. The use of these alloys increased greatly during the Second World War, particularly in the automobile industry and in the manufacture of diesel engines. The most widely used alloy is SAE 15 (ASTM grade 15), which contains 1% arsenic. Automobile bearings of this alloy are usually made from continuously cast bimetal (steel and babbitt) strip. When properly handled, this alloy can withstand the considerable strain that results from forming the bimetal strip into bearings.

Diesel engine bearings often are cast as individual bearing shells by either centrifugal or gravity methods. An alloy that contains 3% arsenic (alloy B in Table 11) has been used successfully for applications where higher hardness is required and where formability requirements are less severe (rolling mill bearings, for example).

For many years, lead-base bearing alloys were considered to be only inferior low-cost substitutes for tin alloys. However, the two groups of alloys do not differ greatly in antiseizure characteristics, and when lead-base alloys are used with steel backs and in thicknesses below 0.75 mm (0.03 in.), they have a fatigue resistance that is equal to, if not better than, that of tin alloys. Bearings of any of these alloys remain serviceable longest when they are no more than 0.13 mm (0.005 in.) thick (Fig. 7). The superiority of lead alloys over tin alloys becomes more marked as operating temperatures increase. For this reason, automotive engineers generally favor lead-base alloys of compositions that approximate ASTM alloys 7 and 15, and SAE alloy 16. The SAE alloy is cast into and on porous sintered matrix, usually of copper-nickel, that is bonded to steel. The surface layer of the babbitt is 0.025 to 0.13 mm (0.001 to 0.005 in.) thick.

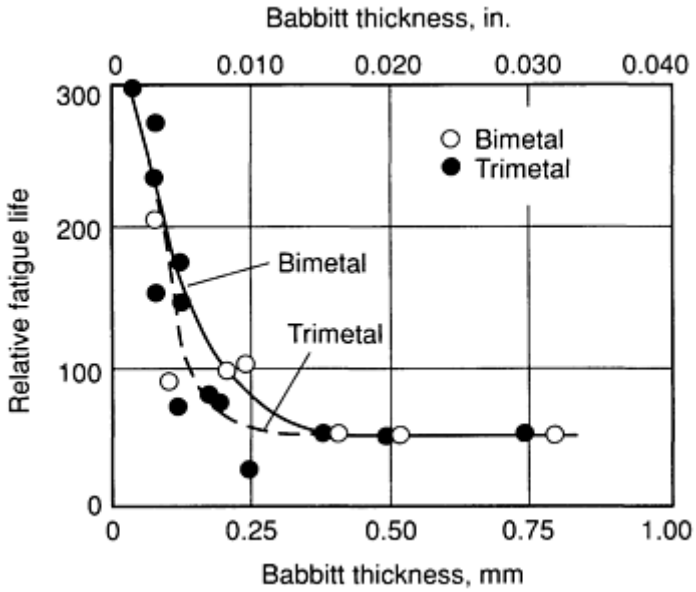

Fig. 7 Variation of bearing life with babbitt thickness for lead or tin babbitt bearings. Bearing load, 14 MPa (2000 psi) for all tests

The use of lead babbitts containing calcium and alkaline earth metals is confined almost entirely to railway applications, although these babbitts also are employed to some extent in certain diesel engine bearings. One of the more widely used alloys contains 1.0 to 1.5% Sn, 0.50 to 0.75% Ca, and small amounts of various other elements. The strength of this alloy approximates that of a tin alloy containing 90% Sn, 8% Sb, and 2% Cu. The hardness of this lead alloy is about 20 HB,

the solidus temperature is 321 °C (610 °F), and the liquidus temperature is probably near 338 °C (640 °F). The pouring temperature, which varies from 500 to 520 °C (930 to 970 °F), is relatively high. The high temperature and reactive nature of calcium accounts for the formation of a much larger volume of dross than that encountered in the melting of lead-antimony-tin alloys. Care must be taken to avoid contamination of the alloy with antimonial lead babbitts, and vice versa. Deformability and resistance to wear are of the same order as those of the other lead babbitts. Most alloys of this type are subject to corrosion by acidic oils.

The fatigue resistance of bearing materials depends to a great extent on the design of the bearing. The strength and rigidity of the supporting structure, the thickness of the backing metal (steel or bronze), the thickness of the bearing material, and the character of the bond between the bearing material and the backing are all factors of consequence in bearings for use in high-speed reciprocating engines, such as the main and connecting-rod bearings of automobile and aircraft engines.

Resistance to fatigue is somewhat less important in bearings that operate under static load, for example, journal bearings in traction motor supports for diesel locomotives and in railway freight cars. In such bearings, antiseizure characteristics, conformability, compressive strength, and resistance to abrasion and corrosion are of greater significance. The lining metal generally employed in such journal bearings is the low-arsenic Association of American Railroads alloy M501 (ASTM B 67) (Table 11) cast onto a leaded-bronze back.

Ammunition. Large quantities of lead are used in ammunition for both military and sporting purposes. Alloys used for shot contain up to 8% Sb and 2% As; those used for bullet cores contain up to 2% Sb.

Terne Coatings. Long terne steel sheet is carbon steel sheet that has been continuously coated by various hot dip processes with terne metal (lead with 3 to 15% Sn). This coated sheet is duller in appearance than conventional tin-coated sheet; this accounts for the name terne, which means dull or tarnished in French. The smooth, dull coating gives the sheet corrosion resistance, formability, excellent solderability, and paintability. The term long terne is used to describe terne-coated sheet, whereas short terne is used for terne-coated plate.

Because of its unusual properties, long terne sheet has been adapted to a wide variety of applications. Its principal use is in automotive gasoline tanks. Its excellent solderability and special corrosion resistance make the product well-suited for this application. Other typical applications include:

- Automotive parts such as air conditioners, air filters, cylinder head covers, distributor tubes, oil filters, oil pans, radiator parts, and valve rocker arm covers
- Caskets
- Electronic chassis and parts for radios, tape recorders, and television sets
- File drawer tracks
- Fire doors and frames
- Furnace and heating equipment parts
- Railroad switch lamps
- Small fuel tanks for lawn mowers, power saws, tractors, and outboard motors

Long terne sheet is often produced in accordance with ASTM A 308. For applications requiring good formability, the coating is applied over commercial quality, drawing quality, or drawing quality special killed low-carbon steel sheet. The terne coating acts as a lubricant and facilitates forming, and the strong bond of the terne metal allows it to be formed along with the basis metal. When higher strength is required, the coating can be applied over low-carbon steel sheet of structural (physical) quality, although this will result in some loss in ductility. The mechanical properties of long terne sheet are essentially the same as those of hot dip galvanized or aluminized steel sheet.

Lead has excellent corrosion resistance, and terne metal is principally lead, with 3 to 15% tin added to react with the steel to form a tight intermetallic bond. However, because lead does not offer galvanic protection to the steel basis metal, care must be exercised to avoid scratches and pores in the coating. Small openings can be sealed by corrosion products of iron, lead, and oxygen, but larger ones can corrode in an environment unfavorable to the steel basis metal.

Long terne sheet can be readily soldered with noncorrosive fluxes using normal procedures because the sheet is already presoldered. This makes it a good choice for applications in which ease of solderability is important, such as television

and radio chassis and gasoline tanks. It also can be readily welded by either resistance seam welding or spot welding; however, when the coating is subjected to high temperatures, significant concentrations of lead fumes can be released. Therefore, the U.S. Occupational Safety and Health Administration and similar state agencies have promulgated standards that must be followed when welding, cutting, or brazing metals containing lead or metals coated with lead or lead alloys.

Long terne sheet has excellent paint adherence, which allows it to be painted using conventional systems; however, it is not usually painted. When painting is done, no prior special surface treatment or primer is necessary, except for the removal of ordinary dirt, oil, and grease. Oiled sheet, however, should be thoroughly cleaned to remove the oil. Alternatively, a wash primer treatment or a paint that will tolerate a slight residue of manufacturing oil can be used.

Long terne sheet normally is furnished dry and requires no special handling. It should be stored indoors in a warm, dry place. Unprotected outdoor storage of coils or bundles can result in white or gray staining of the terne coating. Also, if pores are present in the terne coating, rust staining can occur.

Lead foil, generally known as composition metal foil, is usually made by rolling a sandwich of lead between two sheets of tin, producing a tight union of the metals. Thicknesses of 0.01 mm (0.0005 in.) or less are common. Lead foil is used for moisture protection in the construction industry and for oxygen barriers on wine and champagne bottles. Lead-tin composite foils also are used in the electronics industry.

Fusible Alloys. Lead alloyed with tin, bismuth, cadmium, indium, or other elements, either alone or in combination, forms alloys with particularly low melting points. Some of these alloys, which melt at temperatures even lower than the boiling point of water, are referred to as fusible alloys. They are used for automatic sprinkler systems, electric fuses, and boiler plugs. Additional information on fusible alloys is contained in the article "Indium and Bismuth" in this Volume.

Anodes made of lead alloys are used in the electrowinning and plating of metals such as manganese, copper, nickel, and zinc. Rolled lead-calcium-tin and lead-silver alloys are the preferred anode materials in these applications, because of their high resistance to corrosion in the sulfuric acid used in electrolytic solutions. Lead anodes also have high resistance to corrosion by seawater, making them economical to use in systems for the cathodic protection of ships and offshore rigs. Anodes for these purposes are sometimes made of unalloyed lead, but they are usually made of lead alloyed with silver, tin, or antimony. These anodes are produced not only in cast form but also as extruded bars or supported sheet. Lead-7% tin anodes are used in chrome plating.

Structures

In many applications, lead is combined with stiffer and stronger materials to make structures that have the best qualities of both materials. An example of this type of structure is the series of lead and lead-coated structures described below, which are used for corrosion-resistant equipment. However, lead also is combined with plastics having relatively low stiffness and strength to make structures with superior sound control characteristics.

The plumbum series is a group of material combinations, each of which features lead as a major constituent. These materials are used in applications requiring good strength and high resistance to corrosion. Lead or lead alloy coatings provide the corrosion resistance; the strength is provided by steel, concrete, wood, brick, or another suitable material.

The six members of the plumbum series are described below, along with examples of typical uses for each type. They are presented in roughly increasing order of cost and strength:

- *Basic plumbum:* Lead or lead alloys in cast or extruded form with limited support. Used for cast antimonial lead valves, pipe fittings, pumps, anodes, and vessels
- *Supported plumbum:* Lead or lead alloys in sheet, pipe, or other extruded forms that are mechanically fastened to supporting structures of steel, wood, concrete, copper, or other metals. Used for concrete cells lined with lead sheet (loosely lined or cage supported) that are needed for the electrolytic refining of metals; also used for flues, ducts, towers, floors, expanded lead-lined pipe, cable sheathing, roofing, and anodes
- *Adhesive plumbum:* Lead or lead alloys in sheet, pipe, or other forms that are joined with an adhesive to steel, concrete, wood, or any other material that can provide extensive support. Used for acid storage tanks made of lead sheet joined with an adhesive to a steel outer shell
- *Bonded plumbum:* A heavy lead or lead alloy layer metallurgically bonded to steel, copper, or another

metal. Used for homogeneously bonded lead-lined steel reaction vessels and lead-clad copper heating and cooling coils

- *Brick plumbum:* Lead or lead alloy sheet sandwiched between an outer shell of concrete or steel and an inner layer of chemical-resistant ceramic brick or masonry (usually acid brick). The sheet is metallurgically or chemically bonded to the outer sheet and the inner layer; for some applications a layer of cushioning material is placed between the sheet and the inner layer. Used for sulfuric acid mist scrubbers, precipitators, concentrators, and storage tanks
- *Plumbum coatings:* Thin lead or lead alloy coatings metallurgically or mechanically bonded to equipment to protect it from corrosion. Used for lead-tin alloy coatings on steel for roofing, gutters, and downspouts

The five major characteristics of the plumbum series are relatively low material costs, low-to-moderate installation and maintenance costs, inherently high corrosion resistance, long service life, and adaptability to a wide range of operating conditions.

The relatively low material costs of plumbum series equipment are due to the fact that the three basic component materials--steel, lead, and concrete--are comparatively inexpensive. A fourth component, wood, is used only in applications such as the manufacture of explosives, where its nonsparking property makes it essential. The fifth major component, chemical-resistant masonry, is not low in cost. However, it is used only where high-temperature strength or abrasion resistance is required. Under those conditions, the cost of using the only other suitable materials or material combinations is usually comparable or higher.

All plumbum series equipment can be used in cold climates without failure due to embrittlement. Temperatures as high as 1000 °C (1830 °F) have been handled successfully by brick plumbum. Both brick plumbum and bonded plumbum have high resistance to damage from thermal shock caused by large and rapid fluctuations in temperature. High heat conductivity is a normal feature of bonded plumbum, basic plumbum, and most types of plumbum coatings. A strong barrier to heat transfer is provided by brick plumbum, adhesive plumbum, and a few types of supported plumbum. Thus, bonded plumbum is used to make heating and cooling coils, and brick plumbum is widely used as insulation in ducts handling very hot gases.

Basic plumbum performs reliably under pressures up to 0.3 MPa (3 atm). All other plumbums can withstand substantially higher pressures; bonded plumbum is especially resistant to damage. Both bonded plumbum and brick plumbum can be used to handle vacuums as well as pressures that fluctuate both above and below atmospheric level. Adequate abrasion resistance often is provided by using the harder alloys of lead. However, for extremely abrasive conditions, the hard masonry of brick plumbum is required. The pliability and malleability of soft lead make possible the manufacture of a wide variety of intricately shaped items such as corrugated helical heating and cooling coils. These qualities also allow the manufacture of glassy smooth lead pipes that minimize friction energy losses.

Plumbum coatings and the basic, brick, and supported plumbums are electrically conductive. However, they can be made into insulating barriers by incorporating a layer of nonconducting material. By choosing the appropriate adhesive, adhesive plumbum can be made either insulating or conductive. Bonded plumbum is always electrically conductive. Equipment with nonsparking surfaces can be constructed using supported or adhesive plumbum combinations that contain only wood and lead as the major components.

Sound Control Materials. Lead is an excellent barrier to sound transmission. Essentially, a good sound barrier should have high density and low stiffness, and it should be impermeable. Lead and lead composites more than satisfy these requirements. In addition, the high internal damping capacity of lead and lead composites make them even more effective in controlling sound. Several examples of sound control materials that contain lead are given in Table 13. An advantage of these products is that they are unaffected by coolants, cutting oils, drawing compounds, and similar industrial fluids.

Table 13 Sound control materials containing lead

Material	Description	Uses

Sheet lead	Usual weight, 0.25 to 2 kg ($\frac{1}{2}$ to 4 lb)	Used alone or laminated to substrates of various types
Lead-foam composites	Lead sheet with a usual weight of 0.25 or 0.5 kg ($\frac{1}{2}$ or 1 lb) sandwiched between layers of polyurethane foam	Laminated to enclosures
Leaded plastic sheets	Lead-loaded vinyl or neoprene sheet with or without fabric reinforcement	As a curtain or to line enclosures
Damping tile	Lead-loaded epoxy or urethane tiles	Damping heavy machinery
Casting compounds	Lead-loaded epoxy	Potting; filling complex voids
Troweling compounds	Lead-loaded epoxy or urethane	Damping enclosures, surfaces, resonating members, and rattling panels
Lead-fiberglass composites	Sandwich composite of lead and fiberglass with a usual weight of 0.25 to 0.5 kg ($\frac{1}{2}$ to 1 lb)	Damping enclosures; sound isolation between walls and rooms

Refractory Metals and Alloys

Chairman: John B. Lambert, Fansteel Inc.

Introduction

John B. Lambert and John J. Rausch, Fansteel Inc.

THE REFRACTORY METALS include niobium (also known as columbium), tantalum, molybdenum, tungsten, and rhenium. With the exception of two of the platinum-group metals, osmium and iridium, they have the highest melting temperatures and lowest vapor pressures of all metals. The refractory metals are readily degraded by oxidizing environments at moderately low temperatures, a property that has restricted the applicability of the metals in low-temperature or nonoxidizing high-temperature environments. Protective coating systems have been developed, mostly for niobium alloys, to permit their use in high-temperature oxidizing aerospace applications.

Refractory metals at one time were limited to use in lamp filaments, electron tube grids, heating elements, and electrical contacts; however, they have since found widespread application in the aerospace, electronics, nuclear and high-energy physics, and chemical process industries. Each of the refractory metals, with the exception of rhenium is consumed in quantities exceeding 900 Mg (1000 tons) annually on a worldwide basis. In 1988, consumption of refractory metals in the United States was:

Metal	Amount, Mg[(a)]

Niobium	2,665[b][c]
Tantalum	422[d]
Tungsten	8,298
Molybdenum	17,422
Rhenium	8[b]

(a) 1 Mg = 1 metric ton.

(b) Estimated.

(c) Used primarily in the form of ferrocolumbium; includes nickel-niobium and a small quantity of other niobium materials.

(d) Apparent

Applications

Most niobium is consumed as a ferroalloy used in the production of high-strength low-alloy and stainless steels; the consumption of niobium-base metals and alloys accounts for about 6% of the total. The single largest use for tantalum is as powder and anodes for electronic capacitors, representing about 50% of total consumption. Mill products--sheet and plate, rod and bar, and tubing--constitute nearly 25% of tantalum consumption. The major end use for tungsten is in cemented carbides, which are used for cutting tools and wear-resistant materials. Tungsten carbides make up nearly 60% of tungsten consumption; mill products account for approximately 25%. Most molybdenum is used as an alloying addition in steels, irons, and superalloys. Molybdenum-base mill products represent less than 5% of usage. Platinum-rhenium reforming catalysts account for 85% of rhenium consumption.

As a result primarily of experience gained in aerospace programs, applications for refractory metals now encompass almost every type of industry. Table 1 summarizes the commercially significant uses of these metals. Table 2 compares the physical, thermal, electrical, magnetic, and optical properties of pure refractory metals. Figures 1 and 2 compare the temperature-dependent ultimate tensile strengths and elastic moduli of the refractory metals. The values for hexagonal close-packed (hcp) rhenium are quite different from those of the other metals, which are body-centered cubic (bcc). Table 3 lists nominal compositions of commercially prominent refractory metal alloys.

Table 1 Commercial applications of refractory metals and alloys by industry

Application	**Material**
Aerospace and nuclear industries	
Counterweights (aircraft, inertial guidance systems)	Tungsten alloys
Solid-propellant rockets	

2650-2750 °C (4800-4980 °F) flame temperature	Molybdenum, tungsten
3425-3550 °C (6195-6420 °F) flame temperature	Silver and copper-infiltrated tungsten
Lifting and guidance structures for glide reentry vehicles	Cb-752[(a)], FS-85[(a)], C-129Y[(a)]
Leading edges and nose caps for hypersonic flight vehicles	Cb-752[(a)], FS-85[(a)], Ta-10W[(a)]
Thrust chambers	C-103[(a)]
Radiation nozzle extensions	C-103[(a)], FS-85
Jet engine components	
Augmenter liners	C-103[(a)]
Center body	Cb-752[(a)]
Flame holders	Cb-752[(a)]
Rocket nozzles	FS-85[(a)], Ta-10W (Ta-Hf clad)
Thermal shields	C-129Y[(a)]
Porous ionizer plates	Tungsten
Heat shields and cesium vapor inlet tubes (ion engine)	Tantalum
Fasteners	Nb-Ti
Honeycomb structures	Molybdenum, Cb-752, Ta-10W
Hot gas tubing	Ta10W[(a)]
Hot gas bellows	C-103[(a)]
Solid propellant expansion nozzle	C-103[(a)]
Nuclear and high-energy physics	
Linear accelerators, microwave cavities	Niobium

Superconductors	Nb-Ti, Nb_3Sn
Liquid metal containers and piping	Nb-1Zr
Electronics industry	
Capacitors	Tantalum powder, foil, wire
Capacitor cases	Tantalum strip
Rectifiers, railway signals	Tantalum
Battery chargers	Tantalum
Transducers	Molybdenum, tungsten
Electron tube parts	
Heaters	Tungsten, W-Re
Supports	Molybdenum
Cathodes	Tantalum
Anodes	Molybdenum, tungsten
Superconducting wire	Nb-Ti, Nb_3Sn
X-ray targets	Tungsten, molybdenum, rhenium, composite W-Mo
Electrodes (mercury switches)	Molybdenum, tungsten
Thin-film substrates	Molybdenum, tungsten
Electrical contacts	Tungsten, rhenium, W-Ag, W-Cu
Heat sinks	Molybdenum, tungsten
Backing wafers, semiconductors	Molybdenum, tungsten
Filaments, ion gages, photoflash	Rhenium, W-Re

Process industries	
Heating and cooling coils	Tantalum, Ta-Nb
Shell and tube heat exchangers	Tantalum
Condensers	Tantalum
Tantalum-clad steel vessels	Tantalum
Distillation towers	Tantalum
Valves for hot sulfuric acid service	Molybdenum, tantalum, Ta-Nb
Expansion joints (bellows)	Tantalum
Glass-processing equipment	Tantalum
Crucibles, all sizes up to 1 m (3 ft) diameter × 1.3 m (4 ft) high	Tungsten, tantalum, Ta-40Nb
Spinnerettes, textile industry	Tantalum, niobium
Thermocouple protection tubes	Tantalum-coated copper or steel
Rupture discs	Tantalum
Thermowells	Tantalum-clad copper, tantalum
Spargers, funnels, jet ejectors	Tantalum
Bayonet heaters	Tantalum
Pumps for hydrogen chloride service at 200 kPa (30 psi) and 150 °C (300 °F)	Tantalum (exposed parts)
Cathodic protection electrodes	Niobium
Special equipment	
Furnace parts	
Heating elements, shields, boats, trays, platens, fixtures	Tungsten, molybdenum, tantalum

Susceptors (induction furnace)	Tungsten
Extrusion dies	Tungsten, molybdenum
Piercing points, hot punches	Tungsten, molybdenum
Cups	Tungsten, molybdenum, tantalum
Fasteners (nuts, screws, studs, rivets)	Tantalum, molybdenum, C-3009, C-129Y
Die casting molds, cores	Molybdenum, tungsten
Vacuum-metallizing coils, boats	Tungsten, molybdenum
Springs	Tungsten, molybdenum, tantalum
Boring bars	Tungsten, molybdenum
Surgical implants	Tantalum
Instruments	Tantalum
Electroplating equipment	Tantalum
Thermocouples, spot weld electrodes	W, W-Re alloys
Cathodes, plasma generator	W-1Ni
Rapid-fire gun barrels	C-3009[(a)]
Sodium vapor lamp electrodes	Nb-1Zr

(a) Parts are silicide-coated in use.

(a) C-3009 is in the literature as a family of alloys ranging from 9-15% W and ≤5% Ti. The hafnium content is constant at 30%.

(b) Various molybdenum contents; two most common alloys listed.

(c) Various rhenium contents to ≤26%; three most common alloys listed.

(d) See also Table 22.

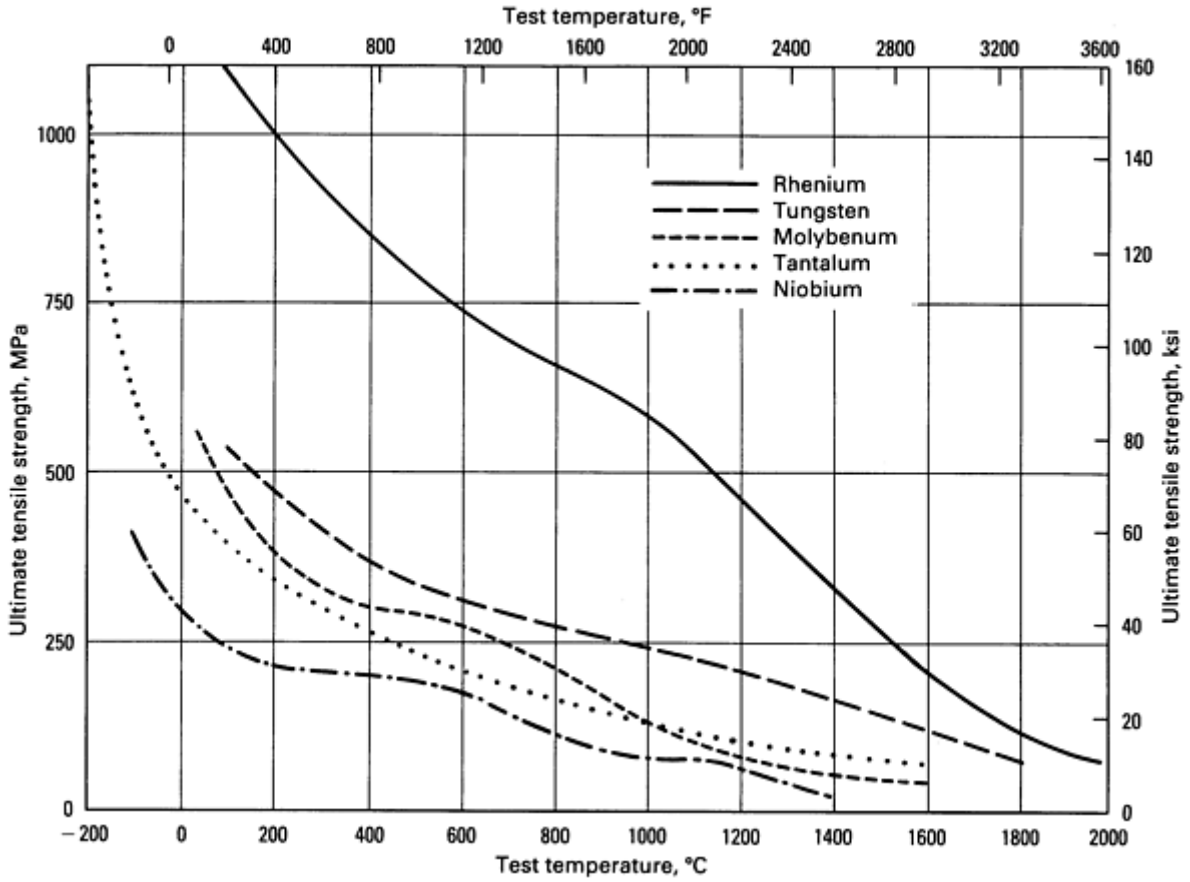

Fig. 1 Test temperature versus ultimate tensile strength for pure refractory metals

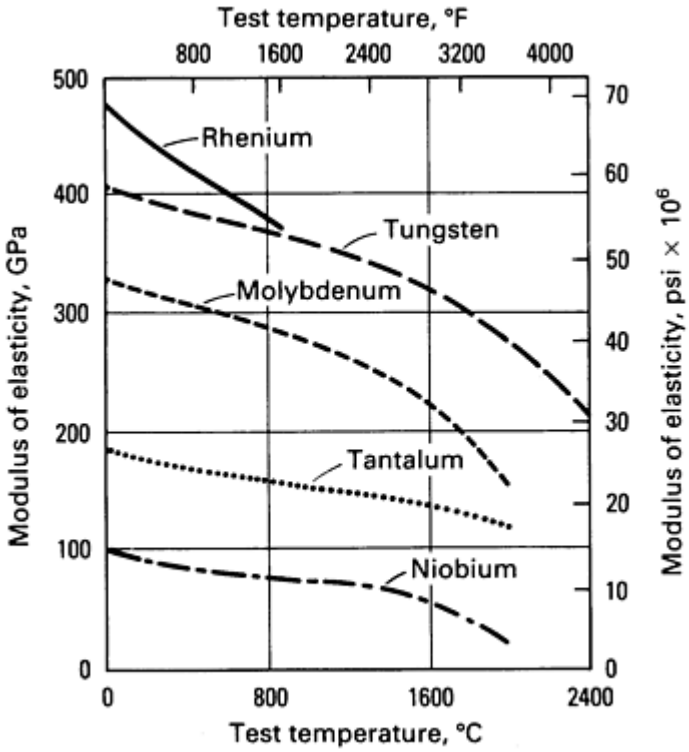

Fig. 2 Test temperature versus modulus of elasticity for pure refractory metals

Selection of a specific alloy from the refractory metal group often is based on fabricability rather than on strength or corrosion resistance. Niobium, tantalum, and their alloys are the most easily fabricated refractory metals. They can be formed, machined, and joined by conventional methods. They are ductile in the pure state and have high interstitial solubilities for carbon, nitrogen, oxygen, and hydrogen. Because of the high solubilities in niobium and tantalum, these embrittling contaminants normally do not present problems in fabrication. However, tantalum and niobium dissolve sufficient amounts of oxygen at elevated temperatures to destroy ductility at normal operating temperatures. Therefore, elevated-temperature fabrication of these metals is used only when necessary. Protective coatings or atmospheres are mandatory unless some contamination can be tolerated. The allowable level of contamination, in turn, determines the maximum permissible exposure time in air at elevated temperature.

Molybdenum, molybdenum alloys, tungsten, and tungsten alloys require special fabrication techniques. Fabrication involving mechanical working should be performed below the recrystallization temperature. These materials have limited solubilities for carbon, nitrogen, oxygen, and hydrogen. Because the residual levels of these elements required to prevent embrittlement are impractically low, the microstructure must be controlled to ensure a sufficiently low ductile-to-brittle transition temperature (DBTT).

The resistance of refractory metals to corrosion by liquid metals and aggressive acid solutions can cut maintenance and downtime if high initial costs can be accepted. Systems for containing liquid metals such as lithium and cesium at high temperatures have been fabricated of Nb-1Zr alloy tubing; tantalum and tantalum-clad steel processing equipment have performed well in high-temperature sulfuric acid service.

Most refractory metals and alloys are available as wire. Tungsten wire, for example, which comes in diameters as small as 0.0102 mm (0.0004 in.), is used as fiber reinforcement in composite materials in which the matrix is any one of various ductile alloys. Tantalum wire is used extensively in capacitor manufacture and in surgical applications.

In the nuclear field, tungsten crucibles that are pressed and sintered, shear spun, chemical vapor deposited, or plasma sprayed and sintered are used in recovering uranium and plutonium from spent reactor fuel.

Tantalum and, to a lesser extent, molybdenum have been used for many years in the chemical process industries. The severe corrosion problems accompanying many chemical processes have given impetus to greater use of refractory alloys. Recently, chemical equipment has been fabricated from steel plate explosively clad with tantalum. Forming and welding methods have been developed for fabrication of the clad plate into reactor vessels, tanks, and other types of chemical equipment. Explosive bonding produces a metallurgical bond at the tantalum/steel interface. Bond efficiency is over 98%, and bond shear strength exceeds the American Society of Mechanical Engineers (ASME) minimum acceptable value for clad material.

Electronic applications constitute one of the major uses for refractory metals. The largest use for tantalum is in electrolytic capacitors. Porous sintered powder metallurgy (P/M) anodes are used in both solid and wet electrolytic capacitors, and, to a lesser extent, precision tantalum foil is used in foil capacitors. The dielectric film of tantalum oxide is electrolytically formed on the tantalum surface in the manufacturing process. It has been reported that commercial quantities of P/M niobium capacitors are being produced in the Soviet Union. Although the dielectric constant of niobium oxide is greater than that of tantalum oxide (41.4 versus 25.3), niobium powder is not extensively used for capacitors. The problem with niobium is that the amorphous anodic oxide film, formed as the dielectric, crystallizes at a relatively low temperature, thereby causing performance decay in the capacitor.

Tantalum cases (or cans) are used for hermetically sealing wet electrolytic tantalum capacitors. The package consists of a cold drawn can having a porous sintered tantalum powder lining that serves as a cathode, a cap or a header, and a glass-to-metal seal in the header; the seal insulates a tantalum lead wire that passes through the header and connects to the porous tantalum powder capacitor anode. The lead is either embedded in the anode during powder pressing or spot welded after the anode is sintered. After the slug has been inserted and the can filled with electrolyte, the header is resistance or laser welded to the tantalum can, forming a hermetic seal. Headers are formed in progressive dies, although recent designs also supply a stamped tantalum washer for the end seal. Cans approximately 9.52 mm (0.375 in.) in diameter and 19.0 mm (0.750 in.) in length are usually made either by drawing on a transfer press or by spinning.

Other electronic components in which refractory metals are used include a composite x-ray target, which consists of a forged or spun molybdenum substrate with a plasma-sprayed optical track of tungsten-rhenium alloy; molybdenum cathode supports for radar devices; and magnetron end hats.

In vacuum metallizing equipment, evaporation boats are commonly fabricated by coating formed molybdenum substrates with plasma-sprayed refractory oxides.

Chemical vapor deposition has proved useful for fabricating free-standing refractory metal parts for advanced electronics applications. Tungsten emitters of preferred crystal orientation, tungsten collectors, and sandwich insulators (Nb-Al_2O_3-Nb, for example) are used in nuclear thermionic conversion devices.

Production of Refractory Metals

The refractory metals, except for niobium, are produced exclusively as metal powders, which are consolidated by sintering and/or melting. The process for niobium differs only in that the metal is most commonly reduced by aluminothermic reduction of oxide. In this process, oxide impurities slag from the molten niobium.

For tantalum and niobium, electron beam (EB) melting is widely used for further purification. Powders can also be produced for these metals from ingot by the hydride-crush-dehydride process. Alloys are made by adding alloying agents during melting. Low-volatility metals such as tungsten and tantalum can be added during EB melting. More volatile agents such as titanium, hafnium, or zirconium are frequently added in vacuum arc remelting.

Hot forging or extrusion is used for breaking down ingots into rounds or rectangular sheet bar. These bars, as well as sintered products, are processed into sheet, plate, foil, tubing, and bar. Table 4 gives typical mill-processing temperatures for the refractory metals.

(a) Where a range is given, the higher temperature is the typical starting temperature and the lower temperature is the minimum working temperature for that process.

Fabrication

A general flow sheet for the fabrication of refractory metals is shown in Fig. 3.

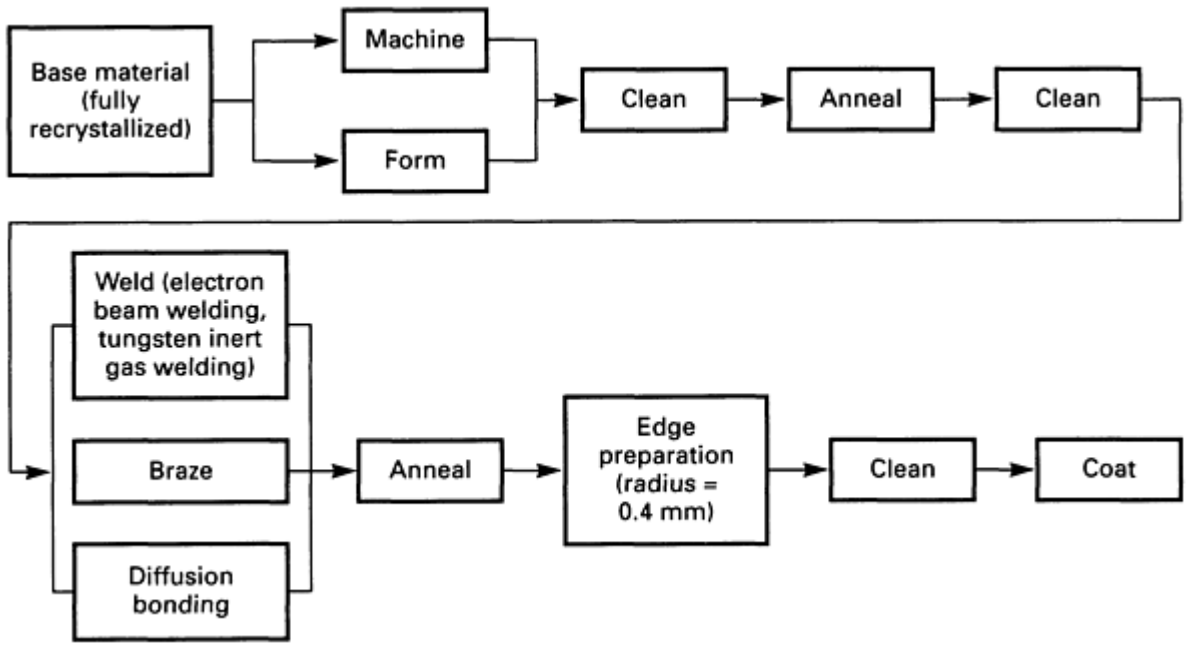

Fig. 3 Typical sequence of operations for the fabrication of refractory metals

Machining

Equipment for machining refractory metals must be rigid and powerful to ensure optimum results. Carbide and, on occasion, cast cobalt tools give acceptable tool life and cutting properties. Detailed information is available in the articles "Cemented Carbides" and "Cast Cobalt Alloys" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Niobium alloys and tantalum alloys are readily machined using high-speed steel (see the articles "High-Speed Tool Steels" and "P/M High-Speed Tool Steels" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals*

Handbook) or carbide tools. The machining and grinding characteristics of these alloys vary from being similar to those of soft copper to those of annealed stainless steel. Tooling recommendations are summarized in Table 5.

Table 5 Tooling recommendations for machining niobium and tantalum

Approach angle	15-20°
Side rake	30-35°
Side and end clearance	5°
Plan relief angle	15-20°
Nose radius	0.50-0.75 mm (0.020-0.030 in.)
Cutting speed High-speed steel tools	0.3-0.4 m/s (60-80 sfm)
Carbide tools	1.3-1.5 m/s (250-300 sfm)
Feed Roughing	0.23-0.30 mm/rev (0.009-0.012 in./rev)
Finishing	0.13 mm/rev (0.005 in./rev) max
Depth of cut	0.75-3.2 mm (0.030-0.125 in.)

Molybdenum is machined using carbide tools of the same configurations as those used for machining 1040 and 4340 steel because the machining characteristics of these two metals are similar to those of molybdenum. Machining speeds for molybdenum alloys (TZM, for example) are about 40% higher than those for type 302 stainless steel. Finish grinding of molybdenum requires a heavy coolant flow and the use of aluminum oxide wheels to prevent heat checking. Tool configurations and grinding techniques are similar to those for grinding cast iron; conventional machines with standard feeds and speeds are satisfactory.

Turning is a problem only with tungsten. For tungsten, the use of carbide tools ground with a negative back rake, 15° lead, and 0° side rake are mandatory. All turning is done at room temperature. However, machinable tungsten heavy-metal alloys bonded with copper, nickel, and iron are produced (see the section "Tungsten" in this article for additional information).

For grinding tungsten, wheels of 60-grit silicon carbide or 46-grit alumina are recommended. Normal precautions, extra-light pressures, and heavy coolant flow are required.

Tungsten and molybdenum must be punched and sheared at temperatures above their ductile-to-brittle transition temperatures. Sheets over 1.3 mm (0.050 in.) thick must have an excess thickness of 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) to allow for belt sanding to final dimensions. Cutting can be done using abrasive (60-grit silicon carbide) cutoff wheels.

Electrical discharge machining can be used for shaping niobium and tantalum. Some limited work has been done to apply electrochemical machining to these metals, but the formation of the tenacious anodic oxide layer on the metals, which

inhibits the process, and hydrogen embrittlement are problems. Both electrochemical machining and electrical discharge machining are suitable for molybdenum and tungsten.

Photoetching and chemical blanking have been used on molybdenum. In these processes, photographic masking is followed by etching in a solution of HNO_3 and HF. Such techniques are used for applications in which complex integral shapes or weight reductions are required. Chemical blanking is a particularly attractive process for simultaneously cutting parts with many different shapes from the same plate or sheet.

Band or circular saws can be used to cut molybdenum sheet. Sheet thicknesses in the range of 1.0 to 1.5 mm (0.039 to 0.059 in.) require band speeds of 37 m/min (120 sfm); thinner sections with thicknesses from 0.4 to 0.75 mm (0.016 to 0.030 in.) can be cut at band speeds of 76 to 91 m/min (250 to 300 sfm). Sheets in the thickness range of 0.50 to 1.52 mm (0.020 to 0.060 in.) can be cut with abrasive wheels rotating at 1000 to 1400 rev/min.

Molybdenum sheet can be effectively drilled using high-speed steel drills and conventional oil lubricants. Table 6 shows some typical drill parameters for the use of automatic drill machines.

Table 6 Parameters for drilling holes in molybdenum sheet

Drill size			Speed, rev/min	Feed	
Number	mm	in.		mm/rev	in./rev
40	2.49	0.0980	1200	0.127	0.0050
30	3.25	0.1285	900	0.178	0.0070

Acceptable machining techniques for rhenium include electrical discharge machining, electrochemical milling, abrasive cutting, and grinding. Rhenium is very difficult to machine with carbide tools and other conventional methods. Rhenium sheet and plate can be sheared, but the cold-worked area should be removed during subsequent grinding and polishing.

Vibration radiusing using loose abrasive and frequencies of 23 to 30 Hz can be used to eliminate sharp corners on all refractory metals. The abrasive action rounds edges, eliminating the need for hand filing and polishing. Additional information is available in the article "Machining of Refractory Metals" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook.*

Forming

Niobium and tantalum sheet are formed using a number of techniques, including conventional form (but usually not shear) spinning, hydroforming, bulge forming, and chemical milling. For the production of a complex part, the designer may need to use several forming and joining operations before the final part shape is achieved. The forming behavior of these metals is similar to that of mild steel, except that they are more prone to galling, seizing, and tearing. In thicknesses from 0.1 to 1.5 mm (0.004 to 0.060 in.), tantalum and niobium can be readily blanked, punched, stamped, or deep drawn at room temperature in steel dies (6% *t* clearance, where *t* is the sheet thickness). Sheet must have a homogeneous, fine grain size (generally ASTM No. 5 or finer) for satisfactory results. Coarse-grain sheet is likely to fail by localized necking during severe forming.

For conventional forming of molybdenum sheet, as well as for blanking, punching, and shearing with heated dies, the following temperature-thickness relationships apply:

Thickness		Temperature	
mm	**in.**	**°C**	**°F**
0.5	0.02	20	70
0.5-1.0	0.02-0.04	95-165	200-325
1.0	0.04	480-540	900-1000

Despite difficulties in fabrication, tungsten is used in more applications than any other refractory metal besides tantalum. Many tungsten parts are die formed or deep drawn. Recrystallization and thermal conductivity data for tungsten appear in Fig. 4 and 5.

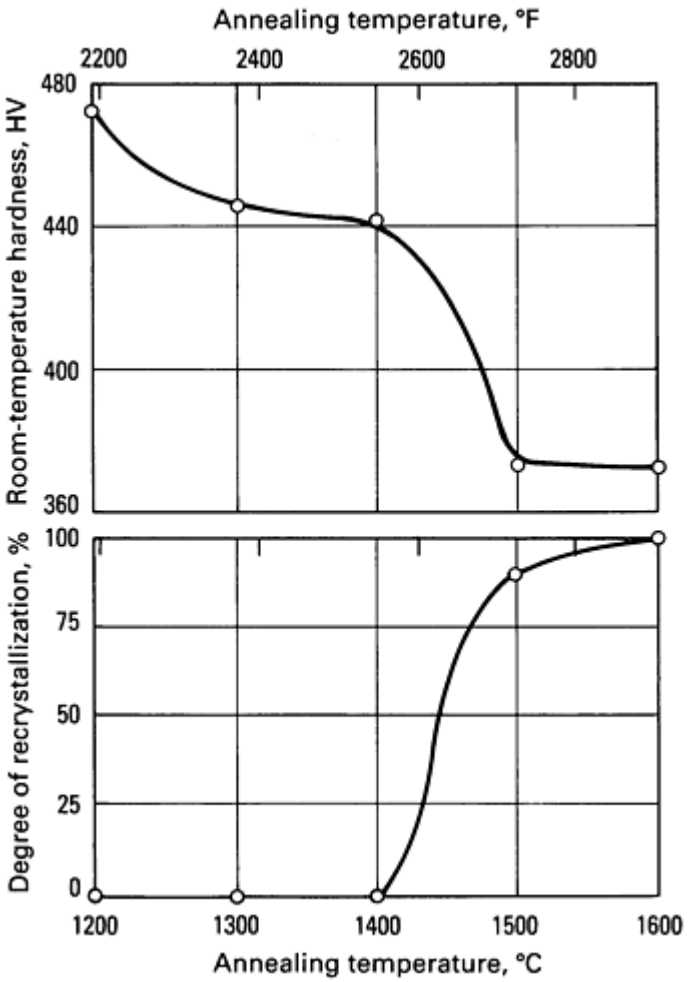

Fig. 4 Recrystallization behavior of undoped tungsten bar

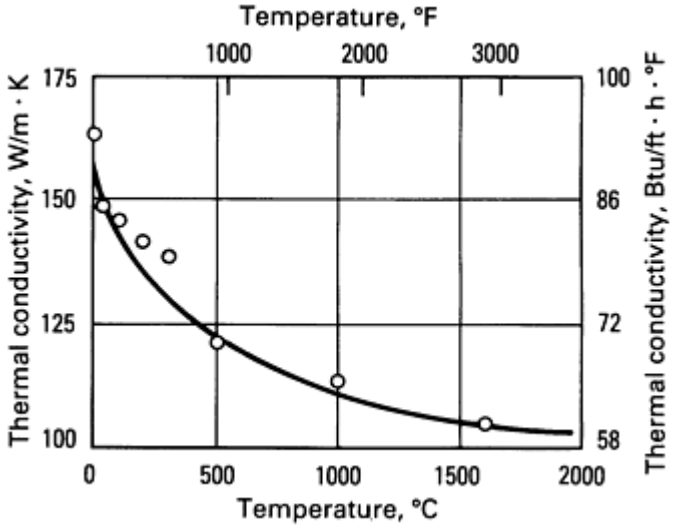

Fig. 5 Thermal conductivity of undoped tungsten

Fabricators can shear, draw, or form tungsten by a variety of techniques if they understand its directional and recrystallization properties. This sections can be formed into simple shapes from room temperature to about 95 °C (200 °F). Heavier, sections, however, require higher forming temperatures:

Thickness		**Temperature**	
mm	**in.**	**°C**	**°F**
0.25-0.4	0.010-0.016	205-260	400-500
0.4-1.0	0.016-0.039	540	1000
1.0	0.039	1260-1595	2300-2900

Punching and shearing must be done hot in accordance with the same temperature-thickness relationships. Material 1.3 mm (0.050 in.) or greater in thickness should be sheared to within 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.) of final dimensions, and parts should be finished by edge grinding.

Table 7 gives blanking pressures, shear strengths, and approximate blanking temperatures for tungsten blanks of various sizes. Shear strengths were derived from strain gage tests on disks about 32 and 50 mm ($1\frac{1}{4}$ and 2 in.) in diameter.

Table 7 Blanking characteristics of tungsten sheet

Blank thickness	**Blank diameter**	**Blanking**	**Blanking pressure**	**Shear strength**

				temperature					
mm	**in.**	**mm**	**in.**	**°C**	**°F**	**kN**	**lbf**	**MPa**	**ksi**
1.5	0.060	51	2	1000	1830	128	28,750	480	70
2.3	0.090	51	2	1050	1920	145	32,500	405	59
3.2	0.125	51	2	1100	2010	189	42,500	380	55
1.5	0.060	32	1.250	950	1740	67	15,000	440	64
2.3	0.090	32	1.250	1000	1830	91	20,500	400	58
3.2	0.125	32	1.250	1100	2010	98	22,000	390	57

In rolling, open die forming, and closed die forming of tungsten and molybdenum, rolls and dies are heated to 425 to 540 °C (800 to 1000 °F). Otherwise, conventional techniques prevail.

The refractory metals can be spun in air if careful attention to temperature and time are maintained. Generally, the metal to be formed is mounted on a heavy spinning lathe and one or (preferably) two rollers. An oxypropane torch is used to heat the workpiece to the following temperatures:

Metal	**Temperature**	
	°C	**°F**
Niobium		
Protected	400-620	750-1150
Unprotected	425 max	800 max
Tantalum		
Protected	480-650	900-1200
Unprotected	400 max	900 max
Molybdenum	480-1065	900-1950

Tungsten	760-1315	1400-2400

Form spinning, shear spinning (flow turning), and extrusion spinning cn be used singly or in combination to fabricate refractory metal plates, sheets, or tubular blanks into configurations that are impractical to produce by conventional forming processes. Often, the only alternative is a combination of open die forging and machining, which is comparatively expensive. Spinning involves relatively low tooling and finishing costs and short setup times; it also can produce parts within relatively tight dimensional tolerances.

Small-size tubing or molybdenum, niobium, and tantalum is made by a variety of techniques, depending on the desired quality, quantity, and size. Most heat exchangers require tubing 1.6 to 13 mm ($\frac{1}{16}$ to $\frac{1}{2}$ in.) in diameter and 0.25 to 0.75 mm (0.010 to 0.030 in.) in wall thickness. Methods for producing tubes of niobium, molybdenum, and tantalum alloys include gas tungsten arc welding and drawing, extruding a tube shell and reducing (rocking) it to finished size, and cupping and drawing. A low-temperature back-extrusion spinning technique and a floating-mandrel extrusion technique have been used for producing tantalum and molybdenum tube shells. Tantalum tubing for chemical process applications is either welded and drawn or seamless. Tantalum has good drawing properties and can be reduced in area up to 60% without intermediate annealing. Niobium alloy tubing is produced using a similar process.

Tubing of tungsten and its alloys can be made by extrusion. Tungsten tubing has been extruded from billets at ram speeds of 0.13 to 0.2 m/s (0.43 to 0.66 ft/s). Seamless tungsten tubing has been produced experimentally by a filled-billet technique. Tungsten tubing is also made by sinking with a deformable mandrel, by tube drawing with a removable hardened mandrel, and by plug drawing.

Chemical vapor deposition (CVD) has proved useful for fabricating freestanding refractory metal parts. Tungsten tubing produced by CVD can range from 0.025 to 305 mm (0.001 to 12 in.) in inside diameter, 0.10 to 3.18 mm (0.004 to 0.125 in.) in wall thickness, and up to 1.8 m (6 ft.) in length. Other processes such as extrusion cost more and impose greater limitations on size. Tungsten tubing produced by the CVD process has lower mechanical properties than as-worked wrought tubing because of the inherently low ductility of its columnar microstructure. After annealing, however, CVD tungsten displays superior properties. The CVD technique is also used for making tubing of molybdenum, tungsten-rhenium alloys, and other refractory metals in diameters of 3.2 mm ($\frac{1}{8}$ in.) or less.

Because the crystal structure of rhenium is hexagonal close packed rather than body-centered cubic, it does not exhibit a ductile-to-brittle transition temperature. Annealed rhenium is very ductile and can be bent, coiled, or rolled. Rhenium typically will undergo 20% tensile elongation versus less than 2% for tungsten. However, even though the fabrication of rhenium is possible by conventional methods such as swaging, rolling, and drawing, it does require some special techniques. For the purpose of cold fabrication, the hardness of the metal must be brought below 300 HV, which usually requires 2-h anneals at temperatures above 1700 °C (3090 °F) for material of commercial purity. Traditional hot working generally results in hot shortness caused by the formation and melting of rhenium heptoxide (Re_2O_7) (melting point, T_m, 297 °C, or 567 °F; boiling point, T_b, 363 °C, or 685 °F) at the grain boundaries. Hot swaging and hot extrusion above 1000 °C (1830 °F) are possible if the metal is not exposed to oxygen. Previous cold work helps to prevent hot shortness.

The preferred fabrication technique for sintered compacts involves limiting initial cold reductions to a maximum of approximately 3% per pass between anneals to avoid cracking. In the production of strip, 10 to 20% reductions between anneals can be achieved after an initial 10% reduction pass. Rolling at room temperature is generally performed on combination two-high and four-high mills with smaller-diameter (19.0 to 44.5 mm, or 0.75 to 1.75 in.) tungsten carbide work rolls. Tubing has been fabricated by electron beam welding a 13 mm (1 in.) wide and 0.20 mm (0.008 in.) thick rhenium strip to form a tube approximately 7.88 mm (0.31 in.) in diameter. In addition to a room-temperature straightening and sizing operation, which achieves about 3% strain, the tubing is put through five alternating cold drawing and 1425 °C (2595 °F) dry hydrogen annealing steps with about a 5 to 7% reduction in area per drawing step to achieve a 7.62 mm (0.30 in.) diameter and a 0.18 mm (0.007 in.) wall final size.

Cleaning

Cleaning is critical throughout the fabrication process, especially for niobium and tantalum. Cleaning should both precede and follow welding, heat treating, or any thermal process. Cleaning for these metals is accomplished in a hot alkaline

solution (minimum 10-min exposure), followed by a chemical cleaning in a mixture of hydrofluoric, nitric, and sulfuric acids. A coupon of the same alloy must accompany each lot of hardware to record material removal. The coupon should have a reference point for measurement. Each cleaning operation should remove approximately 0.0025 mm (0.0001 in.) per side. The activity of the acid should be checked before the hardware is placed in the acid. If the oxide is thicker than 0.0025 mm (0.0001 in.) per side, it is likely that the entire component has been contaminated.

After cleaning, the part should be handled with clean, lint-free white gloves, and the edges to be welded should be wrapped in a clean, lint-free material such as plastic. Welding should commence as soon as possible after cleaning; the time between cleaning and welding should never exceed 4 h. All weld tooling should be thoroughly cleaned with methyl ethyl ketone (MEK) or an equivalent residue-free compound; an argon or helium cover gas should be kept flowing at 0.6 to 1.1 m^3/h (20 to 40 ft^3/h) during welding. If copper tooling is used, it must be chromium plated to avoid copper contamination.

Joining

All refractory metals can be joined by electron beam welding, gas tungsten arc welding, or resistance welding. Two major problems are encountered in joining: chemical changes due chiefly to atmospheric contamination and microstructural changes resulting from thermal cycling. The latter changes include grain growth and different stages of precipitation hardening (solution, precipitation, and overaging). Preheating and postheating generally are required to minimize deleterious effects arising from precipitation hardening as well as from the residual stresses normally induced by welding.

Although recrystallization and grain growth are unavoidable in weldments of wrought tungsten and molybdenum, proper choice of welding process and procedure can localize these effects. Electron beam welding has proved effective in achieving full weld penetration with an extremely narrow heat-affected zone. As larger EB chambers become available, size limitations for electron beam welding have become less restrictive. Chambers capable of handling hardware up to 1.5 m (5 ft) in the longest dimension are in commercial use.

Rhenium welds made by inert gas or EB methods are extremely ductile and can be formed further at room temperature. Care must be taken during welding to protect the rhenium against oxidation, however. All other refractory metals suffer losses in ductility and increases in ductile-to-brittle transition temperature when welded, but niobium and tantalum alloys are less affected than are molybdenum and tungsten alloys. Tantalum and niobium alloys generally retain greater than 75% joint efficiency after gas tungsten arc welding. Preheating is not required, but postweld annealing can restore large amounts of ductility and toughness to commercial alloys. Table 8 summarizes recommended postweld annealing treatments for selected refractory metal alloys; Table 9 lists recommended welding conditions.

Table 8 Recommended postweld annealing treatments for selected refractory alloys

Alloy	Annealing temperature[(a)]			
	Gas tungsten arc welds		Electron beam welds

(a) Direct current, straight polarity.

(b) Beam deflection at 60 cycles parallel to weld direction

For niobium and tantalum alloys, joint design is particularly important. The surface to be melted must be twice the thickness of the thickest component; that is, if welding a 1.5 mm (0.060 in.) part to a 1.0 mm (0.040 in.) part, weld height

(thickness) must be 3.0 mm (0.120 in.). Weld tooling should be of hard chromium-plated copper. No copper can contact the refractory metal. Before use, the hard chromium plate should be wire brushed to check adhesion. If the chromium flakes, the tooling must be stripped and replated.

For gas tungsten arc welding, the weld zone should be well flushed with inert cover gas before striking the arc, and the fusion zone should be allowed to cool below 205 °C (400 °F) with gas coverage. Prior to welding, all burrs should be removed by draw filing with a file used only for one particular alloy. All hand welding should be accomplished in chambers that are evacuated prior to back-filling with argon and/or helium.

Although pure niobium shows no evidence of an aging reaction, Nb-1Zr undergoes abrupt losses in strength and ductility when treated at 815 to 980 °C (1500 to 1800 °F) for up to 500 h. Welds are subject to such embrittlement but can be restored to a ductile condition by postweld vacuum annealing at 1040 to 1205 °C (1900 to 2200 °F) for 3 h. This treatment produces overaging, preventing embrittlement on subsequent heating at a lower temperature.

In contrast to welds in niobium and tantalum, which retain good ductility, welds in molybdenum and tungsten are brittle (<50% joint efficiency), and thus these metals are difficult to join. Before welding, molybdenum and tungsten must be preheated above their ductile-to-brittle transition temperatures to prevent fracture. Sections in thicknesses of 0.64 mm (0.025 in.) and less demand special attention in this respect and, at best, present serious cracking problems. Welds in these metals are always brittle, and joint efficiency depends on the reinforcing effect of the weld bead. Resistance welding is feasible, but some problems with electrode sticking can arise. Resistance Welding Manufacturers' Association (RWMA) class I copper electrodes show the least susceptibility to sticking. Projection welding can result in relatively high mechanical properties.

Tungsten is the most difficult refractory metal to join for satisfactory high-temperature service. Welding, especially the EB process, offers the best compromise for joining tungsten for service at high temperatures. Mechanical joints are unsatisfactory unless molybdenum fasteners are used. Diffusion bonding is impractical because of severe tooling problems. Brazing for relatively low-temperature applications is done using precious metals (silver, palladium, and platinum alloys) and transition metals (nickel and manganese alloys) as filler metals.

Table 10 lists typical brazing filler metals and their maximum service temperatures for all refractory metal systems. Molybdenum brazing has received much attention: Brazed molybdenum honeycomb configurations are used for structural and heat shield applications at temperatures from 1370 to 1650 °C (2500 to 3000 °F). Low-temperature brazing processes have been developed for TZM. The high remelt temperatures of the filler metals listed in Table 10 permit relatively high service temperatures.

Niobium and its alloys may be silicide-coated with a chromium- and titanium-containing material before being subjected to temperature-oxidizing environments; the preferred braze alloy is Ti-33Cr because it is compatible with the coating. Foil, 0.13 mm (0.005 in.) thick, is fit metal-to-metal to ensure good filleting of the joint. The foil should be held in place with resistance spot welds. Cleanliness of the mating surfaces will ensure good flow of the alloy. A clean vacuum furnace is heated to 1315 °C (2400 °F) and held for 5 min, then increased to 1480 °C (2700 °F) and held for 8 min. The parts must be furnace cooled to 205 °C (400 °F) before exposure to air. After brazing, the hardware should be pickled and diffusion treated at 1315 °C (2400 °F) in a vacuum for a period of 16 h. When possible, the parts should be wrapped in tantalum foil to minimize contamination.

Diffusion bonding also is used to join refractory metals, primarily niobium and tantalum. The same rationale is required as for brazing. Vanadium foil, 0.05 to 0.08 mm (0.002 to 0.003 in.) thick is placed in the joint and weighted using molybdenum or tungsten tooling. Diffusion bonding with vanadium is considered superior to brazing because a bimetallic

system is not necessary, and the joint is microstructurally clean because vanadium forms a continuous solid solution with niobium and tantalum.

Coatings

Surface protection is the most significant obstacle to widespread use of refractory metals in high-temperature oxidizing environments. The existing temperature ceiling of about 1650 °C (3000 °F) is dictated by coating limitations: Coatings have insufficient life at reduced pressures (below ~13 kPa, or 100 torr) and high temperatures (~1370 °C, or 2500 °F) in oxidizing atmospheres and give unreliable protection, particularly at edges and corners. From a practical standpoint, however, niobium is theonly refractory metal for which commercial uses of coated parts have been developed. These coatings are primarily of the silicide type; aluminides are also used, but to a much lesser degree. Silicide coatings have been developed for molybdenum; however, they have seen virtually no commercial use because any failure of the coating at high temperatures causes catastrophic failure by vaporization of MoO_3. Further details on coating systems are described in the section "Niobium" in this article.

Niobium

Sam Gerardi, Fansteel Inc., Precision Sheet Metal Division

COMMERCIALLY PURE EB NIOBIUM is ductile and easy to fabricate at room temperature by conventional forming practices. Niobium alloys are used extensively for aerospace applications because they are relatively light in weight and high in elevated-temperature strength.

Alloy C-103 has been widely used for rocket components that require moderate strength at temperatures of about 1095 to 1370 °C (2000 to 2500 °F). Alloy Nb-1Zr is used in nuclear applications because it has a low thermal neutron absorption cross section, good corrosion resistance, and good resistance to radiation damage. It is used extensively for liquid metal systems operating at temperatures from 980 to 1205 °C (1800 to 2200 °F). The Nb-1Zr alloy combines moderate strength with excellent fabricability. As a result, it is used for parts in sodium vapor or magnesium vapor lamps.

Vapor deposition of Nb-1Zr or niobium on the inside surface of type 316 stainless steel tubing improves the performance of the tubing in many chemical process applications without degrading the mechanical properties of the stainless steel. An intermediate layer of pure niobium under Nb-1Zr improves adherence to the steel substrate.

Alloys C-129Y, FS-85, and Cb-752 have shown higher elevated-temperature tensile and creep strengths than C-103 while maintaining good fabricability, coatability, and thermal stability. They are used for leading edges, nose caps for hypersonic flight vehicles, rocket nozzles, gas turbines, and guidance structures for reentry vehicles. Alloy C-3009 is being evaluated for potential use in fasteners and gun barrels.

An Nb-46.5Ti alloy is being used as a low-temperature superconductor material. Superconducting magnets for magnetic resonance imaging machines employ the alloy in the superconducting composite wire, in which very fine filaments of the alloy (with thicknesses of <1 μm, or 40 μin.) are embedded in a copper matrix (see the article "Niobium-Titanium Superconductors" in this Volume and the section "The Manufacture of Commercial Superconductors" in the article "Wire, Rod, and Tube Drawing" in *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition of *Metals Handbook*). Magnets required by the superconducting super collider may contain nearly 800 Mg (1.8×10^6 lb) of the alloy. The more brittle niobium-tin (Nb_3Sn) superconductor has a higher transition (critical) temperature (T_c) than does niobium-titanium, 18.1 K versus 9 K. Use of the niobium-tin alloy has been limited by fabrication difficulties. An Nb-55Ti alloy is used in significant quantities for fasteners for aerospace structures.

Recently, niobium of very low total interstitial content has been produced for superconducting microwave cavity electron accelerators. Chemical analysis for carbon, oxygen, hydrogen, and nitrogen is unreliable at very low levels; therefore, purity is determined by measuring the residual resistance ratio (RRR) value, which is defined as direct current resistivity of niobium at room temperature to the resistivity of niobium at 4 K in the normal conducting state. An RRR value greater than 250, which represents total carbon, oxygen, hydrogen, and nitrogen contents of less than 25 ppm, can be achieved by electron beam drip melting in a modern high-vacuum furnace at pressures of 1 mPa (10^{-5} torr) at rates of 45 kg/h (100 lb/h) or less.

There is also a substantial market for niobium carbide, primarily in Europe, as an additive in conjunction with tantalum carbide for cemented carbide cutting tools.

Production

Reduction Processes. At present, the major process for the recovery of niobium is the aluminothermic reduction of pyrochlore concentrates to ferroniobium. Niobium metal is purified by a chlorination process wherein volatile $NbCl_5$ is distilled and then hydrolyzed to the oxide. The metal is then recovered by a second aluminothermic reduction:

$$3Nb_2O_5 + 10Al \overset{accelerator}{\rightarrow} 6Nb + 5Al_2O_3 \qquad \textbf{(Eq 1)}$$

During the exothermic reaction, oxide impurities slag from the molten niobium. Carbothermic reduction has also been practiced.

Another niobium recovery process involves the collection of niobium oxide as a by-product in the processing of tantalum ores. The ore is digested in mixed acids containing hydrofluoric acid and sulfuric acid, and solvent extraction is employed for purification. After aluminothermic reduction of the recovered oxide, the metal is further purified and consolidated by EB melting.

Powder Production. Powders are produced from ingot by hydriding, crushing, and dehydriding; in addition, some recent efforts have been directed toward producing complex metastable alloy powders, such as niobium-aluminum and niobium-silicon alloys, by liquid metal atomization and rapid quenching. The particle structure of degassed hydride niobium powder (Fig. 6) is completely analogous to that of a tantalum powder produced in a similar process for capacitors. Typical compositions of niobium and C-103 alloy powder made by this process are compared in Table 11. Niobium powders produced by the hydride-crush-degas process are not normally used for capacitors, and thus milling to a very fine particle size (that is, a high surface area) is not required. Normally, powders are crushed to pass an 80-mesh screen, and a mean particle size of 10 to 15 μm (400 to 600 μin.) is typical. Although thermal agglomeration is feasible and is commonly employed to form clusters for very fine tantalum powders, it is rarely necessary for niobium.

Table 11 Typical composition of niobium and C-103 niobium alloy powder made by the hydride-dehydride process

Element	Analysis, ppm

Niobium powder is frequently used as the starting material to blend with alloying agent powders. The blend is pressed to bars and melted, thereby promoting alloy homogeneity. Niobium alloy scrap, which is reduced to powder by the hydride-dehydride process, can also be incorporated into the alloy blends. One P/M dispersion-strengthened alloy containing 0.5% TiO_2 is claimed to have improved yield strength and high-temperature grain stability.

Coatings

The general fabrication practices for niobium are described in the section "Production of Refractory Metals" in this article. However, niobium and its alloys are the only refractory metals for which large parts are coated to prevent oxidation in high-temperature service (>425 °C, or 800 °F). Early coating development for niobium was centered on pack cementation and chemical vapor deposition. However, experience with these two processes showed that they increased the ductile-to-brittle transition temperature of the metal and caused part distortions. Later, spurred by the needs of the Apollo space program, techniques to apply slurry coatings of complex aluminides and, subsequently, silicides were devised. When properly prepared and applied, these coatings were more reliable, exhibited excellent cyclic performance characteristics without drastic mechanical property deterioration, and caused minimal hardware distortion.

The Si-20Cr-20Fe composition, made using elemental powder suspended in nitrocellulose lacquer with a thermotropic gelling agent, became the mainstay coating. Comparative mechanical properties for three coated niobium alloys (Cb-752, C-129Y, and FS-85) are shown in Fig. 7, 8, 9. Other variants contain hafnium silicide, which gives the final coating a higher remelt temperature. Methods for applying the slurry include dipping, spraying, and touch-up painting. Following application of approximately 0.08 mm (0.003 in.) of slurry per side, the coating is heated to about 1300 to 1400 °C (2370 to 2550 °F) for reaction bonding and diffusion.

Fig. 7 Effect of temperature on the mechanical properties of three niobium alloys coated with Si-20Cr-20Fe silicide coating. (a) Tensile yield strength and specific strength. (b) Stress. Specific strength is the ratio of tensile yield strength (F_{ty}) (in lb/in.^{2}) to mass density (ρ) (in lb/in.^{3}) and has been converted directly from inches to millimeters. Stress levels are based on material thickness prior to application of coating.

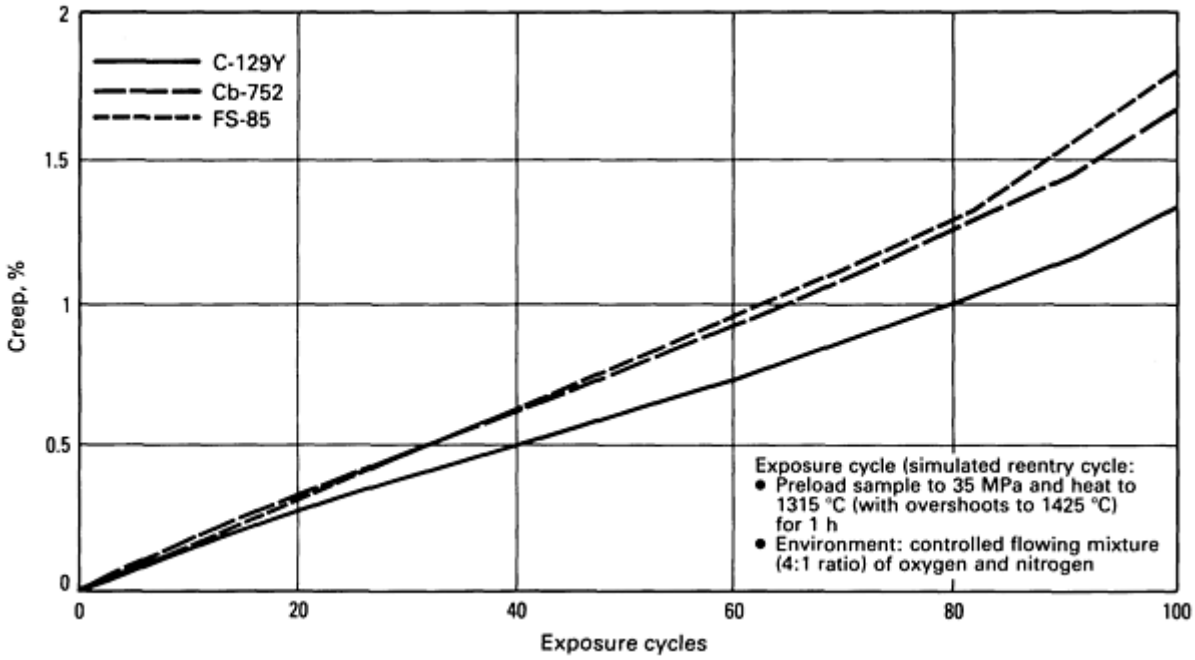

Fig. 8 Cyclic creep in three niobium alloys coated with Si-20Cr-20Fe silicide coating

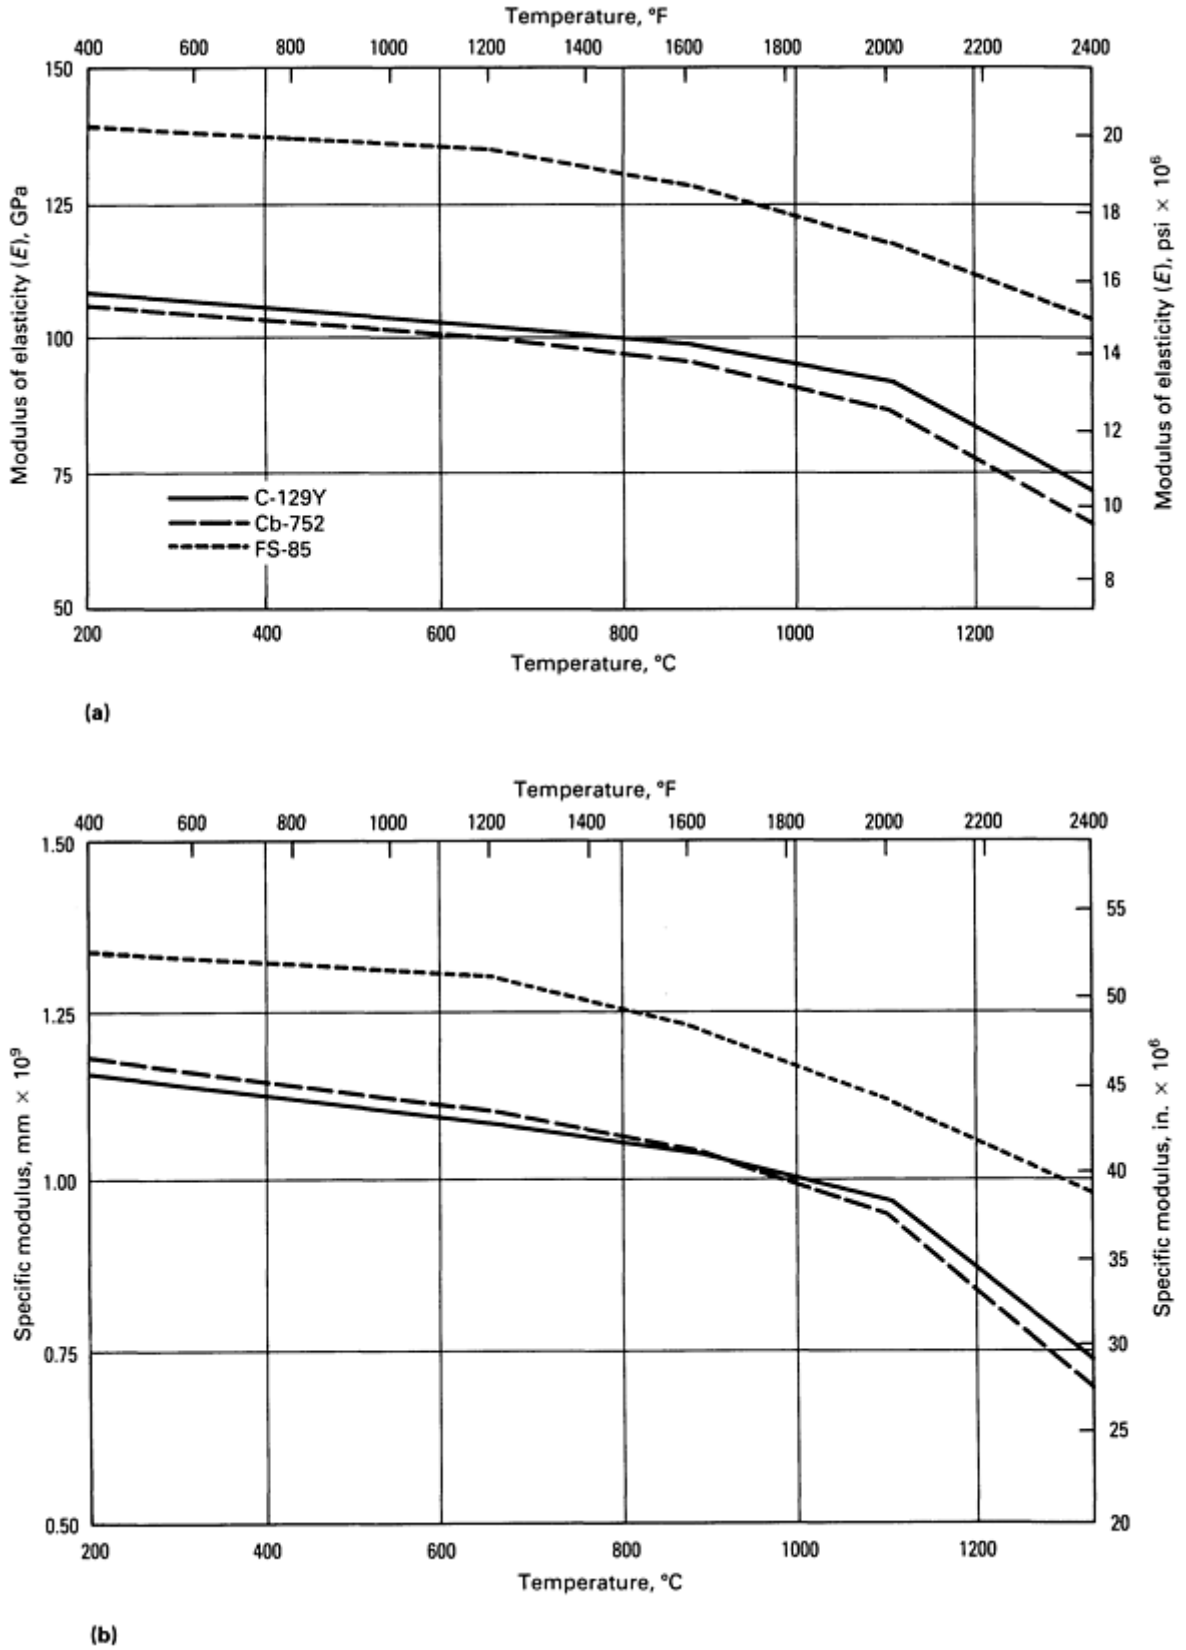

Fig. 9 Effect of temperature on the elastic properties of three niobium alloys coated with Si-20Cr-20Fe silicide coating. (a)Modulus of elasticity. (b)Specific modulus. Specific modulus is the ratio of the modulus of elasticity (*E*) (in lb/in.^{2}) to mass density (ρ) (in lb/in.^{3}); it has been converted directly from inches to millimeters.

The improvements in high-temperature oxidation resistance with the use of slurry coating technology have not been achieved without side effects. Compared with base metal, coated metal has lower strength and ductility, higher emissivity,

and increased weight. A more serious limitation imposed by the presence of coatings is a reduction in design and fabrication options. For aerospace applications, because of the coating requirement, sharp edges must be eliminated. Spot welding and riveting are not recommended for coated hardware fabrication.

Chemical Properties

Niobium forms an oxide coating in most acid environments. This coating provides excellent corrosion resistance, especially to nitric and hydrochloric acids. Strong alkaline solutions and hydrofluoric acid attack niobium severely. Table 12 presents typical data on the corrosion of niobium in various acids and alkalis (additional information is available in the article "Corrosion of Niobium and Niobium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*). At elevated temperatures, the metal reacts with halogens, oxygen, nitrogen, carbon, hydrogen, and sulfur. It forms high-melting-point compounds with elements such as carbon, boron, silicon, and nitrogen.

(a) Original specimen dimensions; thickness, 0.2 mm (0.008 in.); surface area, 26 cm^2 (4 $in.^2$). 75% of specimen surface was immersed in the liquid.

Niobium can be used in contact with liquid lithium, sodium, and sodium-potassium eutectic at temperatures well above 800 °C (1470 °F). Addition of 1% Zr increases the resistance of niobium to embrittlement caused by oxygen absorbed from the liquid metal.

Mechanical and Physical Properties

Properties of unalloyed niobium are shown in Table 2. Additional information on unalloyed niobium is available in the section "Niobium" in the article "Properties of Pure Metals" in this Volume. Property data for selected niobium alloys are listed below.

Nb-1Zr

Commercial Names

UNS number. Commercial grade, R04261; reactor grade, R04251

Trade name. Wah Chang WC-1Zr, Fansteel 80

Common name. Nb-1Zr

Specifications

ASTM. B 391, B 392, B 393, B 394

Chemical Composition

Composition limits. Commercial grade: 98.5 Nb min, 0.8 to 1.2 Zr, 0.0100 C max, 0.0300 N max, 0.0300 O max, 0.0020 H max, 0.01 Hf max, 0.01 Fe max, 0.005 Mo max, 0.005 Ni max, 0.005 Si max, 0.2 Ta max, 0.05 W max. For reactor grade, Fe is 0.005 max, O is 0.015 max, Ta is 0.1 max, and W is 0.03 max.

Consequence of exceeding impurity limits. Increasing interstitial content decreases ductility of the material.

Mechanical Properties

Tensile properties. Recrystallized: typical tensile strength, 241 MPa (35 ksi); yield strength, 138 MPa (20 ksi); elongation, 20% in 25.4 mm (1 in.). See also Table 13.

Creep-rupture properties. See Fig. 10.

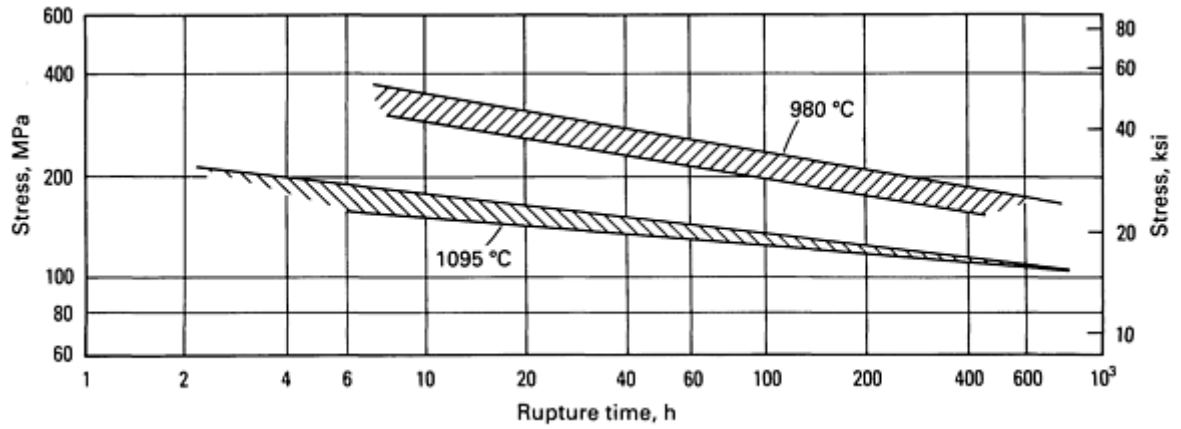

Fig. 10 Stress-rupture properties of Nb-1Zr

Mass Characteristics

Density. 8.59 g/cm^3 (0.31 lb/in.^{3})

Thermal Properties

Liquidus temperature. 2407 °C (4365 °F)

Coefficient of linear thermal expansion. 7.54 μm/m · K (4.19 μin./in. · °F) at 20 to 400 °C (68 to 750 °F)

Specific heat. 0.270 kJ/kg · K (0.065 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 41.9 W/m · K (24.2 Btu/ft · h · °F) at 25 °C (77 °F)

Electrical Properties

Electrical resistivity. 14.7 nΩ · m at 0 °C (30 °F)

Chemical Properties

Resistance to specific corroding agents. Especially resistant to liquid metals

Fabrication Characteristics

Machinability. 80% of C36000 (free-cutting brass)

Forgeability. 75% at 650 to 980 °C (1200 to 1800 °F)

Formability. Extrusion: reduction ratio of 10:1 at 1065 °C (1950 °F). Rolling: 85% reduction at 205 to 315 °C (400 to 600 °F) and at finish. Readily formable by conventional metal-forming processes

Weldability. Can be joined by electron beam welding, resistance, welding, and gas tungsten arc welding

Recrystallization temperature. 980 to 1205 °C (1800 to 2200 °F)

Hot-working temperature. 1095 to 1205 °C (2000 to 2200 °F)

Stress-relief temperature. 1 h at 900 to 980 °C (1650 to 1800 °F)

C-103
89Nb-10Hf-1Ti

Commercial Names

Trade name. WC 103, C-103

Chemical Composition

Composition limits. 0.0100 C max, 9 to 11 Hf, 0.7 to 1.3 Ti, 0.7 Zr max, 0.0300 O, 0.0300 N max, 0.0020 H max, 0.5 W max, 0.5 Ta max, bal Nb

Applications

Typical uses. Thrust chambers and radiation skirts for rocket and aircraft engines, guidance structure for glide reentry vehicles, thermal shields, piping or containers for chromic and other acids, piping for liquid alkali metal containment, and sodium-vapor lamp electrodes

Precautions in use. For elevated-temperature applications, aluminide or silicide coatings should be

used. Not recommended for use in hydrofluoric acid or strong alkaline solutions

Mechanical Properties

Tensile properties. Typical. Cold rolled: tensile strength, 725 MPa (105 ksi); yield strength, 670 MPa (97 ksi); elongation, 4.5% in 50 mm (2 in.). Recrystallized: tensile strength, 405 MPa (59 ksi); yield strength, 310 MPa (45 ksi); elongation, 26% in 50 mm (2 in.). See also Table 16.

Creep-rupture properties. See Fig. 11.

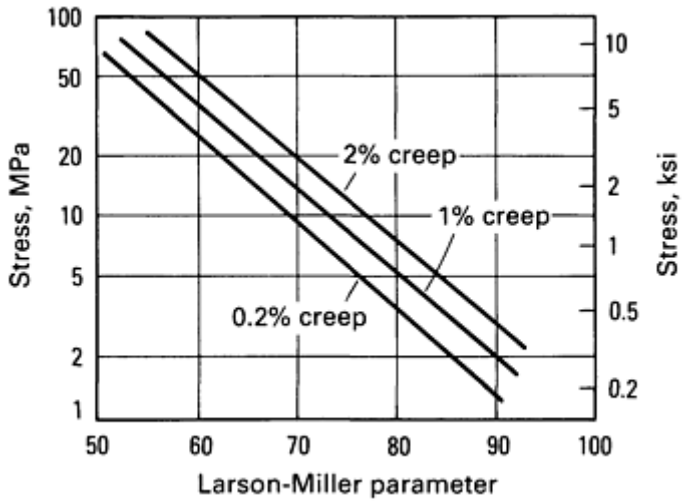

Fig. 11 Larson-Miller parameter plot for recrystallized C-103. Larson-Miller parameter = $T \cdot 10^{-3}$ (20 + log$t$), where T is the test temperature in K and t is the rupture time in hours

Mass Characteristics

Density. 8.87 g/cm^3 (0.32 lb/$in.^3$) at 25 °C (77 °F)

Thermal Properties

Liquidus temperature. 2350 °C (4260 °F)

Coefficient of linear thermal expansion. 8.10 μm/m · K (4.5 μin./in. · °F) at 20 to 1205 °C (68 to 2200 °F)

Specific heat. 0.340 kJ/kg · K (0.082 Btu/lb · °F) at 20 °C (70 °F)

Thermal conductivity. 41.9 W/m · K (24.2 Btu/ft · h · °F) at 25 °C (77 °F)

Chemical Properties

General corrosion behavior. A protective oxide forms on C-103 in most acid media, providing excellent corrosion resistance.However, the alloy is severely attacked by hydrofluoric acid and strong alkaline solutions.

Resistance to specific corroding agents. Excellent resistance to nitric acid of all concentrations and to dilute hydrochloric acid

Fabrication Characteristics

Forgeability. 60% total reduction at 1205 to 925 °C (2200 to 1700 °F).

Hot formability. Extrusion: reduction ratio is 10:1 at 1205 °C (2200 °F). Rolling: 50% reduction at 425 °C (800 °F); 60 to 80% reduction at finish

Weldability. Good gas tungsten arc weldability

Recrystallization temperature. 1040 to 1315 °C (1900 to 2400 °F)

Stress-relief temperature. 1 h at 870 °C 1600 °F)

C-129Y
80Nb-10W-10Hf-0.1Y

Commercial Name

Trade name. C-129Y

Chemical Composition

Composition limits. 9 to 11 W, 9 to 11 Hf, 0.05 to 0.3 Y, 0.5 Ta, 0.5 Zr max, 0.015 max, 0.025 O max, 0.015 N max, 0.0015 H max.

Consequence of exceeding impurity limits. Increasing interstitial content decreases material ductility.

Applications

Typical uses. For high-temperature applications, space vehicles, missiles; leading edges, nose caps for hypersonic flight vehicles, rocket nozzles; guidance structure for glide reentry vehicles, and so on

Precautions in use. Interstitial contamination should be avoided during welding. A postweld annealing at 1205 to 1315 °C (2200 to 2400 °) for 1 h is recommended. For elevated-temperature applications, silicide or aluminide coatings are required.

Mechanical Properties

Tensile properties. Tensile strength, 620 MPa (90 ksi); yield strength, 515 MPa (75 ksi); elongation, 25% in 25 mm (1 in.). See also Fig. 12.

Mass Characteristics

Density. 9.50 g/cm^3 (0.343 lb/in.^{3})

Thermal Properties

Liquidus temperature. 2400 °C (4350 °F)

Coefficient of linear thermal expansion. 6.88 µm/m · K (3.82 µin./in. · °F) at 20 to 1100 °C (70 to 2010 °F)

Specific heat. 0.268 kJ/kg · K (0.064 Btu/lb · °F) at 1095 °C (2000 °F)

Thermal conductivity. 69.6 W/m · K (40 Btu/ft · h · °F)

Chemical properties

General corrosion behavior. Good elevated-temperature properties combined with heat and oxidation resistance. Excellent corrosion resistance to most acid media. However, C-129Y is severely attacked by hydrofluoric acid and strong alkaline solutions.

Fabrication Characteristics

Machinability. 75% of C36000 (free-cutting brass)

Forgeability. 50% at 930 to 1205 °C (1705 to 2200 °F)

Formability. Extrusion: reduction ratio of 4:1 at 1205 °C (2200 °F). Rolling: reduction of 50% at 430 °C (805 °F), 60 to 70% reduction at finish

Weldability. Weldments exhibit ductility as low as -170 °C (-275 °F) if measures to prevent atmosphere contamination are taken.

Recrystallization temperature. 1315 °C (2400 °F)

Annealing temperature. 980 to 1315 °C (1800 to 2400 °F)

Hot-working temperature. 980 to 1315 °C (1800 to 2400 °F)

Stress-relief temperature. 1 h at 870 °C (1800 °F)

Cb-752
Nb-10W-2.5Zr

Commercial Name

Trade name. Cb-752

Chemical Composition

Composition limits. 9 to 11 W, 2 to 3 Zr, 0.015C max, 0.02 O max, 0.01 N max, 0.001 H max

Consequence of exceeding impurity limits. Increasing interstitial content decreases alloy ductility.

Applications

Typical uses. Guidance structure for glide reentry vehicles, jet engine structure, thermal radiation, and ducting for space power systems

Precautions in use. Resistance to high-temperature oxidation is poor, and protective coatings are required for elevated-temperature applications.

Mechanical Properties

Tensile properties. Annealed sheet: tensile strength, 540 MPa (78 ksi); yield strength, 400 MPa (58 ksi); elongation, 20% minimum in 50 mm (2 in.). At 1205 °C (2200 °F): tensile strength, 195 MPa (28 ksi); yield strength, 150 MPa (22 ksi); elongation, 25% minimum in 50 mm (2 in.). Figure 16 shows elongation in 25 mm (1 in.).

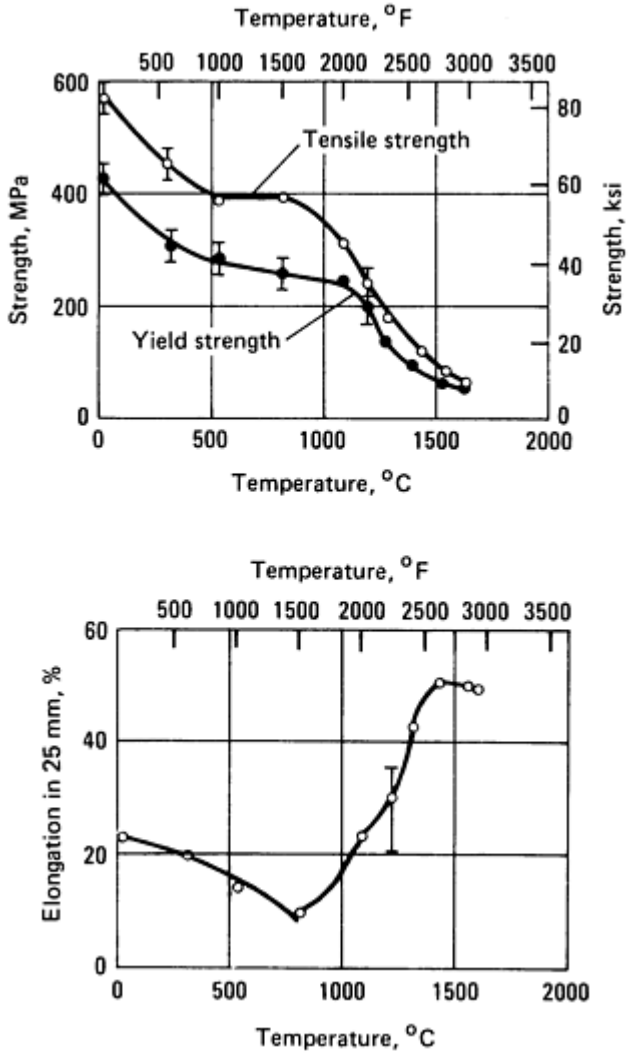

Fig. 16 Effect of test temperature on average tensile properties of duplex-annealed Cb-752 sheet

Shear strength. 425 MPa (62 ksi)

Compressive properties. Compressive strength, 351 MPa (50.9 ksi)

Bearing properties. Bearing strength, ultimate, 703 MPa (102 ksi); bearing strength, yield, 625 MPa (91 ksi)

Hardness. 180 HK, annealed 1 h at 1370 °C (2500 °F)

Elastic modulus. Tension, 110 GPa (16×10^6 psi)

Fatigue strength. 275 MPa (40 ksi) at 10^6 cycles

Creep-rupture properties. See Fig. 17.

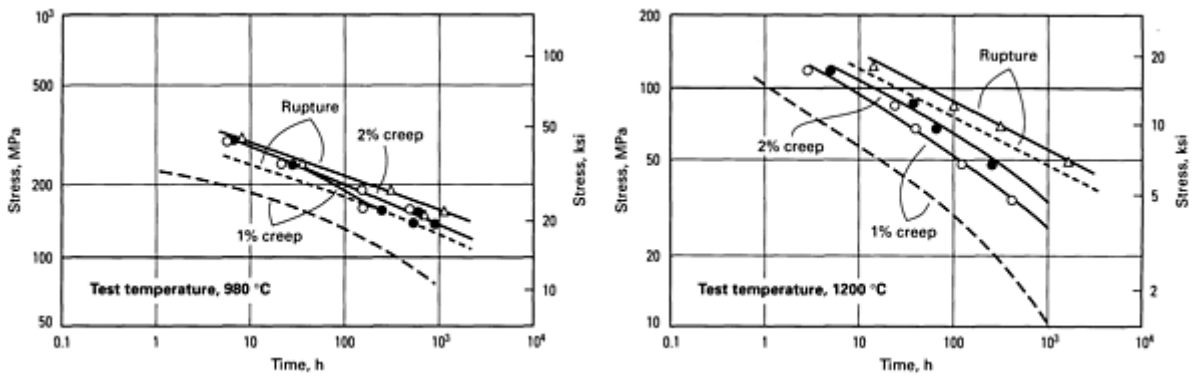

Fig. 17 Total creep curves for Cb-752 sheet. Data points represent material duplex annealed, then aged 1 h at 1595 °C (2900 °F). Dashed lines are for duplex-annealed material that did not undergo aging treatment.

Mass Characteristics

Density. 9.03 g/cm^3 (0.326 lb/in.^{3}) at 25 °C (77 °F)

Thermal Properties

Liquidus temperature. 2425 °C (4400 °F)

Coefficient of linear thermal expansion. 7.4 μm/m · K (4.1 μin./in. · °F) at 20 to 1205 °C (68 to 2200 °F)

Specific heat. 0.281 kJ/kg · K (0.067 Btu/lb · °F) at 540 °C (1000 °F); temperature coefficient, 0.0335 per K at 0 to 540 °C (32 to 1000 °F). See also Fig. 18.

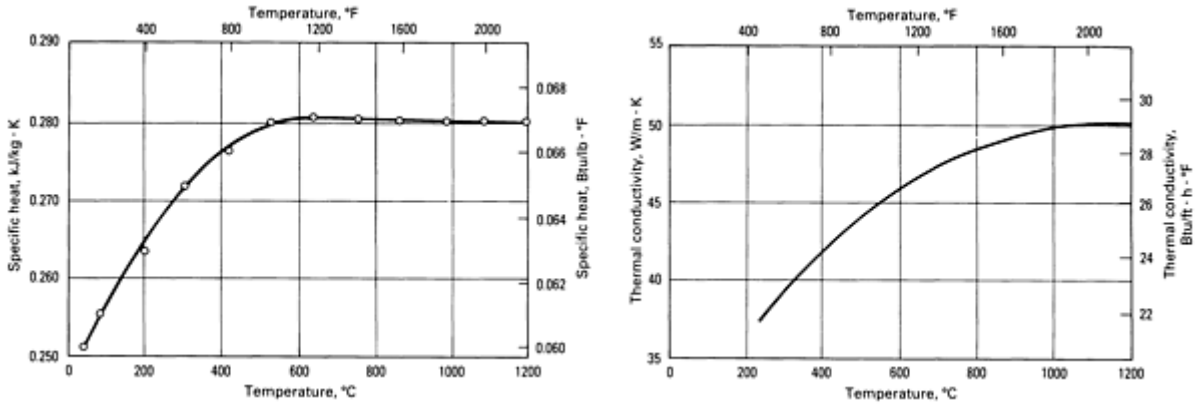

Fig. 18 Thermal properties of Cb-752

Thermal conductivity. 48.7 W/m · K (28 Btu/ft · h · °F) at 760 °C (1400 °F); temperature coefficient, 0.0219 per K at 205 to 760 °C (400 to 1400 °F). See also Fig. 18.

Chemical Properties

General corrosion behavior. Excellent corrosion resistance to most acid media, but severely attacked by hydrofluoric acid and strong alkaline solutions

Resistance to specific corroding agents. Good corrosion resistance to oxygen-free liquid metals, for example, potassium and lithium at elevated temperatures (980 to 1205 °C, or 1800 to 2200 °F) for approximately 4000 h

Fabrication Characteristics

Machinability. 80% of C36000 (free-cutting brass)

Forgeability. 50% at 930 to 1205 °C (1705 to 2200 °F)

Formability. The alloy can be formed using most of the conventional methods. Primary ingot breakdown must be done above the recrystallization temperature. Subsequent working may be accomplished in the range from room temperature to 425 °C (800 °F).

Weldability. Fusion welding by gas tungsten arc and electron beam processes can be readily accomplished if measures are taken to prevent atmosphere contamination.

Recrystallization temperature. 1205 to 1315 °C (2200 to 2400 °F)

Annealing temperature. 1205 to 1315 °C (2200 to 2400 °F)

Solution temperature. 1425 to 1540 °C (2600 to 2800 °F)

Aging temperature. 1095 °C (2000 °F)

Hot-working temperature. 980 to 1315 °C (1800 to 2400 °F)

Stress-relief temperature. 1 h at 980 to 1095 °C (1800 to 2000 °F)

FS-85
Cb-28Ta-10W-1Zr

Chemical Composition

Composition limits. 0.01 C max, 26 to 29 Ta, 10 to 12 W, 0.6 to 1.1 Zr, 0.03 O max, 0.015 N max, 0.001 H max

Mechanical Properties

Stress-relief temperature. 1 h at 1010 °C (1850 °F)

Tantalum

Charles Pokross, Fansteel Inc.

CURRENTLY, THE LARGEST USE of tantalum is in electrolytic capacitors. Tantalum P/M anodes are used in solid and wet electrolytic capacitors, and precision tantalum foil is used, although to a lesser extent, in foil capacitors. Tantalum is also used in chemical process equipment such as heat exchangers, condensers, thermowells, and lined vessels; most notably, it is used for the condensing, reboiling, preheating, and cooling of nitric acid, hydrochloric acid, sulfuric acid, and combinations of these acids with many other chemicals. Because of its high melting point, tantalum is used for heating elements, heat shields, and other components in high-temperature vacuum furnaces, and it has found some use for trueing of grinding wheels. Tantalum and its alloys have been used in specialized aerospace and nuclear applications and have found increasing use in military components. Because of its corrosion resistance to body fluids, it is used in prosthetic devices and in surgical staples. Tantalum is used as an alloying element in superalloys. Tantalum carbide is an important constituents in complex cemented carbides used in cutting tools.

Production

The production of tantalum metal is accomplished by the extraction of tantalum from either ores or certain tin slags, primarily those from Thailand and Malaysia; further extraction is necessary to separate tantalum from other metals present. The purified extract is recovered by precipitation of $Ta(OH)_5$, which is then calcined to the pentoxide or by crystallization with potassium fluoride to the intermediate salt, potassium fluorotantalate (K_2TaF_7).

Several methods for reducing tantalum compounds to tantalum metal have been developed, but sodium reduction of K_2TaF_7 to produce tantalum metal powder is the most commonly used today. The product of the sodium reduction can then be further refined by melting. The powder may also be pressed and sintered into bar or sold as capacitor-grade powder. By varying the parameters of sodium reduction (for example, time, temperature, sodium feed rate, and diluent), powders of various particle sizes can be manufactured.

A wide range of sodium-reduced capacitor powders are currently available, with unit capacitances ranging from 5000 $\mu F \cdot V/g$ to greater than 25,000 $\mu F \cdot V/g$. Capacitor powders are also manufactured from hydrided, crushed, and degassed EB-melted ingot. These melt-grade powders have higher purity than the sodium-reduced types and have better dielectric properties. However, unit capacitance is usually lower for EB-type powder.

Tantalum and its alloys are produced in semifinished metallic form by further processing of the sodium-reduced powders. The powder is isostatically pressed into bars, which can then be electron beam melted or sintered at high temperature under vacuum. Tantalum ingots up to 305 mm (12 in.) in diameter can be produced by electron beam melting.

The EB-melting process utilizes evaporation, volatilization of suboxides, and carbon deoxidation as purifying reactions. All of these reactions are more favorable in high vacuum (<130 mPa, or 10^{-3} torr). Because of its high melting point and very low vapor pressure, tantalum can be produced with a purity exceeding 99.95%. In addition, certain metallurgical properties can be imparted to the ingot by the addition of a vacuum arc remelt of the EB-melted ingot. One such property is grain size refinement. A flow chart outlining production of tantalum products from ore is shown in Fig. 20.

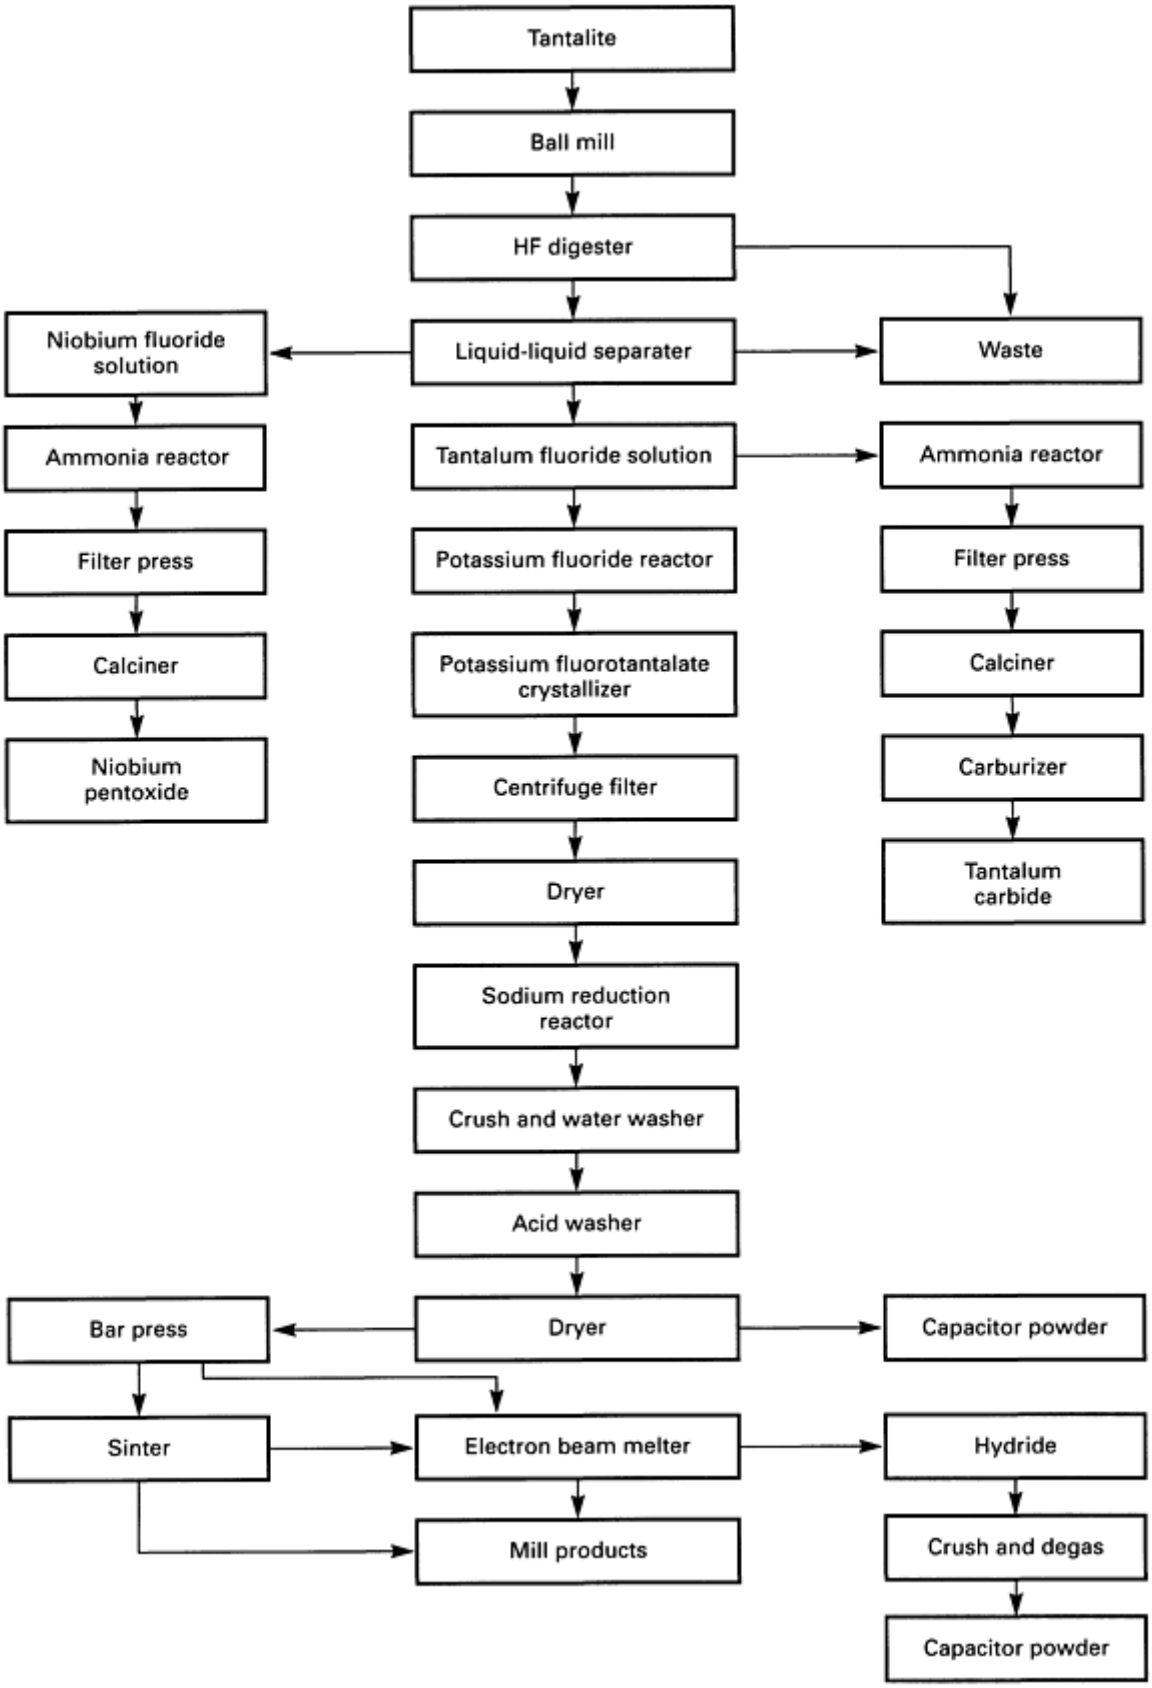

Fig. 20 Processing sequence for tantalum from ore to finished products

Fabrication

Unalloyed tantalum and tantalum alloy ingots can be broken down by either forging or extrusion. Arc cast ingots should be extruded only after upsetting and side forging. Powder metallurgy sintered bars can be rolled directly without any prior breakdown. Tantalum products can be subsequently be manufactured by standard cold-working techniques, such as rolling, drawing, tube reducing, and swaging. Typical reductions between anneals are 75 to 80%, but reductions in excess of 95% are not uncommon. Rolled sheet having a controlled, predominant {111} crystallographic texture is being produced because of its superior drawing and forming characteristics. The texture control is achieved by a specific thermomechanical process history.

Powder metallurgy tantalum has superior deep-drawing properties, but it should not not welded because of the porosity that forms in the heat-affected zone. However, EB-melted tantalum can be used for various welded products, including welded and drawn tubing.

Corrosion

Tantalum oxidizes in air at temperatures above 300 °C (570 °F). It is attacked by hydrofluoric acid, fuming sulfuric acid, and strong alkalis. Salts that hydrolyze to form hydrofluoric acid or strong alkalis also attack tantalum. The metal can be embrittled by hydrogen if it is the cathodic member of a galvanic couple exposed in an acid environment or if it is exposed to a hydrogen-containing atmosphere at elevated temperature. Other agents that can attack tantalum include bromine plus methanol, and halogen gases (fluorine at or above room temperature; chlorine at 250 °C, or 480 °F; bromine at 300 °C, or 570 °F; and iodine at somewhat higher temperatures).

Tantalum has excellent resistance to corrosion by most acids, by most aqueous salt solutions, and by organic chemicals. It also has good resistance to many corrosive gases and liquid metals.

Mechanical and Physical Properties

Selected mechanical and physical properties for commercially prepared pure EB-melted and P/M tantalum and tantalum alloys are given in Table 19. Additional properties for these materials appear in the compilations that follow.

Table 19 Typical properties of tantalum and tantalum-base alloys

Grade[(a)]	Hardness HV	Density		Melting point		Temperature		Tensile strength		Yield strength		Elongation, %	Modulus of elasticity

Molybdenum	0.02	0.02
Silicon	0.005	0.005
Nickel	0.01	0.01
Other	0.01	0.01

Additional information on unalloyed tantalum is available in the section "Tantalum" in the article "Properties of Pure Metals" in this Volume.

Ta-2.5W

Commercial Names

Trade name. Tantaloy 63 metal, Cabot-6

Chemical Composition

Composition limits. 2.0 to 3.0 W, 0.5 Nb max

Applications

Typical uses. An EB-melted solid-solution alloy used for heat exchangers, linings for towers, valves, and tubing

Ta-7.5W

Commercial Name

Trade name. 61 metal

Chemical Composition

Composition limits. 7 to 8 W, bal Ta

Applications

Typical uses. A P/M product typically cold drawn into wire for springs, elastic parts for gas chlorinators, and

elastic parts for other equipment subjected to severe acid conditions

Ta-10W

Commercial Name

Trade name. Tantaloy 60 metal, Cabot-10

Chemical Composition

Composition limits. 9 to 11 W, bal Ta

Applications

Typical uses. Used at temperatures up to 2480 °C (4500 °F) in aerospace applications, such as hot gas metering valves, rocket engine extension skirts, complex manifold assemblies, and fasteners. Chemical process industry applications include machined solid valves, internal seats and plugs for large valves, liners requiring abrasion and corrosion resistance, and disks used in patching glass-lined steel vessels; also used for tubing in some nuclear applications.

Molybdenum

Walter A. Johnson, Institute of Materials Processing, Michigan Technological University

IN ITS MOST COMMON application, molybdenum is used as an alloying element in cast irons, steels, heat-resistant alloys, and corrosion-resistant alloys to improve hardenability, toughness, abrasion resistance, corrosion resistance, and strength and creep resistance at elevated temperatures. In its pure form or as a base alloy, molybdenum is used in a wide range of industries in tools (see the articles "Wrought Tool Steels" and "P/M Tool Steels" in *Properties and Selection: Iron, Steels, and High-Performance Alloys,* Volume 1 of ASM Handbook, formerly 10th Edition *Metals Handbook*) and components that can perform satisfactorily at high temperatures or under severe abrasive or corrosive conditions.

In the electrical and electronic industries, molybdenum is used in cathodes, cathode supports for radar devices, current leads for thoria cathodes, magnetron end hats, and mandrels for winding tungsten filaments. Molybdenum is also used as a filler metal for brazing tungsten. Molybdenum resistance heating elements are used in electric furnaces that operate at temperatures up to 2205 °C (4000 °F).

Molybdenum is important in the missile industry, where it is used for high-temperature structural parts such as nozzles, leading edges of control surfaces, support vanes, struts, reentry cones, heat-radiation shields, heat sinks, turbine wheels, and pumps. Molybdenum alloys are particularly well-suited for use in airframes because of their high stiffness, high recrystallization temperature, retention of mechanical properties after thermal cycling, and good creep strength. Alloy Mo-0.5Ti has been used in many aerospace applications, but TZM is preferred where higher hot strength is needed.

In the metalworking industry, molybdenum is used for die casting cores; for hot work tools such as piercer points and extrusion and isothermal forging dies; for boring bars, tool shanks, and chill plates; and for tips on resistance welding electrodes. It is also used for cladding, for equipment for trueing grinding wheels, for molds, and for thermocouples.

Molybdenum has also been useful in the nuclear, chemical, glass, and metallizing industries. Service temperatures for molybdenum alloys in structural applications are limited to a maximum of about 1650 °C (3000 °F). Pure molybdenum has good resistance to hydrochloric acid and is used for acid service in chemical process industries.

Production

Figure 21 is a flow chart for the production of molybdenum mill products. Molybdenum oxides are converted to metallic powders via conventional hydrogen reduction processes. These powders can then be cold pressed and sintered to billet.

The P/M billets can be used as arc melting electrodes, or they can undergo subsequent metalworking directly from the P/M billet.

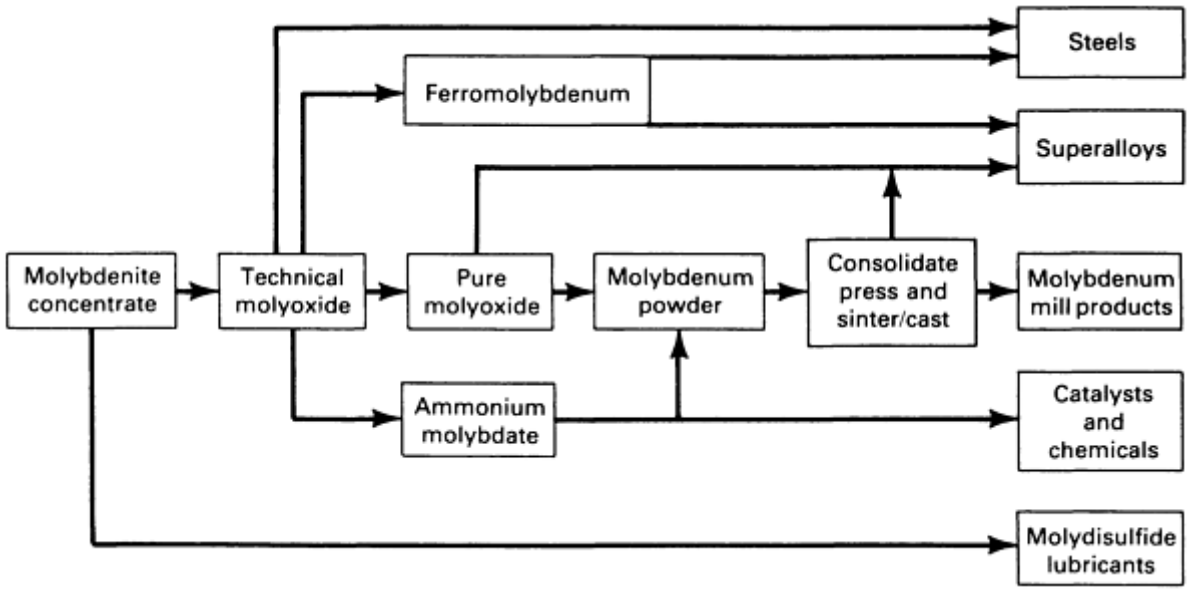

Fig. 21 Processing sequence for molybdenum from ore to finished products

Forging induces strain hardening in the billet, thereby controlling mechanical properties at temperatures below recrystallization. Upset forging breaks up the cast microstructure and improves transverse mechanical properties. Unalloyed molybdenum and TZM can be readily forged with a variety of tools, including steam hammers, drop hammers, and hydraulic forging presses using either open or closed dies.

High-capacity forging equipment is the most desirable because it minimizes work-piece heat loss, thereby extending the working time period and reducing the need for reheating. Minimum reported forging section size is 3.56 mm (0.14 in.), which can be accomplished using standard hot work tool steels. Unalloyed molybdenum and TZM typically are forged in the 870 to 1260 °C (1600 to 2300 °F) temperature range. Billet heating is conducted in commercial gas or oil-fired furnaces. Billets and workpieces will lose weight from volatilization of the oxide at temperatures above 650 °C (1200 °F); however, there is no scale formation. Weight losses of 1 to 5% can be anticipated. Molybdenum and its alloys have high thermal conductivity and low specific heat; therefore, rapid cooling and frequent billet reheats can be anticipated. These materials are typically reheated for 10 to 15 min to a temperature of 1250 °C (2280 °F). Annealing of the forging is accomplished at 1290 °C (2355 °F) for 1 h; stress relief is conducted at 980 °C (1800 °F) for 1 h for pure molybdenum and 1 h at 1200 °C (2190 °F) for TZM.

Molybdenum and its alloys are readily extruded to form a variety of shapes including tubes, round to round bars, round to square bars, and round to rectangular bars. Pure molybdenum is typically extruded in the temperature range from 1065 to 1090 °C (1950 to 1995 °F), and TZM is extruded in the temperature range from 1120 to 1150 °C (2050 to 2100 °F). Large tubes and rings are fabricated from back-extruded solid billets. Additional ring-forming operations are undertaken via ring rolling.

Molybdenum and its alloys can be fabricated in sheet form by conventional rolling and cross-rolling processes. Molybdenum and TZM sheet are typically supplied in the annealed condition.

Corrosion Resistance

Molybdenum has particularly good resistance to corrosion by mineral acids, provided that oxidizing agents are not present. The metal is relatively inert in carbon dioxide, hydrogen, ammonia, and nitrogen atmospheres at temperatures up to about 1095 °C (2000 °F); it is also relatively inert in reducing atmospheres containing hydrogen sulfide. Molybdenum

has excellent resistance to corrosion by iodine vapor, bromine, and chlorine up to clearly defined temperature limits and good resistance to attack by several liquid metals, including bismuth, lithium, magnesium, potassium, and sodium. In inert atmospheres, it is unaffected at temperatures up to at least 1750 °C (3180 °F) by refractory oxides such as alumina, zirconia, beryllia, magnesia, and thoria. Molybdenum is subject to attack by fused caustic alkalis but not by aqueous caustic solutions. Molten tin, aluminum, iron, and cobalt attack molybdenum severely, as do molten oxidizing salts such as potassium nitrate and potassium carbonate.

Because unprotected molybdenum oxidizes rapidly at temperatures above 500 °C (930 °F) in oxidizing atmospheres, it is not suitable for continued service under such conditions unless it is protected by an adequate coating. Silicide coatings, which provide the best temperature protection, have not been applied commercially to any significant extent.

Mechanical Properties

The mechanical properties of molybdenum and molybdenum alloys greatly depend on the amount of working performed below the recrystallization temperature and on the ductile-to-brittle transition temperature. The minimum recrystallization temperature for molybdenum is 900 °C (1650 °F). Detailed information on the properties of unalloyed molybdenum is available in the section "Molybdenum" in the article "Properties of Pure Metals" in this Volume.

Table 20 summarizes the chemistry and basic mechanical property data for 0.38 mm (0.015 in.) wire fabricated from unalloyed molybdenum and several of the newer molybdenum alloys. Additional property data for molybdenum alloys appear in the compilations that follow.

Mo-0.5Ti
Mo-0.5Ti-0.02C

Commercial Names

UNS number. R03620

ASTM designation. Molybdenum alloy 362

Specifications

ASTM. B 384, B 385, B 386, B 387

Chemical Composition

Composition limits. 0.010 to 0.040 C, 0.010 Fe max, 0.001 N max, 0.005 Ni max, 0.003 O max, 0.010 Si max, 0.40 to 0.55 Ti, bal Mo

Mechanical Properties

Tensile properties. Typical tensile strength: 895 MPa (130 ksi) at 20 °C (70 °F); 415 MPa (60 ksi) at 1095 °C (2000 °F); 76 MPa (11 ksi) at 1650 °C (3000 °F). Typical yield strength: 825 MPa (120 ksi) at 20 °C (70 °F); 345 MPa (50 ksi) at 1095 °C (2000 °F); 48 MPa (7 ksi) at 1650 °C (3000 °F)

Elongation. 10% at 20 °C (70 °F)

Elastic modulus. Tension: 315 GPa (46×10^6 psi) at 20 °C (70 °F); 180 GPa (26×10^6 psi) at 1095 °C (2000 °F)

Mass Characteristics

Density. 10.2 g/cm^3 (0.367 lb/in.^{3})

Thermal Properties

Liquidus temperature. 2610 °C (4730 °F)

Coefficient of linear thermal expansion. 6.1 μm/m · K (3.41 μin./in. · °F) at 20 to 1010 °C (68 to 1850 °F)

Fabrication Characteristics

Recrystallization temperature. 1315 to 1425 °C (2400 to 2600 °F)

Stress-relief temperature. 1 h at 1095 to 1205 °C (2000 to 2200 °F)

TZC
Mo-1Ti-0.3Zr

Chemical Composition

Nominal composition. 1.25 Ti, 0.3 Zr, 0.15 C, bal Mo

Applications

Typical uses. Aerospace equipment and components

Mechanical Properties

Tensile properties. Stress relieved: tensile strength, 995 MPa (144 ksi); yield strength, 725 MPa (105 ksi); elongation, 22% in 50 mm (2 in.); reduction in area, 36%. At 1095 °C (2000 °F): tensile strength, 640 MPa (93 ksi). At 1315 °C (2400 °F): tensile strength, 415 MPa (60 ksi)

TZM
Mo-0.5Ti-0.1Zr

Commercial Names

UNS number. Arc cast, R03630; P/M, R03640

ASTM designation. Arc cast: molybdenum alloy 363. P/M: molybdenum alloy 364

Specifications

ASTM. B 384, B 385, B 386, B 387

Chemical Composition

Composition limits. Arc cast: 0.40 to 0.55 Ti, 0.06 to 0.12 Zr, 0.01 to 0.04 C, 0.010 Fe max, 0.010 Si max, 0.005 Ni max, 0.001 N max, 0.0030 O max, 0.0005 H max. For P/M products: 0.002 N max, 0.030 O max, and 0.005 Si max; all other limits remain the same.

Applications

Typical uses. Used in heat engines, heat exchangers, nuclear reactors, radiation shields, extrusion dies, boring bars

Mechanical Properties

Tensile properties. See Table 21.

Table 21 Typical tensile properties of TZM

Temperature		Tensile strength		Yield strength at 0.2% offset		Elongation in 50 mm (2 in.), %
°C	°F	MPa	ksi	MPa	ksi	
Stress-relieved condition						

20	70	965	140	860	125	10
1095	2000	490	71	435	63	. . .
1650	3000	83	12	62	9	. . .
Recrystallized material						
20	70	550	80	380	55	20

1315	2400	369	53.5	. . .	. . .	. . .

Elastic modulus. Tension, 315 GPa (46 × 10^6 psi) at 20 °C (68 °F); 205 GPa (30 × 10^6 psi) at 1095 °C (2000 °F)

Mass Characteristics

Density. 10.16 g/cm^3 (0.367 lb/$in.^3$) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. 2620 °C (4750 °F)

Coefficient of linear thermal expansion. 4.9 μm/m · K (2.7 μin./in. · °F) at 20 to 40 °C (68 to 100 °F)

Thermal conductivity. See Fig. 22.

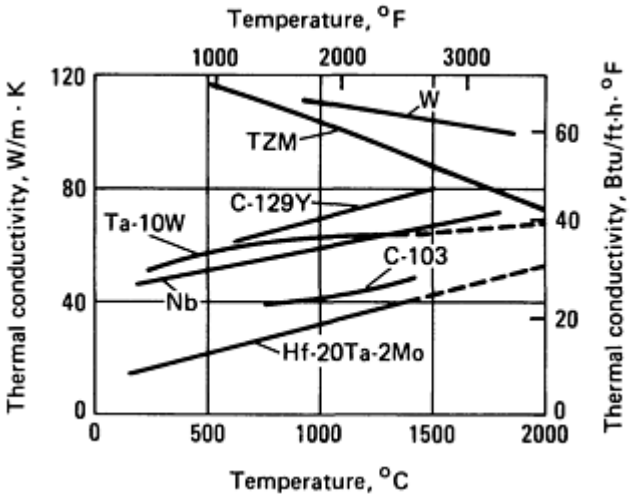

Fig. 22 Thermal conductivities of TZM and selected other refractory metals and alloys

Fabrication Characteristics

Recrystallization temperature. 1425 to 1595 °C (2600 to 2900 °F)

Stress-relief temperature. 1 h at 1095 to 1260 °C (2000 to 2300 °F)

Tungsten

Walter A. Johnson, Institute of Materials Processing, Michigan Technological University

TUNGSTEN is consumed in four forms:

- Tungsten carbide
- Alloying additions
- Pure tungsten
- Tungsten-based chemicals

Tungsten carbide accounts for about 65% of tungsten consumption. It is combined with cobalt as a binder to form the so-called cemented carbides, which are used in cutting and wear applications (see the article "Cemented Carbides" in this Volume). Metallic tungsten and tungsten alloy mill products account for about 16% of consumption. Tungsten and tungsten alloys dominate the market in applications for which a high-density material is required, such as kinetic energy penetrators, counterweights, flywheels, and governors. Other applications include radiation shields and x-ray targets. In wire form, tungsten is used extensively for lighting, electronic devices, and thermocouples. Tungsten chemicals make up approximately 3% of the total consumption and are used for organic dyes, pigment phosphors, catalysts, cathode-ray tubes, and x-ray screens.

The high melting point of tungsten makes it an obvious choice for structural applications exposed to very high temperatures. Tungsten is used at lower temperatures for applications that can use its high elastic modulus, density, or shielding characteristics to advantage.

Production

Tungsten and tungsten alloys can be pressed and sintered into bars and subsequently fabricated into wrought bar, sheet, or wire. Many tungsten products are intricate and require machining or molding and sintering to near-net shape and cannot be fabricated from standard mill products.

Shortly before World War II, an easily machinable, relatively ductile family of tungsten-base materials containing a relatively soft and ductile binder phase was developed. These materials, commonly called tungsten heavy metals, are a classic example of the application of liquid-phase sintering to the production of P/M parts. In this case, the basic metal is tungsten, nd the liquid phase in which tungsten is partly soluble is primarily nickel. In the original heavy-metal alloys, it was found that the addition of copper was desirable because it lowered the melting temperature of the liquid phase, thereby lowering the sintering temperature. The resulting tungsten-nickel-copper alloy had good mechanical properties, fair ductility, and good machinability. Subsequently, tungsten-nickel-iron alloys that had greater ductility than the tungsten-nickel-copper materials were developed. It was also found that the tungsten-nickel-iron alloys with higher percentages of tungsten could be sintered to near-theoretical density, thereby producing materials of even higher specific gravity.

Tungsten

Tungsten mill products can be divided into three distinct groups on the basis of recrystallization behavior. The first group consists of EB-melted, zone-refined, or arc-melted unalloyed tungsten; other very pure forms of unalloyed tungsten; or tungsten alloyed with rhenium or molybdenum. These materials exhibit equiaxed grain structures upon primary recrystallization. The recrystallization temperature and grain size both decrease with increasing deformation.

The second group, consisting of commercial grade or undoped P/M tungsten, demonstrates the sensitivity of tungsten to purity. Like the first group, these materials exhibit equiaxed grain structures (Fig. 23), but their recrystallization temperatures are higher than those of the first-group materials. Also, these materials do not necessarily exhibit decreases in recrystallization temperature and grain size with increasing deformation. In EB-melted tungsten wire, the

recrystallization temperature can be 900 °C (1650 °F) or lower, whereas in commercially pure (undoped) tungsten it can be as high as 1205 to 1400 °C (2200 to 2550 °F).

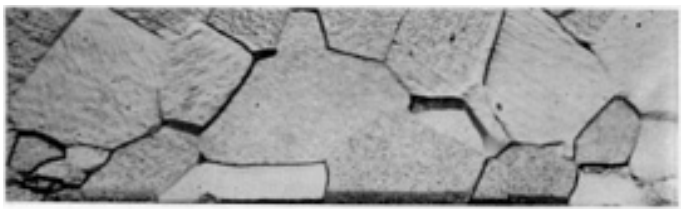

Fig. 23 Recrystallized microstructure of undoped tungsten wire

The third group of materials consists of AKS-doped tungsten (that is, tungsten doped with aluminum-potassium-silicon), doped tungsten alloyed with rhenium, and undoped tungsten alloyed with more than 1% ThO_2. These materials are characterized by higher recrystallization temperatures (>1800 °C, or 3270 °F) and unique recrystallized grain structures (Fig. 24). The structure of heavily drawn wire or rolled sheet consists of very long interlocking grains. This structure is most readily found in AKS-doped tungsten or in doped tungsten alloyed with 1 to 5% Re. The potassium dopant is spread out in the direction of rolling or drawing; when heated, it volatilizes into a linear array of submicron-size bubbles. These bubbles pin grain boundaries in the manner of a dispersion of second-phase particles. As the rows of bubbles become finer and longer with increasing deformation, the recrystallization temperature rises, and the interlocking structure becomes more pronounced. A comparative impurity analysis of the three grades of tungsten is given in Table 22. Higher concentrations of rhenium (7 to 10%) destroy this effect. In W-2ThO_2, the occurrence of this elongated, interlocking structure depends on the thermomechanical treatment and on the fineness of the thoria dispersion. Addition of 1.5% or more ThO_2 raises the recrystallization temperature of tungsten in much the same way as the potassium dopant raises it, but ThO_2 additions generally result in a much finer grain structure. Rhenium in amounts up to about 5% inhibits recrystallization; in greater amounts, it lowers resistance to recrystallization.

Table 22 Typical purity of the three commercial grades of tungsten

Impurity element	Concentration, ppm, in tungsten		
	Electron beam zone refined	Undoped	Doped
Iron	1	10	11
Nickel	2	5	5
Silicon	5	21	47
Aluminum	<2	<5	15
Potassium	<1	12	91
Oxygen	10	27	36
Carbon	20	31	24

Fig. 24 Recrystallized microstructure of doped tungsten wire

Tungsten Alloys

Three tungsten alloys are produced commercially: tungsten-ThO_2, tungsten-molybdenum, and tungsten-rhenium. The W-ThO_2 alloy contains a dispersed second phase of 1 to 2% thoria. The thoria dispersion enhances thermionic electron emission, which in turn improves the starting characteristics of gas tungsten arc welding electrodes. It also increases the efficiency of electron discharge tubes and imparts creep strength to wire at temperatures above one-half the absolute melting point of tungsten.

A flow diagram outlining the processing of tungsten ore concentrate into major products is shown in Fig. 25. Tungsten mill products, sheet, bar, and wire are all produced via powder metallurgy. These products are available in either commercially pure (undoped) tungsten or commercially doped (AKS-doped) tungsten. These additives improve the recrystallization and creep properties of tungsten, which are especially important when tungsten is used for incandescent lamp filaments. Wrought P/M stock can be zone refined by EB melting to produce single crystals that are higher in purity than the commercially pure product. Electron beam zone-melted tungsten single crystals are of commercial interest for applications requiring single crystals with very high electrical resistance ratios.

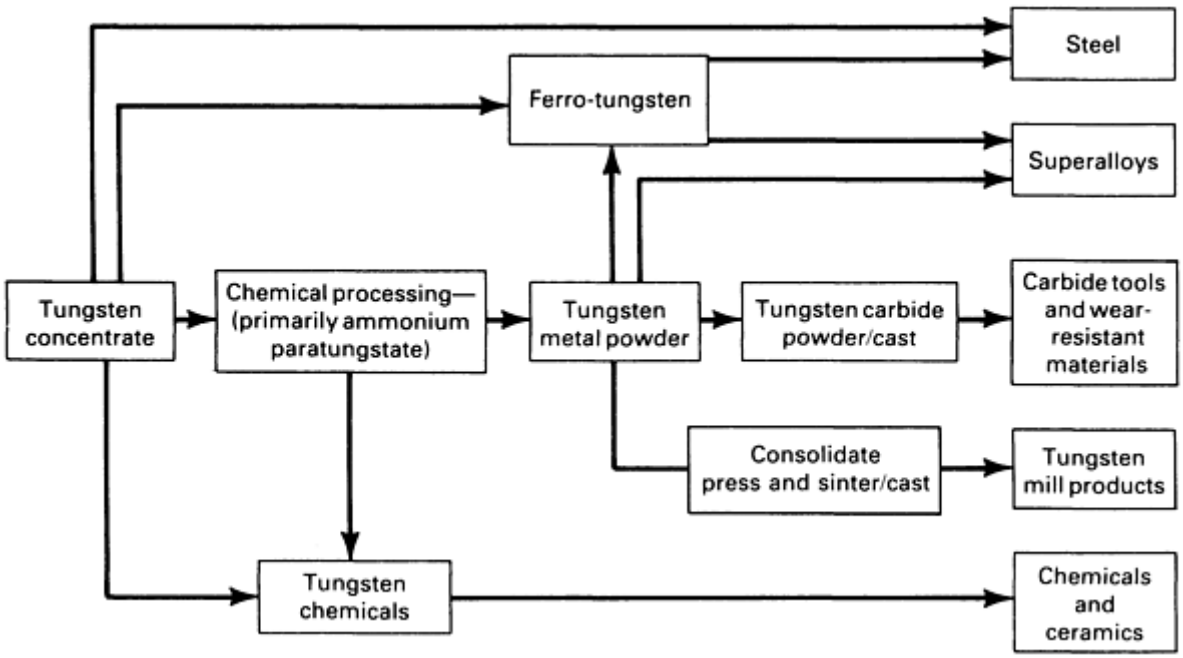

Fig. 25 Processing sequence for tungsten from ore to finished products

Processes for Manufacturing Tungsten Heavy-Metal Alloys. Heavy-metal alloys usually are produced from a mixture of elemental, high-purity, fine-particle-size metal powders. The tungsten powder has an average particle size of about 2 to 3 μm (80 to 120 μin.) and is 99.99% pure. Fine high-purity nickel powder (such as carbonyl nickel), fine electrolytic copper powder, and fine high-purity iron powder (such as carbonyl iron) are used. The powders are blended in a powder blender or ball mill for sufficient time to produce a homogeneous mixture and to achieve an apparent density compatible with the molding operation. If molding is by isostatic pressing, no binder is required. If molding is by pressing

in a steel or carbide die in a hydraulic or mechanical press, the powder is coated with paraffin or another suitable organic binder. Molding pressures of about 70 to 140 MPa (10 to 20 ksi) are used. The molded compact must be designed to allow for considerable shrinkage during the sintering operation, usually of the order of 20% lineal or more than 50% by volume. Because of the high shrinkage, most parts produced from these alloys require finish machining if close dimensional tolerances are required.

Sintering. The molded parts are usually sintered in box-type electric sintering furnaces by stoking. The furnaces must have molybdenum or tungsten heating elements because sintering temperatures range from about 1425 to 1650 °C (2600 to 3000 °F), depending on the exact composition of the alloy. In some instances, vacuum furnaces are used for sintering these materials, but normally the operation utilizes dry hydrogen or dissociated ammonia for the sintering atmosphere. Sintering times at temperature range from about 20 min for small parts to several hours for large blanks. Part weights can range from a few grams to 20 kg (45 lb) or more.

During sintering, rapid densification of the compact occurs as the fine tungsten particles dissolve in the liquid phase and then reprecipitate on the larger tungsten particles. The compact shrinks in this process, and a very dense structure is produced with rounded tungsten-rich grains that are considerably greater in diameter than the original tungsten particles. The blanks are cooled to room temperature in the cooling chamber of the furnace and then removed. Tensile bars and other test blanks usually are sintered from each powder mix and tested for mechanical and physical properties before the mix is approved for production.

Hot Pressing. Some vary large parts are produced by hot pressing rather than by cold pressing and sintering. Hot pressing usually is done by leveling the powder mix in a graphite mold and heating the mold in an induction coil while light pressure--sufficient to compact the mix to the required density at temperatures similar to those for sintering--is applied to the assembly. Hot-pressed compacts of this type usually are more brittle and lower in strength than the cold-pressed and sintered materials. Also, the graphite mold may cause a carburized layer to form on the surface of the blank that is difficult to remove in machining.

Coatings

Some promising systems for protecting tungsten from atmospheric exposure at temperatures from 1650 to 2205 °C (3000 to 4000 °F) have been developed, including:

- Roll cladding with tantalum-hafnium alloys
- Slurry-type coatings of iridium-base alloys such as Ir-30Rh
- Duplex and triplex silicide-base coating systems that combine slurry, slip, chemical vapor deposition, and pack cementation processes

Corrosion and Chemical Resistance

At room temperature, tungsten is generally resistant to most chemicals, but it can be easily dissolved with a solution of nitric and hydrofluoric acids. At higher temperatures, tungsten becomes more prone to attack. At about 250 °C (480 °F), it reacts rapidly with phosphoric acid and chlorine. It begins to oxidize readily at 500 °C (930 °F); at 1000 °C (1830 °F), tungsten reacts with many gases, including water vapor, iodine, bromine, and carbon monoxide. Above 1000 °C (1830 °F), tungsten begins to form compounds with various metals.

Mechanical and Physical Properties

Undoped Tungsten and Tungsten Alloys. Tungsten has high tensile strength and good creep resistance. At temperatures above 2205 °C (4000 °F), tungsten has twice the tensile strength of the strongest tantalum alloys and is only 10% denser. However, its high density, poor low-temperature ductility, and strong reactivity in air limit its usefulness. Maximum service temperatures for tungsten range from 1925 to 2480 °C (3500 to 4500 °F), but surface protection is required for use in air at these temperatures.

Wrought tungsten (as-cold worked) has high strength, strongly directional mechanical properties, and some room-temperature toughness. However, recrystallization occurs rapidly above 1370 °C (2500 °F) and produces a grain structure that is crack sensitive at all temperatures.

Mechanical property data for unalloyed tungsten and tungsten-molybdenum and tungsten-rhenium alloys are shown in Fig. 26, 27, 28, 29, 30, 31. Additional information on the properties of undoped tungsten is available in the section "Tungsten" in the article "Properties of Pure Metals" in this Volume.

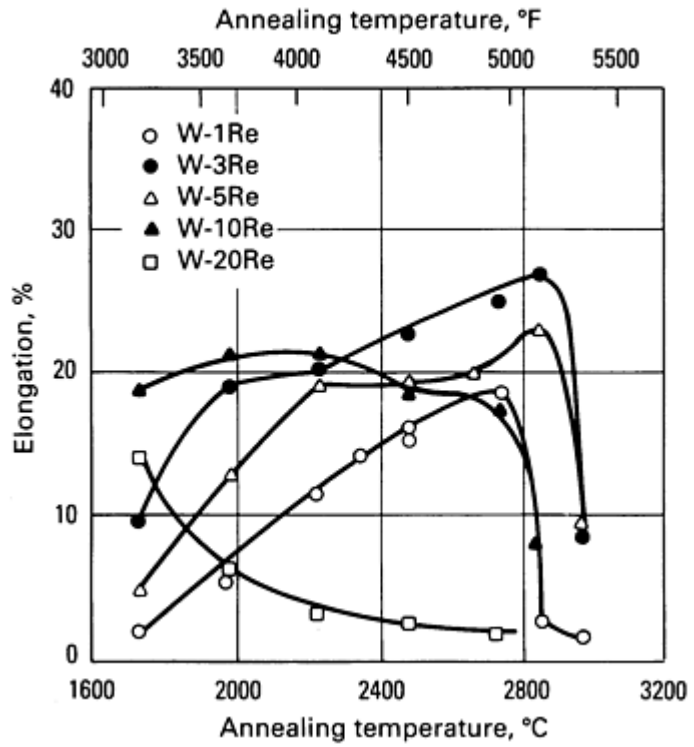

Fig. 29 Room-temperature ductility of annealed wire for five tungsten-rhenium alloys

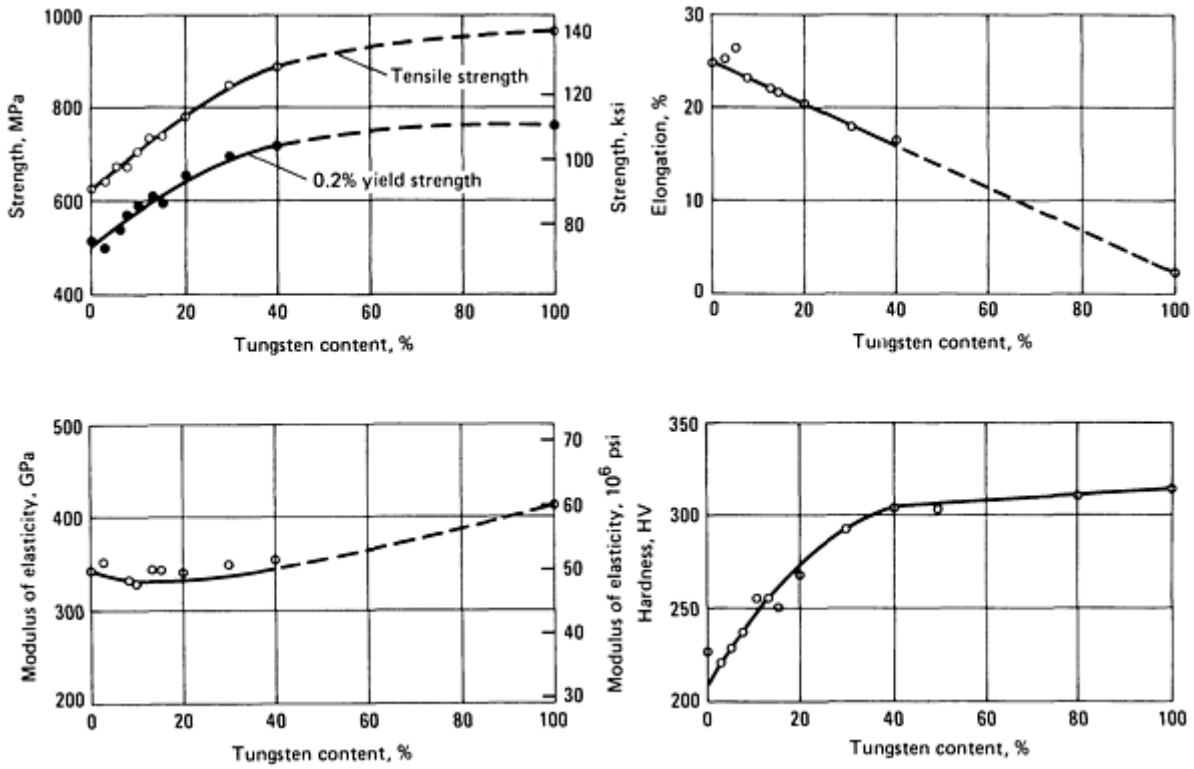

Fig. 30 Effect of tungsten content on the room-temperature mechanical properties of tungsten-molybdenum alloys

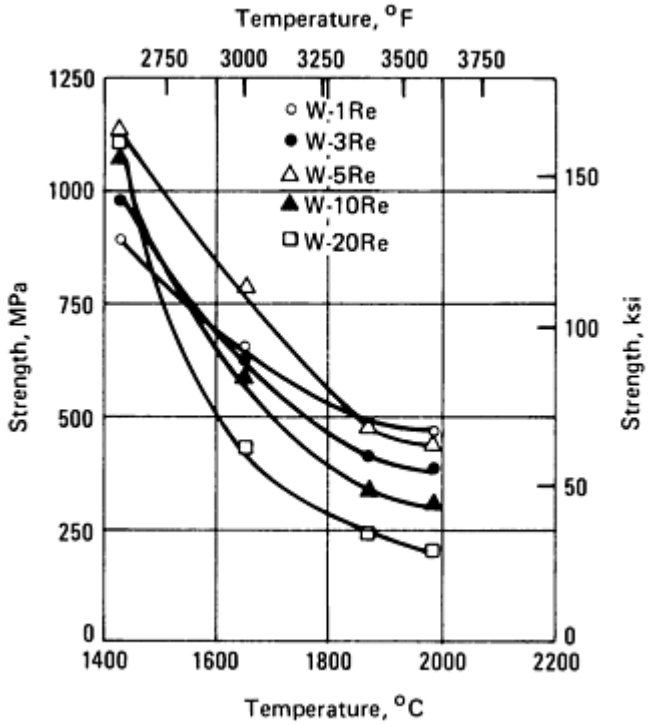

Fig. 31 Short-time tensile strengths of five tungsten-rhenium alloys

Recrystallized tungsten undergoes a ductile-to-brittle transition above 205 °C (40 °F). Only by heavy warm or cold working is the DBTT lowered to below room temperature (Fig. 32). Annealing raises the DBTT of cold-worked tungsten until it approaches that of recrystallized material.

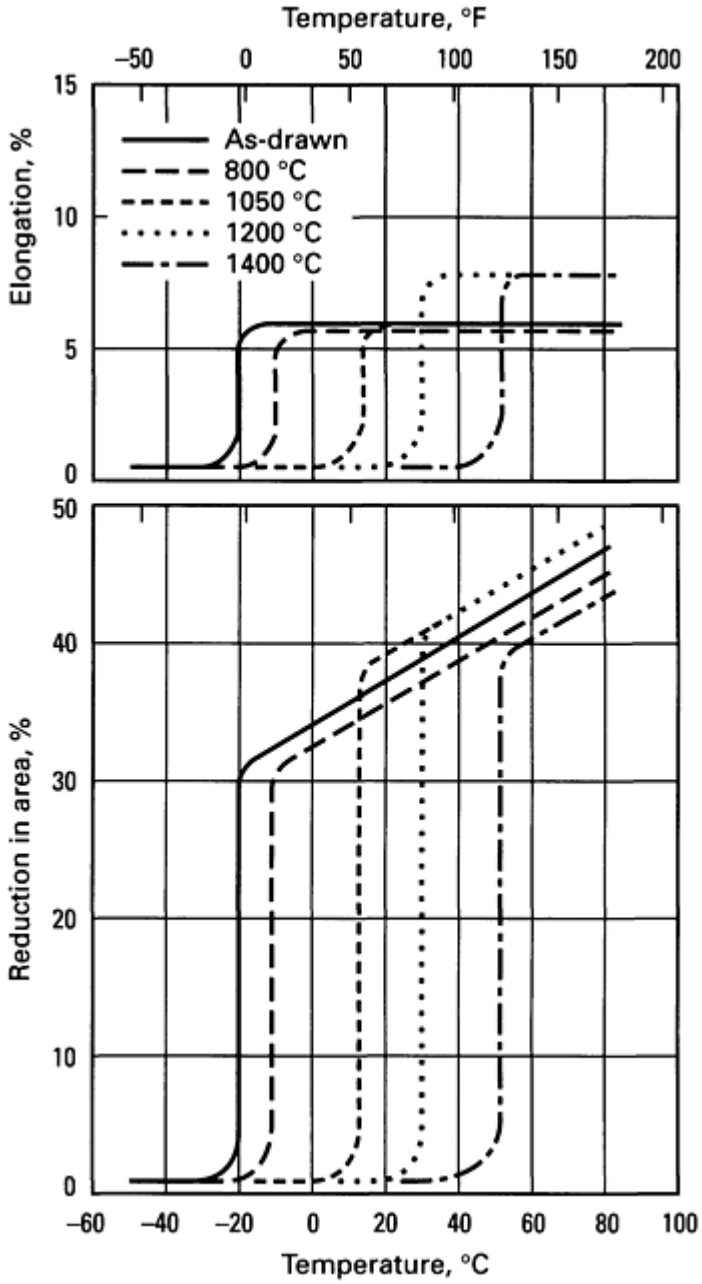

Fig. 32 Variation of DBTT with annealing temperature for undoped tungsten. Data are for 10-min recovery annealing of heavily worked 0.75 mm (0.030 in.) diam wire.

The exact ductile-to-brittle transition temperature is influenced by many factors, including grain size, strain rate, and impurity levels. The DBTT decreases with grain size unless the grains are larger than 1 mm (0.04 in.) in diameter. The DBTT also drops with increases in strain rate, but it climbs rapidly as impurity levels increase. Like all brittle metals, tungsten is very notch sensitive. Therefore, removal of even minute surface flaws by grinding, oxidizing, or electrolytic polishing prior to service improves ductility and lowers the DBTT.

Alloying can have a beneficial effect on the DBTT; the effect of rhenium in producing a ductile alloy is the best-known example. Doping with AKS dopant or alloying with a dispersion of thoria retards recrystallization, thereby improving the

ductility of annealed wire. In addition, a fine dispersion of thoria causes a decrease in grain size, which in turn promotes a reduction in the DBTT.

Below the DBTT, recrystallized tungsten fails by a combination of cleavage and grain-boundary fracture. Near the DBTT, fracture by cleavage increases. At higher temperatures, usually above 500 °C (930 °F), grain-boundary and ductile fracture predominate. Generally, grain-boundary fracture predominates in commercially pure tungsten and ductile fracture in AKS-doped tungsten.

Aside from its uses in abrasive and wear-resistant tools and as an alloying element, tungsten finds its primary commercial application in filaments for incandescent lamps. Thoria particles and the potassium bubble dispersion that occurs in AKS-doped tungsten impede the annealing process that progressively eliminates substructure. This allows tungsten to retain hardness and tensile strength at temperatures higher than those at which commercially pure or refined tungsten is softened and weakened. It also improves the creep resistance of tungsten wire at elevated temperatures. Upon recrystallization, a nonsag, interlocking grain structure forms. This structure gives tungsten wire added creep resistance at high temperatures, allowing tungsten filaments in incandescent lamps to burn at high temperatures without sagging.

Alloying with rhenium improves the tensile strength of AKS-doped or undoped tungsten. Although small additions of less than 5% Re cause softening of tungsten-rhenium alloys, hardness increases when solid-solution strengthening becomes the overriding factor. Alloying with molybdenum has a softening effect that is proportional to molybdenum content.

Tungsten is not as anisotropic in elastic behavior as are some other cubic metals, but its stress-strain curve does vary somewhat with crystallographic direction.

Tungsten Heavy-Metal Alloys. Minimum mechanical properties of machinable heavy-metal tungsten alloys are specified at the time of purchase. Three specifications are in general use: MIL-T-21014, ASTM B 459, and AMS 7725. The specifications for machinable high-density tungsten-base alloys usually divide them into four classes based on composition (Table 23) and three types based on tensile properties (Table 24). Tables 25 and 26 give typical mechanical and physical properties of tungsten heavy metal alloys according to these class and type divisions.

Table 23 Classification of tungsten heavy-metal alloys by composition, density, and hardness

Class	Tungsten content, %	Density		Hardness, HRC	Type classification[(a)]
		g/cm^3	lb/in.^{3}		
1	89-91	16.85-17.25	0.609-0.633	30-36	I
1	89-91	16.85-17.25	0.609-0.623	32 max	II, III
2	91-94	17.15-17.85	0.620-0.645	33 max	II, III
3	94-96	17.75-18.35	0.641-0.663	34 max	II, III

(a) See Table 24.

Table 24 Classification of tungsten heavy-metal alloys by tensile properties

Average	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .	. . .

(a) For a key to the three type divisions of tungsten heavy-metal alloys, see Table 24.

(b) This type is used almost exclusively for radiation shielding; data for properties other than modulus of rupture are not available.

Class 1 alloys are basically tungsten-nickel-copper or tungsten-nickel-iron alloys. The tungsten-nickel-copper alloys of this class typically contain 90% W, 6 to 7% Ni, and 3 to 4% Cu. Minor additions of other metals, such as molybdenum or cobalt, can be added to modify properties such as hardness. Class 1 tungsten-nickel-iron alloys usually contain 90% W, 5 to 7.5% Ni, and 3 to 5.5% Fe.

Class 2, 3, and 4 alloys are usually tungsten-nickel-iron alloys with tungsten contents in the range shown in Table 23. They contain a balance of nickel-iron in a ratio of 4Ni:1Fe (class 2), 7Ni:3Fe (class 3), and 1Ni:1Fe (class 4). Sometimes a portion of the iron may be replaced with copper.

Electrical Properties

The electrical resistivity and temperature coefficient of electrical resistivity properties of tungsten are both strongly affected by purity and deformation. The effects of recovery annealing on these two properties for commercially pure tungsten wire are shown in Table 27. The product of resistivity and temperature coefficient is a nearly constant value that is independent of the degree of residual cold work. The addition of rhenium, molybdenum, or thoria increases the resistivity of tungsten wire but has no appreciable effect on its temperature coefficient. Some typical electrical resistivity data are shown in Fig. 33, 34, 35.

Table 27 Effect of annealing on the electrical resistivity and temperature coefficient of drawn tungsten wire

Annealing temperature	Electrical resistivity, μΩ· m	Temperature coefficient	Matthiessen's rule[(a)]

°C	°F	μΩ· m

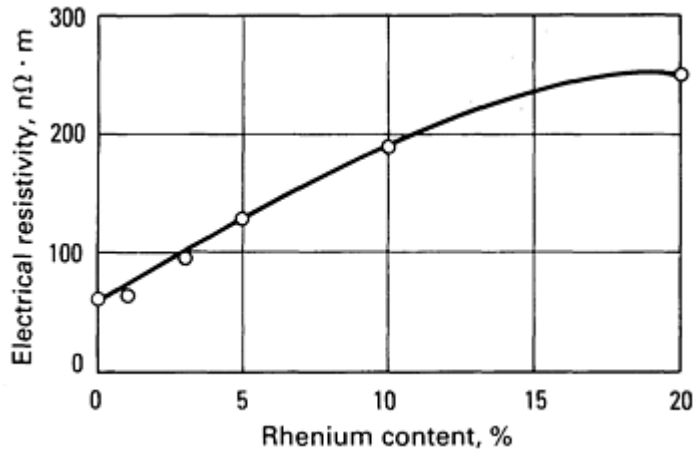

Fig. 34 Specific electrical resistivity of tungsten-rhenium alloys as a function of rhenium content

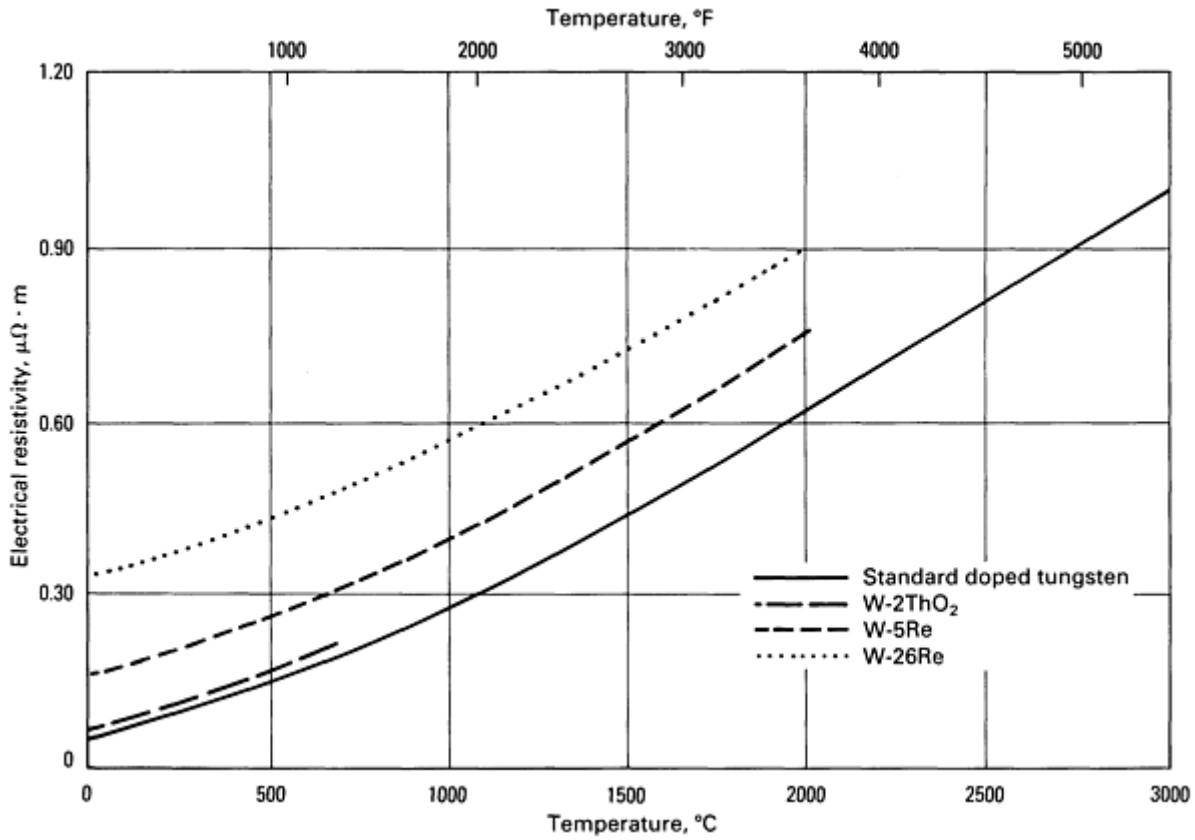

Fig. 35 Effect of temperature on the electrical resistivity of standard doped tungsten and of tungsten-rhenium alloys

Thermocouples in which tungsten is one of the thermoelements are used extensively at very high temperatures. Tungsten-molybdenum thermocouples, for example, can be used at temperatures up to 2205 °C (4000 °F) if maintained in a protective envelope or a reducing atmosphere.

Rhenium

Toni Grobstein, Robert Titran, and Joseph R. Stephens, NASA Lewis Research Center

PLATINUM-RHENIUM REFORMING CATALYSTS are the major rhenium end-use products and account for about 85% of rhenium consumption. Rhenium catalysts are exceptionally resistant to poisoning from nitrogen, sulfur, and phosphorus. They are used for the hydrogenation of fine chemicals and for hydrocracking, reforming, and the disproportionation of olefins, including increasing the octane rating in the production of lead-free petroleum products. Rhenium is also used in the production of heating elements, x-ray tubes and targets, and metallic coatings. Indium-coated rhenium nozzles for small chemical rockets and resistojet thrusters are used in space for satellite orientation. Rhenium is a solid-solution-strengthening alloying element in superalloys; in tungsten and molybdenum-based alloys, it markedly increases room-temperature ductility (this increase is known as the rhenium effect).

Rhenium metal is widely used in filaments for mass spectrographs and ion gages because of its high electrical resistivity and low vapor pressures at high temperatures. Rhenium-molybdenum alloys are superconductive at 10 K. Rhenium is used as an electrical contact material because of its wear resistance and its ability to withstand arc erosion. Thermocouples made of rhenium-tungsten are used for measuring temperatures up to 2200 °C (3990 °F), and rhenium wire is used in photoflash lamps for photography.

Relatively little development work has been done for rhenium-base alloys as compared with that for other refractory metals. The use of rhenium in aerospace applications has been restricted by its high density; in terrestrial applications, its short supply and consequent high cost have been the limiting factors. For example, the addition of 3% Re to tungsten wire doubles the cost of the wire.

Occurrence and Production

Most rhenium occurs in porphyry copper deposits. Identified sources are estimated to to about 4.5×10^3 Mg (5.0×10^3 tons) in the United States, and approximately 5.9×10^3 Mg (6.5×10^3 tons) in the rest of the world. The United States relies on imports for most of its rhenium supply, with 71% coming form Chile. it is estimated that the United States consumed about 6.35 Mg (7.00 tons) of rhenium in 1989. Rhenium is available as perrhenic acid ($HReO_4$), ammonium perrhenate (NH_4ReO_4), and metal powder. In 1988, the average price of rhenium metal was $1.05/g ($475/lb); the price was $0.66/g ($300/lb) for ammonium perrhenate.

Ammonium perrhenate is converted to metal powder by hydrogen reduction. The reduction is carried out at 380 °C (715 °F) and is followed by a purification and reduction cycle at 700 to 800 °C (1290 to 1470 °F) to remove any residual rhenium oxide. The powder is generally consolidated by cold pressing at about 205 MPa (30 ksi) to a density of 35 to 40% using stearic acid in ether as a lubricant on the punch and the die walls. Subsequent sintering at 1200 °C (2190 °F) for 2 h in vacuum results in little densification but increases the mechanical strength of the compact and burns off volatile impurities. Finally, resistance heating in a vacuum or hydrogen atmosphere at 2700 to 2900 °C (4890 to 5250 °F) produces sintered compacts with densities of more than 90%.

Electron beam remelting is sometimes used to reduced the impurity content of rhenium compacts. Chemical vapor deposition is also a practical fabrication method.

Corrosion Resistance

Rhenium oxidizes catastrophically at temperatures above 600 °C (1110 °F). Oxidation occurs as a result of the formation of rhenium heptoxide (Re_2O_7), which has a melting point of 297 °C (567 °F) and a boiling point of 363 °C (685 °F). The white oxide vapor has been reported to be nonpoisonous. Iridium is currently used as an oxidation-resistant coating for rhenium at high temperatures. Rhenium is unique among the refractory metals in that it does not form a carbide; however, it is similar to the other metals in the group in that it is resistant to liquid lithium metal corrosion. Rhenium is resistant to water cycle corrosion in high-temperature filaments in vacuum. Rhenium has good resistance to sulfuric acid and hydrochloric acid but can be dissolved by nitric acid; it is also resistant to aqua regia at room temperature. In addition, rhenium is resistant to attack by molten tin, zinc, silver, copper, and aluminum.

Mechanical and Physical Properties

Temperature-dependent tensile strength, elastic modulus, and physical property data for rhenium are presented in the introductory section of this article (see Table 2 and Fig. 1 and 2). One of the most outstanding characteristics of rhenium is its very high strain-hardening rate, which is about 3.5 times that of tungsten or molybdenum. The general trend of existing data indicates about a twofold increase in hardness for 25% deformation. This unusually rapid work hardening requires frequent intermediate annealing in inert or reducing atmospheres during fabrication, with low cold reduction levels to avoid cracking. Because impurity levels are critical to fabricability, a vacuum level of 1 to 0.1 mPa (10^{-5} to 10^{-6} torr) or a dry hydrogen atmosphere is used. Hydrogen-nitrogen mixtures, such as dissociated ammonia or annealing hydrogen ($H_2 + 7N_2$), have also been successfully used. The ultimate tensile strength of annealed rhenium sheet has been reported to increase from 1158 MPa to 2220 MPa (168 to 322 ksi) as a result of 30.7% cold reduction. Detailed property data for unalloyed rhenium are given in the section "Rhenium" in the article "Properties of Pure Metals" in this Volume.

Refractory Metal Fiber-Reinforced Composites

Toni Grobstein and Donald W. Petrasek, NASA Lewis Research Center

REFRACTORY METAL WIRES, in spite of their poor oxidation resistance and high density, have received a great deal of attention as fiber reinforcement materials for use in high-temperature composites. Although the theoretical specific strength potential of refractory alloy fiber-reinforced composites is less than that of ceramic fiber-reinforced composites, the more ductile metal fiber systems are more tolerant of fiber-matrix reactions and thermal expansion mismatches. When refractory metal fibers are used to reinforce a ductile and oxidation-resistant matrix, they are protected from oxidation, and the specific strength of the composite is much higher than that of superalloys at elevated temperatures.

The majority of the studies conducted on this topic have been on refractory wire and superalloy composites that use tungsten or molybdenum wire (available as lamp filament or thermocouple wire) as the reinforcement material. These refractory alloy wires were not designed for use in composites, nor were they developed to achieve optimum mechanical properties in the temperature range of interest for component application, 1000 to 1200 °C (1830 to 2190 °F). The stress-rupture properties of a tungsten lamp filament wire used in early studies were superior to those of rod and bulk forms of tungsten, and this wire showed promise for use as composite reinforcement. After the need for stronger wire was recognized, high-strength tungsten, tantalum, molybdenum, and niobium alloys that were originally used for rod and/or sheet fabrication were drawn into wire.

Excellent progress has been made in providing wires with increased strength. Tungsten alloy wires have been fabricated that have tensile strengths 2.5 times higher than those obtained for potassium-doped tungsten lamp filament wire. The strongest wire fabricated, tungsten-rhenium-hafnium-carbon, has a tensile strength of 2165 MPa (314 ksi) at 1093 °C (2000 °F), which is more than 6 times the strength of the strongest nickel-base or cobalt-base superalloy. Although the ultimate tensile strength values of the tungsten alloy wires were higher than those obtained for molybdenum, tantalum, or niobium wires, their advantage is lessened when the higher density of tungsten is taken into account. Nevertheless, high-strength tungsten alloy wires rank alongside molybdenum wires as offering the most promise for composite applications.

Processing of Composites. The consolidation of matrix and fibers into a composite material with useful properties is one of the most difficult steps in developing composites reinforced with refractory metal wire. Fabrication methods are currently in the laboratory phase of development because satisfactory techniques have not yet been developed for producing large numbers of specimens for extensive property characterization. Fabrication techniques currently being developed can be classified as either liquid-phase or solid-phase methods.

Liquid-phase methods consist of casting the molten matrix using investment casting techniques so that the matrix infiltrates the bundle of fibers. The molten metal must wet the fibers, form a chemical bond, and yet be controlled so as not to degrade the fibers by dissolution, reaction, or recrystallization.

Solid-phase methods generally use processing temperatures much lower than those reached during liquid-phase processing; diffusion rates are therefore much lower, and reaction with the fiber can be less severe. The prerequisite for solid-state processing is that the matrix be in either wire, sheet, foil, or powder form. Cold pressing followed by sintering or hot pressing is used to consolidate the matrix and fiber into a composite component.

Mechanical and Thermal Properties. Refractory fiber-reinforced superalloy composites have demonstrated strengths significantly above those of the strongest superalloys. Tungsten fiber-reinforced superalloy composites, in particular, are potentially useful as high-temperature (1000 to 1200 °C, or 1830 to 2190 °F) materials because of their microstructural stability and superior resistance to stress-rupture and creep deformation, thermal shock, and low- and high-cycle fatigue. Compared with conventional superalloys, refractory metal fiber-reinforced composites have improved ductility, impact damage resistance, and thermal conductivity.

Refractory fiber-reinforced niobium alloy composites have demonstrated a potential for use at temperatures in excess of 1200 °C (2190 °F). The tensile and creep strength properties of these composites have been improved an order of magnitude by adding 50 vol% tungsten fiber to the niobium alloys.

Applications. Refractory metal alloy fiber-reinforced composites are being considered for many different and demanding applications. For example, tungsten fibers are being investigated for use as a reinforcement in copper for strengthening high-conductivity materials in regeneratively cooled rocket nozzles. A volume fraction addition of 10% tungsten fibers in copper has a dramatic effect on the strength of the material without significantly decreasing its thermal conductivity. With the addition of the tungsten fibers, copper can be used at temperatures and stresses that would normally exceed its yield strength.

Tungsten fiber-reinforced superalloy composites are being developed for use in rocket engine turbine blades (Fig. 36). Tungsten fiber-reinforced superalloy composites have a highly attractive combination of properties at temperatures from 870 to 1100 °C (1600 to 2010 °F); these properties make them well suited for advanced rocket engine turbopump blade applications. The composites offer the potential of significantly improved operating life, higher operating temperature capability, and reduced strains induced by transient thermal conditions during engine start and shutdown.

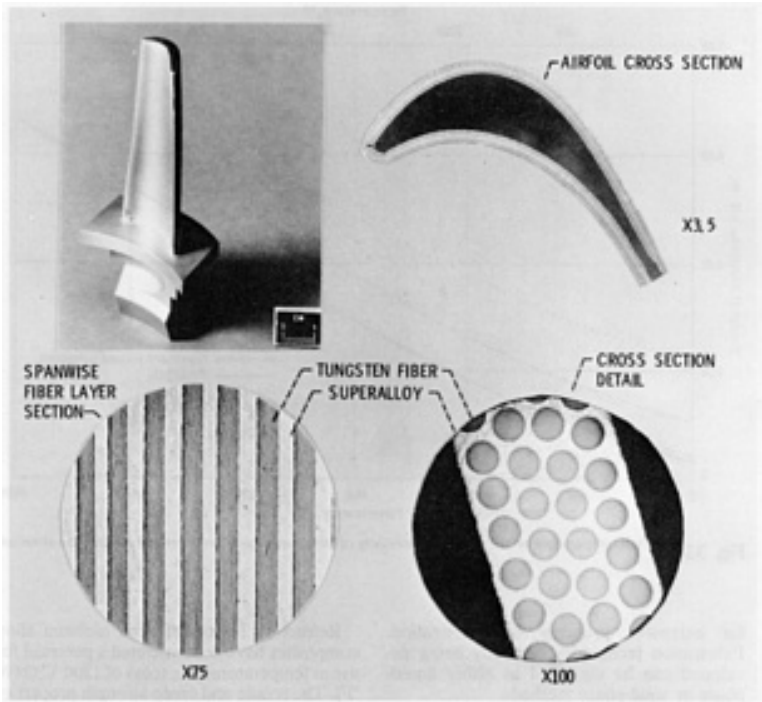

Fig. 36 Location and structure of tungsten fibers in fiber-reinforced superalloy composite turbine blades for rocket engine turbopumps. Courtesy NASA Lewis Research Center

Tungsten fiber-reinforced niobium alloy systems are being investigated for potential long-term high-temperature applications in space power systems. In addition, molybdenum-base fibers are being proposed for use in intermetallic-matrix composites for aerospace applications.

Introduction to Titanium and Titanium Alloys

James D. Destefani*, Bailey Controls Company

Introduction

TITANIUM has been recognized as an element for 200 years. Only in the last 40 years or so, however, has the metal gained strategic importance. In that time, commercial production of titanium and titanium alloys in the United States has increased from zero to more than 23 million kg/yr (50 million lb/yr).

The catalyst for this remarkable growth was the development by Dr. Wilhelm J. Kroll of a relatively safe, economical method to produce titanium metal in the late 1930s. Kroll's process involved reduction of titanium tetrachloride ($TiCl_4$), first with sodium and calcium, and later with magnesium, under an inert gas atmosphere (Ref 1). Research by Kroll and many others continued through World War II. By the late 1940s, the mechanical properties, physical properties, and alloying characteristics of titanium were defined and the commercial importance of the metal was apparent.

Commercial titanium production soon began in earnest in the United States, and by 1956 U.S. production of titanium mill products was more than 6 million kg/yr (13 million lb/yr) (Ref 2).

Alloy development progressed rapidly. The beneficial effects of aluminum additions were realized early on, and titanium-aluminum alloys were soon commercially available. Two alloys that are still widely used, Ti-6Al-4V and Ti-5Al-2.5Sn, were both developed in the early 1950s. The Ti-6Al-4V alloy, in fact, accounts for more than half of the current U.S. titanium market (Ref 3).

General Metal Characteristics. The rapid growth of the titanium industry is testimony to the metal's high specific strength and corrosion resistance. With density about 55% that of steel, titanium alloys are widely used for highly loaded aerospace components that operate at low to moderately elevated temperatures, including both airframe and jet engine components (see the section "Applications" in this article).

Titanium's corrosion resistance is based on the formation of a stable, protective oxide layer. This passivating behavior makes the metal useful in applications ranging from chemical processing equipment to surgical implants and prosthetic devices. The corrosion behavior of titanium is discussed in detail in the article "Corrosion of Titanium and Titanium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Current titanium technology encompasses a variety of products and processes. Some of the latest developments, which are briefly reviewed in the section "New Developments" in this article, include new sponge production and melting practices, titanium-matrix composites, oxide dispersion-strengthened powder metallurgy (P/M) alloys with novel compositions and properties, superplastic forming and diffusion bonding (SPF/DB) of titanium alloy sheet and plate, and titanium-base ordered intermetallic compounds.

This article is intended to provide an overview of contemporary titanium technology. Detailed information on the properties, processing, and application of specific titanium alloys and product forms is available in the articles "Wrought Titanium and Titanium Alloys," "Titanium and Titanium Alloy Castings," "Titanium P/M Products," "Metal-Matrix Composites," and "Ordered Intermetallics" in this Volume.

Alloy Types

Titanium exists in two crystallographic forms. At room temperature, unalloyed (commercially pure) titanium has a hexagonal close-packed (hcp) crystal structure referred to as alpha (α) phase. At 883 °C (1621 °F), this transforms to a body-centered cubic (bcc) structure known as beta (β) phase. The manipulation of these crystallographic variations through alloying additions and thermomechanical processing is the basis for the development of a wide range of alloys and properties. These phases also provide a convenient way to categorize titanium mill products. Based on the phases present, titanium alloys can be classified as either α alloys, βalloys, or α+ β alloys.

Alpha alloys contain elements such as aluminum and tin. These α-stabilizing elements work by either inhibiting change in the phase transformation temperature or by causing it to increase (Ref 4). Alpha alloys generally have creep resistance superior to β alloys, and are preferred for high-temperature applications. The absence of a ductile-to-brittle transition, a feature of β alloys, makes α alloys suitable for cryogenic applications.

Alpha alloys are characterized by satisfactory strength, toughness, and weldability, but poorer forgeability than β alloys (Ref 5). This latter characteristic results in a greater tendency for forging defects. Smaller reductions and frequent reheating can minimize these problems.

Unlike β alloys, alpha alloys cannot be strengthened by heat treatment. They most often are used in the annealed or recrystallized condition to eliminate residual stresses caused by working.

Alpha + beta alloys have compositions that support a mixture of α and β phases and may contain between 10 and 50% β phase at room temperature. The most common α + β alloy is Ti-6Al-4V (Ref 4). Although this particular alloy is relatively difficult to form even in the annealed condition, α + β alloys generally have good formability.

The properties of these alloys can be controlled through heat treatment, which is used to adjust the amounts and types of β phase present. Solution treatment followed by aging at 480 to 650 °C (900 to 1200 °F) precipitates α, resulting in a fine mixture of α and β in a matrix of retained or transformed β phase.

Beta alloys contain transition elements such as vanadium, niobium, and molybdenum, which tend to decrease the temperature of the α to β phase transition and thus promote development of the bcc β phase. They have excellent forgeability over a wider range of forging temperatures than α alloys, and β alloy sheet is cold formable in the solution-treated condition.

Beta alloys have excellent hardenability, and respond readily to heat treatment. A common thermal treatment involves solution treatment followed by aging at temperatures of 450 to 650 °C (850 to 1200 °F). This treatment results in formation of finely dispersed α particles in the retained β.

Market Development

From its inception, the titanium industry was tied very closely to the market for commercial and military jet aircraft. Dependence on the aerospace industry, which is cyclical in nature, resulted in numerous setbacks. Despite this, growth of the U.S. titanium industry has been relatively steady. Figure 1 illustrates the increase of U.S. titanium ingot production since 1951.

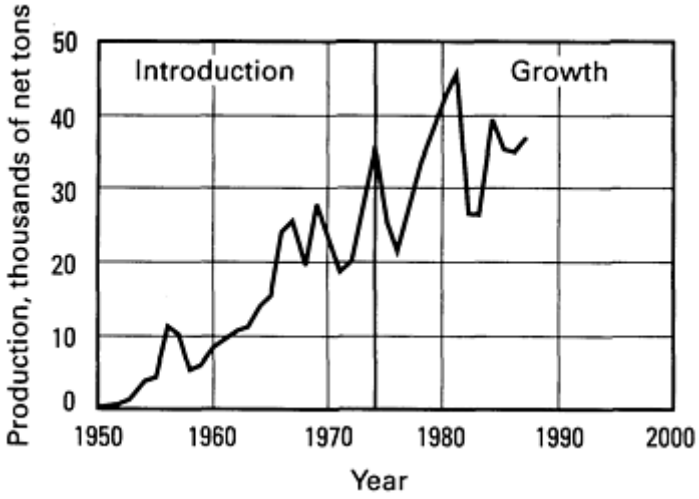

Fig. 1 Growth of U.S. titanium ingot production, 1951 to 1989. Introduction and growth indicate phases of titanium product life cycle. Source: Ref 6

The Product Life Cycle of Titanium (Ref 6). Product life cycle theory has been used for nearly 40 years to analyze the rise and fall of product demand. A typical product life cycle begins with a product's introduction into the marketplace. As shown in Fig. 2, this is followed by several more or less well-defined stages of rapid growth, maturity, and ultimate decline as replacement products enter the marketplace. Using product life-cycle models originally developed for and applied to the U.S. steel and aluminum industries, this theory has recently been applied to relate U.S. titanium demand to industrial economic growth.

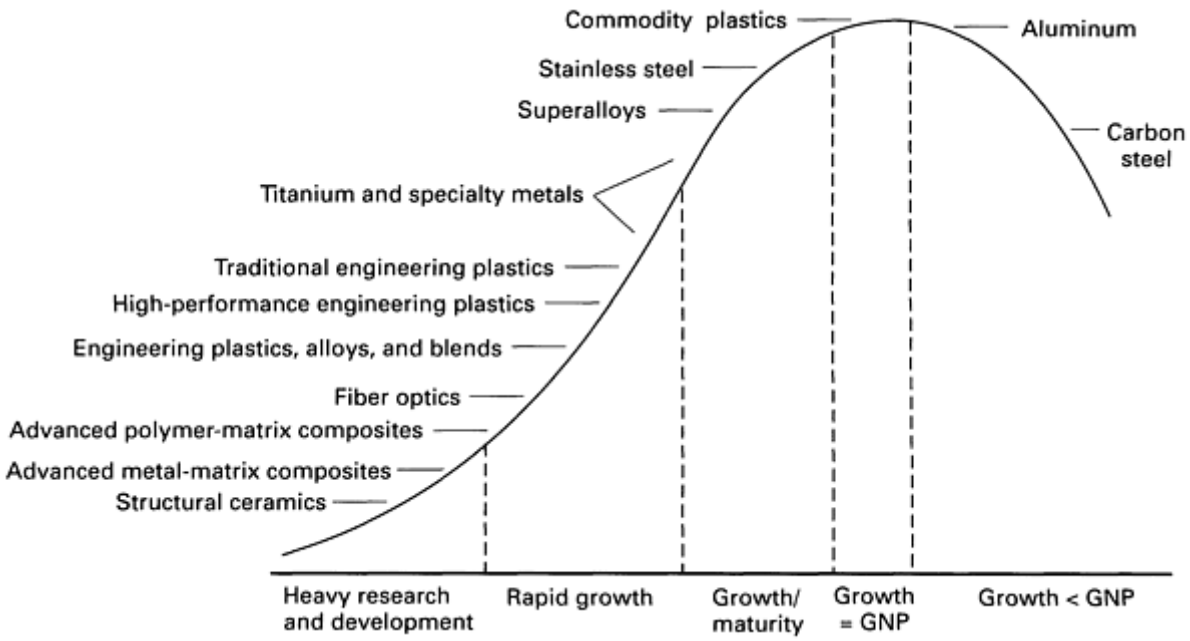

Fig. 2 Schematic product life cycle curve, showing position of various technologies on curve. Depending on market area, titanium ranges from rapid growth to growth/maturing stage. Source: Ref 6

Reference 6 concludes that, despite continued development of new alloys and product forms, titanium has moved rapidly through its product life cycle to maturity in the aircraft industry. The metal is still in the growth stage in applications

where corrosion resistance is important, such as the marine and biomedical industries. Other commercial and consumer applications, such as in the automotive industry and in architecture, are only in the developmental stage.

These more varied applications should strengthen and stabilize demand for titanium, making titanium producers less susceptible to fluctuations in any one application area. This diversification should accelerate as the industry continues to mature and titanium makes the transition from a technology product to a commodity product.

Market Trends. Reference 6 also used product life-cycle analysis to forecast future demand for titanium mill products through the end of the century. Table 1 compares past and predicted average annual demands for titanium ingot, castings, and mill products.

Table 1 Past and predicted average annual U.S. demand for titanium and titanium alloys

Product form	Demand, kg × 1000 (lb × 1000)		
	1984-1988	1989-1993	1994-1999
Ingot	34,635	38,909	44,182
	(76,196)	(85,600)	(97,200)
Mill products	20,630	23,273	26,545
	(45,387)	(51,200)	(58,400)
Castings	392	727	1,455
	(862)	(1,600)	(3,200)

Applications

Aerospace applications--including use in both structural (airframe) components and jet engines--still account for the largest share of titanium alloy use. Titanium, in fact, was so successful as an aerospace material that other potential applications were not fully exploited. These have only more recently begun to be explored; some are in development stages, while others are using or starting to use significant quantities of metal. These include:

- Applications where titanium is used for its resistance to corrosion, such as chemical processing, the pulp and paper industry, marine applications, and energy production and storage
- Biomedical applications that take advantage of the metal's inertness in the human body for use in surgical implants and prosthetic devices
- Special applications that exploit unique properties such as superconductivity (alloyed with niobium) and the shape-memory effect (alloyed with nickel)

- New application areas where the metal's high specific strength is important, such as the automotive industry
- Consumer applications ranging from cameras to jewelry, musical instruments, and sports equipment

Table 2 provides a list of many uses for titanium in all of these application areas.

Table 2 Applications for titanium and titanium alloys

Applications area	**Typical uses**
Aerospace	
Airframes	Fittings, bolts, landing gear beams, wing boxes, fuselage frames, flap tracks, slat tracks, brake assemblies, fuselage panels, engine support mountings, undercarriage components, inlet guide vanes, wing pivot lugs, keels, firewalls, fairings, hydraulic tubing, deicing ductings, SPF parts
Engines	Compressor disks and blades, fan disks and blades, casings, afterburner cowlings, flange rings, spacers, bolts, hydraulic tubing, hot-air ducts, helicopter rotor hubs
Satellites, rockets	Rocket engine casings, fuel tanks
Chemical processing	Storage tanks, agitators, pumps, columns, frames, screens, mixers, valves, pressurized reactors, filters, piping and tubing, heat exchangers, electrodes and anode baskets for metal and chlorine-alkali electrolysis
Energy industry	
Power generating plants	Condensers, cooling systems, piping and tubing, turbine blades, generator retaining rings, rotor slot wedges, linings for FGD units, nuclear waste disposal
Geothermal energy	Heat exchangers, evaporators, condensers, tubes
Marine engineering	
Shipbuilding	Heat exchangers, condensers, piping and tubing, propellers, propeller and rudder shafts, data logging equipment, gyrocompasses thruster pumps, lifeboat parts, radar components, cathodic protection anodes, hydrofoil struts
Diving equipment	Deep-sea pressure hulls, submarines (Soviet Union), submarine ball valves (United States)
Seawater desalination	Vapor heaters, condensers, thin-walled tubing
Offshore installations	Cooling equipment, condensers, heat exchangers, piping and tubing, flanges, deep-drilling riser pipes, flexible risers, desulfurizes, catalytic crackers, sour water strippers, regenerators, structural components
Biomedical engineering	Hip- and knee-joint prostheses, bone plates, screws and nails for fractures, pacemaker housings, heart valves, instruments, dentures, hearing aids, high-speed centrifugal separators for blood, wheelchairs, insulin pumps

Deep drilling	Drill pipes, riser pipes, production tubulars, casing liners, stress joints, instrument cases, wire, probes
Automotive industry	Connecting rods, valves, valve springs and retainers, crankshafts, camshafts, drive shafts, torsion bars, suspension assemblies, coil springs, clutch components, wheel hubs, exhaust systems, ball and socket joints, gears
Machine tools	Flexible tube connections, protective tubing, instrumentation and control equipment
Pulp and paper	Bleaching towers, pumps, piping and tubing
Food processing	Tanks (dairies, beverage industry), heat exchangers, components for packaging machinery
Construction	Facing and roofing, concrete reinforcement, monument refurbishment (Acropolis), anodes for cathodic protection
Superconductors	Wire rod of Ti-Nb alloys for manufacture of powerful electromagnets, rotors for superconductive generators
Fine art	Sculptures, fountain bases, ornaments, doorplates
Consumer products	
Jewelry industry	Jewelry, clocks, watches
Optics	Eyeglass frames, camera shutters
Sports equipment	Bicycle frames, tennis rackets, shafts and heads for golf clubs, mountain climbing equipment (ice screws, hooks) luges, bobsled components, horse shoes, fencing blades, target pistols
Musical instruments	Harmonica reeds, bells
Personal security and safety	Armor (cars, trucks, helicopters, fighter aircraft), helmets, bulletproof vests, protective gloves
Transportation	Driven wheelsets for high-speed trains, wheel tires
Cutting implements	Scissors, knives, pliers
Shape-memory alloys	Nickel-titanium alloys for springs and flanges
Miscellaneous	Pens, nameplates, telephone relay mechanisms, pollution-control equipment, titanium-lined vessels for salt-bath nitriding of steel products

Source: Ref 7

Aerospace Applications

High specific strength, good fatigue resistance and creep life, and good fracture toughness are characteristics that make titanium a preferred metal for aerospace applications. Figure 3 illustrates the rapid increase in use of titanium alloys in both airframe and engine applications for commercial aircraft.

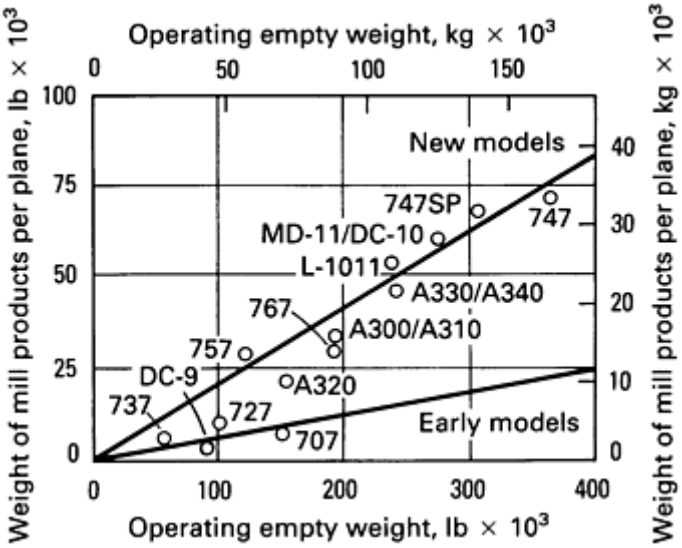

Fig. 3 Increase of titanium consumption on commercial aircraft for both airframe and engine applications. Source: Ref 3

Airframe Components. The earliest production application of titanium was in 1952, for the nacelles and firewalls of the Douglas DC-7 airliner. Since that time titanium and titanium alloys have been used for structural components on aircraft ranging from the Boeing 707, to the supersonic SR-71 Blackbird reconnaissance aircraft, to space satellites and missiles.

Jet Engine Components (Ref 8). Titanium fan disks (Fig. 4), turbine blades and vanes, and structurals are commonly used in aircraft turbine engines. Titanium research is an important aspect of the drive to increase engine efficiencies, and use of titanium in jet engine hot sections is expected to increase as materials capable of withstanding higher temperatures are developed (Ref 9; see also the section "New Developments" in this article).

Fig. 4 Forged Ti-6Al-4V jet engine fan disks are 890 mm (35 in.) in diameter and weigh 249 kg (548 lb). Courtesy of Wyman-Gordon Company

Titanium-base intermetallic compounds are another class of materials that promise increased engine thrust-to-weight ratios. These are discussed briefly in the section "New Developments" in this article and in the article "Ordered Intermetallics" in this Volume.

Use of precision titanium castings in jet engine applications such as inlet cases and compressor frames is on the rise. The article "Titanium and Titanium Alloy Castings" in this Volume contains more information on titanium casting technology.

Corrosion Applications

Commercially pure titanium is more commonly used than titanium alloys for corrosion applications, especially when high strength is not a requirement. Economics are often the deciding factor in selection of titanium for corrosion resistance. Some of the most common applications where the corrosion resistance of titanium is important are briefly described here. A comprehensive review of the corrosion behavior of titanium materials is available in the article "Corrosion of Titanium and Titanium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Chemical and Petrochemical Processing. Titanium equipment including vessels, pumps, fractionation columns, and storage tanks is essential in the manufacture of certain chemicals (Ref 10). Figure 5 illustrates two different uses for titanium in the chemical processing industry, and the article "Corrosion in the Chemical Processing Industry" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* contains more information on the use of titanium in the industry.

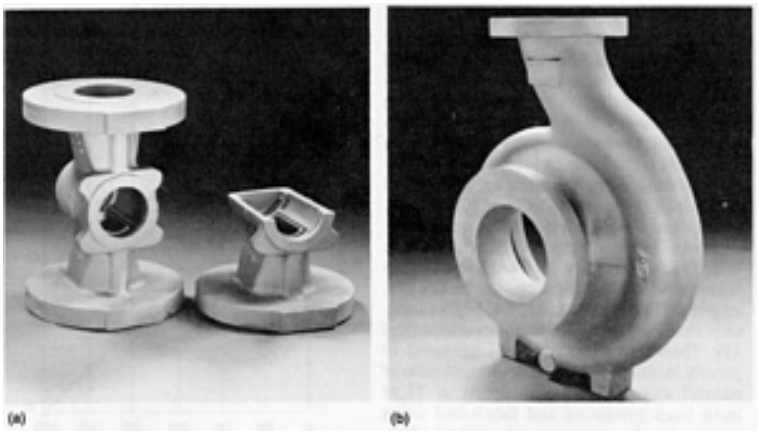

Fig. 5 Two common corrosion applications for commercially pure titanium components. (a) Valve body. (b) Pump body. Both are used in the chemical processing industry. Courtesy of Oregon Metallurgical Corporation

Marine Engineering. Titanium use in ship designs and for offshore oil platforms has increased steadily in the last few years. Applications include propeller and rudder shafts, thruster pumps, lifeboat parts, deep-sea pressure hulls, and submarine components (Ref 7). More information on titanium in marine applications is available in the article "Marine Corrosion" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Energy Production and Storage. Titanium plate-type heat exchangers, condensers, and piping and tubing are common in energy facilities using seawater for cooling. In power generating plants, titanium steam-turbine blades and generator retaining rings are used. A critical application is in the main condensers of nuclear power plants, which must remain leak-free (Ref 10). Titanium-clad steel produced by roll cladding also is used for condenser and heat-exchanger tubesheets (Ref 10).

Two relatively new uses for titanium alloys are in flue gas desulfurization (FGD) units used to scrub emissions from coal-fired power plants, and as canisters to contain low-level radioactive waste such as spent fuels from nuclear power plants. These applications are discussed in the articles "Corrosion of Emission-Control Equipment" and "Corrosion in the Nuclear Power Industry" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Surgical Implants and Prosthetic Devices. The value of titanium in biomedical applications lies in its inertness in the human body, that is, resistance to corrosion by body fluids. Titanium alloys are used in biomedical applications ranging from implantable pumps and components for artificial hearts, to hip and knee implants. Titanium implants with specially prepared porous surfaces promote ingrowth of bone, resulting in stronger and longer-lasting bonds between bone and implant (see the article "Corrosion of Metallic Implants and Prosthetic Devices" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*).

A recent biomedical application for titanium alloys is the use of Ti-15Mo-5Zr-3Al wire for sutures and for implant fixation. Using titanium wire eliminates the galvanic corrosion that can occur when titanium implants come in contact with other implant materials such as stainless steels and cobalt-base alloys (Ref 11). Another biomedical application exploits the shape-memory effect seen in nickel-titanium alloys to create compressive stresses that promote knitting of broken bones. Shape-memory Ni-Ti alloys also have been employed experimentally to dilate blood vessels, thus increasing the flow of blood to vital organs (Ref 12).

Other Applications

The unique properties of titanium make it attractive to designers in a variety of industries. Titanium is still relatively expensive compared to steel and aluminum, but increasing use of the metal in the areas discussed in this section is expected to accelerate cost reductions, resulting in still more growth in application diversity (Ref 10).

Automotive Components (Ref 10). At least one automobile maker is investigating the use of titanium in valve systems and suspension springs; however, no manufacturer has yet used titanium on production models. Automotive parts considered to have excellent commercial potential for use of titanium are valves and valve retainers. Racing automobiles

have made extensive use of titanium alloys for engine parts (Fig. 6), drive systems, and suspension components for some years, while a titanium alloy connecting rod has been used successfully by a Japanese motorcycle manufacturer. Development of low-cost, durable surface treatments is considered essential to the increased automotive use of titanium.

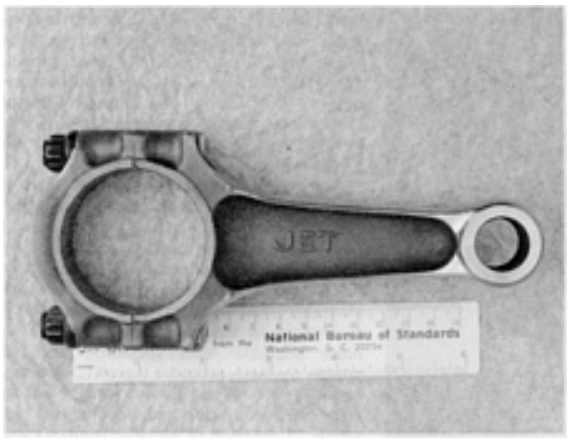

Fig. 6 Forged alloy connecting rod for a racing engine is indicative of increasing automotive applications for titanium. Component, courtesy of Jet Engineering Inc.; photograph by R.T. Kiepura, ASM INTERNATIONAL

Architecture. Japanese architects have used titanium as a building material for some time (Ref 10). An example is the roof of the Kobe Municipal Aquarium, which used approximately 11,000 kg (24,000 lb) of titanium. Although more costly than stainless steels, titanium is considered cost-effective in structures erected in the tropics and other areas where buildings are exposed to strong, warm sea winds (Ref 10).

Consumer Goods. Interest in titanium as a material for a wide variety of consumer products is on the rise. Figure 7 shows a consumer application, and Table 2 lists numerous decorative and functional consumer applications for titanium.

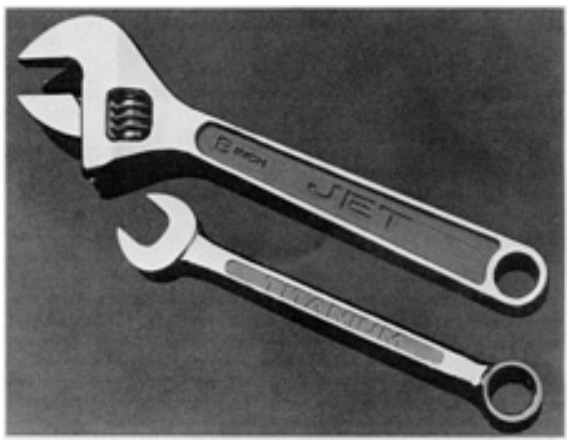

Fig. 7 Lightweight forged titanium alloy wrenches are typical of growing consumer applications for titanium. Courtesy of Jet Engineering Inc.

New Developments

Several titanium processing and materials technologies currently in various stages of development have the potential to profoundly impact future titanium use, and for this reason they merit explanation. These include development of new sponge production and melting processes, oxide dispersion-strengthened alloys prepared using P/M techniques, titanium-base intermetallic compounds, titanium-matrix composites, SPF/DB of titanium alloys, and increased use of titanium scrap materials.

Sponge Production (Ref 13). Recent work has aimed at not only improving the efficiency of the Kroll process, but also developing new production methods. One of the recently developed methods involves reduction of sodium fluorotitanate (Na_2TiF_5) by an aluminum-zinc alloy to produce a molten titanium-zinc alloy. The zinc is then removed from this by evaporation. Another process uses electrolysis to reduce either $TiCl_4$ or titanium dioxide (TiO_2) to titanium metal.

Melting Practice. Titanium sponge is most commonly double vacuum-arc remelted with recycled scrap material and alloying elements to produce titanium alloy ingot. Electron beam and plasma cold-hearth melting are relatively new melting practices designed to minimize internal ingot defects. Longer dwell times in the liquid pool, longer solution periods, and better mixing prevent nonmetallic inclusions and unmelted refractory metals from being incorporated into the ingot.

Powder Metallurgy Alloys. Powder metallurgy production techniques such as rapid solidification processing and mechanical alloying are being used to produce titanium alloys with novel compositions that would be impossible to achieve through conventional processing (Ref 9, 14). Titanium alloys produced by these methods may contain rare earth elements such as cerium, or large quantities of β stabilizers, which tend to segregate under normal processing conditions. Oxide dispersion-strengthening, an approach widely used to enhance the properties of nickel-base alloys, is also possible using P/M techniques to incorporate dispersion-forming elements such as silicon and boron into the titanium alloy matrix.

Titanium-Base Intermetallic Compounds. Ordered intermetallics with composition near Ti_3Al (actually Ti-24Al-11Nb) have better oxidation resistance, lower density, improved creep resistance, and higher modulus than conventional titanium alloys (Ref 15). These materials have the potential to greatly increase the thrust-to-weight ratio of aircraft engines. Full-scale heats of Ti_3Al have been produced and fabricated using conventional equipment into billet, plate, and sheet. The article "Ordered Intermetallics" in this Volume contains more information on titanium aluminide intermetallics.

Titanium-Matrix Composites. Metal-matrix composites (MMCs) combine the attributes of the base (matrix) metal with those of a reinforcing phase. In the case of titanium-base MMCs, this combination of properties translates to low density with increased high-temperature strength and stiffness (Fig. 8). Titanium-matrix composites have been fabricated using a variety of techniques, including P/M processing (Ref 16, 17). More information on MMCs is available in the article "Metal-Matrix Composites" in this Volume.

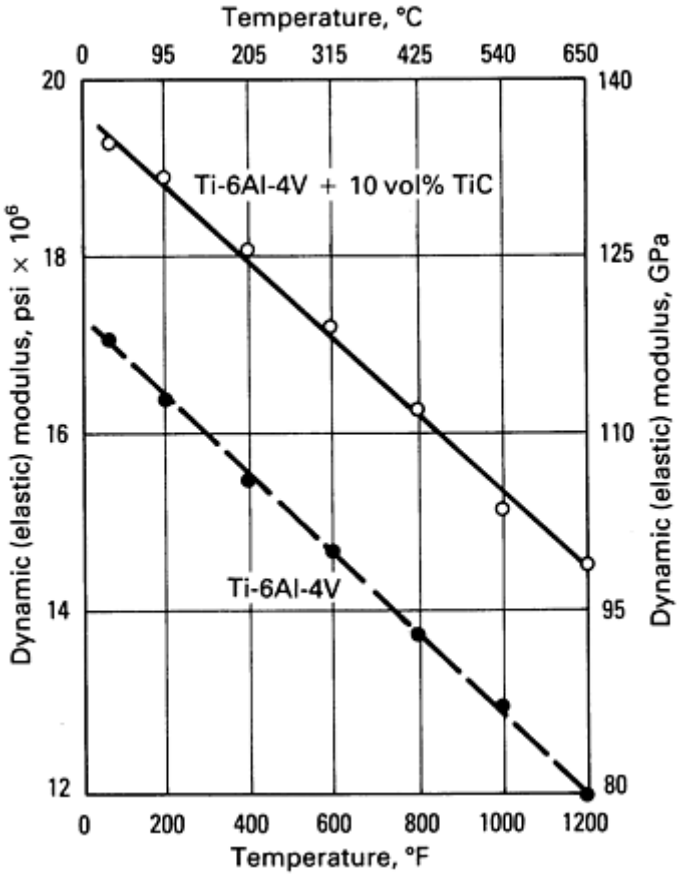

Fig. 8 High-temperature strength and stiffness of a titanium MMC compared to conventional alloy Ti-6Al-4V. Produced using powder metallurgy techniques, the MMC consists of a Ti-6Al-4V matrix reinforced with 10% titanium carbide (TiC) particles. Source: Ref 16

Superplastic Forming and Diffusion Bonding. Superplastic forming and concurrent diffusion bonding of titanium alloy sheet components is a technology that has moved out of the laboratory and into commercial production (Ref 18, 19). The process has the potential to drastically reduce the number of parts and fasteners needed in airframe structures and other complex components. More information on SPF/DB of titanium also is available in the articles "Forming of Titanium and Titanium Alloys" and "Superplastic Sheet Forming" in *Forming and Forging,* Volume 14 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Recycling of Titanium Scrap. As the titanium industry has matured, the use of recycled material has increased. In recent years even machine turnings and chips have been approved for recycling, and U.S. titanium producers used nearly 18 million kg (40 million pounds) of titanium scrap in 1988 (Ref 20). More information on recycling of titanium alloys is available in the article "Recycling of Nonferrous Alloys" in this Volume.

Wrought Titanium and Titanium Alloys

S. Lampman, ASM INTERNATIONAL

Introduction

THE WROUGHT product forms of titanium and titanium-base alloys, which include forgings and the typical mill products, constitute (on a weight basis) more than 70% of the market in titanium and titanium-alloy production. Various specifications for wrought titanium-base products are listed in Table 1. The wrought products are the most readily available product form of titanium-base materials, although cast and powder metallurgy (P/M) products are also available for applications that require complex shapes or the use of P/M techniques to obtain microstructures not achievable by conventional ingot metallurgy. Powder metallurgy of titanium has not gained wide acceptance and is restricted to space and missile applications. Cast and P/M titanium-base products are discussed in the subsequent articles in this Volume.

(a) MAM, metric aerospace recommended practice.

(b) Except for the TIS 7607 standard for forgings, the listed TIS are for titanium-palladium alloys only.

The primary reasons for using titanium-base products stem from the outstanding corrosion resistance of titanium and/or its useful combination of low density (; 4.5 g/cm^3, or 0.16 lb/in.^{3}) and high strength (minimum 0.2% yield strengths vary from 480 MPa, or 70 ksi, for some grades of commercial titanium to about 1100 MPa, or 160 ksi, for structural titanium alloy products and over 1725 MPa, or 250 ksi, for special forms such as wires and springs). Some titanium alloys (especially the low-interstitial alpha alloys) are also useful in subzero and cryogenic applications because these alpha alloys do not exhibit a ductile-brittle transition.

Another important characteristic of titanium-base materials is the reversible transformation (or allotropy) of the crystal structure from an alpha (α) (hexagonal close-packed) structure to a beta (β) (body-centered cubic) structure when the temperatures exceed a certain level. This allotropic behavior, which depends on the type and amount of alloy contents, allows complex variations in microstructure and more diverse strengthening opportunities than those of other nonferrous alloys such as copper or aluminum. This diversity of microstructure and properties depends not only on alloy additions but also on thermomechanical processing. By varying thermal or mechanical processing, or both, a broad range of properties can be produced in titanium alloys.

The elevated-temperature strength and creep resistance of titanium-base materials (along with the pickup of interstitial impurities due to the chemical reactivity of titanium) limits the elevated-temperature application of wrought and cast products to about 540 °C (1000 °F) or perhaps 600 °C (1100 °F) in some cases. For higher temperatures, Ti-aluminide products are an active area of research and development (see the article "Ordered Intermetallics" in this Volume).

Commercially Pure Titanium

Pure titanium wrought products, which have minimum titanium contents ranging from about 98.635 to 99.5 wt% (Table 2), are used primarily for corrosion resistance. Titanium products are also useful in applications requiring high ductility for fabrication but relatively low strength (Table 2) in service.

(a) Unless a range is specified, all listed values are minimums.

(b) Only for sheet, plate, and coil.

(c) Hydrogen limits vary according to product form as follows: 0.015H (sheet), 0.0125H (bar), and 0.0100H (billet).

Corrosion Resistance and Chemical Reactivity. Although titanium is a highly reactive metal, titanium also has an extremely high affinity for oxygen and thus forms a very stable and highly adherent protective oxide film on its surface. This oxide film, which forms spontaneously and instantly when fresh metal surfaces are exposed to air and/or moisture, provides the excellent corrosion resistance of titanium. However, anhydrous conditions in the absence of a source of oxygen may result in titanium corrosion, because the protective film may not be regenerated if damaged. This is particularly true of crevice corrosion. Titanium and titanium alloys may be subject to localized attack in tight crevices exposed to hot (>70 °C, or 160 °F) chloride, bromide, iodide, fluoride, or sulfate-containing solutions. Crevices can stem from adhering process stream deposits or scales, metal-to-metal joints (for example, poor weld joint design or tube-to-tubesheet joints), and gasket-to-metal flange and other seal joints. The mechanism for crevice corrosion of titanium is similar to that for stainless steels, in which oxygen-depleted reducing acid conditions develop within tight crevices.

General corrosion rates for unalloyed titanium (99.2 wt% Ti with traces of oxygen) in selected media are given in Table 3. These data should be used only as a guideline for general performance. Rates may vary depending on changes in medium chemistry, temperature, length of exposure, and other factors. Also, total suitability of an alloy cannot be assumed from these values alone, because other forms of corrosion, such as localized attack, may be limiting. These and other factors affecting the corrosion of titanium are discussed in more detail in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Precautions in Use. Hydrogen embrittlement of titanium can occur in pickling solutions (or other hydrogenating solutions) at room temperature and at elevated temperatures during air exposure or in exposures to reducing atmospheres. Nonetheless, titanium alloys are widely used in hydrogen-containing environments and under conditions in which galvanic couples or cathodic charging (impressed current) causes hydrogen to be evolved on metal surfaces. Although hydrogen embrittlement has been observed, traces of moisture or oxygen in hydrogen gas containing environments effectively form the protective oxide film, thus avoiding or limiting hydrogen uptake (Ref 2, 3, 4, 5). On the other hand, anhydrous hydrogen gas atmospheres may lead to absorption, particularly as temperatures and pressures increase. Hydrogen embrittlement can also occur at relatively low hydrogen levels due to the hydrogen in the material in the presence of a stress riser under certain conditions.

Elevated temperature atmospheric exposure also results in oxygen and nitrogen contamination that increases in severity with increasing temperature and time of exposure. Violent oxidation reactions can occur between titanium and liquid oxygen or between titanium and red fuming nitric acid. Titanium alloys exhibit good corrosion resistance to white fuming nitric acids.

Crystal Structure. Pure titanium at room temperature has an alpha (hexagonal close-packed) crystal structure, which transforms to a beta (body-centered cubic) structure at a temperature of about 885 °C (1625 °F). This transformation temperature can be raised or lowered depending on the type and amount of impurities or alloying additions. The addition of alloying elements also divides the single temperature for equilibrium transformation into two temperatures--the alpha transus, below which the alloy is all-alpha, and the beta transus, above which the alloy is all-beta. Between these temperatures, both alpha and beta are present. Depending on the level of impurities, the beta transus is about 910 ± 15 °C (1675 ± 25 °F) for commercially pure titanium with 0.25 wt% O_2 max and 945 ± 15 °C (1735 ± 25 °F) with 0.40 wt% O_2 max. For the various ASTM grades of commercially pure titanium, typical transus temperatures (with an uncertainty of about ± 15 °C, or ±25 °F) are:

Designation	Typical β transus		Typical α transus	
	°C	°F	°C	°F
ASTM grade 1	888	1630	880	1620
ASTM grade 2	913	1675	890	1635
ASTM grade 3	920	1685	900	1650
ASTM grade 4	950	1740	905	1660
ASTM grade 7	913	1675	890	1635

Typical unit cell parameters for an alpha crystal structure at 25 °C (77 °F) are:

$$a = 0.2950 \text{ nm}$$
$$c = 0.4683 \text{ nm}$$

Impurity elements (commonly oxygen, nitrogen, carbon, and iron) influence unit cell dimensions. The typical unit cell parameter for the beta structure is 0.329 nm at 900 °C (1650 °F).

The microstructure of unalloyed titanium at room temperature is typically a 100% alpha-crystal structure. As amounts of impurity elements increase (primarily iron), small but increasing amounts of beta are observed metallographically, usually at alpha grain boundaries. Annealed unalloyed titanium may have an equiaxed or acicular alpha microstructure. Acicular alpha occurs during beta-to-alpha transformation on cooling through the transformation temperature range. Platelet width decreases with cooling rate. Equiaxed alpha can only be produced by recrystallization of material that has been extensively worked in the alpha phase. The presence of acicular alpha, therefore, is an indication that the material has been heated to a temperature above the beta transus. A beta structure cannot be retained at low

temperatures in unalloyed titanium, except in small quantities in materials containing beta stabilizing contaminants such as iron.

Effect of Impurities on Mechanical Properties. Besides the effect on transformation temperatures and lattice parameters, impurities also have important effects on the mechanical properties of titanium. Residual elements such as carbon, nitrogen, silicon, and iron raise the strength and lower the ductility of titanium products. The effect of carbon, oxygen, and nitrogen is shown in Fig. 1.

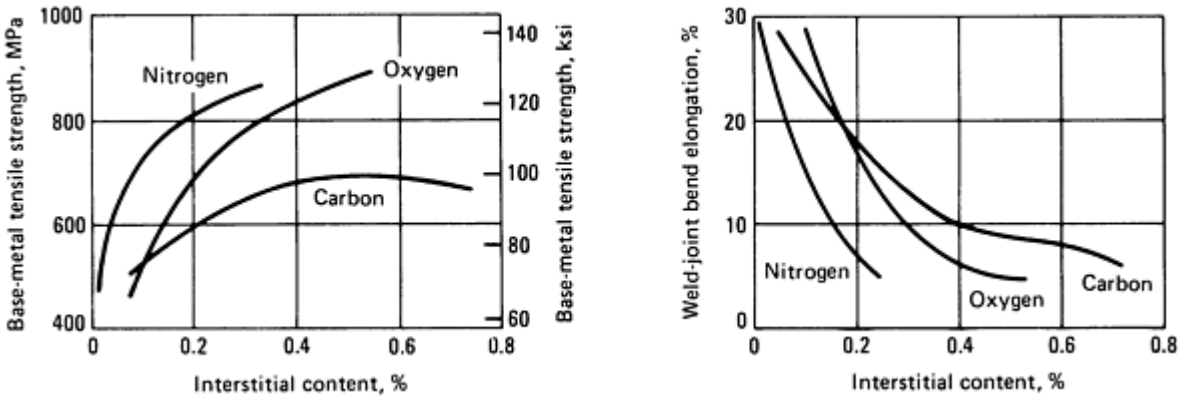

Fig. 1 Effects of interstitial-element content on strength and ductility of unalloyed titanium

Basically, oxygen and iron contents determine strength levels of commercially pure titanium. In higher strength grades, oxygen and iron are intentionally added to the residual amounts already in the sponge to provide extra strength. On the other hand, carbon and nitrogen usually are held to minimum residual levels to avoid embrittlement.

When good ductility and toughness are desired, the extra-low interstitial (ELI) grades are used. In ELI grades, carbon, nitrogen, oxygen, and iron must be held to acceptably low levels because they lower the ductility of the final product (see, for example, the effect of carbon, oxygen, and nitrogen in Fig. 1).

The titanium for ingot production may be either titanium sponge or reclaimed scrap. In either case, stringent specifications must be met for control of ingot composition. Most important are the hard, brittle, and refractory titanium oxide, titanium nitride, or complex titanium oxynitride particles that, if retained through subsequent melting operations, could act as crack initiation sites in the final product.

Titanium sponge is manufactured by first chlorinating the ore (most commonly rutile or synthetic rutile) and then reducing the resulting $TiCl_4$ with either sodium or magnesium metal. Sodium-reduced sponge is leached with acid to remove the NaCl by-product of reduction. Magnesium-reduced sponge may be leached, inert-gas swept, or vacuum distilled to remove the excess $MgCl_2$ by-product. Vacuum distilling results in lower residual levels of magnesium, hydrogen, and chlorine. Modern melting techniques remove volatile substances from sponge, so that ingot of high quality can be produced regardless of which method is used for production of sponge. Electrolytic methods are being used to produce a very high purity titanium sponge on a pilot-plant scale.

Reclaimed scrap makes production of ingot titanium more economical than production solely from sponge. If properly controlled, addition of scrap (commonly referred to as revert) is fully acceptable and can be used even in materials for critical structural applications, such as rotating components for jet engines.

All forms of scrap can be remelted--machining chips, cut sheet, trim stock, and chunks. To be utilized properly, scrap must be thoroughly cleaned and carefully sorted by alloy and by purity before being remelted. During cleaning, surface scale must be removed, because adding titanium scale to the melt could produce refractory inclusions or excessive porosity in the ingot. Machining chips from fabricators who use carbide tools are acceptable for remelting only if all carbide particles adhering to the chips are removed; otherwise, hard high-density inclusions could result. Improper segregation of alloy revert could produce off-composition alloys and could potentially degrade the properties of the resulting metal.

Melting Practice for Ingot Production. Double melting is considered necessary for all applications to ensure an acceptable degree of homogeneity in the resulting product. Triple melting is used to achieve better uniformity. Triple melting also reduces oxygen-rich or nitrogen-rich inclusions in the microstructure to a very low level by providing an additional melting operation to dissolve them.

Most titanium and titanium alloy ingot is melted twice in an electric-arc furnace under vacuum--a procedure known as the double consumable-electrode vacuum-melting process. In this two-stage process, titanium sponge, revert, and alloy additions are welded together and then are melted to form ingot. Ingots from the first melt are used as the consumable electrodes for second-stage melting. Processes other than consumable-electrode arc melting are used in some instances for first-stage melting of ingot for noncritical applications. Usually, all melting is done under vacuum, but in any event the final stage of melting must be done by the consumable-electrode vacuum-arc process. Newer hearth melting technologies utilizing electron beams or plasma as a heat source are casting commercially pure slabs in ore melting operations.

Segregation and other compositional variations directly affect the final properties of mill products. Melting technique alone does not account for all segregation and compositional variations and thus cannot be correlated with final properties.

Melting in a vacuum reduces the hydrogen content of titanium and essentially removes other volatiles. This tends to result in high purity in the cast ingot. However, anomalous operating factors such as air leaks, water leaks, arc-outs, or large variations in power level affect both soundness and homogeneity of the final product.

Still another factor is ingot size. Normally, ingots are 650 to 900 mm (26 to 36 in.) in diameter and weigh 3600 to 9000 kg (8000 to 20,000 lb). Larger ingots are economically advantageous to use and are important in obtaining refined macrostructures and microstructures in very large sections, such as billets with diameters of 400 mm (16 in.) or greater. Ingots up to 1065 mm (42 in.) in diameter and weighing more than 13.5 Mg (30,000 lb) have been melted successfully, but there appear to be limitations on the improvements that can be achieved by producing large ingots due to increasing tendency for segregation with increasing ingot size.

Segregation in titanium ingot must be controlled because it leads to several different types of imperfections that cannot be readily eliminated by homogenizing heat treatments or combinations of heat treatment and primary mill processing. In aircraft-grade titanium, type I and type II imperfections are not acceptable because they degrade critical design properties.

Type I imperfections, usually called high interstitial defects, are regions of interstitially stabilized alpha phase that have substantially higher hardness and lower ductility than the surrounding material and also exhibit a higher beta transus temperature. They arise from very high nitrogen or oxygen concentrations in sponge, master alloy, or revert. Type I imperfections frequently, but not always, are associated with voids or cracks. Although type I imperfections sometimes are referred to as low-density inclusions (LDI's), they often are of higher density than is normal for the alloy.

Type II imperfections, sometimes called high-aluminum defects, are abnormally stabilized alpha-phase areas that may extend across several beta grains. Type II imperfections are caused by segregation of metallic alpha stabilizers, such as aluminum and contain an excessively high proportion of primary (untransformed) alpha having a microhardness only slightly higher than that of the adjacent matrix. Type II imperfections sometimes are accompanied by adjacent stringers of beta--areas low in both aluminum content and hardness. This condition is generally associated with closed solidification pipe into which alloy constituents of high vapor pressure migrate, only to be incorporated into the microstructure during primary mill fabrication. Stringers normally occur in the top portions of ingots and can be detected by macroetching or anodized blue etching. Material containing stringers usually must undergo metallographic review to ensure that the indications revealed by etching are not artifacts.

Properties of Commercially Pure Titanium. The minimum tensile properties of titanium mill products are listed in Table 2. In terms of tensile and fatigue strength, commercially pure titanium is not as strong as steel or titanium alloys (Fig. 2). Titanium has an intermediate modulus of elasticity (Fig. 3), which can be influenced by texture.

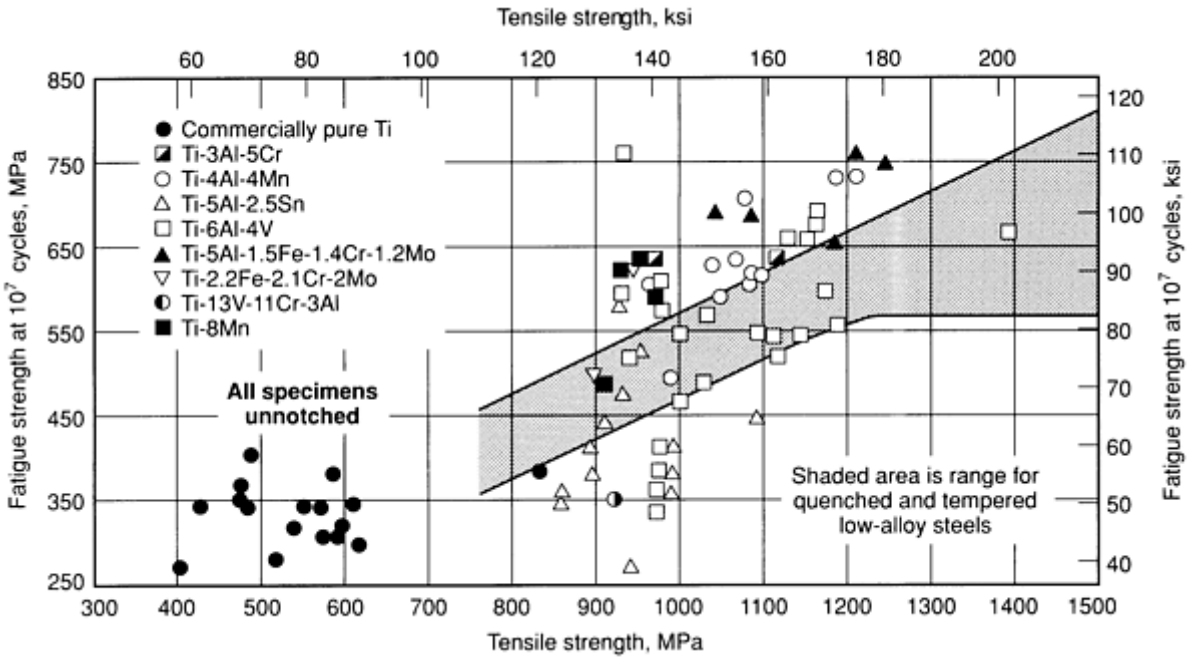

Fig. 2 Fatigue data for titanium and titanium alloys, compared with quenched and tempered low-alloy steels

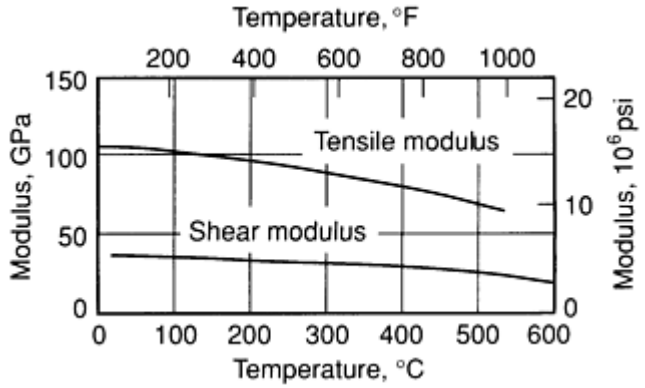

Fig. 3 Variation of elastic modulus with temperature for unalloyed titanium (ASTM grade 4)

Impact Toughness. Commercially pure titanium has impact strengths comparable to that of quenched and tempered low-alloy steel. Titanium may even exhibit an increase in toughness at low temperatures (Fig. 4), depending on the control of interstitial impurities and brittle refractory constituents.

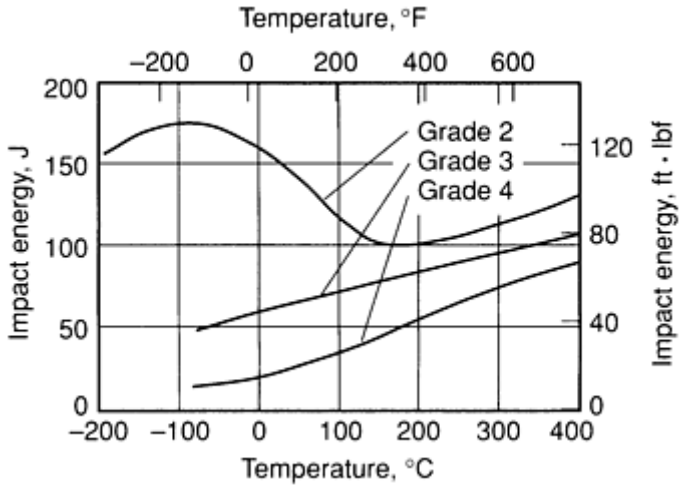

Fig. 4 Charpy V-notch impact strength of unalloyed titanium (ASTM grades 2, 3, and 4) at low temperatures

Creep Behavior. Whether yield strength or creep strength for a given maximum allowable deformation is the significant selection criterion depends on which is lower at the service temperature in question. Between 200 and 315 °C (400 and 600 °F), the deformation of titanium (and some titanium alloys with an alpha or near-alpha crystal structure) loaded to the yield point does not increase with time. Thus, creep strength is seldom a factor in this range. Above 315 °C (600 °F), creep strength becomes an important selection criterion. Typical creep behavior of titanium is shown in Fig. 5.

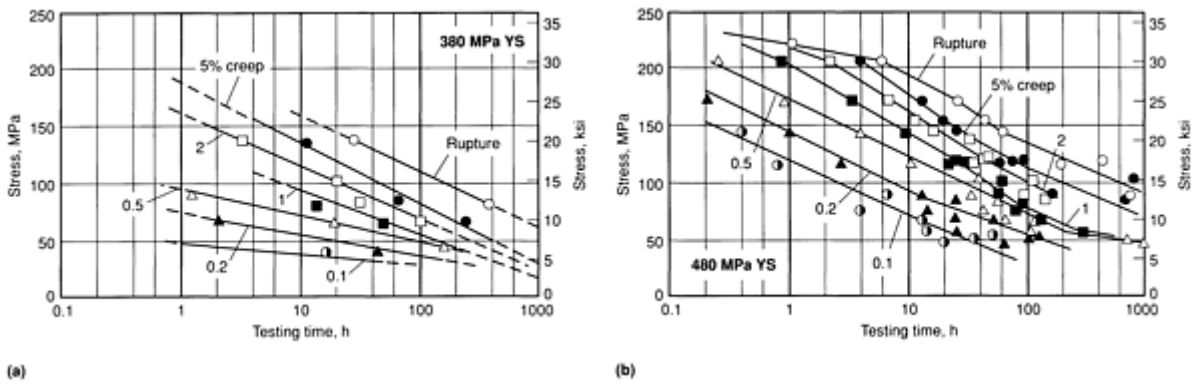

Fig. 5 Creep characteristics at 425 °C (800 °F) for mill-annealed titanium (99.0% Ti) with a 0.2% yield strength (YS) of (a) 380 MPa (55 ksi) and (b) 480 MPa (70 ksi)

Physical properties of titanium are described in the article "Properties of Pure Metals" in this Volume. Of the various physical properties shown in Fig. 6, titanium is characterized by a somewhat low thermal conductivity. However, even though titanium has a low thermal conductivity compared to that of other metals, its heat-transfer rate is greater than that of most copper-base alloys. The reason for this has to do with favorable surface film characteristics and lack of corrosion. The major factor in heat transfer relates to material thickness, corrosion resistance, and surface films, not the thermal conductivity of the metal. In this regard, titanium has the following advantages:

- Good strength
- Resistance to erosion and erosion-corrosion
- Very thin, conductive oxide surface film
- Hard, smooth surface that limits adhesion of foreign materials

- Surface promotes dropwise condensation

Consequently, titanium is a useful material in heat exchangers (Fig. 7).

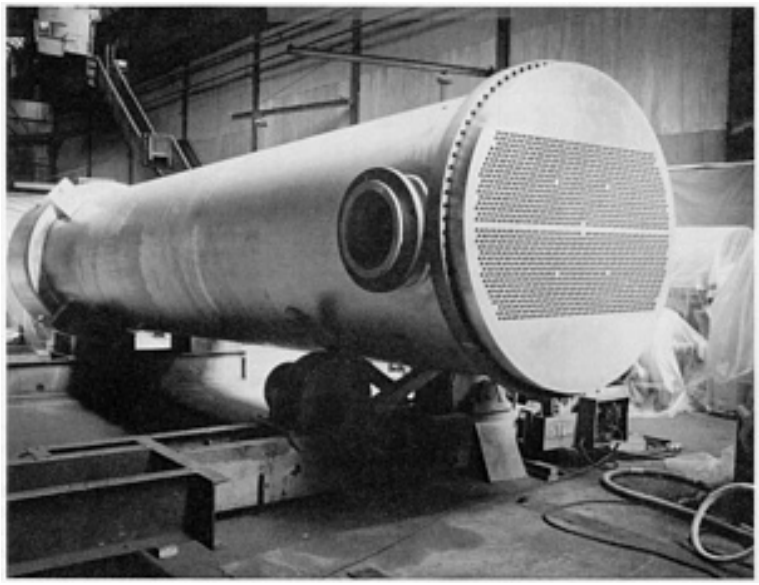

Fig. 7 Solid titanium heat exchanger using commercially pure ASTM grades 2, 7, and 12. Courtesy of Joseph Oat Corporation

Commercially pure titanium with minor alloy contents include various titanium-palladium grades and alloy Ti-0.3Mo-0.8Ni (ASTM grade 12 or UNS R53400). The alloy contents allow improvements in corrosion resistance and/or strength.

Titanium-palladium alloys with nominal palladium contents of about 0.2% Pd (Table 2) are used in applications requiring excellent corrosion resistance in chemical processing or storage applications where the media is mildly reducing or fluctuates between oxidizing and reducing. The palladium-containing alloys extend the range of titanium application in hydrochloric, phosphoric, and sulfuric acid solutions (Table 4). Characteristics of good fabricability, weldability, and strength level are similar to those of corresponding unalloyed titanium grades.

Table 4 Comparative corrosion rates for Ti-Pd, grade 7, and unalloyed titanium, grade 2

(a) Acidified: pH 1.2

Palladium additions of less than specified minimums are less effective in promoting an improved corrosion resistance. Excess palladium (above specified range) is not cost effective. Only alpha soluble amounts of palladium are added to make titanium-palladium alloys; therefore, microstructures are essentially the same as for equivalent grades of unalloyed titanium. Titanium-palladium intermetallic compounds formed in this system have not been reported to occur with normal heat treatments.

Alloy Ti-0.3Mo-0.8Ni (UNS R53400, or ASTM grade 12) has applications similar to those for unalloyed titanium but has better strength (Fig. 8) and corrosion resistance (Fig. 9). However, the corrosion resistance of this alloy is not as good as the titanium-palladium alloys. The ASTM grade 12 alloy is particularly resistant to crevice corrosion (Fig. 10) in hot brines (see the section "Corrosion Resistance and Chemical Reactivity" in this article for a brief discussion on crevice corrosion). The microstructure of R53400 is either equiaxed or acicular alpha with minor amounts of beta. Acicular alpha microstructures are found primarily in welds or heat-affected zones.

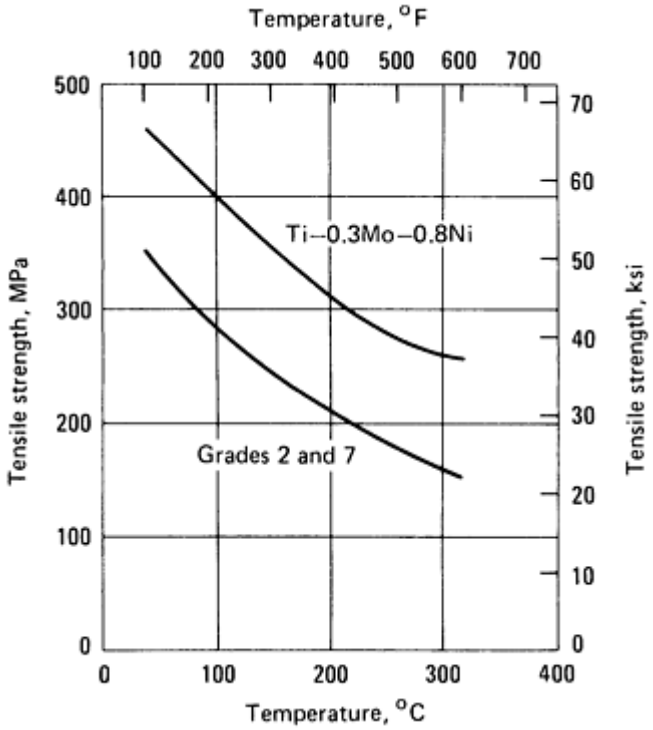

Fig. 8 Minimum tensile strength of low-strength titanium metals

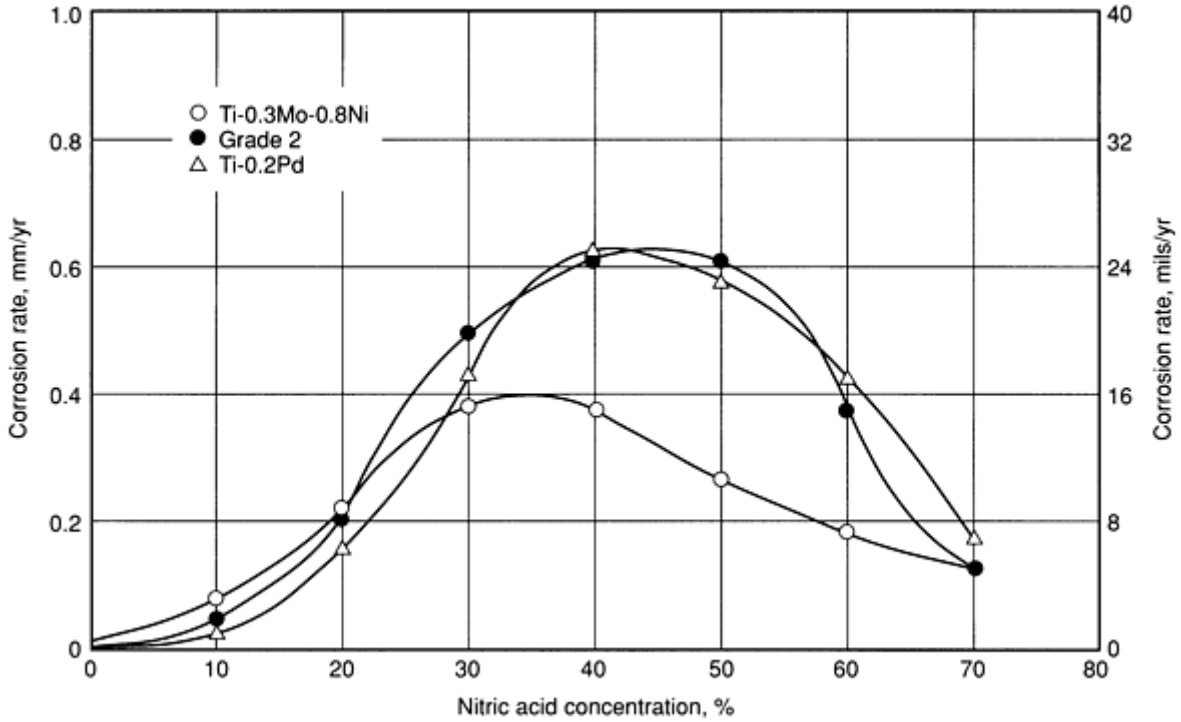

Fig. 9 Corrosion of titanium metals in boiling nitric acid. Solution replaced with fresh solution every 24 h; total exposure time, 480 h

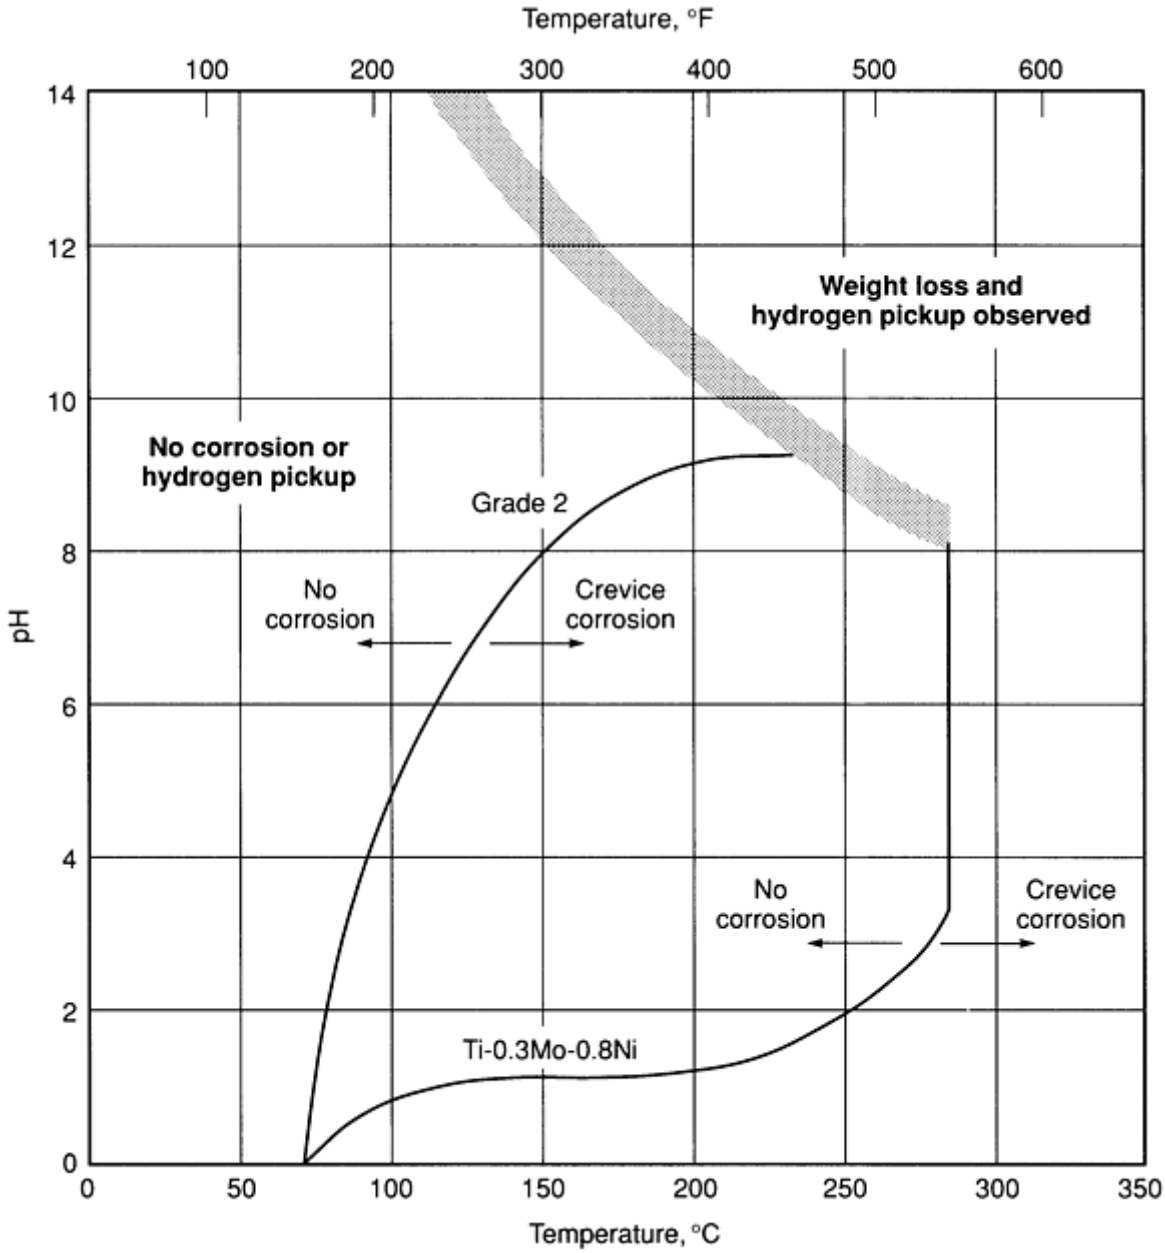

Fig. 10 Crevice corrosion of Ti-0.3Mo-0.8Ni and grade 2 unalloyed Ti in saturated NaCl solution. Shaded band represents transition zone between active and passive behavior.

In a series of crevice corrosion tests, Ti-0.3Mo-0.8Ni was completely resistant in 500-h exposures to the following boiling solutions: saturated $ZnCl_2$ at pH of 3.0; 10% $AlCl_3$; $MgCl_2$ at pH of 4.2; 10% NH_4Cl at pH of 4.1; saturated NaCl, and saturated NaCl + Cl_2, both at pH of 1.0; and 10% Na_2SO_4 at pH of 1.0. In a similar test in boiling 10% $FeCl_3$, crevice corrosion was observed in metal-to-Teflon crevices after 500 h. Ti-0.3Mo-0.8Ni also exhibits the following typical corrosion rates:

Environment	Corrosion rate

	mm/yr	mils/yr
Wet Cl_2 gas	0.00089	0.035
5% NaOCl + 2% NaCl + 4% NaOH[(a)]	0.06	2.4
70% $ZnCl_2$	0.005-0.0075	0.2-0.3
50% citric acid	0.013	0.5
10% sulfamic acid	11.6	455
45% formic acid	nil	nil
88-90% formic acid	0-0.56	0-22
90% formic acid[(b)]	0.56	2.2
10% oxalic acid	104	4100

(a) No crevice corrosion in metal-to-metal or metal-to-Teflon crevices.

(b) Anodized specimens

Titanium Alloys

Tables 5(a), 5(b), and 5(c) list the compositions of various titanium alloys. Because the allotropic behavior of titanium allows diverse changes in microstructures by variations in thermomechanical processing, a broad range of properties and applications can be served with a minimum number of grades. This is especially true of the alloys with a two-phase, $\alpha+\beta$, crystal structure.

The most widely used titanium alloy is the Ti-6Al-4V alpha-beta alloy. This alloy is well understood and is also very forgiving with variations in fabrication operations, despite its relatively poor room-temperature shaping and forming characteristics (compared to steel and aluminum). Alloy Ti-6Al-4V, which has limited section size hardenability, is most commonly used in the annealed condition.

Other titanium alloys are designed for particular application areas. For example:

- *Alloys Ti-5Al-2Sn-2Zr-4Mo-4Cr (commonly called Ti-17) and Ti-6Al-2Sn-4Zr-6Mo* are designed for high strength in heavy sections at elevated (moderate) temperatures
- *Alloys Ti-6242S, IMI 829, and Ti-6242* (Ti-6Al-2Sn-4Zr-2Mo) are designed for creep resistance
- *Alloys Ti-6Al-2Nb-1Ta-1Mo and Ti-6Al-4V-ELI* are designed both to resist stress corrosion in aqueous salt solutions and for high fracture toughness
- *Alloy Ti-5Al-2.5Sn* is designed for weldability, and the ELI grade is used extensively for cryogenic applications
- *Alloys Ti-6Al-6V-2Sn, Ti-6Al-4V, and Ti-10V-2Fe-3Al* are designed for high strength at low-to-moderate

temperatures

The typical applications of other titanium alloys are listed in Table 6.

Table 6 Typical applications of various titanium-base materials

Nominal contents and common name or specifications	Available mill forms	General description	Typical applications
Commercially pure titanium			
Unalloyed titanium: see Table 2	Bar, billet, extrusions, plate, sheet, strip, wire, rod, pipe, tubing, castings	For corrosion resistance in the chemical and marine industries, and where maximum ease of formability is desired. Weldability: good	Jet engine shrouds, cases, airframe skins, firewalls, and other hot-area equipment for aircraft and missiles; heat-exchangers; corrosion resistant equipment for marine and chemical-processing industries. Other applications requiring good fabricability, weldability, and intermediate strength in service
Ti-0.2Pd: ASTM grades 7 and 11	Bar, billet, extrusions, plate, sheet, strip, wire, pipe, tubing, castings	The Pd-containing alloys extend the range of application in HCl, H_3PO_4, and H_2SO_4 solutions. Characteristics of good fabricability, weldability, and strength level are similar to those of corresponding unalloyed titanium grades.	For corrosion resistance in the chemical industry where media are mildly reducing or vary between oxidizing and reducing
Ti-0.3Mo-0.8Ni: ASTM grade 12	Bar, billet, extrusions, plate, sheet, strip, wire, pipe, tubing, castings	Compared to unalloyed Ti, Ti-0.3Mo-0.8Ni has better corrosion resistance and higher strength. The alloy is particularly resistant to crevice corrosion in hot brines.	For corrosion resistance in the chemical industry where media are mildly reducing or vary between oxidizing and reducing
α alloys			
Ti-2.5 Cu: AECMA Ti-P11, or 1MI 230	Bar, billet, rod, wire, plate, sheet, extrusions	Ti-2.5Cu combines the formability and weldability of titanium with improved mechanical properties from precipitation strengthening.	Useful for its improved mechanical properties, particularly up to 350 °C (650 °F). Aging doubles elevated-temperature properties and increases room-temperature strength by 25%.
Ti-5Al-2.5Sn (UNS R54520)	Bar, billet, extrusions, plate, sheet, wire, castings	Air frame and jet engine applications requiring goods weldability, stability, and strength at elevated temperatures	Gas turbine engine casings and rings, aerospace structural members in hot spots, and chemical-processing equipment that require good weldability and intermediate strength at service temperatures up to 480 °C (900 °F)
Ti-5Al-2.5Sn-ELI (UNS R54521)	Same as UNS R54520	Reduced level of interstitial impurities improves ductility and toughness.	High-purity grade for pressure vessels for liquefied gases and other applications requiring better ductility and toughness, particularly in hardware for service to cryogenic temperatures

Near-α alloys			
Ti-8Al-1Mo-1V (UNS R54810)	Bar, billets, extrusions, plate, sheet, wire, forgings	Near-α or α-β microstructure (depending on processing) with good combination of creep strength and fatigue strength when processed high in the α-β region (that is, near the β transus)	Fan blades are main use; forgings for jet engine components requiring good creep strength, high strength at elevated temperatures (compressor disks, plates, hubs). Other applications where light, high strength, highly weldable material with low density is required (cargo flooring)
Ti-6Al-2Sn-4Zr-2Mo (Ti-6242, or UNS 54620)	Bar, billet, sheet, strip, wire, forgings	Used for creep strength and elevated-temperature service. Fair weldability	Forgings and flat-rolled products used in gas turbine engine and air-frame applications where high strength and toughness, excellent creep resistance, and stability at temperatures up to 450 °C (840 °F) are required
Ti-6Al-2Sn-4Zr-2Mo-0.1Si (Ti-6242S)	Same as UNS54620 but also castings	Silicon imparts additional creep resistance.	Same as UNS 54620 but maximum-use temperature up to about 520 °C (970 °F)
Ti-6Al-2Nb-1Ta-0.8Mo (UNS R56210)	Plate, sheet, strip, bar, wire, rod	. . .	Plate for naval shipbuilding applications, submersible hulls, pressure vessels, and other high-toughness applications
Ti-2.25Al-11Sn-5Zr-1Mo (Ti-679, UNS R54790)	Forgings, bar billet, plate	. . .	Jet engine blades and wheels, large bulkhead forgings, other applications requiring high-temperature creep strength plus stability and short-time strength
Ti-5Al-5Sn-2Zr-2Mo-0.25Si (Ti-5522S, UNS 54560)	Forged billet and bar, special products available in plate and sheet	Semicommercial; no longer used	Specified in MIL-T-9046 and MIL-T-9047
IMI-685 (Ti-6Al-5Zr-0.5Mo-0.2Si)	Rod, bar, billet, extrusions	Weldable medium-strength alloy	Alloy for elevated-temperature uses up to about 520 °C (970 °F)
IMI-829 (Ti-5.5Al-3.5Sn-3Zr-1Nb-0.3Mo-0.3Si)	Rod, bar, billet, extrusions	Weldable, medium-strength alloy with good thermal stability and high creep resistance up to 600 °C (1110 °F)	Elevated-temperature alloy for service up to about 580 °C (1075 °F)
IMI-834 (Ti-5.8Al-4Sn-3.5Zr-0.7Nb-0.5Mo-0.3Si)	Rod, bar, billet, extrusions	Weldable, high-temperature alloy with improved fatigue performance as compared to IMI 829 and 685	Maximum-use temperature up to about 590 °C (1100 °F)
Ti-1100	. . .	Elevated-temperature alloy	Maximum-use temperature of 590 °C (1100 °F)
α-β alloys			

Ti-6Al-4V (UNS R56400 and AECMA Ti-P63)	Bar, billet, rod, wire, plate, sheet, strip, extrusions	Ti-6Al-4V is the most widely used titanium alloy. It is processed to provide mill-annealed or β-annealed structures, and is sometimes solution treated and aged. Ti-6Al-4V has useful creep resistance up to 300 °C (570 °F) and excellent fatigue strength. Fair weldability	Ti-6Al-4V is used for aircraft gas turbine disks and blades. It is extensively used, in all mill product forms, for airframe structural components and other applications requiring strength at temperatures up to 315 °C (600 °F); also used for high-strength prosthetic implants and chemical-processing equipment. Heat treatment of fastener stock provides tensile strengths up to 1100 MPa (160 ksi).
Ti-6Al-4V-ELI (UNS R56401)	Same as UNS T56400	Reduced interstitial impurities improve ductility and toughness.	Cryogenic applications and fracture-critical aerospace applications.
Ti-6Al-7Nb (IMI-367)	Rod, bar, billet, extrusions	High-strength alloy with excellent biocompatibility	Surgical implant alloy
Corona 5 (Ti-4.5Al-5Mo-1.5Cr)	Alloy researched for plate, forging, and superplastic forming sheet	Improved fracture toughness over Ti-6Al-4V with less restricted chemistry. Easier to work than Ti-6Al-4V	Once investigated as a possible replacement for Ti-6Al-4V in aircraft, but no longer considered of interest
Ti-6Al-6V-2Sn (UNS T56620)	Bar, billet, extrusions, plate, sheet, wire	In the forms of sheet, light-gage plate, extrusions, and small forgings, this alloy is used for airframe structures where strength higher than that of Ti-6Al-4V is required. Usage is generally limited to secondary structures, because attractiveness of higher strength efficiency is minimized by lower fracture toughness and fatigue properties.	Applications requiring high strength at temperatures up to 315 °C (600 °F). Rocket engine case airframe applications including forgings, fasteners. Limited weldability. Susceptible to embrittlement above 315 °C (600 °F)
Ti-8Mn (UNS R56080)	Sheet, strip, plate	Limited usage	Aircraft sheet and structural parts
Ti-7Al-4Mo (UNS R56740)	Bar and forgings	Limited usage	Jet engine disks, compressor blades and spacers, sonic horns
Ti-6Al-2Sn-4Zr-6Mo (UNS R56260)	Sheet, plate, and bar or billet for forging stock	Should be considered for long-time load-carrying applications at temperatures up to 400 °C (750 °F) and short-time load-carrying applications. Limited weldability	Forgings in intermediate temperature range sections of gas turbine engines, particularly in disk and fan blade components of compressors
Ti-6Al-2Sn-2Zr-2Cr-2Mo-0.25Si	Forgings, sheet	Heavy section forgings requiring high strength, fracture toughness, and high modulus	Forgings and sheet for airframes
Ti-3Al-2.5V (UNS R56320)	Bar, tubing, strip	Normally used in the cold-worked stress-relieved condition	Seamless tubing for aircraft hydraulic and ducting applications; weldable sheet; mechanical fasteners
IMI 550 and 551	Rod, bar, billet, extrusions	High-strength alloys; IMI 551 has increased room-temperature strength due to higher tin contents than IMI 550.	Two high-strength alloys with useful creep resistance up to 400 °C (750 °F)

β alloys			
Ti-13V-11Cr-3Al (UNS R58010)	Sheet, strip, plate, forgings, wire	High-strength alloy with good weldability	High-strength airframe components and missile applications such as solid rocket motor cases where extremely high strengths are required for short periods of time. Springs for airframe applications. Very little use anymore
Ti-8Mo-8V-2Fe-3Al (UNS R58820)	Rod, wire, sheet, strip, forgings	Limited weldability	Rod and wire for fastening applications; sheet, strip, and forgings for aerospace structures
Ti-3Al-8V-6Cr-4Zr-4Mo (Beta C)	Sheet, plate, bar, billet, wire, pipe, extrusions, castings	High-strength alloy with excellent ductility not available in other β alloys. Excellent cold-working characteristics; fair weldability	Airframe high-strength fasteners, rivets, torsion bars, springs, pipe for oil industry and geothermal applications
Ti-11.5Mo-6Zr-4.5Sn (Beta III)	Not being produced anymore	Excellent forgeability and cold workability. Very good weldability	Aircraft fasteners (especially rivets) and sheet metal parts where cold formability and strength potential can be used to greatest advantage. Possible use in plate and forging applications where high-strength capability, deep hardenability, and resistance to stress corrosion are required and somewhat lower aged ductility can be accepted
Ti-10V-2Fe-3Al	Sheet, plate, bar, billet, wire, forgings	The combination of high strength and high toughness available is superior to any other commercial titanium alloy. For applications requiring uniformity of tensile properties at surface and center locations	High-strength airframe components. Applications up to 315 °C (600 °F) where medium to high strength and high toughness are required in bar, plate, or forged sections up to 125 mm (5 in.) thick. Used primarily for forgings
Ti-15V-3Al-3Cr-3Sn (Ti-15-3)	Sheet, strip, plate	Cold formable β alloy designed to reduce processing and fabrication costs. Heat treatable to a tensile strength of 1310 MPa (190 ksi)	High-strength aircraft and aerospace components
Ti-5Al-2Sn-2Zr-4Mo-4Cr (Ti-17)	Forgings	α-rich near-β alloy that is sometimes classified as an α-β alloy. Unlike other βor near-β alloys, Ti-17 offers good creep strength up to 430 °C (800 °F).	Forgings for turbine engine components where deep hardenability, strength, toughness, and fatigue are important. Useful in sections up to 150 mm (6 in.)
Transage alloys	Sheet, plate, bar, forging	Developmental	High-strength (Transage 134) and high-strength elevated-temperature (Transage 175) alloys

Effects of Alloy Elements

In titanium alloys, the principal effect of an alloying element is its effect on the alpha-to-beta transformation temperature. Some elements stabilize the alpha crystal structure by raising the alpha-to-beta transformation temperature, while other elements stabilize the beta structure by lowering the alpha-to-beta transformation temperature.

Table 7 classifies the common alloying elements as alpha or beta stabilizers. The addition of alloying elements also divides the single temperature for equilibrium transformation into two temperatures--the alpha transus, above which the alpha phase begins transformation to beta, and the beta transus, above which the alloy is all-beta. Between these

temperatures, both alpha and beta are present. Transus temperatures vary with impurity levels and the uncertainty range of alloy additions.

Table 7 Ranges and effects of some alloying elements used in titanium

Alloying element	Range (approx), wt %	Effect on structure
Aluminum	2-7	α stabilizer
Tin	2-6	α stabilizer
Vanadium	2-20	β stabilizer
Molybdenum	2-20	β stabilizer
Chromium	2-12	β stabilizer
Copper	2-6	β stabilizer
Zirconium	2-8	α and β strengthener (see text)
Silicon	0.05 to 1	Improves creep resistance

Alpha Stabilizers. Aluminum is the primary alpha stabilizer in titanium alloys. Other alloying elements that favor the alpha crystal structure and stabilize it by raising the alpha-beta transformation temperatures include gallium, germanium, carbon, oxygen, and nitrogen.

Beta stabilizers are classified into two groups: beta isomorphous and beta eutectoid. Isomorphous alpha phase results from the decomposition of the metastable beta in the first group, whereas in the second group, an intimate eutectoid mixture of alpha and a compound form.

The isomorphous group consists of elements that are completely miscible in the beta phase; included in this group are molybdenum, vanadium, tantalum, and niobium.

The eutectoid-forming group, which has eutectoid temperatures as much as 335 °C (600 °F) below the transformation temperature of unalloyed titanium, includes manganese, iron, chromium, cobalt, nickel, copper, and silicon. Active eutectoid formers (for example, nickel or copper) promote rapid decomposition, and sluggish eutectoid formers (for example, iron or manganese) induce a slower reaction.

Aluminum is a principal alpha stabilizer in titanium alloys that increases tensile strength, creep strength, and the elastic moduli. The maximum solid solution strengthening that can be achieved by aluminum is limited, because above 6% Al promotes ordering and Ti_3Al (α_2) formation, which is associated with embrittlement. Thus, aluminum content of all titanium alloys is typically below 7%. Formation of α_2, which is closely related to O_2 content, can actually occur at lower levels of aluminum.

Tin has extensive solid solubilities in both alpha and beta phases and is often used as a solid solution strengthener in conjunction with aluminum to achieve higher strength without embrittlement. Tin is a less potent alpha stabilizer than aluminum, but does retard the rates of transformation. Tin is used as the main alpha stabilizer in IMI-679 (Table 5(b)). This alloy has a good combination of strength and temperature capability but higher density and lower modulus than Ti-

6Al-2Sn-4Zr-2Mo-0.1Si (Ti-6242S), which uses aluminum as its main alpha stabilizer. Tin will react in concert with aluminum to promote ordering, $Ti_3(Al,Sn)$.

Zirconium forms a continuous solid solution with titanium and increases strength at low and intermediate temperatures. The use of zirconium above 5 to 6% may reduce ductility and creep strength (Ref 6). Zirconium is a weak beta stabilizer (Ref 7), but does retard the rates of transformation.

Molybdenum is an important beta stabilizer that promotes hardenability and short-time elevated-temperature strength. Molybdenum makes welding more difficult (Ref 8) and reduces long-term, elevated-temperature strength.

Niobium is a beta stabilizer that is added primarily to improve oxidation resistance at high temperatures.

Iron is a beta stabilizer that tends to reduce creep strength (see the section "Elevated-Temperature Mechanical Properties" in this article). Reduced iron content is utilized in alloy Ti-1100 (Table 5(a)) as a way of improving creep strength.

Carbon is an alpha stabilizer that also widens the temperature difference between the alpha transus and the beta transus. Typically, beta stabilizers cause a widening (or flattening) between the alpha and beta transus temperature. In Fig. 11, for example, the lean beta stabilizer content of alloy IMI 829 produces a near-alpha alloy with a steep beta-transus approach curve. In contrast, an alloy with additional beta stabilizer (in this case Ti-6Al-4V) results in an alpha-beta alloy with a flattened approach curve.

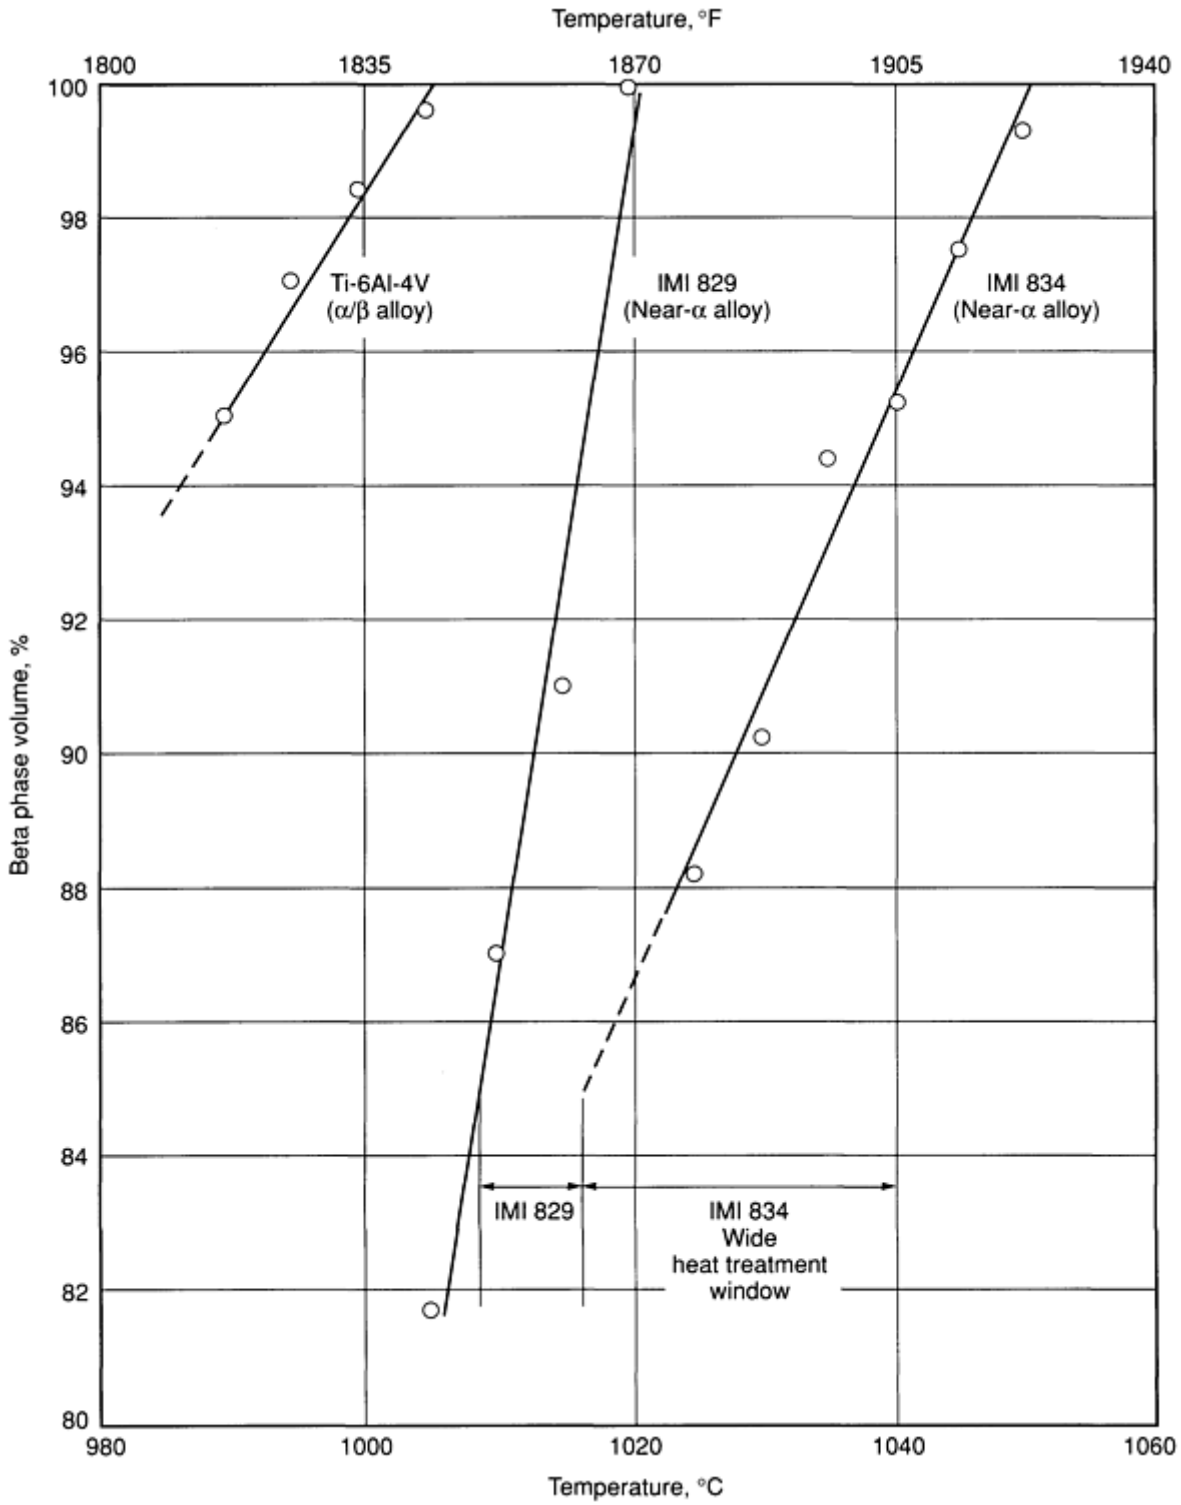

Fig. 11 Beta transus approach curves of IMI 834, IMI 829, and Ti-6Al-4V. Source: Ref 9

The use of carbon to flatten the approach curve while also stabilizing the alpha phase is the basis for near-alpha alloy IMI 834 (Ref 10). Alloy IMI 834 is heat treated high in the alpha-beta region (Fig. 11) to give about 7.5 to 15 vol% of primary alpha in a fine grain (~0.1 mm) matrix of transformed beta. This combination of equiaxed alpha and transformed beta provides a good combination of creep and fatigue strength (Ref 9). Carbon also improves strength and fatigue performance.

Alloy Classes

Titanium alloys are classified as alpha alloys, alpha-beta alloys, and beta alloys. Alpha alloys have essentially all-alpha microstructures. Beta alloys have largely all-beta microstructures after air cooling from the solution treating temperature above the beta transus. Alpha-beta alloys contain a mixture of alpha and beta phases at room temperature. Within the alpha-beta class, an alloy that contains much more alpha than beta is often called a near-alpha alloy. The names super-alpha and lean-beta alpha are also used for this type of alpha-beta alloy. For the purposes of this discussion, the near-alpha alloys are grouped with the alpha alloys, even though they may have some microstructural similarities with the alpha-beta alloys.

Alpha alloys (Table 5(a)) such as Ti-5Al-2.5Sn are slightly less corrosion resistant but higher in strength than unalloyed titanium. Alpha alloys generally are quite ductile, and the ELI grades retain ductility and toughness at cryogenic temperatures. Alpha alloy cannot be strengthened by heat treatment because the alpha structure is a stable phase. The principal microstructural variable of alpha alloys is the grain size. For a fixed composition, short-time strength (yield) and long-time strength (creep rupture) are influenced by grain size and stored energy (if any) of deformation.

The principal alloying element in alpha alloys is aluminum, but certain alpha alloys, and most commercial unalloyed titanium, contain small amounts of beta-stabilizing elements. Alpha alloys that contain small additions of beta stabilizers (Ti-8Al-1Mo-1V or Ti-6Al-2Nb-1Ta-0.8Mo, for example) sometimes have been classed as superalpha or near-alpha alloys. Although they contain some retained beta phase, these alloys consist primarily of alpha and may behave more like conventional alpha alloys in that their response to heat treatment (age hardening) and processing more nearly follows that of the alpha alloy than the conventional alpha-beta alloys.

Because near-alpha alloys contain some beta stabilizers, near-alpha alloys can exhibit microstructural variations (Fig. 12) similar to that of alpha-beta alloys. The microstructures can range from equiaxed alpha (Fig. 12a), when processing is performed in the alpha-beta region, to an acicular structure (Fig. 12c) of transformed beta after processing above the beta transus. Because these microstructural variations are related to different property improvements (Table 8), the processing temperatures of near-alpha alloys generally influence properties in the following way:

Property	**β processed**	**α/β processed**
Tensile strength	Moderate	Good
Creep strength	Good	Poor
Fatigue strength	Moderate	Good
Fracture toughness	Good	Poor
Crack growth rate	Good	Moderate
Grain size	Large	Small

In heat treating titanium alloys above the beta transus, a coarse beta grain size is likely unless adequate precautions are taken in forging and/or heat treatment. In contrast, a beta grain size of **;** 0.1 mm can be achieved by processing near-alpha alloys high in the alpha-beta region (that is, near the beta transus) as compared to a typical beta grain size of 0.5 to 1.0 mm for beta-processed alloys. The quench rate also has a significant effect on the transformation product in that slow rates will give aligned alpha plates, which tend to be good for creep but somewhat worse than the faster quenched structures, basket-weave alpha, in fatigue.

Table 8 Relative advantages of equiaxed and acicular morphologies in near-alpha and alpha-beta alloys

Equiaxed:
Higher ductility and formability
Higher threshold stress for hot-salt stress corrosion
Higher strength (for equivalent heat treatment)
Better low-cycle fatigue (initiation) properties
Acicular:
Superior creep properties
Higher fracture-toughness values
Slight drop in strength (for equivalent heat treatment)
Superior stress-corrosion resistance
Lower crack-propagation rates

(b) Equiaxed grains of primary alpha (light) in a matrix of transformed beta (dark) containing fine acicular alpha. (c) Transformed beta containing coarse and fine acicular alpha (light). Etchant: Kroll's reagent (192). All micrographs at 250×

Alpha-beta alloys (Table 5(b)), which contain one or more alpha stabilizers plus one or more beta stabilizers, can be strengthened by heat treatment or thermomechanical processing. Generally, when strengthening is desired, the alloys are rapidly cooled from a temperature high in the alpha-beta range or even above the beta transus. This solution treatment is followed by an intermediate-temperature treatment (aging) to produce an appropriate mixture of alpha and transformed beta products. Response to heat treatment is a function of cooling rate from the solution temperature and therefore may be affected by section size.

Like the near-alpha alloy in Fig. 12, the microstructure of alpha-beta alloys can take on different forms, raging from equiaxed to acicular or some combination of both. Equiaxed structures are formed by working an alloy in the alpha-beta range and annealing at lower temperatures. Acicular structures (Fig. 13c) are formed by working or heat treating above the beta transus and rapid cooling. Rapid cooling from temperatures high in the alpha-beta range (Fig. 13d and e) will result in equiaxed primary (prior) alpha and acicular alpha from the transformation of beta structures. Generally, there are property advantages and disadvantages for each type of structure. Table 8 compares, on a relative basis, the advantages of each structure.

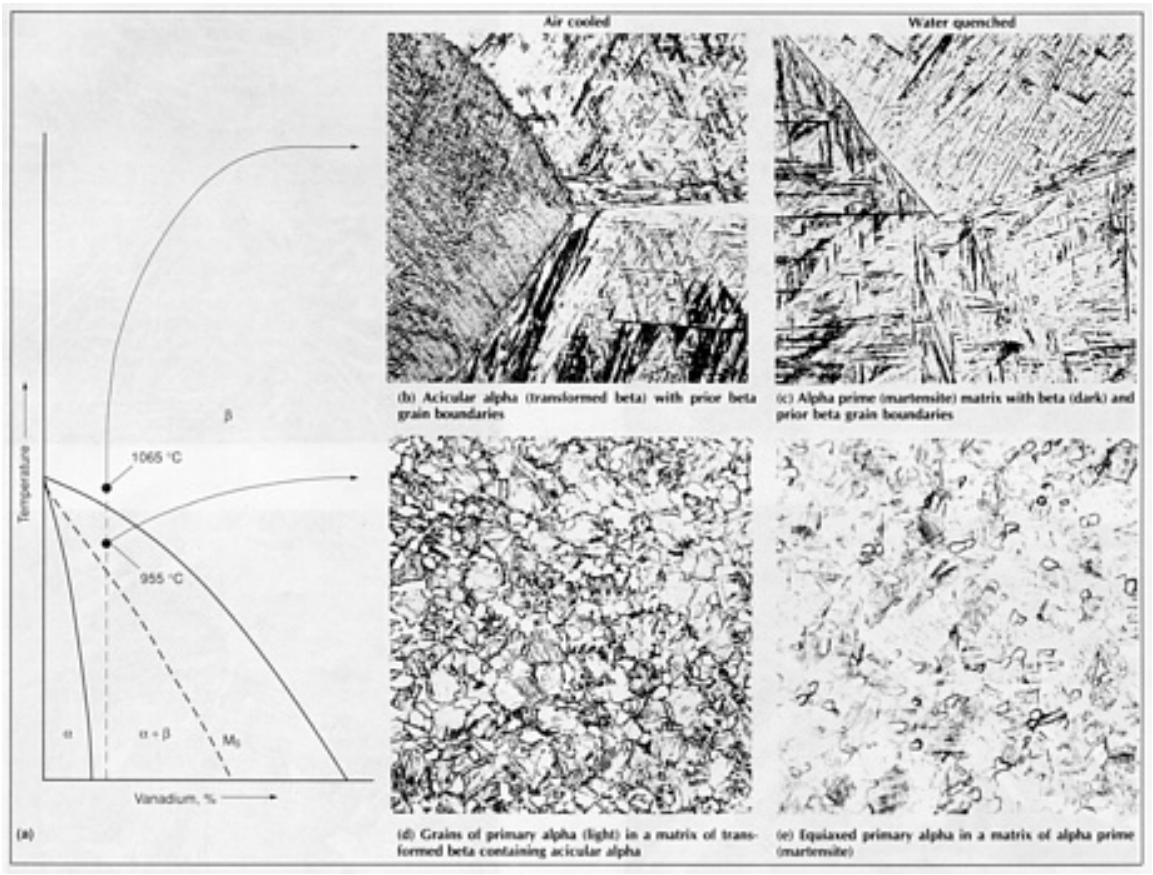

Fig. 13 Microstructures of alloy Ti-6Al-4V after cooling from different areas of the phase field shown in (a). The specimens represented in micrograph (e) provided the best combination of strength and ductility after aging. See the text and Table 9. Etchant: 10 HF, 5 HNO_3, 85 H_2O. All micrographs at 250×

By a suitable manipulation of forging and heat treatment schedules, a wide range of properties is attainable in alpha-beta alloys. In particular, the alpha-beta alloys are more responsive to aging than the near-alpha alloys. The near-alpha alloys are less responsive to aging because little, if any, change in properties can be expected when phases are in a nearly equilibrium condition prior to aging.

In the alpha-beta alloys, the presence of nonequilibrium phases, such as alpha-prime or metastable beta, results in substantial increases in tensile and yield strengths following the aging treatment. Table 9, for example, shows the response to heat treatment for the widely used Ti-6Al-4V alloy. The tensile data show that no response to aging occurs upon furnace cooling from solution temperatures. Only a slight response occurs upon air cooling (microstructures in Fig. 13b and d), while the greatest response is experienced with water quenching from the solution temperature (microstructures in Fig. 13c and e). Good response to aging takes place upon water quenching from the beta field (Fig. 13c); however, ductilities are quite low (Table 9). The best combination of properties can be produced by solution treating and rapidly quenching from close to but below the beta transus temperature (Fig. 13d or e), followed by an aging treatment (Table 9).

Table 9 Effect of heat treatment on the tensile properties of Ti-6Al-4V

(a) Aging in all instances: 540 °C (1000 °F) for 4 h; air cool. WQ, water quench; AC, air cool; FC, furnace cool. β transus: 1000 ± 14 °C (1820 ± 25 °F). All specimens are 16 mm ($\frac{5}{8}$ in.) diameter bars.

(b) See Fig. 13 for corresponding microstructures before aging.

Beta alloys (Table 5(c)) are sufficiently rich in beta stabilizers (and lean in alpha stabilizers) that the beta phase can be completely retained with appropriate cooling rates. Beta alloys are metastable, and precipitation of alpha phase in the metastable beta is a method used to strengthen the alloys. Beta alloys contain small amounts of alpha-stabilizing elements as strengthening agents.

As a class, beta and near-beta alloys offer increased fracture toughness over alpha-beta alloys at a given strength level, with the advantage of heavy section heat treatment capability. However, beta and near-beta alloys may require close control of processing and fabrication steps to achieve optimal properties, though this is not always the case. In the past, beta alloys had rather limited applications, such as springs and fasteners, where very high strength was required.

In recent years, however, beta alloys have received closer attention because their fracture toughness characteristics respond to the increased need for damage tolerance in aerospace structures. In addition, some beta alloys containing molybdenum have good corrosion characteristics. Beta alloys also exhibit:

- Better room-temperature forming and shaping characteristics than alpha-beta alloys
- Higher strength than alpha-beta alloys at temperatures where yield strength (instead of creep strength) is the applicable criterion
- Better response to heat treatment (solution treatment, quenching, and aging) in heavier sections than the alpha-beta alloys

The use of beta alloys is increasing. Alloy Ti-10V-2Fe-3Al is used for forgings, alloy Ti-15V-3Cr-3Al-3Sn is used for sheet applications, and alloy Ti-3Al-8V-6Cr-4Mo-4Zr is being utilized for springs and extrusions.

Terminology in Classifying Beta Alloys. Although there are a number of ways to define the term beta alloy, T. Duerig and J. Williams (Ref 11) suggest the following operational definition: "A beta-titanium alloy is any titanium composition which allows one to quench a very small volume of material into ice water from above the material's beta-transus temperature without martensitically decomposing the beta phase." The point of such a detailed definition is to exclude all titanium alloys in which martensite can be formed athermally or with the assistance of residual stresses that may arise during the quenching of large pieces. It also excludes the diffusional decomposition of beta, which is section size dependent through cooling rates.

Within this definition, Fig. 14 illustrates the constitution of beta alloys. Within the general class of beta alloys, the solute lean alloys tend to decompose much more readily than do the more stable, solute rich alloys. Therefore, it is useful to divide the general classification of beta alloys into two subclassifications: the lean beta alloys and the rich beta alloys. In Fig. 14, for example, alloys which form the brittle metastable phase, omega (ω) phase, during aging would be defined as lean alloys, and alloys which are too stable to decompose isothermally to a β+ ω mixture would be classified as rich alloys. Alternatives to this definition would be to define the lean alloys as those that deform by either a twinning or a martensitic shearing process when in the solution treated and quenched condition, or to give a processing-oriented definition that would identify the lean alloys as those that can be effectively thermomechanically processed in the α + β phase field (although this definition is certainly the least distinct of the three) (Ref 11). In terms of the most common commercial alloys, these three definitions basically coincide: any alloy classified as lean or rich by one definition would be classed the same way by either of the other definitions, although one could, without doubt, develop compositions that could not be unambiguously defined by all three definitions. Nevertheless, these definitions are more meaningful than the terms metastable beta and near-beta because all commercial beta alloys are metastable and decompose into alpha-beta structures.

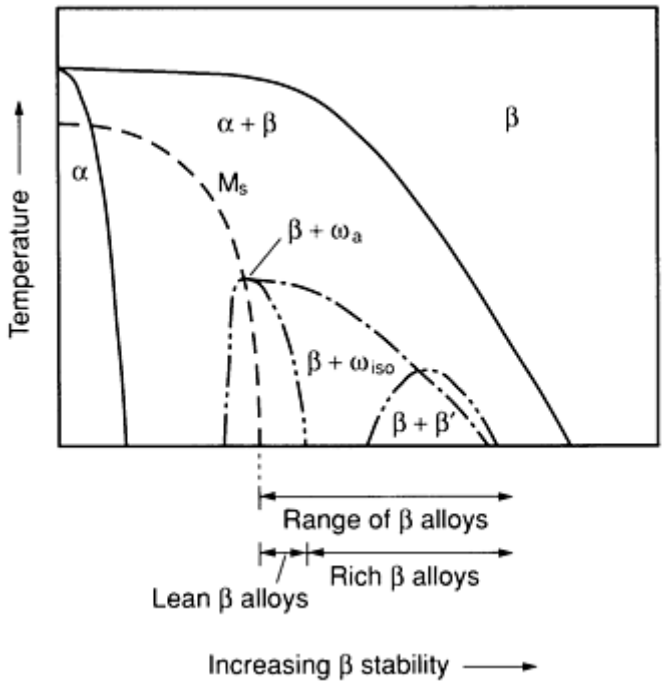

Fig. 14 Schematic phase diagram of a beta-stabilized titanium system, indicating the compositional range that would be considered beta alloys and the subdivision of this range into the lean and rich beta alloys. Source: Ref 11

Microstructural Constituents

The basis for microstructural manipulation during heat treatment of titanium alloys centers around the β → α transformation that occurs in these alloys during cooling. This transformation can occur by nucleation and growth, or it can occur martensitically, depending on the alloy composition and the cooling rate. The martensitic product is usually hcp and is designated α'. There also is an orthorhombic martensite, designated α", which forms in alloys that contain higher concentrations of refractory elements such as molybdenum, tantalum, or niobium. Literally all thermomechanical processing is conducted above the M_s temperature for either α' or α". Alloys that contain enough β-stabilizing elements to depress the M_s temperature below room temperature can be rapidly cooled to retain the metastable βphase. More detailed information of the phase transformations in titanium alloys is given in several of the "Selected References" listed at the end of this article.

Alpha Structures. Equiaxed alpha grains (Fig. 12a) usually are developed by annealing cold-worked alloys above the recrystallization temperature. Elongated alpha grains (Fig. 15b) result from unidirectional working of the metal and are commonly found in longitudinal sections of rolled or extruded alloys. Elongated alpha may be enhanced by the prior presence of blocky and/or grain-boundary alpha.

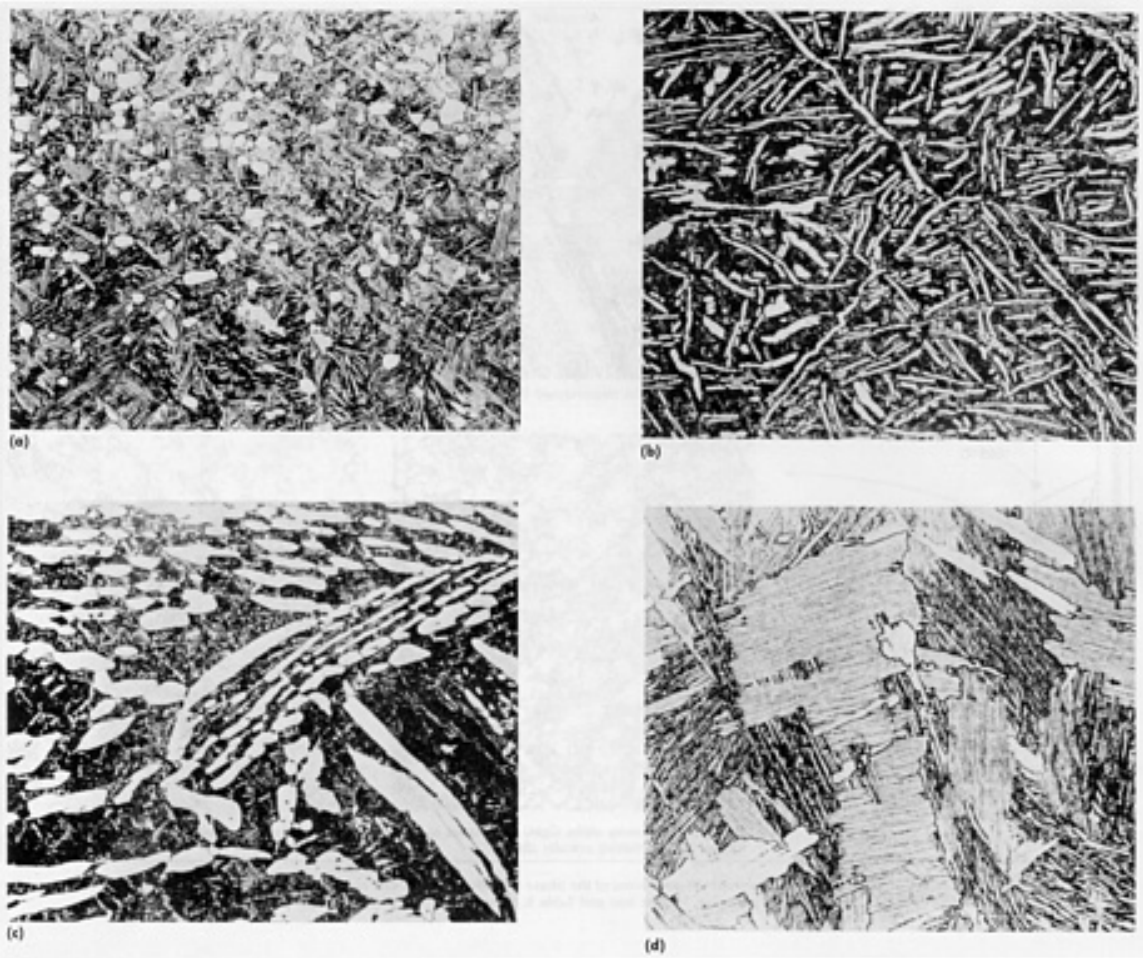

Fig. 15 Microstructures corresponding to different combinations of properties in Ti-6Al-4V forgings. (a) 6% equiaxed primary alpha plus fine platelet alpha in Ti-6Al-4V alpha-beta forged, then annealed 2 h at 705 °C (1300 °F) and air cooled. (b) 23% elongated, partly broken up alpha plus grain-boundary alpha in Ti-6Al-4V, alpha-beta forged and water quenched, then annealed 2 h at 705 °C and air cooled. (c) 25% blocky (spaghetti) alpha plates plus very fine platelet alpha in Ti-6Al-4V alpha-beta forged from a spaghetti-alpha starting structure, then solution treated 1 h at 955 °C (1750 °F) and reannealed 2 h at 705 °C. (d) 92% alpha basket-weave structure in Ti-6Al-4V beta forged and slow cooled, then annealed 2 h at 705 °C. Structures in (a) and (b) produced excellent combinations of tensile properties, fatigue strengths and fracture toughness. Structure in (c) produced very poor combinations of mechanical properties. Structure in (d) produced good fracture toughness, but poor tensile properties and fatigue resistance. Source: Ref 12

Primary alpha refers to the alpha phase in a crystallographic structure that is retained from the last high-temperature alpha-beta working or heat treatment. The morphology of alpha is influenced by the prior thermomechanical history.

Transformed Beta. Although some of the areas of alpha phase that appear in micrographs of heat-treated titanium and titanium alloys may have been present before the heat treatment (primary alpha), other areas of alpha have been produced by transformation from beta. The alpha in these latter areas appears in different structures known as serrated, acicular, platelike, Widmanstätten, and alpha prime (martensite). The term transformed beta is used to describe these various alpha structures plus any beta that may remain at room temperature.

Acicular alpha, which is the most common transformation product formed from beta during cooling, is produced by nucleation and growth along one set of preferred crystallographic planes of the prior-beta matrix (Fig. 12a) or along several sets of planes (Fig. 15d); in the latter instance, a basket-weave appearance results that is characteristic of a Widmanstätten structure. Acicular alpha and Widmanstätten alpha are generally interchangeable terms.

Under some conditions, the long grains of alpha that are produced along preferred planes in the beta matrix take on a wide, platelike appearance. Under other conditions, grains of irregular size and with jagged boundaries, called serrated alpha, are produced.

Alpha prime (hexagonal martensite) is a nonequilibrium supersaturated alpha structure produced by diffusionless (martensitic) transformation of beta. The needlelike structure, similar in appearance and in mode of formation to martensite in steel, is often difficult to distinguish from that of acicular alpha, although acicular alpha usually is less well-defined and has curved rather than straight sides.

Alpha double prime (orthorhombic martensite) is a supersaturated nonequilibrium orthorhombic phase formed by a diffusionless transformation of the beta phase in certain alloys.

Alpha-2 (α_2) or Ti_3Al is an ordered phase that can form within the alpha phase in alloys containing more than 6% Al. The reaction is promoted by increased oxygen.

Omega is a nonequilibrium, submicroscopic phase that forms as a nucleation growth product, often thought to be a transition phase during the formation of alpha from beta. It occurs in metastable beta alloys and can lead to severe embrittlement. It typically occurs during aging at low temperatures, but can also be induced by high hydrostatic pressures. It can also form athermally upon quenching within beta of certain compositions.

Beta Structures. In alpha-beta and beta alloys, some equilibrium beta is present at room temperature. A nonequilibrium, or metastable, beta phase can be produced in alpha-beta alloys that contain enough beta-stabilizing elements to retain the beta phase at room temperature upon rapid cooling from between the alpha transus and beta transus temperatures. The composition of the alloy must be such that the temperature for the start of martensite formation is depressed to below room temperature. Metastable beta is partially or completely transformed to martensite, alpha, or eutectoid decomposition products with thermal or strain energy activation during processing or service exposure.

Beta flecks are alpha-lean regions in an alpha-beta microstructure. This beta-rich region has a beta transus measurably below that of the matrix. Beta flecks have reduced amounts of primary alpha (or may even be devoid of alpha) and, in alpha-beta alloys, may exhibit a different morphology than the primary alpha in the surrounding matrix. Beta flecks have a higher content of beta stabilizers than the matrix and, through partitioning, probably are lean in alpha stabilizers.

Beta flecks are attributed to microsegregation during solidification of ingots of alloys that contain strong beta stabilizers. They are most often found in products made from large-diameter ingots. Beta flecks also may be found in beta-lean alloys such as Ti-6Al-4V that have been heated to a temperature near the beta transus during processing.

Beta flecks are not considered harmful in alloys lean in beta stabilizers if they are to be used in the annealed condition. However, they constitute regions that incompletely respond to heat treatment, and thus microstructural standards have been established for allowable limits on beta flecks in various alpha-beta alloys. Beta flecks are more objectionable in beta-rich alpha-beta alloys and beta alloys than in leaner alloys.

Aged Structures. Aging of martensite results in the formation of equilibrium $\alpha + \beta$ but most aged martensite structures cannot be distinguished from unaged martensite by light microscopy. Precipitation of alpha during aging of beta results in some darkening of the aged-beta structure. Aging, or stressing, could change metastable beta to alpha or to eutectoid products.

Wrought Alloy Processing

Because the microstructures of titanium alloys are readily affected by process variables, microstructural control is basic to successful processing of titanium alloys. Undesirable structures (grain-boundary alpha, beta fleck, "spaghetti" or elongated alpha) can interfere with optimal property development (Fig. 15). Titanium ingot structures, discussed in the section "Melting Practice for Ingot Production," can also carry over to the final product.

Several factors are important in the processing of titanium and titanium alloys. Among the most important are:

- Amounts of specific alloying elements and impurities
- Melting process used to make ingot
- Method for mechanically working ingots into mill products
- The final step employed in working, fabrication, or heat treatment

This section focuses on primary fabrication, in which ingots are converted into general mill products, and secondary fabrication of finished shapes from mill products. Secondary fabrication refers to manufacturing processes such as die forging, extrusion, hot and cold forming, machining, chemical milling, and joining, all of which are used for producing finished parts from mill products. Each of these processes may strongly influence properties of titanium and its alloys, either alone or by interacting with effects of processes to which the metal has previously been subjected.

Primary Fabrication

Primary fabrication includes all operations that convert ingot into general mill products--billet, bar, plate, sheet, strip, extrusions, tube, and wire. Besides the reduction of section size, the basic objective of primary processing is the refinement of grain size and the production of a uniform microstructure. Primary fabrication is very important in establishing final properties, because many secondary fabrication operations may not involve sufficient reductions for grain refinement by recrystallization. However, some secondary fabrication processes, such as forging and ring rolling, do impart sufficient reduction to play the major role in establishing material properties. In fact, forgings usually recrystallize more uniformly because forging is an efficient method of introducing large amounts of stored energy in the material.

Because titanium alloys utilize many of the same methods (and sometimes the same processing facilities) as other metals, the primary fabrication processes were first designed around the capabilities of steel mill equipment. As the titanium industry matured, special furnace equipment, presses, and mills were developed in response to the different processing requirements of titanium alloys. One of the basic distinctions is the high reactivity of titanium and the possibility of surface contamination (see the section "Heat Treatment" for a discussion on surface contamination). Other major factors affected by thermomechanical processing that appear to be important are: primary alpha morphology, primary alpha volume fraction, and grain boundary alpha. The effects of thermomechanical processing on these microstructural features, which are important in both alpha-beta and beta alloys, are discussed in Ref 13.

In beta alloys, however, thermomechanical processing affects not only the microstructure, but also the decomposition kinetics of the metastable beta phase during aging. The increased dislocation density after working beta alloys leads to extensive heterogeneous nucleation of the equilibrium alpha phase and can thus suppress formation of the brittle omega phase (Ref 13). Strain-rate sensitivity as a function of beta content is also important (see, for example, the section "Superplastic Forming" in this article). Because the flow stress of beta alloys can be affected by their high strain-rate sensitivity, primary processing is frequently accomplished at temperatures higher than those for other titanium alloys with the attendant higher number of reheats and increased wear on forging dies. Beta alloys thus exhibit slightly greater

evidence of sensitivity to the thermomechanical processing route in obtaining and retaining uniformly recrystallized microstructure and less tendency for texturing when compared with α + β or alpha alloys.

Reduction to Billet. Generally, the first breakdown of production ingot is a press cogging operation done in the beta temperature range. Modern processes utilize substantial amounts of working below the beta transus to produce billets with refined structures. These processes are carried out at temperatures high in the alpha region to allow greater reduction and improved grain refinement with a minimum of surface rupturing. Where maximum fracture toughness is required beta processing (or alpha-beta processing followed by beta heat treatment) is generally preferred. Table 10 gives standard forging-temperature ranges for manufacture of billet stock.

Table 10 Standard forging temperatures for manufacturing titanium billet stock

β alloy								

Some billets intended for further forging, rolling, or extrusion go through a grain-refinement process. This technique, developed in the early 1970s, utilizes the fact that titanium recrystallizes when it is heated above the beta transus. However, because grain boundary alpha forms when most (and especially beta-rich) alloys are cooled from above the beta transus, working in the alpha-beta region may be needed to control the formation of grain boundary alpha. Working during continuous cooling through the beta transus is a very effective method of eliminating grain boundary alpha (Ref 13). By starting with grain-refined billet, secondary fabricators may be able to produce forgings that meet strict requirements with respect to macrostructure, microstructure, and mechanical properties without extensive hot working below the beta transus.

Final tensile properties of alpha-beta alloys are strongly influenced by the amount of processing in the alpha-beta field--both below the beta transus temperature and after recrystallization. Such processing increases the strength of high alpha grades in large section sizes. With modern processing techniques, billet and forged sections readily meet specified tensile properties prior to final forging. Table 11 shows how billet and forging section size affects room-temperature tensile properties of various titanium alloys.

(g) Annealed 1 h at 954 °C (1750 °F), air cooled, then heated 8 h to 600 °C (1100 °F) and air cooled

Rolling of Bar, Plate, and Sheet. Roll cogging and hot roll finishing of bar, plate, and sheet are now standard operations, and special rolling and auxiliary equipment have been installed by the larger titanium producers to allow close control of all rolling operations. Rolling processes used by each manufacturer are proprietary and in some respects unique, but because all techniques must produce the same specified structures and mechanical properties, a high degree of similarity exists among the processes of all manufacturers.

A representative range of temperatures used for hot rolling of titanium metals is presented in Table 12. Rolling at these temperatures produces end products with the desired grain structures. When production limitations require the suppression of aging reaction kinetics, the beta phase stability of the beta alloys allows manufacture of hot band and cold-rolled strip product. Because of the body-centered cubic crystal structure of the beta phase, flat-rolled products and even cold-rolled strip are relatively free of in-plane texture (Ref 14). This makes possible strip and plate mill products with very uniform properties.

Bars up to about 100 mm (4 in.) in diameter are unidirectionally rolled, and their properties commonly reflect total reduction in the alpha-beta range. For example, a round bar 50 mm (2 in.) in diameter rolled from a Ti-6Al-4V billet 100 mm (4 in.) square typically is 140 to 170 MPa (20 to 25 ksi) lower in tensile strength than rod 7.8 mm ($\frac{5}{16}$ in.) in diameter rolled on a rod mill from a billet of the same size at the same rolling temperatures. For bars about 50 to 100 mm (2 to 4 in.) in diameter, strength does not decrease with section size, but transverse ductility and notched stress-rupture strength at room temperature do become lower. In diameters greater than about 75 to 100 mm (3 to 4 in.), annealed Ti-6Al-4V bars usually do not meet prescribed limits for notched stress rupture at room temperature--1170 MPa (170 ksi) minimum to cause rupture of a notched specimen in 5 h--unless the material is given a special duplex anneal. Transverse ductility is lower in bars about 65 to 100 mm ($2\frac{1}{2}$ to 4 in.) in diameter because it is not possible to obtain the preferred texture throughout bars of this size.

Plate and sheet commonly exhibit higher tensile properties in the transverse direction relative to the final rolling direction (Table 13). Cross rolling is used to achieve a balance in transverse and longitudinal properties. Unidirectional rolling (Table 13) is not yet used for alpha-beta titanium alloys.

(a) In 50 mm (2 in.)

Directionality in properties is observed only as a slight drop in transverse ductility of plate greater than 25 mm (1 in.) thick. Military, AMS, and customer specifications all prescribe lower minimum tensile and yield strengths as plate thickness increases. For forming applications, some customers specify a maximum allowable difference between tensile strengths in the transverse and longitudinal directions.

Forging

Forging is a common method of producing wrought titanium articles, and titanium alloy forgings are produced by all of the forging methods currently available, including open-die (or hand) forging, closed-die forging, upsetting, roll forging, orbital forging, spin forging, mandrel forging, ring rolling, and forward and backward extrusion. Selection of the optimal forging method for a given forging shape is based on the desired forging shape, the sophistication of the design of the forged shape, the cost, and the desired mechanical properties and microstructure. In many cases, two or more forging methods are combined to achieve the desired forging shape, to obtain the desired final part microstructure, and/or to minimize cost. For example, open-die forging frequently precedes closed-die forging to preshape or preform the metal to conform to the subsequent closed dies, to conserve the expensive input metal, and/or to assist in overall microstructural development and grain flow control.

Titanium alloys are forged into a variety of shapes and types of forgings, with a broad range of final part forging design criteria based on the intended application. As a class of materials, however, titanium alloys are considerably more difficult to forge than aluminum alloys and alloy steels, particularly with conventional forging techniques, which use nonisothermal die temperatures of 535 °C (1000 °F) or less and moderate strain rates. Therefore, titanium alloy forgings, particularly closed-die forgings, are typically produced to less highly refined final forging configurations than are typical of aluminum alloys (although precision forgings in titanium alloys are produced to the same design and tolerance criteria as aluminum alloys; see the article "Forging of Titanium Alloys" in *Forming and Forging,* Volume 14 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

Most titanium alloy forgings are thermally treated after forging, with heat treatment processes ranging from simple stress-relief annealing to multiple-step processes of solution treating, quenching, aging, and/or annealing designed to modify the microstructure of the alloy to meet specific mechanical property criteria. However, the working history and forging parameters used in titanium alloy forging also have a significant impact on the final microstructure (and therefore the resultant mechanical properties) of the forged alloy--perhaps to a greater extent than in any other commonly forged material. Therefore, the forging process in titanium alloys is used not only to create cost-effective forging shapes but also, in combination with thermal treatments, to create unique and/or tailored microstructures to achieve the desired final mechanical properties through thermomechanical processing techniques. In fact, one of the main purposes of die forging is to obtain a combination of mechanical properties that generally does not exist in bar or billet. Tensile strength, creep resistance, fatigue strength, and toughness all may be better in forgings than in bar or other forms.

The hot deformation processes conducted during the forging of the three classes of titanium alloys form an integral part of the overall thermomechanical processing of these alloys to achieve the desired microstructure. By the design of the working process history from ingot to billet to forging, and particularly the selection of metal temperatures and deformation conditions during the forging process, significant changes in the morphology of the allotropic phases of titanium alloys are achieved that in turn dictate the final mechanical properties and characteristics of the alloy.

The key to successful forging and heat treatment is the beta transus temperature. Figure 16 shows the possible locations for temperature of forging and/or heat treatment of a typical alpha-beta alloy such as Ti-6Al-4V. The higher the processing temperature in the $\alpha+\beta$region, the more beta is available to transform upon cooling. Upon quenching from above the beta transus, a completely transformed, acicular structure arises. The form of the transformed beta structures produced by processing depends on the exact location of the beta transus, which varies from heat to heat of a given alloy, and also on the degree and nature of deformation produced. Section size is important, and the number of working operations can be significant. Conventional forging may require two or three operations, whereas isothermal forging may require only one.

(c) Generalized effect of processing temperature on as-forged room-temperature mechanical properties of beta alloy Ti-13V-11Cr-3Al

Fundamentally, there are two principal metallurgical approaches to the forging of titanium alloys:

- Forging predominantly below the beta transus (alpha-beta forging)
- Forging predominantly above the beta transus (beta forging)

However, within these fundamental approaches, there are several possible variations that blend these two techniques into processes that are used commercially to achieve controlled microstructures that tailor the final properties of the forging to specification requirements and/or intended service applications. Table 14, for example, summarizes four thermomechanical schedules that produced optimal combinations of properties in Ti-6Al-4V test forgings: excellent tensile strength, good-to-excellent notch fatigue strength, low-cycle fatigue strength, and fracture toughness. Also included in the table are three schedules that produced subnormal properties. The microstructures of Ti-6Al-4V shown in Fig. 15 correspond to two of the schedules that produced good combinations of properties and two that produced inferior combinations. Note the substantial difference in microstructure in the same final product, which, in combination with the resulting properties, demonstrates that control of thermomechanical processing can control the microstructures and corresponding final properties of forgings.

Table 14 Thermochemical schedules for producing various combinations of properties in Ti-6Al-4V forgings

Initial microstructure	Blocker forging temperature range	Finish forging temperature range	Finish forging reduction, %	Cooling after forging	Heat treated condition	Final microstructure
Best combinations of properties

Conventional alpha-beta forging of titanium alloys, in addition to implying the use of die temperatures of 540 °C (1000 °F) or less, is the term used to describe a forging process in which most or all of the forging deformation is conducted at temperatures below the beta transus of the alloy. This forging technique involves working the material at temperatures where both alpha and beta phases are present, with the relative amounts of each phase being dictated by the composition of the alloy and the actual temperature used. With this forging technique, the resultant as-forged microstructure is characterized by deformed or equiaxed primary alpha in a transformed beta matrix; the volume fraction and morphology of primary alpha is dictated by the alloy composition and the actual working history and temperature. Alpha-beta forging is typically used to develop optimal strength/ductility combinations and optimal high/low-cycle fatigue properties. With alpha-beta forging, the effects of working on microstructure, particularly alpha morphology changes, are cumulative; therefore, each successive alpha/beta working operation adds to the structural changes achieved in earlier operations. In the beta alloys, manipulation of the alpha phase during forging is less prevalent; therefore, the beta alloys are typically forged above the beta transus.

Beta forging, as the term implies, is a forging technique for alpha, beta, and alpha-beta alloys in which most or all of the forging work is done at temperatures above the beta transus of the alloy. In commercial practice, beta forging techniques typically involve supertransus forging in the early and/or intermediate stages with controlled amounts of final deformation below the beta transus of the alloy. However, isothermal beta forging is finding use in production of the more creep-resistant components of titanium alloys.

The beta-forged alloys tend to show a transformed beta or acicular microstructure, whereas alpha-beta forged alloys show a more equiaxed structure. Because each structure has unique capabilities (Table 8), tradeoffs are required in developing either an equiaxed or acicular structure. Figure 17, for example, compares alpha-beta forging versus beta forging for several titanium alloys. Although yield strength after beta forging was not always as high as that after alpha-beta forging, values of notch tensile strength and fracture toughness were consistently higher for the beta-forged material.

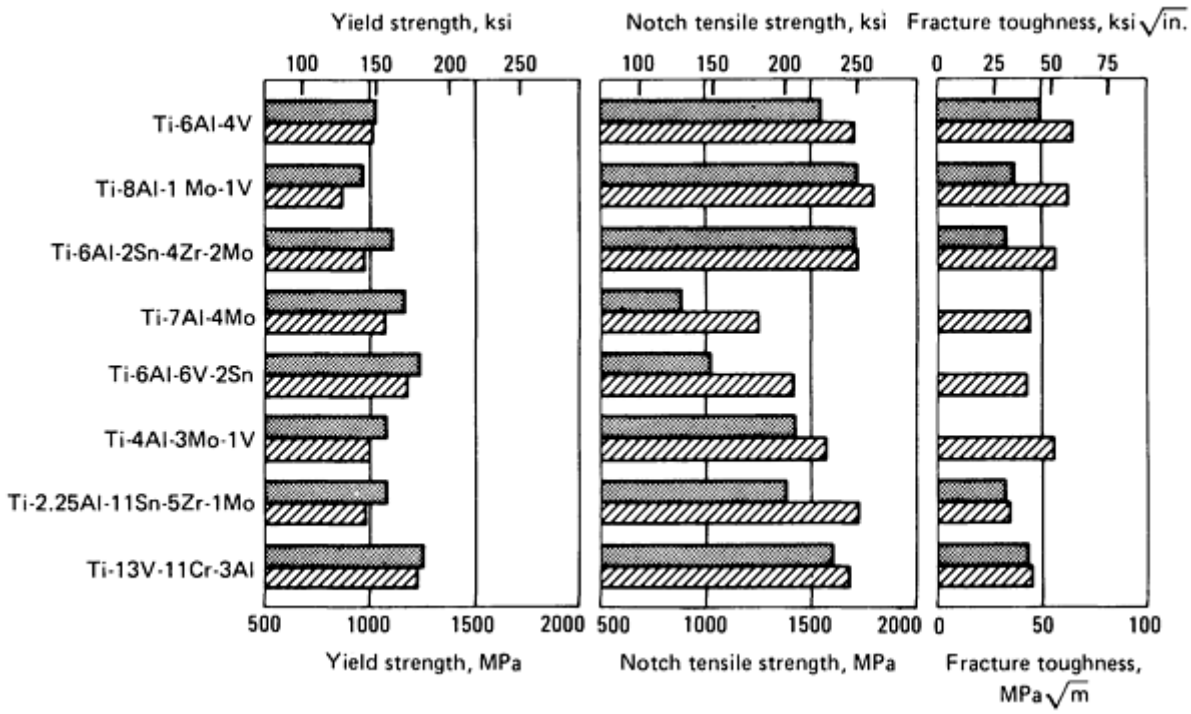

Fig. 17 Comparison of typical mechanical properties of alpha-beta forged and beta forged titanium alloys.

Shaded bars represent alpha-beta forged material; striped bars, beta forged material

Consequently, beta forging is typically used to enhance fracture-related properties, such as fracture toughness and fatigue crack propagation resistance, and to enhance the creep resistance of alpha and alpha-beta alloys. In fact, several recently developed alpha alloys (such as IMI 829 and 834) are designed to be beta forged to develop the desired final mechanical properties. There is often a loss in strength and ductility with beta forging as compared to alpha-beta forging.

In beta forging, the working influences on microstructure are not fully cumulative; with each working-cooling-reheating sequence above the beta transus, the effects of the prior working operations are at least partially lost because of recrystallization from the transformation upon heating above the beta transus of the alloy. Beta forging, particularly of alpha and alpha-beta alloys, has the advantages of significant reduction in forging unit pressures and reduced cracking tendency, but it must be done under carefully controlled forging process conditions to avoid nonuniform working, excessive grain growth, and/or poorly worked structures, all of which can result in final forgings with unacceptable or widely variant mechanical properties within a given forging or from lot to lot of the same forging.

Effect of Deformation Rate. Titanium alloys are highly strain-rate sensitive in deformation processes such as forging--considerably more so than aluminum alloys or alloy steels. The strain-rate sensitivity at forging temperatures is much higher for the beta and near-beta alloys, with the result that alloys such as Ti-13V-11Cr-3Al show marked increases in strength or flow stress as the deformation rate is increased. For example, at 788 °C (1450 °F) this alloy requires 50% more energy at a typical hammer velocity of 508 cm/sec (200 in./sec) than at a typical press velocity of 2.8 cm/sec (1.5 in./sec). However, the differences are much less for alpha and α+ β alloys (Ref 13).

From the known strain-rate sensitivity of titanium alloys, it appears to be advantageous to deform these alloys at relatively slow strain rates in order to reduce the resistance to deformation in forging (Fig. 18); however, under the nonisothermal conditions present in the conventional forging of titanium alloys, the temperature losses encountered by such techniques far out-weigh the benefits of forging at slow strain rates. Therefore, in the conventional forging of titanium alloys with relatively cool dies, intermediate strain rates are typically employed as a compromise between strain-rate sensitivity and metal temperature losses in order to obtain the optimal deformation possible with a given alloy. As discussed in the section "Hot-Die and Isothermal Forging" below, major reduction in resistance to deformation of titanium alloys can be achieved by slow strain-rate forging techniques under conditions where metal temperatures losses are minimized through dies heated to temperatures at or close to the metal temperature.

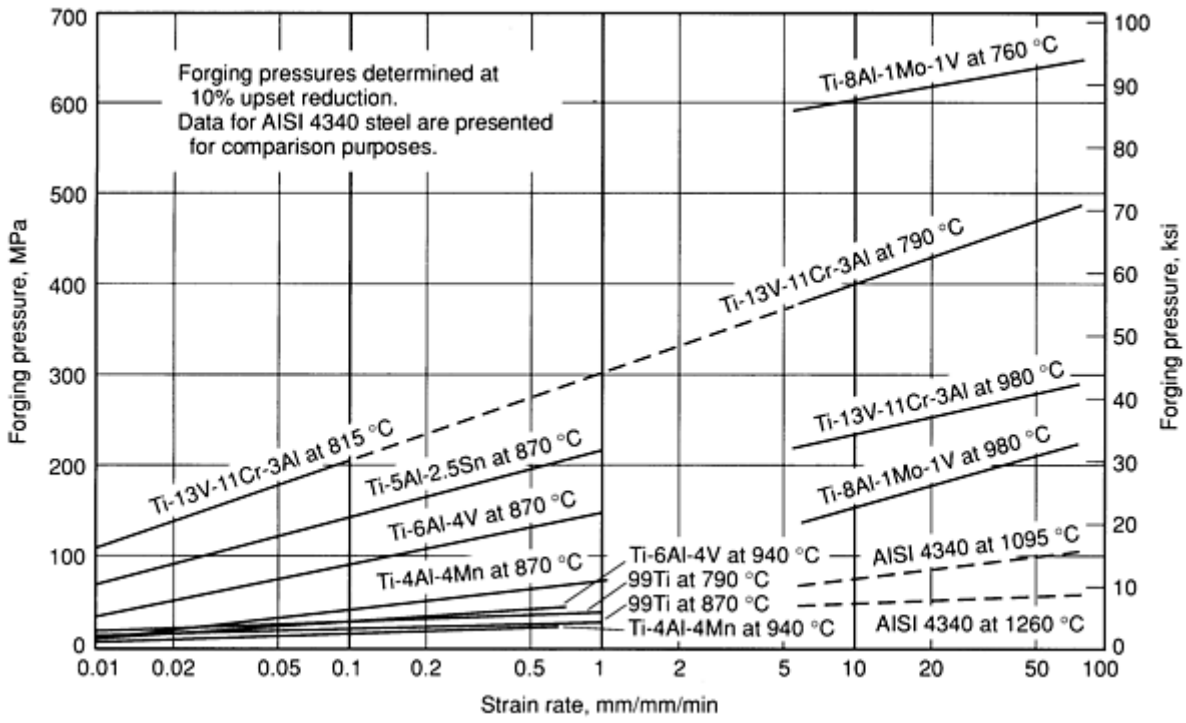

Fig. 18 Effect of strain rate on forging pressures for several titanium alloys at various forging temperatures.

Data for AISI 4340 steel are presented for comparison purposes.

With rapid deformation rate forging techniques, such as the use of hammers and/or mechanical presses, deformation heating during the forging process becomes important. Because titanium alloys have relatively poor coefficients of thermal conductivity, temperature nonuniformity may result, giving rise to nonuniform deformation behavior and/or excursions to temperatures that are undesirable for the alloy and/or final forging mechanical properties. As a result, in the rapid strain-rate forging of titanium alloys, metal temperatures are often adjusted to account for in-process heat-up, or the forging process (sequence of blows, and so on) is controlled to minimize undesirable temperature increases, or both. Therefore, within the forging temperature ranges outlined in Table 15, metal temperatures for optimal titanium alloy forging conditions are based on the type of forging equipment to be used, the strain rate to be employed, and the design of the forging part.

Table 15 Recommended forging temperature ranges for commonly forged titanium alloys

(a) C, conventional forging processes in which most or all of the forging work is accomplished below the β_t of the alloy for the purposes of desired mechanical property development. This forging method is also referred to as α-β forging. B, β forging processes in which some or all of the forging is conducted above the β_t of the alloy to improve hot workability or to obtain desired mechanical property combinations. C/B, either forging methodology (conventional or β) is employed in the fabrication of forgings or for alloys, such as β alloys, that are predominately forged above their β_t but may be finish forged at subtransus temperatures.

(b) These are recommended metal temperature ranges for conventional α-β, or βforging processes for alloys for which the latter techniques are reported to have been employed. The lower limit of the forging temperature range is established for open-die forging operations in which reheating is recommended.

(c) Alloys for which there are several compositional variations (primarily oxygen or other interstitial element contents) that may affect both β_t and forging temperature ranges.

(d) This alloy is forged and used both with and without the silicon addition; however, the β_t and recommended forging temperatures are essentially the same.

(e) Alloys designed to be predominately β forged.

(f) Ti-17 has been classified as an α-β and as a near-β titanium alloy. For purposes of this article, it is classified as an α-β alloy.

(g) Temperature for finish forging; primary forging performed at about 845 °C (1550 °F).

Hot-die and isothermal forging are special categories of forging processes in which the die temperatures are significantly higher than those used in conventional hot-forging processes. This has the advantage of reducing die chill and results in a process capable of producing near-net and/or net shape parts. Therefore, these processes are also referred to as near-net shape forging processes. These processing techniques are primarily used for manufacturing airframe structures and jet-engine components made of titanium and nickel-base alloys, but they have also been used in steel transmission gears and other components.

In the isothermal forging process, the dies are maintained at the same temperature as the forging stock. This eliminates the die chill completely and maintains the stock at a constant temperature throughout the forging cycle. The process permits the use of extremely slow strain rates, thus taking advantage of the strain-rate sensitivity of flow stress for certain alloys. The process is capable of producing net shape forgings that are ready to use without machining or near-net shape forgings that require minimal secondary machining.

The hot-die forging process is characterized by die temperatures higher than those in conventional forging, but lower than those in isothermal forging. Typical die temperatures in hot-die forging are 110 to 225 °C (200 to 400 °F) lower than the temperature of the stock. When compared with isothermal forging, the lowering of die temperature allows wider selection of die materials, but the ability to produce very thin and complex geometries is compromised.

The alloys used for hot-die and isothermal forging include titanium alloys such as Ti-6Al-4V, Ti-6Al-2Sn-4Zr-2Mo-0.1Si, and Ti-10V-2Fe-3Al. Isothermal forging of alpha-beta alloys is technically feasible, although high process and tooling costs, catastrophic die failures, and other engineering problems associated with very high process temperatures combine to minimize its use on conventional alpha-beta alloys.

Die Temperature. Proper selection of die temperature is one of the critical factors in process design for hot-die and isothermal forging. The effect of die temperature on forging pressure is illustrated in Fig. 19 for Ti-6Al-4V. As shown in Fig. 19, a decrease in die temperature from 955 to 730 °C (1750 to 1350 °F) may result in doubling the forging pressure and may affect the shape capability available.

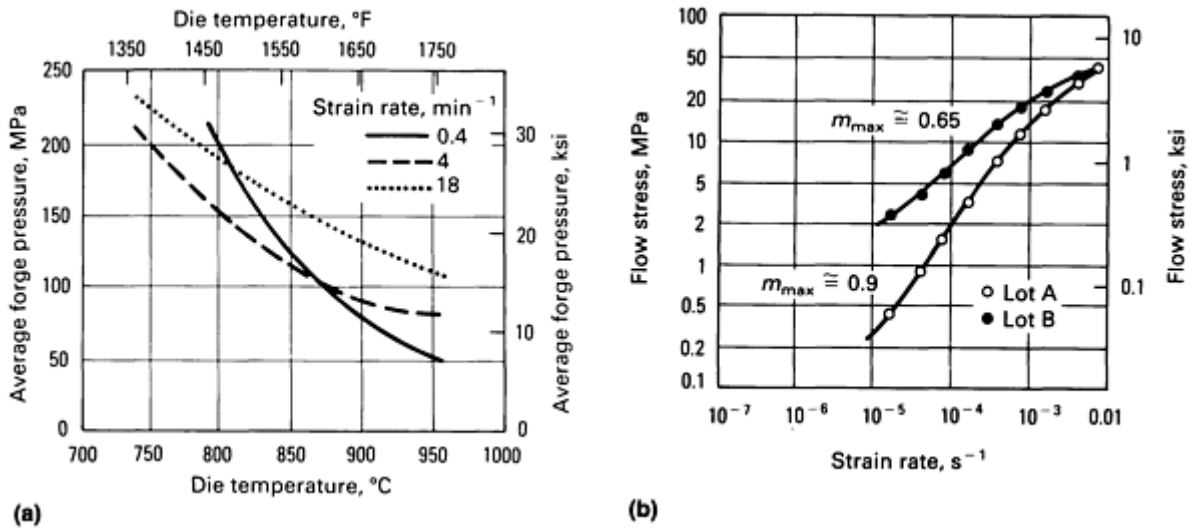

Fig. 19 Forging pressure and flow stress of Ti-6Al-4V. (a) Effect of die temperature at various strain rates. (b) Effect of grain size distribution on flow stress versus strain rate data for Ti-6Al-4V at 927 °C (1700 °F). Lot A, average grain size of 4 μm and grain size range of 1 to 10 μm; lot B, average grain size of 4.6 μm but grain size range of 1 to >20 μm

Die Temperature in Conventional Forging. The dies used in the conventional forging of titanium alloys, unlike some other materials, are heated to facilitate the forging process and to reduce metal temperature losses during the forging process--particularly surface chilling, which may lead to inadequate die filling and/or excessive cracking. Table 16 lists the recommended die temperatures used for several titanium alloy forging processes employing conventional die temperatures. Dies are usually preheated to these temperature ranges using the die heating techniques discussed below. In addition, because the metal temperature of titanium alloys exceeds that of the dies, heat transfer to the dies occurs during conventional forging, frequently requiring that the dies be cooled to avoid die damage. Cooling techniques include wet steam, air blasts, and, in some cases, water.

Table 16 Die temperature ranges for the conventional forging of titanium alloys

Forging process/equipment	Die temperature	
	°C	°F
Open-die forging		
Ring rolling	150-260	300-500
	95-260	200-500

Closed-die forging		
Hammers	95-260	200-500
Upsetters	150-260	300-500
Mechanical presses	150-315	300-600
Screw presses	150-315	300-600
Orbital forging	150-315	300-600
Spin forging	95-315	200-600
Roll forging	95-260	200-500
Hydraulic presses	315-480	600-900

Extrusion

Extrusion is used as an alternative to rolling as a mill process in order to make rodlike and seamless pipe products. Properties are affected by processing conditions in much the same way as they are for rolled or forged products. The properties of extruded products, however, are not identical to those of die-forged structures. Titanium extrusions are typically produced in the beta phase (beta extruded). Even where similar microstructures are produced, the thermomechanical working possible in open- and closed-die forging permits much more control over the resultant properties. One of the more unusual applications of extrusion has been in the production of tapered wing spars for a military aircraft.

Forming

Titanium and titanium alloy sheet and plate are strain hardened by cold forming. This normally increases tensile and yield strengths and causes a slight drop in ductility. Beta alloys generally are easier to form than are alpha and alpha-beta alloys. Titanium metals exhibit a high degree of springback in cold forming. To overcome this characteristic, titanium must be overformed or, as is done frequently, hot sized after cold forming.

In all forming operations, titanium and its alloys are susceptible to the Bauschinger effect. This is a drop in compressive yield strength in one loading direction caused by tensile deformation in another direction and vice versa. The Bauschinger effect is most pronounced at room temperature; plastic deformation (1 to 5% tensile elongation) at room temperature always introduces a significant loss in compressive yield strength, regardless of the initial heat treatment or strength of the alloys. At 2% tensile strain, for instance, the compressive yield strengths of Ti-4Al-3Mo-1V and Ti-6Al-4V drop to less than half the values for solution-treated material. Increasing the temperature reduces the Bauschinger effect; subsequent full thermal stress relieving completely removes it.

Temperatures as low as the aging temperature might remove most of the Bauschinger effect in solution-treated titanium alloys. Heating or plastic deformation at temperatures above the normal aging temperature for solution-treated Ti-6Al-4V causes overaging to occur and, as a result, all mechanical properties decrease.

Cold Forming. Commercially pure titanium and most beta titanium alloys, such as Ti-15V-3Sn-3Cr-3Al and Ti-3Al-8V-6Cr-4Zr-4Mo, can be cold formed to a limited extent. Alloy Ti-8Al-1Mo-1V sheet can be cold formed to shallow shapes by standard methods, but the bends must be of larger radii than in hot forming and must have shallower stretch flanges. The cold forming of other alloys generally results in excessive springback, requires stress relieving between

operations, and requires more power. Titanium and titanium alloys are commonly stretch formed without being heated, although the die is sometimes warmed to 150 °C (300 °F). For the cold forming of all titanium alloys, formability is best at low forming speeds.

To improve dimensional accuracy, cold forming is generally followed by hot sizing. Hot sizing and stress relieving are ordinarily needed to reduce stress and to avoid delayed cracking and stress corrosion. Stress relief is also needed to restore compressive yield strength after cold forming. Hot sizing is often combined with stress relieving, with the workpiece being held in fixtures or form dies to prevent distortion.

The only true cold-formable titanium alloy is Ti-15V-3Sn-3Cr-3Al, but hot sizing is probably required for all but brake forming. Properties must be developed with an aging treatment (8 h at 540 °C, or 1000 °F, is typical). Because of the high springback rates encountered with this alloy, more elaborate tooling must be used.

Hot forming of titanium alloys at temperatures from 595 to 815 °C (1100 to 1500 °F) increases formability, reduces springback, takes advantage of a lesser variation in yield strength, and allows for maximum deformation with minimum annealing between forming operations. It also eliminates the need for subsequent stress relief. The true net effect in any forming operation depends on total deformation and actual temperature during forming. Titanium metals also tend to creep at elevated temperatures; holding under load at the forming temperature (creep forming) is another alternative for achieving the desired shape without having to compensate for extensive springback. Severe forming must be done in hot dies, generally with preheated stock.

The greatest improvement in the ductility and uniformity of properties for most titanium alloys is at temperatures above 540 °C (1100 °F). At still higher temperatures, some alloys exhibit superplasticity (see the section "Superplastic Forming" below). However, contamination is also more severe at the higher temperatures. Above about 650 °C (1200 °F), forming should be done in vacuum or under a protective atmosphere, such as argon, to minimize oxidation. Coatings can also be used to minimize contamination. Most hot-forming operations are done at temperatures above 540 °C (1000 °F). For applications in which the utmost in ductility is required, temperatures below 315 to 425 °C (600 to 800 °F) are usually avoided.

Temperatures generally must be kept below 815 °C (1500 °F) to avoid marked deterioration in mechanical properties. Superplastic forming, however, is performed at 870 to 925 °C (1600 to 1700 °F) for alloys such as Ti-6Al-4V. At these temperatures, care must be taken not to exceed the beta transus temperature of Ti-6Al-4V. Heating temperature and time at temperature is controlled so that the titanium is hot for the shortest time practical and the metal temperature is in the correct range.

Scaling and Embrittlement. Titanium is scaled and embrittled by oxygen-rich surface layers formed at temperatures higher than 540 °C (1000 °F) commonly referred to as alpha case. The subsequent removal of scale and embrittled surface, or a protective atmosphere, should be considered for any heating above 540 °C (1000 °F). Argon gas is a commonly used atmosphere for superplastic forming.

Aging. Some hot-forming temperatures are high enough to age a titanium alloy. Heat-treatable beta and alpha-beta alloys generally must be reheat treated (solution annealed) after hot forming. Alpha-beta alloys should not be formed above the beta transus temperature.

Because of aging, scaling, and embrittlement, as well as the greater cost of working at elevated temperatures, hot forming is ordinarily done at the lowest temperature that will permit the required deformation. When maximum formability is required, the forming should be done at the highest temperature practical that will retain the mechanical properties and serviceability required of the workpiece.

Tools. Titanium alloys are often formed hot in heated dies in presses that have a slow, controlled motion and that can dwell in the position needed during the press cycle. Hot forming is sometimes done in dies that include heating elements or in dies that are heated by the press platens. Press platens heated to 650 °C (1200 °F) can transmit enough heat to keep the working faces of the die at 425 to 480 °C (800 to 900 °F). Other methods of heating include electrical-resistance heating and the use of quartz lamps and portable furnaces.

Accuracy. Hot forming has the advantage of improved uniformity in yield strength, especially when the forming or sizing temperature is above 540 °C (1000 °F). However, care must be taken to limit the accumulation of dimensional errors resulting from:

- Differences in thermal expansion
- Variations in temperature
- Dimensional changes from scale formation
- Changes in dimensions of tools
- Reduction in thickness from chemical pickling operations

Superplastic Forming. Superplasticity is a term used to indicate the exceptional ductility that certain metals can exhibit when deformed under proper conditions. Although there are several different types of superplasticity, only the micrograin superplasticity is of importance in the fabrication of parts. For micrograin superplasticity, the high ductilities are observed only under certain conditions, and the basic requirements for this type of superplasticity are:

- Very fine grain size material (of the order of 10 μm, or 400 μin.)
- Relatively high temperature (greater than about one-half the absolute melting point)
- A controlled strain rate, usually 0.0001 to 0.01 s^{-1}
- A two-phase structure (alpha and beta in titanium)

Because of these requirements, only a limited number of commercial alloys are superplastic, and these materials are formed using methods and conditions that are different from those used for conventional metals.

However, some of the titanium alloys (Table 17) have been found to be superplastic as conventionally produced, without any alloy modifications nor special mill-processing methods to make them superplastic. The characteristic flow properties of a superplastic metal are exemplified in Fig. 20 for a Ti-6Al-4V alloy tested at 927 °C (1700 °F). It is well known that the primary factor related to this behavior is the rate of change of flow stress with strain rate, usually measured and reported as *m*, the strain-rate sensitivity exponent:

$$m = \frac{\partial \ln s}{\partial \ln e} \qquad \textbf{(Eq 1)}$$

where σ is the flow stress and ε is the strain rate. The higher the *m* value of an alloy, the greater its superplasticity.

Table 17 Superplastic characteristics of titanium alloys

Alloy	Test temperature		Strain rate, s^{-1}	Strain rate sensitivity factor, *m*	Elongation, %
	°C	°F			
Commercially pure titanium	850	1560	1.7×10^{-4}	. . .	115
α -β alloys					
Ti-6Al-4V	840-870	1545-1600	1.3×10^{-4} to 10^{-3}	0.75	750-1170
Ti-6Al-5V	850	1560	8×10^{-4}	0.70	700-1100
Ti-6Al-2Sn-4Zr-2Mo	900	1650	2×10^{-4}	0.67	538
Ti-4.5Al-5Mo-1.5Cr	870	1600	2×10^{-4}	0.63-0.81	>510

Ti-6Al-4V-2Ni	815	1500	2×10^{-4}	0.85	720
Ti-6Al-4V-2Co	815	1500	2×10^{-4}	0.53	670
Ti-6Al-4V-2Fe	815	1500	2×10^{-4}	0.54	650
Ti-5Al-2.5Sn	1000	1830	2×10^{-4}	0.49	420
Near-β and β alloys					
Ti-15V-3Sn-3Cr-3Al	815	1500	2×10^{-4}	0.50	229
Ti-13Cr-11V-3Al	800	1470	. . .	. . .	<150
Ti-8Mn	750	1380	. . .	0.43	150

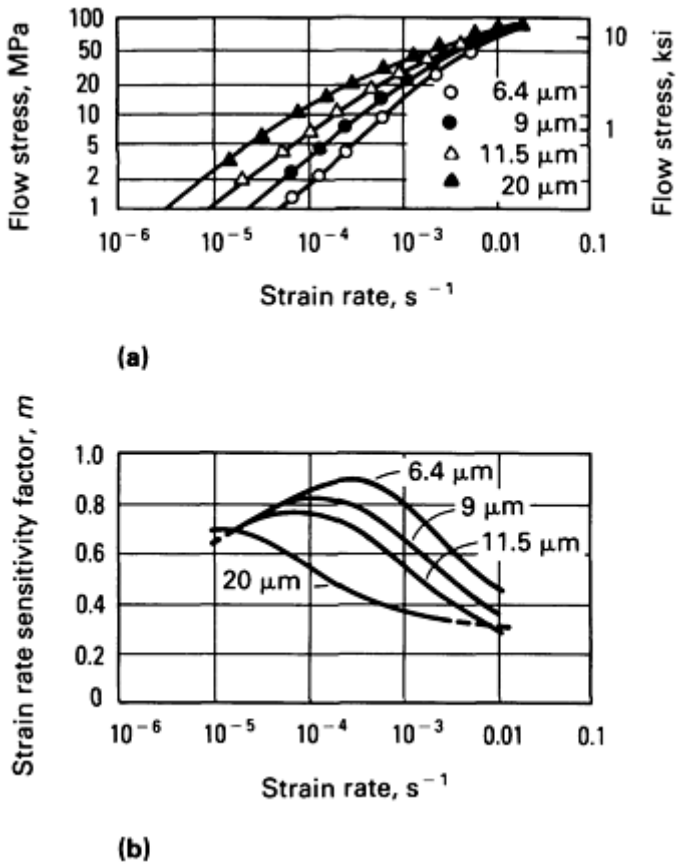

Fig. 20 Flow stress (a) and strain-rate sensitivity factor *m* (b) versus strain rate for Ti-6Al-4V materials with four different grain sizes. Test temperature: 927 °C (1700 °F)

The metallurgical variables affecting superplastic behavior in titanium alloys include grain size, grain size distribution, alpha morphology grain growth kinetics, diffusivity, phase ratio of alpha and beta, and texture. Alloy composition is also significant and can have a pronounced effect on α-β phase ratio and on diffusivity.

Table 17 shows that the alpha-beta titanium alloys seem to exhibit greater superplasticity than other titanium alloys. The alpha and beta phases are quite different in terms of crystal structure (hexagonal close-packed for alpha, and body-centered cubic for beta) and diffusion kinetics. Beta phase exhibits a diffusivity approximately two orders of magnitude greater than that of alpha phase. For this reason alone it should be expected that the amount of beta phase present in a titanium alloy would have an effect on superplastic behavior.

Figure 21 shows elongations and m values for several titanium alloys as a function of the volume fraction of beta phase present in the alloys. It can be readily seen that elongation values reach a peak at approximately 20 to 30 vol% beta phase (Fig. 21a), while m values peak at beta contents of about 40 to 50 vol% (Fig. 21b). Because m is usually considered to be a good indicator of superplasticity, this discrepancy in the location of maxima of the curves in Fig. 21 may be surprising. It is believed that the difference stems from a grain growth effect during superplastic deformation. Beta phase is known to exhibit more rapid grain coarsening than alpha, and the maximum ductility may be the result of a balance between moderated grain growth (due to the presence of alpha phase) and enhanced diffusivity (due to the presence of beta).

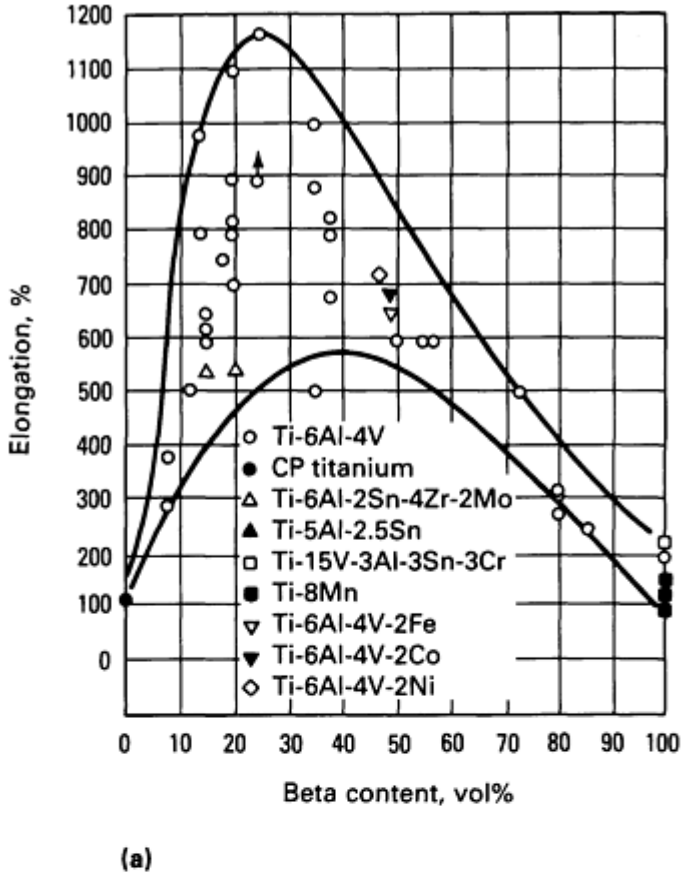

Fig. 21 Elongation (a) and *m* value (b) as a function of beta-phase content for several titanium alloys. See text for details.

The superplastic forming of titanium alloys is currently being used to fabricate a number of sheet metal components for a range of aircraft and aerospace systems. Hundreds of parts are in production, and significant cost savings are being realized through the use of superplastic forming. Other advantages of superplastic forming over other forming processes include the following:

- Very complex part configurations are readily formed
- Lighter, more efficient structures are possible
- It is performed in a single operation, reducing fabrication time
- Depending on part size, more than one piece can be produced per machine cycle
- The force needed for forming is supplied by a gas, resulting in the application of equal amounts of pressure to all areas of the workpiece

The limitations of the process include:

- Heat-resistant tool materials that contain minimal amounts of nickel are required
- Equipment requirements are extensive
- Long preheat times are necessary to reach the forming temperature
- A protective atmosphere, such as argon, is required

Several processes are used in the superplastic forming of titanium alloys. Among these are blow forming, vacuum forming, thermoforming, deep drawing, and superplastic forming/diffusion bonding. All of these processes are discussed in more detail in *Forming and Forging,* Volume 14 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Joining

Adhesive bonding, brazing, mechanical fastening, metallurgical bonding, and welding are all used routinely and successfully to join titanium and its alloys. The first three processes do not affect the properties of these metals as long as joints are properly designed. Metallurgical bonding includes all solid-state joining processes in which diffusion or deformation play the major role in bonding the members together.

Because these processes are performed at elevated temperatures, metallurgical effects, either normally caused by heating at that temperature or resulting from contamination, should be anticipated. Except for adhesive bonds, properly processed joints have the same properties as the base metal and, because bonding is carried out at a temperature high in the alpha-beta field, material properties appear similar to those resulting from high-temperature annealing. With most alloys, a final low-temperature anneal will produce properties characteristic of typical annealed material.

Welding has the greatest potential for affecting material properties. In all types of welds, contamination by interstitial impurities such as oxygen and nitrogen must be minimized to maintain useful ductility in the weldment. Alloy composition, welding procedure, and subsequent heat treatment are highly important in determining the final properties of welded joints. Table 18 reviews mechanical properties for representative alloys and types of welds. The data can be summarized as follows:

- Welding generally increases strength and hardness
- Welding generally decreases tensile and bend ductility
- Welds in unalloyed titanium grades 1, 2, and 3 do not require postweld treatment unless the material will be highly stressed in a strongly reducing atmosphere. In such event, stress relieving or annealing may prove useful
- Welds in more beta-rich alpha-beta alloys such as Ti-6Al-6V-2Sn have a high likelihood of fracturing with little or no plastic straining. Weld ductility can be improved by postweld heat treatment consisting of slow cooling from a high annealing temperature
- Rich beta-stabilized alloys can be welded, and such welds exhibit good ductility. The aging kinetics of the weld metal may be substantially different than that of the parent metal.

Table 18 Typical tensile, bend, and hardness data for as-welded titanium and several titanium alloys

(a) Fracture occurred in base metal.

Electron-beam and laser welds are made without filler metal and weld beads have high ratios of depth to width. This combination allows excellent welds to be made in heavy sections, with properties very close to those of the base metal and little distortion.

Welding must be done under strict environmental controls to avoid pickup of interstitials that can embrittle the weld metal. Small and moderate size weldments ordinarily are enclosed within environmentally controlled chambers during welding or by shielding gas that protects the immediate weld zone. Larger weldments are made with the aid of portable chambers that only partly enclose the components, or with the aid of "trailers," both of which maintain a protective atmosphere on both front and back sides of the weld until it has cooled below about 480 °C (1000 °F).

Heat Treatment

Titanium and titanium alloys are heat treated for the following purposes:

- To reduce residual stresses developed during fabrication (stress relieving)
- To produce an optimal combination of ductility, machinability, and dimensional and structural stability (annealing)
- To increase strength (solution treating and aging)
- To optimize special properties such as fracture toughness, fatigue strength, and high-temperature creep strength

These various types of heat-treating cycles are not applicable to all titanium alloys. The alpha and near-alpha titanium alloys can be stress relieved and annealed, but high strength cannot be developed in these alloys by any type of heat treatment. The commercial beta alloys, on the other hand, all contain metastable beta, which thus allows strengthening during aging as the retained beta decomposes. The beta alloys offer great potential for age hardening and frequently utilize the stability of their beta phase to provide large section hardenability. For beta alloys, stress-relieving and aging treatments can be combined, and annealing and solution treating may be identical operations.

Finally, the alpha-beta alloys, as the name suggests, exhibit heat-treatment characteristics between that of the alpha class and the beta class. Alpha-beta alloys can exhibit age hardening from the decomposition of beta, but these alloys do not exhibit the same section size hardenability as the beta alloys due to the lesser amounts of retained beta. Nonetheless, the alpha-beta alloys are the most versatile in that certain microstructures (Table 19) can be enhanced by processing in either the alpha-beta region or the beta-phase region. In general, the beta or alpha-beta processing of alpha-beta alloys has the following effects on properties:

Property	**β processed**	**α/β processed**

Tensile strength	Moderate	Good
Creep strength	Good	Poor
Fatigue strength	Moderate	Good
Fracture toughness	Good	Poor
Crack growth rate	Good	Moderate
Grain size	Large	Small

Table 19 Summary of heat treatments for alpha-beta titanium alloys

Heat treatment designation	Heat treatment cycle	Microstructure
Duplex anneal	Solution treat at 50-75 °C below $T\beta$[(a)], air cool and age for 2-8 h at 540-675 °C	Primary α, plus Widmanstätten α+ βregions
Solution treat and age	Solution treat at ~40 °C below $T\beta$, water quench[(b)] and age for 2-8 h at 535-675 °C	Primary α, plus tempered α' or a β+ α mixture
Beta anneal	Solution treat at ~15 °C above $T\beta$, air cool and stabilize at 650-760 °C for 2 h	Widmanstätten α+ βcolony microstructure
Beta quench	Solution treat at ~15 °C above $T\beta$, water quench and temper at 650-760 °C for 2 h	Tempered α'
Recrystallization anneal	925 °C for 4 h, cool at 50 °C/h to 760 °C, air cool	Equiaxed α with β at grain-boundary triple points
Mill anneal	α + β hot work + anneal at 705 °C for 30 min to several hours and air cool	Incompletely recrystallized α with a small volume fraction of small β particles

Source: Ref 13

(a) $T\beta$ is the β-transus temperature for the particular alloy in question.

(b) In more heavily β-stabilized alloys such as Ti-6Al-2Sn-4Zr-6Mo or Ti-6Al-6V-2Sn, solution treatment is followed by air cooling. Subsequent aging causes precipitation of α phase to form an α + βmixture.

Beta processing of near-alpha alloys for creep strength is useful because the near-alpha characteristic permits them to be worked or heat-treated in the beta-phase field without risk of the loss of room-temperature ductility encountered in other titanium alloys processed in this way. The near-alpha alloys may also be worked high in the alpha-beta to obtain an intermediate microstructure with a mixture of equiaxed and acicular alpha (Fig. 12b). This intermediate type of

microstructure, which provides a good combination of fatigue and creep strength, is achieved in the near-alpha IMI 834 alloy by the use of carbon additions and processing high in the alpha-beta region (see the section "Carbon" in this article).

Stress Relieving. Titanium and titanium alloys can be stress relieved without adversely affecting strength or ductility. Stress-relieving treatments decrease the undesirable residual stresses that result from:

- Nonuniform hot forging deformation from cold forming and straightening
- Asymmetric machining of plate (hogouts) or forgings
- Welding and cooling of castings
- Residual thermal stresses generated during the cooling of parts with nonuniform cross sections

Removal of such stresses helps maintain shape stability and eliminates unfavorable conditions, such as the loss of compressive yield strength commonly known as the Bauschinger effect. Titanium mill producers offer a stress-free plate desirable for machining hogouts. This is accomplished by high-temperature creep flattening.

Stress-relieving treatments must be based on the metallurgical response of the alloy involved. Generally, this requires holding at a temperature sufficiently high to relieve stresses without causing an undesirable amount of precipitation or strain aging in alpha-beta and beta alloys, or without producing undesirable recrystallization in single-phase alloys that rely on cold work for strength. The higher temperatures usually are used with shorter times, and the lower temperatures with longer times, for effective stress relief. During stress relief of solution-treated and aged titanium alloys, care should be taken to prevent overaging to lower strength. This usually involves selection of a time-temperature combination that provides partial stress relief.

Uniformity of cooling is critical, particularly in the temperature range from 480 to 315 °C (900 to 600 °F). Oil or water quenching should not be used to accelerate cooling because this can induce residual stresses by unequal cooling. Furnace or air cooling is acceptable.

There are no economical nondestructive testing methods that can measure the efficiency of a stress-relief cycle other than direct measurement of residual stresses by x-ray diffraction. No significant changes in microstructure due to stress-relieving heat treatments can be detected by optical microscopy.

Annealing of titanium and titanium alloys serves primarily to increase fracture toughness, ductility at room temperature, dimensional and thermal stability, and creep resistance. Many titanium alloys are placed in service in the annealed state. Because improvement in one or more properties generally is obtained at the expense of some other property, the annealing cycle should be selected according to the objective of the treatment. Common annealing treatments are:

- Mill annealing
- Duplex annealing
- Triplex annealing
- Recrystallization annealing
- Beta annealing

Mill annealing (Table 19) is a general-purpose treatment given to all mill products. It may not be a full anneal, and may leave traces of cold or warm working in the microstructures of heavily worked products (particularly sheet). Duplex, triplex, and beta annealing alter the shapes, sizes, and distributions of phases to those required for improved creep resistance or fracture toughness. Both recrystallization and beta annealing treatments are used to improve fracture toughness. Beta annealing is done at temperatures above the beta transus of the alloy being annealed.

Straightening, sizing, and flattening may be combined with annealing by use of appropriate fixtures. Straightening of titanium alloys is often necessary in order to meet dimensional requirements. Unlike aluminum alloys, titanium alloys are not easily straightened when cold, because the high yield strength and modulus of elasticity of these alloys result in significant springback.

At annealing/aging temperatures, many titanium alloys have creep resistance low enough to permit straightening during annealing. With proper fixturing, and in some instances judicious weighting, sheet-metal fabrications and thin, complex forgings have been straightened with satisfactory results. However, if the annealing/aging temperature is below about 540 to 650 °C (1000 to 1200 °F), depending on the alloy, the times needed to accomplish the desired creep straightening can be long.

Stabilization Annealing. In alpha-beta titanium alloys, thermal stability is a function of beta-phase transformations. During cooling from the annealing temperature, beta may transform and, under certain conditions and in certain alloys, may form the brittle intermediate phase omega. A stabilization annealing treatment is designed to produce a stable beta phase capable of resisting further transformation when exposed to elevated temperatures in service. Alpha-beta alloys that are lean in beta, such as Ti-6Al-4V, can be air cooled from the annealing temperature without impairing their stability. Furnace (slow) cooling may promote formation of Ti_3Al, an ordering reaction that can degrade resistance to stress corrosion. Slight increases in strength (up to 34 MPa, or 5 ksi) can be gained in Ti-6Al-4V and in Ti-6Al-6V-2Sn by cooling from the annealing temperature to 540 °C (1000 °F) at a rate of 56 °C/h (100 °F/h).

Solution Treating and Aging. A wide range of strength levels can be obtained in alpha-beta or beta alloys by solution treating and aging. Except for the IMI 700 and similar alloys (which depend on age hardening from copper precipitates), the origin of heat treating responses of titanium alloys lies in the instability of the high-temperature beta phase at lower temperatures. Heating an alpha-beta alloy to the solution-treating temperature produces a higher ratio of beta phase. The beta is transformed to beta and martensite by quenching; on subsequent aging, decomposition of the unstable martensite and the small amount of residual beta phase occurs, providing high strength.

To obtain high strength with adequate ductility, it is necessary to solution treat at a temperature high in the alpha-beta field, normally 28 to 83 °C (50 to 150 °F) below the beta transus of the alloy. If high fracture toughness or improved resistance to stress corrosion is required, beta annealing or beta solution treating may be desirable. A change in the solution-treating temperature of alpha-beta alloys alters the amount of beta phase and consequently changes the response to aging (see Table 9). Selection of solution-treating temperature usually is based on practical considerations such as the desired level of tensile properties and the amount of ductility to be obtained after aging.

Because solution treating involves heating to temperatures only slightly below the beta transus, proper control of temperature is essential. If the beta transus is exceeded, tensile properties (especially ductility) are reduced and cannot be fully restored by subsequent thermal treatment. Although the reduction in ductility is not drastic and may be acceptable, the near-alpha and alpha-beta alloys are usually solution treated below the beta transus to obtain an optimum balance of ductility, toughness, and creep strength.

Beta alloys may be obtained from producers in the solution-treated, solution treated and aged, as-forged, or annealed conditions depending on product form, gage, and if forming is to be done. If reheating is required, soak times should be only as long as necessary to obtain complete solutioning. Solution-treated temperatures for beta alloys are above the beta transus; because no second phase is present, grain growth can proceed rapidly.

Aging. The final step in heat treating titanium alloys to high strength normally consists of reheating to an aging temperature between 425 and 650 °C (800 and 1200 °F). In the case of alloy IMI 834, however, an aging time up to approximately 700 °C (1300 °F) optimizes creep strength (Fig. 22).

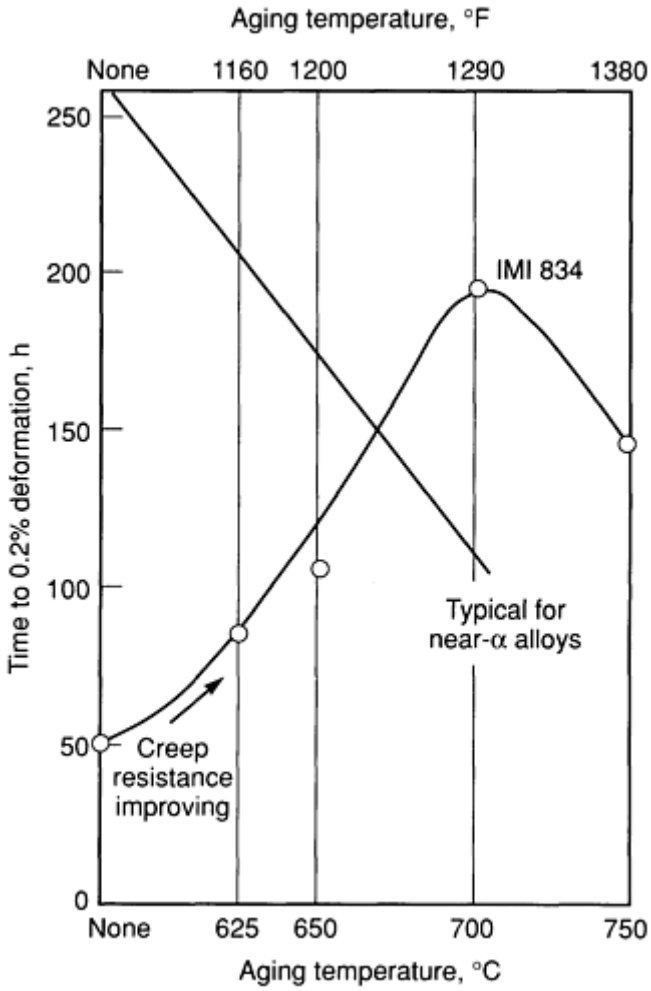

Fig. 22 Effect of aging temperature on creep performance of IMI 834. A higher aging temperature allows more stress relief to be induced, which is important for thick section disks. Source: Ref 9

During aging of some highly beta-stabilized alpha-beta alloys, beta transforms first to a metastable transition phase referred to as omega phase. Retained omega phase, which produces brittleness unacceptable in alloys heat treated for service, can be avoided by severe quenching and rapid reheating to aging temperatures above 425 °C (800 °F). Because a coarse alpha phase forms, however, this treatment might not produce optimal strength properties. An aging practice that ensures that aging time and temperature are adequate to precipitate alpha and revert omega usually is employed. Aging above 425 °C (800 °F) generally is adequate to complete the reaction.

Overaging. Aging at or near the annealing temperature will result in overaging. This condition, called solution treated and overaged, or STOA, is sometimes used to obtain modest increases in strength while maintaining satisfactory toughness and dimensional stability.

Other Special Thermal Treatments. Certain physical properties, such as notch strength, fracture toughness, and fatigue resistance, can be enhanced in some alloys by special thermal treatments. Three such treatments are given below:

- *Solution treating and overaging of Ti-6Al-4V:* Heat 1 h at 955 °C (1750 °F), water quench, then 2 h at 705 °C (1300 °F), air cool. Advantages: improved notch strength, fracture toughness, and creep strength at strength levels similar to those obtained by regular annealing
- *Recrystallization annealing of Ti-6Al-4V or Ti-6Al-4V-ELI:* Heat 4 h or more at 925 to 955 °C (1700 to 1750 °F), furnace cool to 760 °C (1400 °F) at a rate no higher than 56 °C/h (100 °F/h), cool to 480 °C (900 °F) at a rate no lower than 370 °C/h (670 °F/h), air cool to room temperature. Advantages: improved fracture toughness and fatigue-crack-growth characteristics at somewhat reduced levels of

strength. This is usually used with ELI material

- *Beta annealing of Ti-6Al-4V, Ti-6Al-4V-ELI, and Ti-6Al-2Sn-4Zr-2Mo. Ti-6Al-4V or Ti-6Al-4V-ELI:* Heat 5 min to 1 h at 1010 to 1040 °C (1850 to 1900 °F), air cool to 650 °C (1200 °F) at a rate of 85 °C/min (150 °F/min) or higher, then 2 h at 730 to 790 °C (1350 to 1450 °F), air cool. Advantages: improved fracture toughness, high-cycle fatigue strength, creep strength, and resistance to aqueous stress corrosion. Ti-6Al-2Sn-4Zr-2Mo; Heat $\frac{1}{2}$ h at 1020 °C (1870 °F), air cool, then 8 h at 595 °C (1100 °F), air cool. Advantages: improved creep strength at elevated temperatures as well as improved fracture toughness

Post Heat Treating Requirements. Titanium reacts with the oxygen, water, and carbon dioxide normally found in oxidizing heat treating atmospheres and with hydrogen formed by decomposition of water vapor. Unless the heat treatment is performed in a vacuum furnace or in an inert atmosphere, oxygen will react with the titanium at the metal surface and produce an oxygen-enriched layer commonly called "alpha case." This brittle layer must be removed before the component is put into service. It can be removed by machining, but certain machining operations may result in excessive tool wear. Standard practice is to remove alpha case by other mechanical methods or by chemical methods, or by both.

Hydrogen Contamination. Titanium is chemically active at elevated temperatures and will oxidize in air. However, oxidation is not of primary concern. The danger of hydrogen pickup is of greater importance than that of oxidation. This is not normally a problem, but it could be a problem if using a steel heat treating furnace with a reducing atmosphere. Use of these furnaces should only be after complete purging. Current specifications limit hydrogen content to a maximum of 125 to 200 ppm, depending on alloy and mill form. Above these limits, hydrogen embrittles some titanium alloys, thereby reducing impact strength and notch tensile strength and causing delayed cracking. Beta alloys are more susceptible to hydrogen contamination but are also more tolerant of hydrogen.

Heat Treatment Verification. Hardness is not a good measure of the adequacy of the thermomechanical processes accomplished during the forging and heat treatment of titanium alloys, unlike most aluminum alloys and many heat-treatable ferrous alloys. Therefore, hardness measurements are not used to verify the processing of titanium alloys. Instead, mechanical property tests (for example, tensile tests and fracture toughness) and metallographic/microstructural evaluation are used to verify the thermomechanical processing of titanium alloy forgings. Mechanical property and microstructural evaluations vary, ranging from the destruction of forgings to the testing of extensions and/or prolongations forged integrally with the parts.

Properties

The titanium alloys, with their high strengths and low densities, can often bridge the properties gap between aluminum and steel alloys, providing many of the desirable properties of each. For example, titanium, like aluminum, is nonmagnetic and has good heat-transfer properties (despite its relatively low thermal conductivity as discussed in the section "Commercially Pure Titanium" in this article). The thermal expansion coefficient of titanium alloys (Table 20), ranging from about 9 to 11 ppm/°C (5 to 6 × 10^{-6} in./in. · °F), is slightly lower than that of most steels and less than half

that of aluminum. In addition, titanium is nontoxic and biologically compatible, making it useful for surgical-implant devices.

(a) Room temperature.

(b) At 93 °C (200 °F).

(c) In solution treated and aged condition

Other important characteristics of titanium alloys depend on the class of alloy (Fig. 23) and the morphology of the alpha constituents (Table 8). In the near-alpha and alpha-beta alloys, the variations in the alpha morphology are achieved with different heat treatments (Table 19). A fine equiaxed alpha (which is associated with high tensile strength, good ductility, and resistance to fatigue-crack initiation) occurs when alpha-beta alloys are processed well below the beta transus, while an acicular alpha (which is associated with excellent creep strength, high fracture toughness, and resistance to fatigue-crack propagation) occurs by heating above the beta transus and subsequent beta transformation during cooling and aging. Finally, and intermediate microstructure (Fig. 12b) can be achieved by processing near-alpha alloys close to the beta transus. The objective of an intermediate microstructure with acicular and equiaxed alpha is to provide good creep strength without excessively compromising fatigue strength.

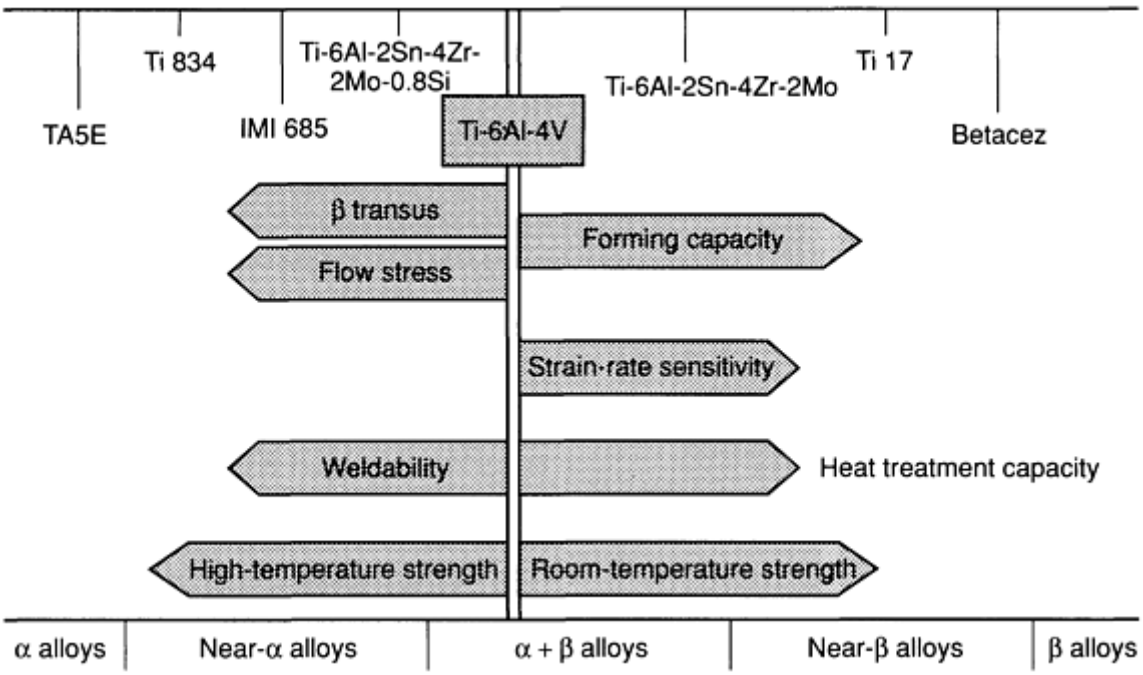

Fig. 23 Main characteristics of the different titanium alloy families

Beta transus temperatures are listed in Table 15. There are typical values that can vary by about ±15 °C (±25 °F) depending on actual composition and impurity levels. Titanium mill producers generally certify the beta transus temperature for each heat supplied, because the beta transus temperature will vary from heat to heat due to small differences in chemistry, particularly oxygen content.

Room-Temperature Tensile Properties. Average tensile properties (and some typical minimum property guarantees) for titanium mill products are listed in Table 21. The effects of alpha morphology and section size are shown in Tables 22 and 23, respectively.

Table 21 Minimum and average mechanical properties of wrought titanium alloys at room temperature

In terms of the principal heat treatments used for titanium, beta annealing decreases strength by 35 to 100 MPa (5 to 15 ksi) depending on prior grain size, average crystallographic texture, and testing direction. Solution treating and aging can be used to enhance strength at the expense of fracture toughness in alloys containing sufficient beta stabilizer (that is, 4 wt%, or more).

Fracture toughness can be varied within a nominal titanium alloys by as much as a multiple of two or three. This may be accomplished by manipulating alloy chemistry, microstructure, and texture. Some trade-offs of other desired properties may be necessary to achieve high-fracture toughness. Strength is often achieved in titanium alloys at the expense of K_{Ic} (Fig. 24)

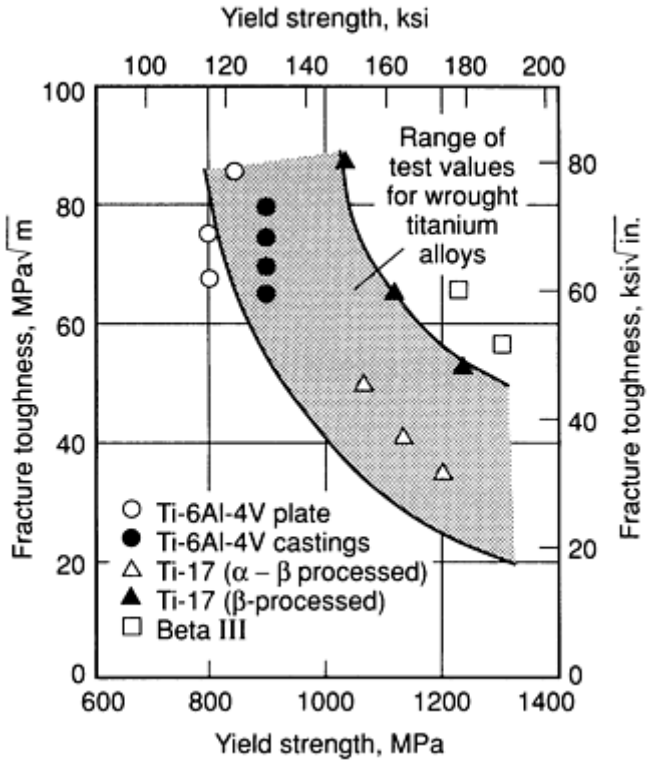

Fig. 24 Fracture toughness of Ti-6Al-4V castings compared to Ti-6Al-4V plate and to other Ti alloys. Sources: Ref 1 and 15

There are significant differences among titanium alloys in fracture toughness, but there also is appreciable overlap in their properties. Table 22 gives examples of typical plane-strain fracture toughness ranges for alpha-beta titanium alloys. From these data is apparent that the basic alloy chemistry affects the relationship between strength and toughness. From Table 22 it also is evident that transformed microstructures may greatly enhance toughness while only slightly reducing strength.

Within the permissible range of chemistry for a specific titanium alloy and grade, oxygen is the most important variable insofar as its effect on toughness is concerned. In essence, if high fracture toughness is required, oxygen must be kept low, other things being equal. Reducing nitrogen, as in Ti-6Al-4V-ELI, is also indicated, but the effect is not as strong as it is with oxygen.

Improvements in toughness can be obtained by providing either of two basic types of microstructures:

- Transformed structures, or structures transformed as much as possible, because fractures in such structures must proceed along many faceted paths
- Equivalent structures composed mainly of regrowth alpha that have both low dislocation-defect densities and low concentrations of nitrogen and oxygen (the so-called "recrystallization annealed" structures)

According to some work, plane-strain fracture toughness is proportional to the fraction of transformed beta in the alloy. The subject is a complex one without clear-cut empirical rules. Furthermore, the enhancement of fracture toughness at one stage of an operation--for example, a forging billet--does not necessarily carry over to a forged part. Because welds in alloy Ti-6Al-4V contain transformed products, one would expect such welds to be relatively high in toughness.

Fatigue Properties. For a given tensile strength, the fatigue strength of titanium alloys compares favorably with quenched and tempered low-alloy steel (Fig. 2). Fatigue life is usually divided into two regimes: low-cycle fatigue (in which failures occur in 10^4 cycles or less) and high-cycle fatigue (in which failures occur in more than 10^4 cycles). The

effects of microstructure on these fatigue regimes are discussed below and in Ref 13 and 16. In general, for low-cycle fatigue and high-cycle fatigue there is a great value in high fracture toughness and low crack-propagation rates.

Low-cycle fatigue (LCF) is very difficult to quantify owing to the wide range of variables and to the limited amount of published data. In general, data are available for both load-controlled and strain-controlled tests. Table 24 gives some strain-controlled LCF data. Results of an LCF study in Ti-6Al-4V are also shown in Fig. 25. In the figure, time to the first crack (at a fixed strain) varies with microstructure. Note that time to crack initiation is optimized with a structure having high amounts of transformed beta, yet still having about 10% of primary alpha. (However, the crack-propagation resistance of the beta-processed structure still exceeds that of alpha-processed material.)

In high-cycle fatigue, surface condition is an important variable affecting fatigue strength. This effect is illustrated in Fig. 26, which shows the effect of different machining operations and shot peening on the fatigue limits of Ti-5Al-2.5Sn. In terms of microstructure, there is general agreement that the Widmanstätten or colony alpha-beta microstructure has decidedly poorer fatigue strength. Solution treated and aged material has good fatigue strength, but not as good as fine-grained equiaxed material or beta-quenched material.

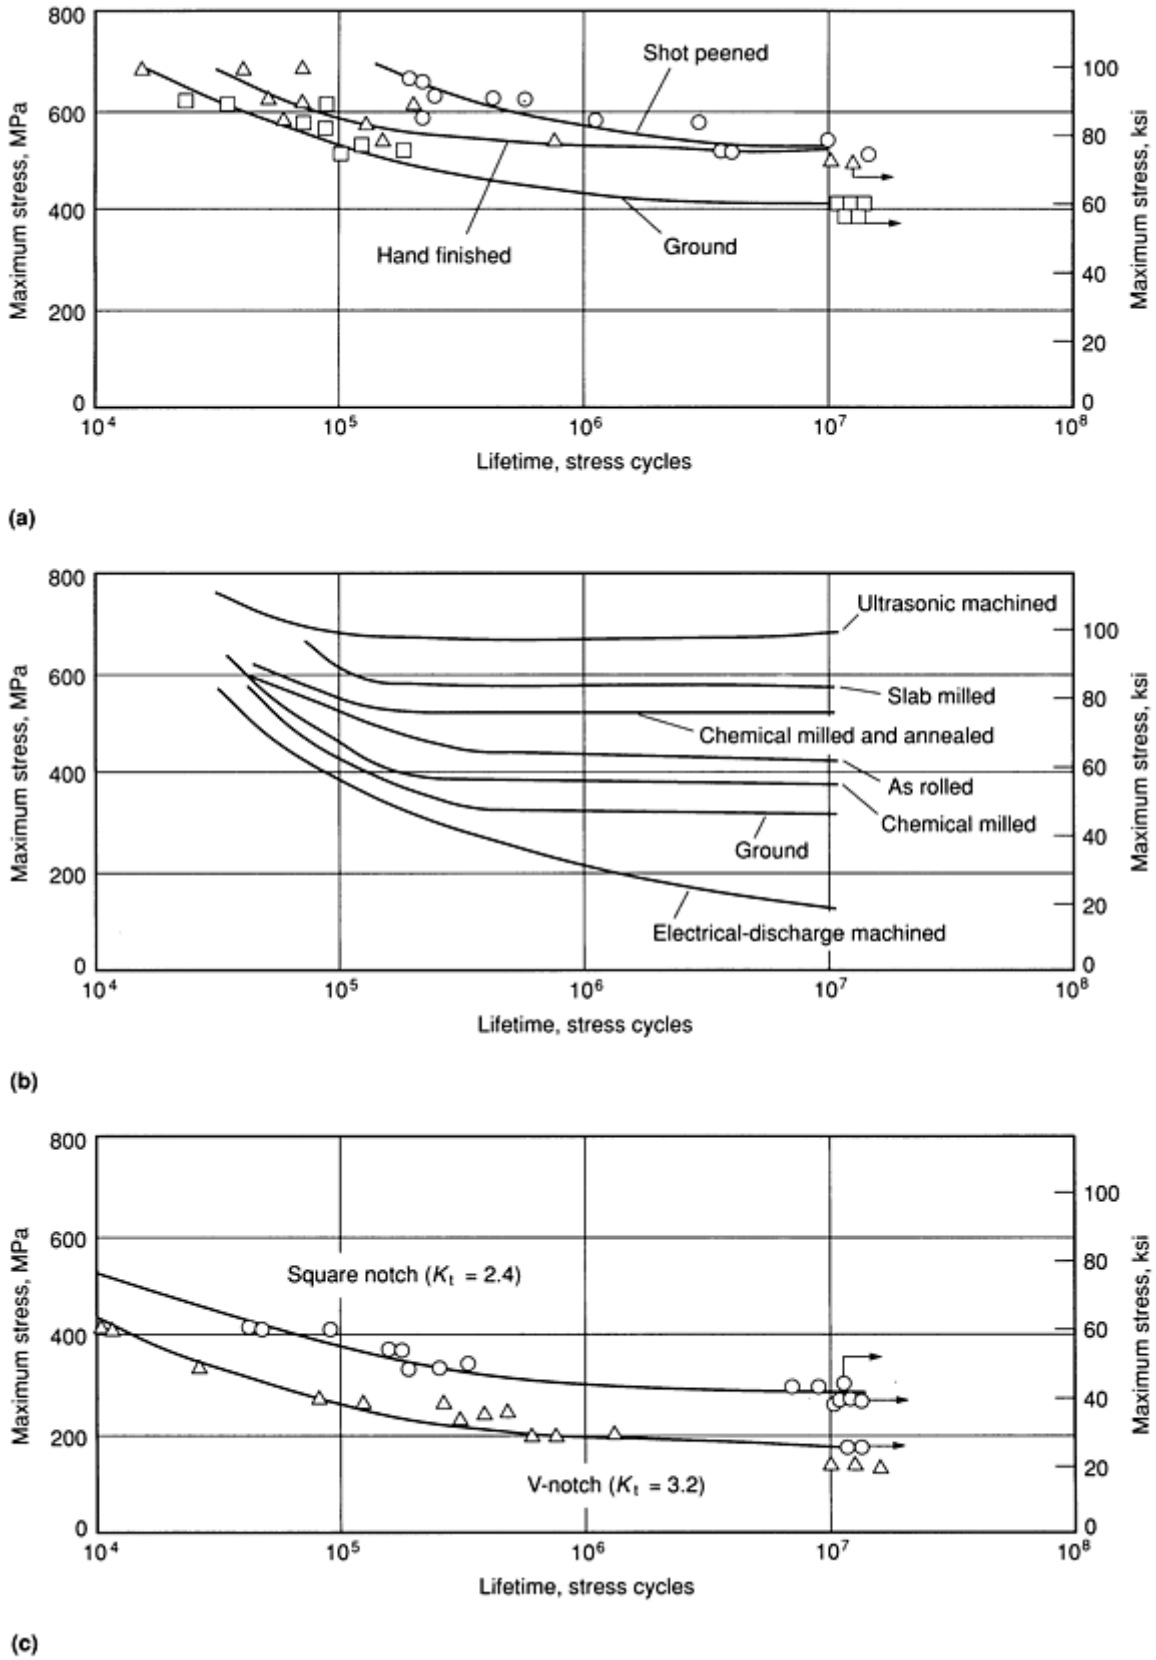

Fig. 26 Rotating-beam fatigue strength of Ti-5Al-25Sn. (a) and (b) Fatigue strengths for different types of surface finish (c) Notch fatigue strength for two different types of notches

Fatigue crack propagation (FCP) is affected by several variables such as strength, microstructure, and texture. In addition, because of the reactive nature of titanium, environmental effects on crack propagation should also be expected.

In general, only the more severe environments (such as 3.5% NaCl solution) affect FCP rates by an order of magnitude, or more. The environmental effects are minimized by beta annealing. Gaseous atmospheres also may play a role in affecting FCP rates.

In terms of microstructure, FCP is affected in much the same way as fracture toughness; that is, crack-propagation rates are reduced with a transformed microstructure. Annealing methods are also important. Generally, beta-annealed microstructures have the lowest fatigue-crack growth rates, whereas mill-annealed microstructures yield the highest growth rates. Mill-annealed alloys also exhibit considerable scatter in FCP rates (Fig. 27), because of variations in microstructure, texture, and strength.

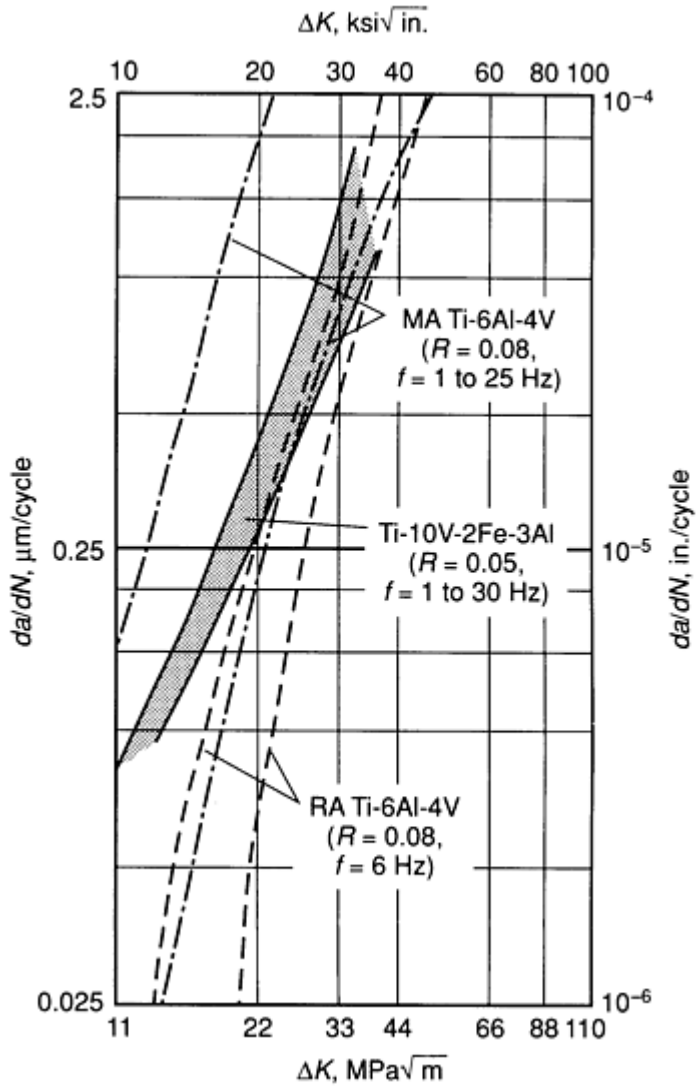

Fig. 27 Comparison of fatigue crack growth rates of beta alloy Ti-10V-2Fe-3Al with mill-annealed (MA) and recrystallization-annealed (RA) Ti-6Al-4V

Finally, different titanium alloys may have different FCP characteristics just as they have different fracture toughness characteristics. Selected data indicate that fatigue cracks propagate more rapidly in Ti-6Al-2Sn-4Zr-6Mo than in Ti-8Al-1Mo-1V or Ti-6Al-2Sn-4Zr-2Mo under the same test conditions. This may be a simple effect of strength. However, the relative amounts of beta phase may lead to intrinsically different fatigue-crack propagation characteristics. The Ti-6Al-2Sn-4Zr-6Mo alloy is also more easily textured. Figure 27 shows the range of FCP rates in Ti-6Al-4V and a beta alloy, which attains higher strength over greater section sizes than Ti-6Al-4V.

Elevated-Temperature Mechanical Properties. As shown schematically in Fig. 23, high-temperature strength is associated with the alpha and near-alpha alloys. However, when creep strength is not a factor in an elevated-temperature

application, the short-time elevated-temperature tensile strengths of beta alloys have a distinct advantage (Fig. 28). Up to about 425 °C (800 °F), beta alloys also have a higher specific strength than H11 die steel (Fig. 28b). The alpha and alpha-beta alloys do not compare as favorably with H11 steels in terms of various specific strengths (Fig. 29).

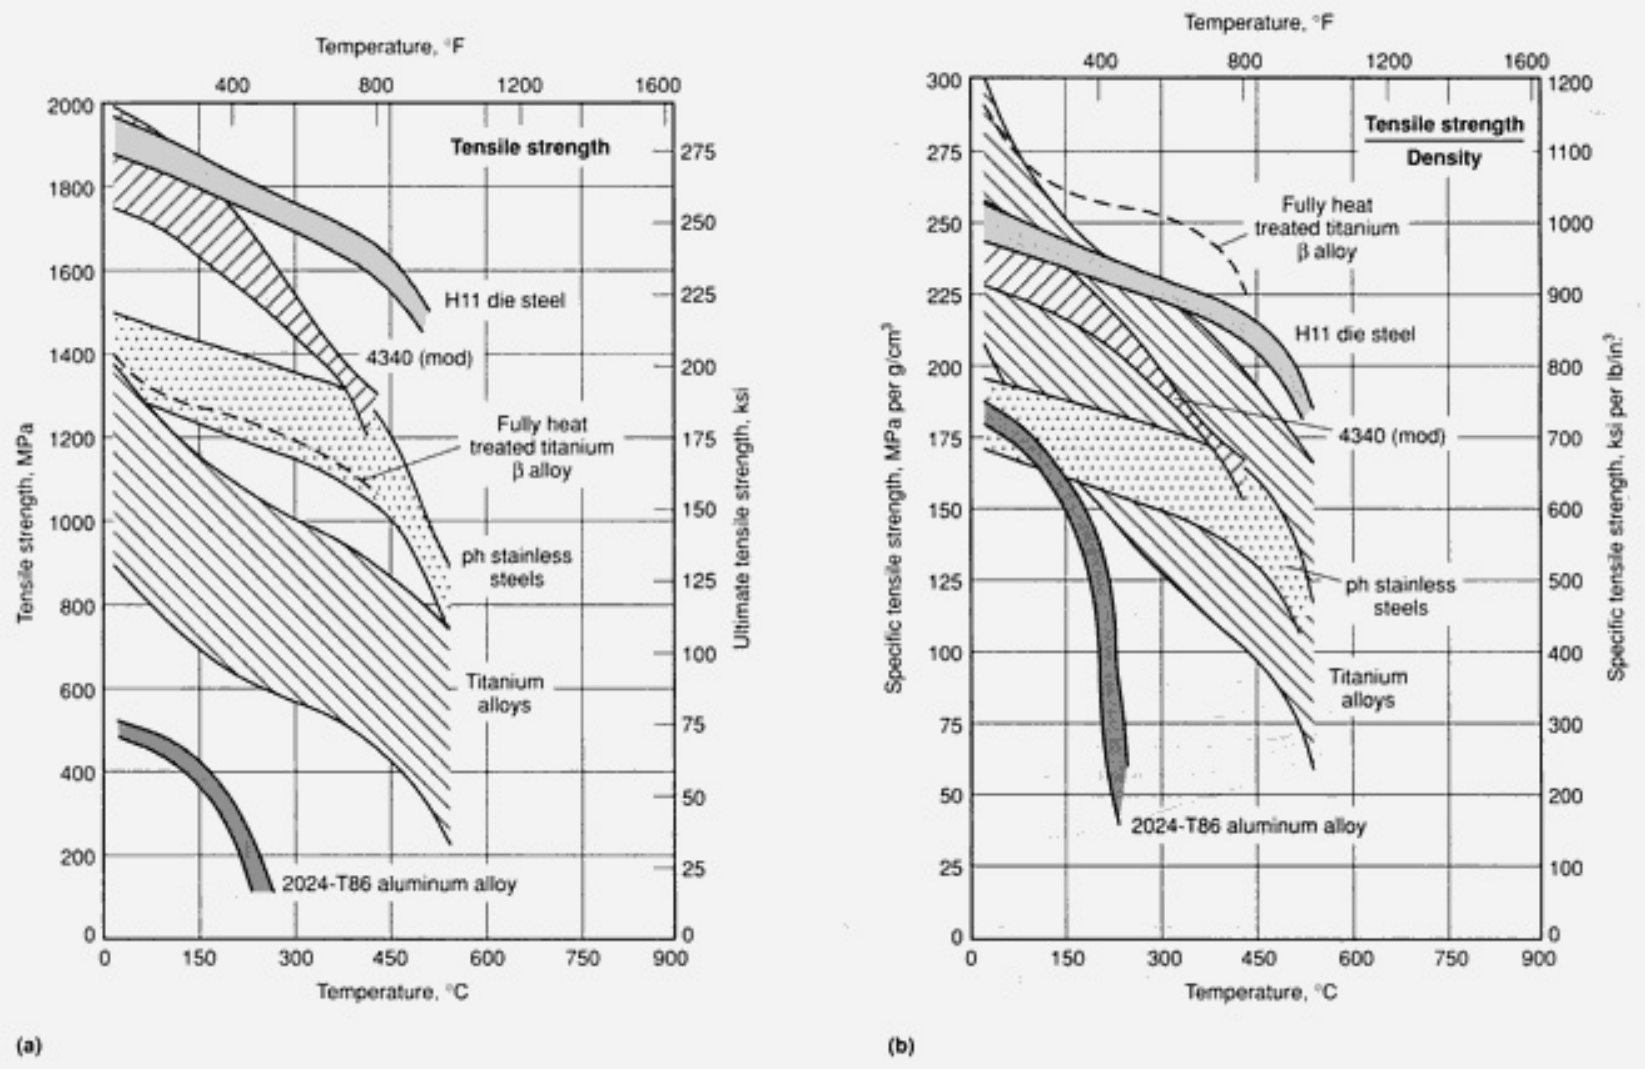

Fig. 28 Comparison of short-time tensile strength and tensile strength/density ratio for titanium alloys, three classes of steel, and 2024-T86 aluminum alloy. Data are not included for annealed alloys with less than 10% elongation or heat-treated alloys with less than 5% elongation.

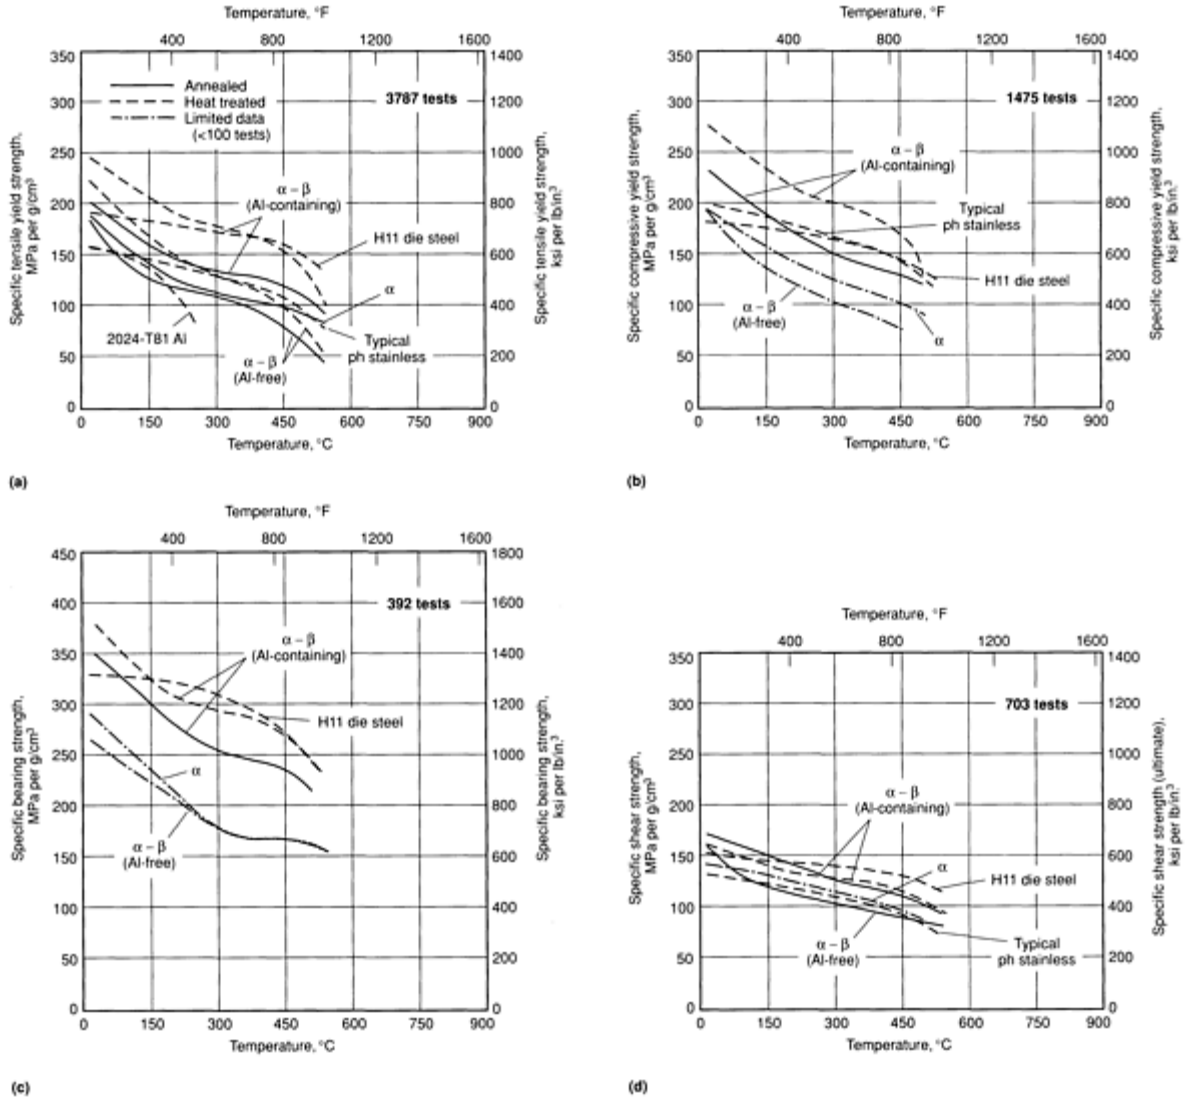

Fig. 29 Specific strengths versus temperature for titanium alloy classes and H11 die steel

Nonetheless, near-alpha and alpha/beta titanium alloys have replaced the steels once used in aircraft turbines. Figure 30 compares the strength/density behavior of two titanium alloys with the behavior of three steels used at one time or another in the lower temperature regimes of aircraft gas turbine engines. Compared with steels, titanium alloys are superior up to about 540 °C (1000 °F). This obvious advantage led to initial use of titanium in aircraft engines, first as compressor blades (Pratt & Whitney Aircraft J-57, Rolls-Royce Avon) and then as disks (Pratt & Whitney Aircraft JT-3D). In fact, titanium alloys made possible the fan-type gas turbine engines now in use and have been the subject of ongoing development for elevated-temperature applications (Table 25).

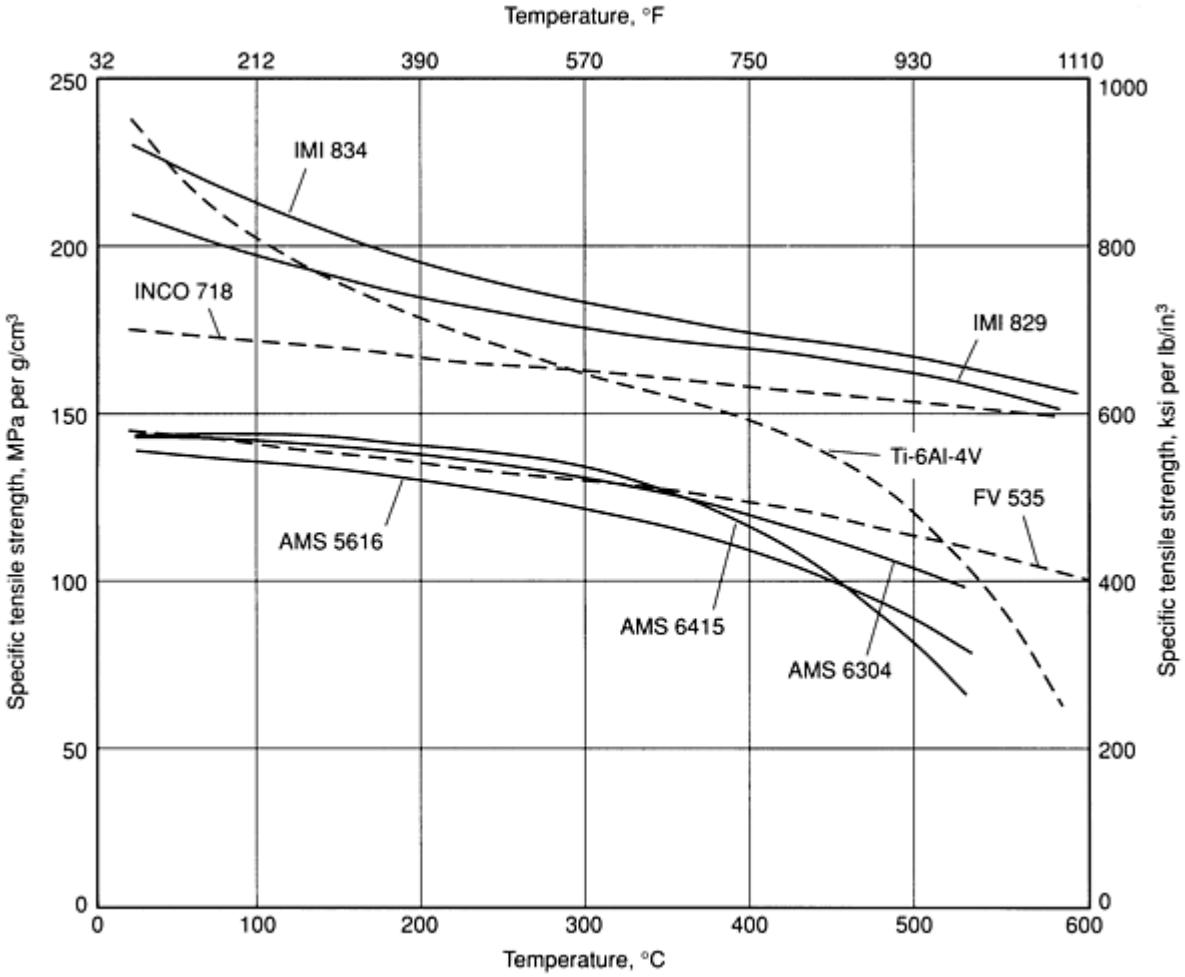

Fig. 30 Specific tensile strength of various titanium alloys compared with steels once used in aircraft turbines

Elevated Temperature Titanium Alloys. Since 1990, a number of titanium alloys have been developed for elevated-temperature application. The starting alloys was Ti-6Al-4V, which was soon superceded by near-alpha and other alpha beta alloys with optimization of certain elevated-temperature properties such as short-time strength or long-term creep strength. Alloy Ti-6246 (Ti-6Al-2Sn-4Zr-6Mo), for example, emphasizes short-term strength with its higher beta-stabilizer content, while alloy Ti-6242 (Ti-6Al-2Sn-4Zr-2Mo) provides good long-term creep strength with its content of alpha stabilizers.

Aluminum, tin, zirconium, and oxygen influence strength and ductility in various degrees depending on their amount. After studying the creep and tensile properties of the then known titanium quaternary systems, Rosenberg (Ref 20) arrived at an empirical formula for use in the design of high-temperature titanium alloys:

$$\mathrm{Al} + \frac{1}{3}\mathrm{Sn} + \frac{1}{6}\mathrm{Zr} + 10 \times 0_2 \leq 9 \qquad \textbf{(Eq 2)}$$

The formula gives the maximum combined weight percent of the alloying elements. All commercial alloys presently in service still meet this requirement. Other important alloying elements are molybdenum, silicon, and niobium. Molybdenum enhances hardenability and enhances short-time high-temperature strength or improves strength at lower temperatures. Minor silicon additions improve creep strength (Fig. 31), while niobium is added primarily for oxidation resistance at elevated temperature.

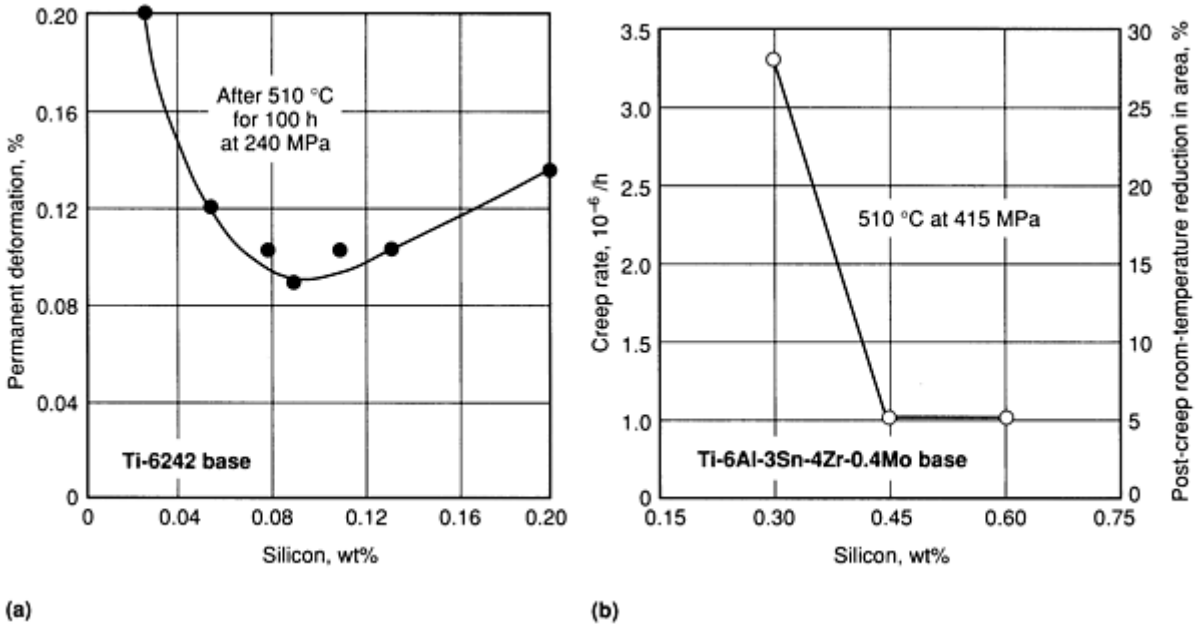

Fig. 31 Effect of silicon content on the creep behavior of (a) Ti-6Al-2Sn-4Zr-2Mo base composition and (b) Ti-6Al-3Sn-4Zr-0.4Mo base composition. Sources: Ref 18 and 19

The current temperature limit of titanium alloys is near 590 °C (1100 °F) for IMI-834 and Ti-1100 (Table 25). Alloy IMI-834 has a near-alpha composition with carbon additions (see the section "Carbon"), which is processed high in the alpha-beta region (≅ 85% beta) so as to re duce beta grain coarsening and achieve a mixture of equiaxed alpha with acicular alpha. This intermediate type of microstructure (shown in Fig. 12b for alloy Ti-8Al-1Mo-1V) provides good creep strength without excessively compromising fatigue strength. Alloy Ti-1100 controls the levels of molybdenum and iron (Fig. 32) to achieve high creep strength (Fig. 33).

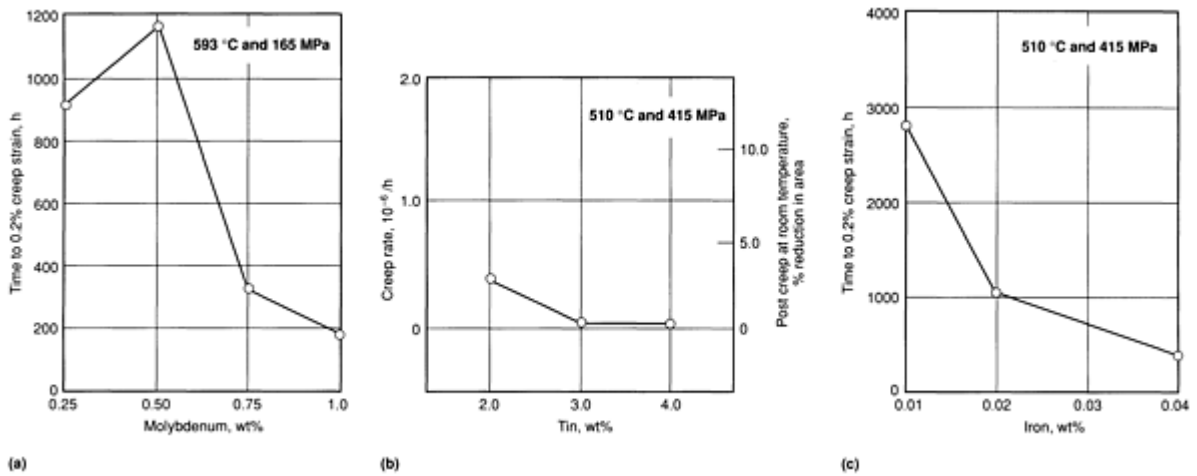

Fig. 32 Chemistry effects on base composition similar to Ti-6Al-3Sn-4Zr-0.4Mo-0.45Si. Source: Ref 19

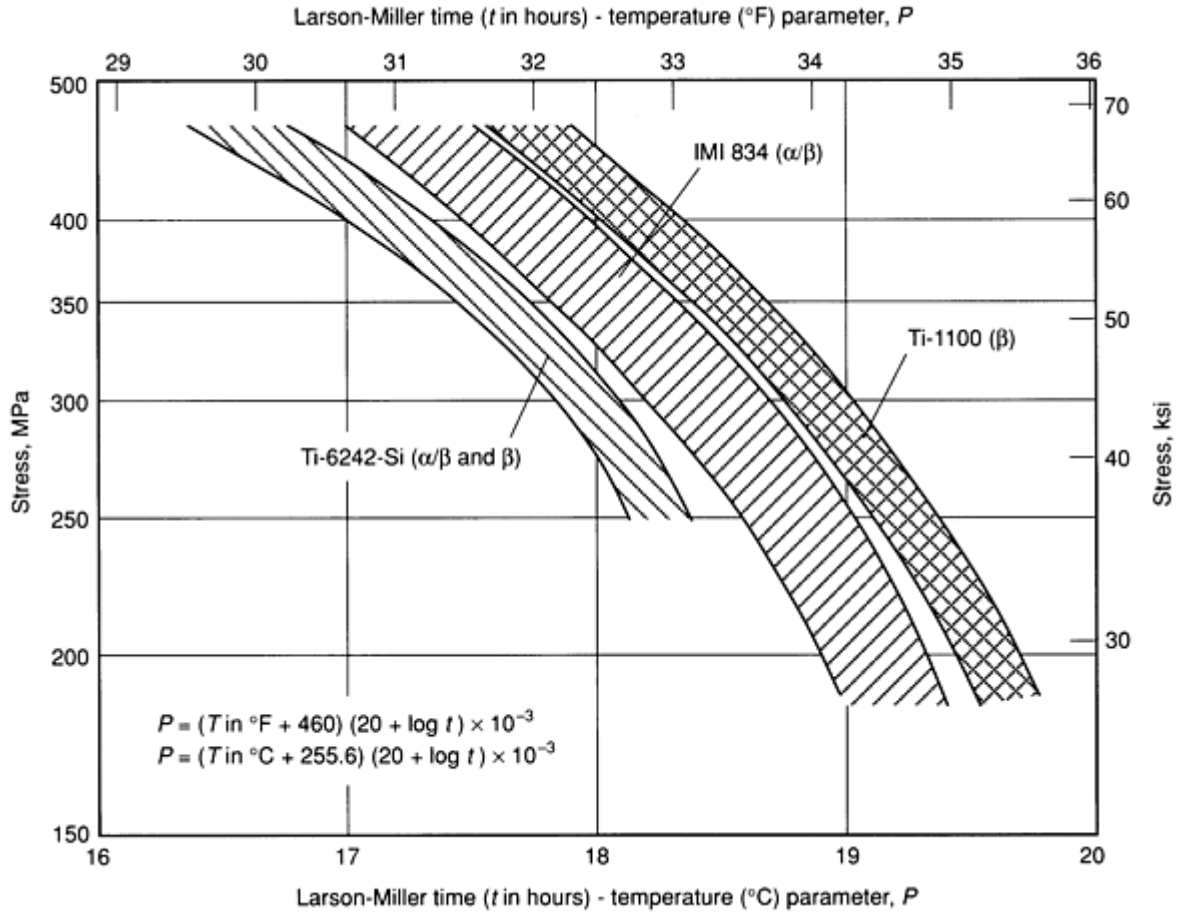

Fig. 33 Creep properties of Ti-6Al-2Sn-4Zr-2Mo(Si), IMI-384, and Ti-1100 alloys. With alpha-beta of beta processing as indicated. Source: Ref 21

The current temperature limit of 590 °C (1100 °F) is due mainly to long-term surface and bulk metallurgical stability problems; creep strength obviously is another factor (depending on deformation limits and stress level). To push the temperature limit higher, there are at least four generic approaches in new alloy system development (Ref 18):

- To develop creep resistance alloys based on a fine dispersion of the α_2 phase (Ti_3Al) in an alpha-titanium matrix (the $\alpha+\alpha_2$ alloy class)
- To develop alloys based on the intermetallic Ti_3Al (α_2)
- To develop alloys using the intermetallic TiAl (γ) as a base
- To strengthen P/M titanium alloys by the incorporation of dispersoids during rapid solidification
- Use of metal-matrix composites

In the $\alpha+\alpha_2$ alloys, the α_2 phase is generally considered to have an embrittling effect on titanium alloys, but it has been demonstrated that niobium (Ref 22) or niobium combined with other beta stabilizing elements (Ref 23) can be used to improve the ductility of $\alpha+\alpha_2$ alloys. Intermetllic Ti_3Al (α_2) and TiAl (γ) matrix materials, which occur at increased aluminum contents, are discussed in the article "Ordered Intermetallics" in this Volume. Titanium P/M products are discussed in the article so-named in the Volume.

Creep Strength. Whether yield strength or creep strength for a given maximum allowable deformation (for example, 0.1% creep strain in 150 h, which is used for aircraft gas-turbine compressor parts) is the significant selection criterion depends on which is lower at the service temperature in question. Between 200 and 315 °C (400 and 600 °F), the deformation of many titanium alloys loaded to the yield point does not increase with time. Thus, creep strength is seldom

a factor in this range. Above 315 °C (600 °F), creep strength becomes an important selection criterion. Typical creep strengths are compared in Fig. 33 and 34. Specific creep strengths with some nickel-base alloys are compared in Fig. 35.

Fig. 35 Specific creep strengths and yield strengths for various titanium-base and nickel-base alloys

In near-alpha and α + β titanium alloys, the creep strength is increased by heat treating or processing the material above the beta transus temperature. Upon cooling, this results in an acicular alpha structure that is associated with improved creep strength. However, because an acicular structure also degrades fatigue performance (which is of particular importance in aircraft), an intermediate microstructure (Fig. 12b) may be desired.

Alloy IMI 834 is aged at ~700 °C (1300 °F) for creep strength (Fig. 22). To obtain maximum creep resistance and stability in the near-alpha alloy Ti-8Al-1Mo-1V and Ti-6Al-2Sn-4Zr-2Mo, a duplex annealing treatment is employed. This treatment begins with solution annealing at a temperature high in the alpha-beta range, usually 28 to 56 °C (50 to 100 °F) below the beta transus for Ti-8Al-1Mo-1V and 19 to 56 °C (35 to 50 °F) below the beta transus for Ti-6Al-2Sn-4Zr-2Mo. Forgings are held for 1 h (nominal) and then air or fan cooled depending on section size. This treatment is followed by stabilization annealing for 8 h at 595 °C (1100 °F). Final annealing temperature should be at least 55 °C (100 °F) above the maximum anticipated service temperature. Maximum creep resistance can be developed in Ti-6Al-2Sn-4Zr-2Mo by beta annealing or beta processing.

Creep-Fatigue Interaction. At room temperature and in nonaggressive environments (and except at very high frequencies), the frequency at which loads are applied has little effect on the fatigue strength of most metals. The effects of frequency, however, become much greater as the temperature increases or as the presence of corrosion becomes more significant. At high temperatures, creep becomes more of a factor, and the fatigue strength seems to depend on the total time stress is applied rather than solely on the number of cycles. The behavior occurs because the continuous deformation (creep) under load at high temperatures affects the propagation of fatigue cracks. This effect is referred to as creep-fatigue interaction. The quantification of creep-fatigue interaction effects and the application of this information to life prediction procedures constitute the primary objective in time-dependent fatigue tests. Time-dependent fatigue tests are also used to assess the effect of load frequency on corrosion fatigue.

Like other metals, creep-fatigue interaction in titanium alloys can be evaluated in terms of a reduction in low-cycle fatigue strength caused by the introduction of a "hold-time" or dwell at the peak of each stress (or strain) cycle. This effect of creep-fatigue interaction has been a subject of various studies (Ref 24, 25, 26, 27), with particular emphasis on the beta-processed near-alpha alloys. In general, creep-fatigue interaction becomes more of a factor with lower rupture ductility (or embrittlement from factors such as internal hydrogen, Ref 25).

Thermal stability is the ability of alloys to retain their original mechanical properties after prolonged service at elevated temperature. An alloy is thermally unstable if it undergoes microstructural changes during use at elevated temperature that affect its properties adversely. Instability may cause either embrittlement or softening, depending on the nature of the microstructural changes. Thermal stability is measured by comparing the properties of an alloy at room temperature before and after exposure (stressed or unstressed) at elevated temperature.

Titanium alloys are generally stable over the temperature ranges where they resist oxidation and retain their useful strength. The alpha alloys are generally stable up to 540 °C (1000 °F) for exposure periods of 1000 h or more, except that alloys high in aluminum, such as Ti-8Al-2Nb-1Ta and Ti-8Al-1Mo-1V, will undergo a small, but generally tolerable, amount of hardening and some loss in ductility because of formation of Ti_3Al (α_2) in the microstructure. Elongation and reduction in area, after exposure to the elevated temperature, will be 10% or more.

The stability of commercial alpha-beta alloys depends on composition and heat treatment. In the mill-annealed condition, the alloys may be considered stable up to 315 to 370 °C (600 to 700 °F), although measurable changes in properties will usually accompany exposure to stress and temperature for long times. Properly fabricated and heat treated, these alloys are generally stable up to about 425 °C (800 °F) in the heat treated condition for periods of 1000 h or more.

Properties of titanium alloys may deteriorate during exposure to elevated temperature and stress because of surface cracking. Cracking may result from oxidation or from stress corrosion caused by atmospheres or surface films containing salt or other halides. When conditions are likely to cause surface cracking, tests should be made to determine the susceptibility of the alloys selected to the surface conditions intended.

Low-Temperature Properties. Unalloyed titanium and alpha titanium alloys have hexagonal close-packed (hcp) crystal structures, which accounts for the fact that the properties of these metals do not follow the same trends at subzero

temperatures as do the properties of metals with fcc or bcc structures. In particular, alpha titanium may not exhibit a ductile-to-brittle transition in Charpy V-notch data (Fig. 4).

Many of the available titanium alloys have been evaluated at subzero temperatures, but service experience at such temperatures has been gained only for Ti-5Al-2.5Sn and Ti-6Al-4V alloys. These alloys have very high strength-to-weight ratios at cryogenic temperatures and have been the preferred alloys for special applications at temperatures from -195 to -270 °C (-320 to -452 °F). Commercially pure titanium may be used for tubing and other small-scale cryogenic applications that involve only low stresses in service.

The Ti-5Al-2.5Sn alloy usually is used in the mill-annealed condition and has a 100% alpha microstructure. The Ti-6Al-4V alloy may be used in the annealed condition or in the solution treated and aged condition, but for maximum toughness in cryogenic applications the annealed condition usually is preferred. The Ti-6Al-4V alloy is an alpha-beta alloy that has significantly higher yield and ultimate tensile strengths than the all-alpha alloy.

Because interstitial impurities such as iron, oxygen, carbon, nitrogen, and hydrogen tend to reduce the toughness of these alloys at both room and subzero temperatures, ELI grades are specified for critical applications. The composition limits for these alloys are given in Table 26. Note that the iron and oxygen contents of the ELI grades are substantially lower than those of the standard, or normal interstitial (NI), grades. The NI grades are suitable for service to -195 °C (-320 °F); for temperatures below -195 °C, ELI grades generally are specified. For ELI grades, reduced creep strength at room temperature must be considered in design for pressure-vessel service. In Ti-5Al-2.5Sn, stress rupture occurs at stresses below the yield strength.

Table 26 Compositions of titanium alloys used in cryogenic applications

Alloy	Composition %

Precautions. There are two precautions that should be emphasized in considering titanium and titanium alloys for service at cryogenic temperatures: titanium and titanium alloys must not be used for transfer or storage of liquid oxygen, and titanium must not be used where it will be exposed to air while below the temperature at which oxygen will condense on its surfaces. Any abrasion or impact of titanium creating a clean, oxide-free surface that is in contact with liquid oxygen will cause ignition. Pressure vessels in contact with liquid oxygen in the Apollo launch vehicles were produced from Inconel 718 rather than from Ti-6Al-4V alloy to avoid this problem.

Typical tensile properties of titanium and of titanium alloys Ti-5Al-2.5Sn and Ti-6Al-4V at room temperature and at subzero temperatures are presented in Table 27. Marked increases in yield and tensile strengths are evident for commercial titanium and for titanium alloys as test temperature is reduced from room temperature to -253 °C (-423 °F).

In the cryogenic temperature range, these alloys have the highest strength-to-weight ratios of all fusion-weldable alloys that retain nearly the same strength in the weld metal as in the base metal. Yield and tensile strengths of an electron-beam weldment of Ti-5Al-2.5Sn(ELI) sheet are presented in Table 27.

(a) K_t = 6.3 for all three sheet forms: K_t = 5 to 8 for Ti-6Al-4V (ELI) forgings.

(b) (b)Recrystallization annealing treatment: 930 °C (1700 °F) 4 h, furnace cool to 760 °C (1400 °F) in 3 h, cooled to 480 °C (900 °F) in $\frac{3}{4}$ h, air cool

The notch strengths given in Table 27 indicate that these two alloys retain sufficient notch toughness for use to -253 °C (-423 °F). However, the tensile data do not show any substantial improvement in ductility or notch toughness for the ELI grade of Ti-5Al-2.5Sn sheet over the normal interstitial grade except at very low temperatures. The recrystallization annealing treatment used for the Ti-6Al-4V(ELI) forging was developed as a means of improving fracture toughness in large forgings and thick plate.

Values of Young's modulus for titanium alloys increase substantially as test temperature is decreased, as shown in Table 27 and by ultrasonic data (Ref 28), which shows an approximate linear increase in the elastic modulus of Ti-2.5Sn and Ti-6Al-4V from about 112 GPa (16.2×10^6 psi) at room temperature to about 122 GPa (17.7×10^6 psi) and 123 GPa (17.8×10^6) at -200 °C (-330 °F) for Ti-6Al-4V and Ti-5Al-2.5Sn, respectively. The same ultrasonic testing (Ref 28) showed a decrease in Poisson's ratio to about 0.31 for Ti-6Al-4V at -200 °C (-330 °F).

Fracture Toughness. Available data on plane-strain fracture toughness (K_{Ic}) at subzero temperatures for alloys Ti-5Al-2.5Sn and Ti-6Al-4V (summarized in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook*), indicate a modest reduction in fracture toughness to about 39 MPa$\sqrt{m}$ (35.5 ksi$\sqrt{in}$) and 42 MPa$\sqrt{m}$ (38 ksi$\sqrt{in}$) for Ti-6Al-4V and Ti-5Al-2.5Sn NI grades, respectively, at -195 °C (-320 °F). The ELI grades have better toughness than the corresponding normal interstitial grades at subzero temperatures. The limited data for electron-beam weldments indicate that at -195 °C (-320 °F) there is a slight reduction in toughness in both fusion and heat-affected zones when compared to the base metal in Ti-6Al-4(ELI) weldments.

Fatigue-Crack-Growth Rates. Data on fatigue-crack-growth rates for Ti-5Al-2.5Sn and Ti-6Al-4V alloys in Volume 3 of the 9th Edition of *Metals Handbook* indicate that low temperature has no effect on the fatigue-crack-growth rates for Ti-5Al-2.5Sn and Ti-6Al-4V(NI). However, over part of the ΔK range, the fatigue-crack-growth rates for Ti-6Al-4V(ELI) are higher at cryogenic temperatures than at room temperature at the same ΔK values.

Fatigue strength at subzero temperatures becomes more sensitive to notches and the presence of welded joints. Therefore, in designing welded structures of titanium alloys that will be subjected to fatigue loading at subzero temperatures, the weld areas usually should be thicker than the remaining areas. Hemispheres for spherical pressure vessels are machined so that the butting sections for the equatorial welds are thicker than the remaining sections, excluding inlet and discharge ports.

Titanium and Titanium Alloy Castings

Daniel Eylon, Graduate Materials Engineering, University of Dayton; Jeremy R. Newman and John K. Thorne, TiTech International, Inc.

Introduction

SINCE THE INTRODUCTION OF TITANIUM and titanium alloys in the early 1950s, these materials have in a relatively short time become backbone materials for the aerospace, energy, and chemical industries (Ref 1). The combination of high strength-to-weight ratio, excellent mechanical properties, and corrosion resistance makes titanium the best material choice for many critical applications. Today, titanium alloys are used for demanding applications such as static and rotating gas turbine engine components. Some of the most critical and highly stressed civilian and military airframe parts are made of these alloys.

The use of titanium has expanded in recent years to include applications in nuclear power plants, food processing plants, oil refinery heat exchangers, marine components, and medical prostheses (Ref 2). However, the high cost of titanium alloy components may limit their use to applications for which lower-cost alloys, such as aluminum and stainless steels, cannot be used. The relatively high cost is often the result of the intrinsic raw material cost of the metal, fabricating costs, and the metal removal costs incurred in obtaining the desired final shape. As a result, in recent years a substantial effort has focused on the development of net shape or near-net shape technologies to make titanium alloy components more competitive (Ref 3). These titanium net shape technologies include powder metallurgy (P/M), superplastic forming (SPF), precision forging, and precision casting. Precision casting is by far the most fully developed and the most widely used titanium net shape technology (for comparison, see the article "Titanium P/M Products" in this Volume).

The annual shipment of titanium castings in the United States increased by 260% between 1979 and 1989 (Fig. 1). With a trend line still strong in the upward direction, this makes titanium casting the fastest growing segment of titanium technology. In fact, the number of sales dollars of castings shipped has grown faster than the number of pounds shipped

because of the increasing complexity of configurations being produced, that is, configurations that are closer to net shape, larger in size, and of higher quality for more critical applications.

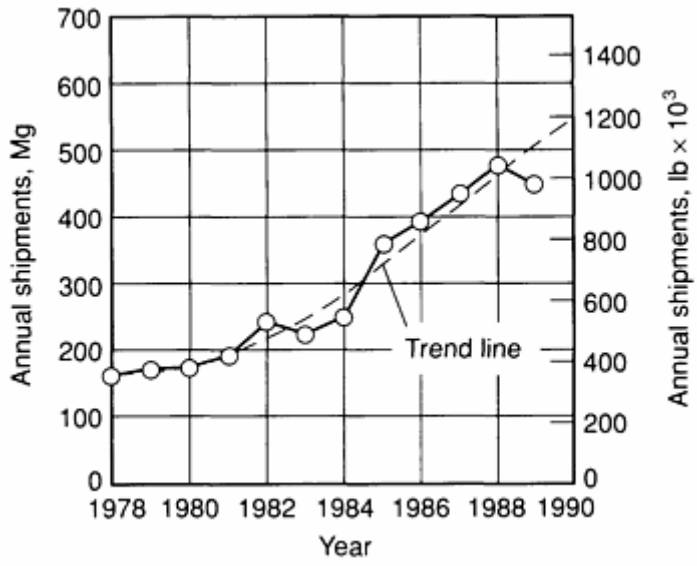

Fig. 1 Plot showing 260% growth in United States titanium casting production in the 10-year period from 1979 to 1989. Source: Ref 4

Even at current levels (approaching 450 Mg, or 9.9×10^5 lb, annually), castings still represent less than 2% of total titanium mill product shipments. This is in sharp contrast to the ferrous and aluminum industries, where foundry output is 9% (Ref 5) and 14% (Ref 6) of total output, respectively. This suggests that the growth trend of titanium castings will continue as users become more aware of industry capability, suitability of cast components in a wide variety of applications, and the net shape cost advantages.

The term castings often connotes products with properties generally inferior to wrought products. This is not true with titanium cast parts. They are generally comparable to wrought products in all respects and quite often superior. Properties associated with crack propagation and creep resistance can be superior to those of wrought products. As a result, titanium castings can be reliably substituted for forged and machined parts in many demanding applications (Ref 7, 8). This is due to several unique properties of titanium alloys. One is the α + β -to-β phase transformation at a temperature range of 705 to 1040 °C (1300 to 1900 °F), which is well below the solidification temperature of the alloys. As a result, the cast dendritic β structure is transformed during the solid state cooling to an α + β platelet structure (Fig. 2a), which is also typical of β-processed wrought alloy. Furthermore, the convenient allotropic transformation temperature range of most titanium alloys enables the as-cast microstructure to be improved by means of post-cast cooling rate changes and subsequent heat treatment or by hot isostatic pressing (HIP).

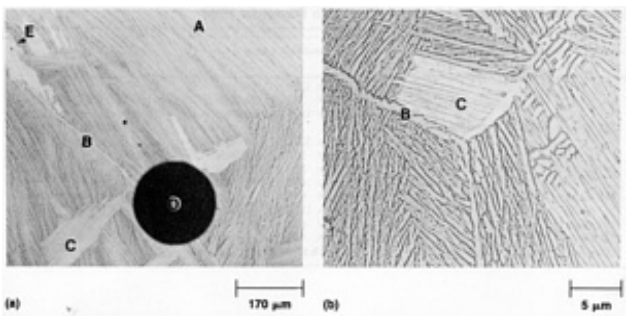

Fig. 2 Comparison of the microstructures of (a) as-cast versus (b) cast + HIP Ti-6Al-4V alloys illustrating lack of porosity in (b). Grain boundary α (B) and α plate colonies (C) are common to both alloys; β grains (A), gas (D), and shrinkage voids (E) are present only in the as-

cast alloy.

Another unique property is the high reactivity of titanium at elevated temperatures, leading to an ease of diffusion bonding. As a result, the hot isostatic pressing of titanium castings yields components with no subsurface porosity. At the HIP temperature range of 815 to 980 °C (1500 to 1800 °F), titanium dissolves any microconstituents deposited on internal pore surfaces, leading to complete healing of casting porosity as the pores are collapsed during the pressure and heat cycle. Both the elimination of casting porosity and the promotion of a favorable microstructure improve mechanical properties. However, the very high reactivity of titanium in the molten state presents a challenge to the foundry. Special, and sometimes relatively expensive, methods of melting (Ref 9), moldmaking, and surface cleaning (Ref 7, 8) may be required to maintain product integrity. Additional information on the hot isostatic pressing of castings can be found in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Historical Perspective of Titanium Casting Technology

Although titanium is the fourth most abundant metallic element in the earth's crust (0.4 to 0.6 wt%) (Ref 9), it has emerged only recently as a technical metal. This is the result of the high reactivity of titanium, which requires complex methods and high energy input to win the metal from the oxide ores. The required energy per ton is 1.7 times that of aluminum and 16 times that of steel (Ref 10). From 1930 to 1947, metallic titanium extracted from the ores as a powder or sponge form was processed into useful shapes by P/M methods to circumvent the high reactivity in the molten form (Ref 11) (see the article "Titanium P/M Products" in this Volume).

Melting Methods. The melting of small quantities of titanium was first experimented with in 1948 using methods such as resistance heating, induction heating, and tungsten are melting (Ref 12, 13). However, these methods never developed into industrial processes. The development during the early 1950s of the cold crucible, consumable-electrode vacuum are melting process, or skull melting, by the U.S. Bureau of Mines (Ref 13, 14) made it possible to melt large quantities of contamination-free titanium into ingots or net shapes. Additional information on numerous melting methods is available in the articles "Melting Furnaces" and "Vacuum Melting and Remelting Processes" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

First Castings. The shape casting of titanium was first demonstrated in the United States in 1954 at the U.S. Bureau of Mines using machined high-density graphite molds (Ref 13, 15). The rammed graphite process developed later, also by the U.S. Bureau of Mines (Ref 16), led to the production of complex shapes. This process, and its derivations, are used today to produce large parts for marine and chemical-plant components (such as the pump and valve components shown in Fig. 3a) because of the rigidity and strength of the mold. Some aerospace components such as the aircraft brake torque tubes, landing arrestor hook, and optic housing shown in Fig. 3(b) have also been produced by this method.

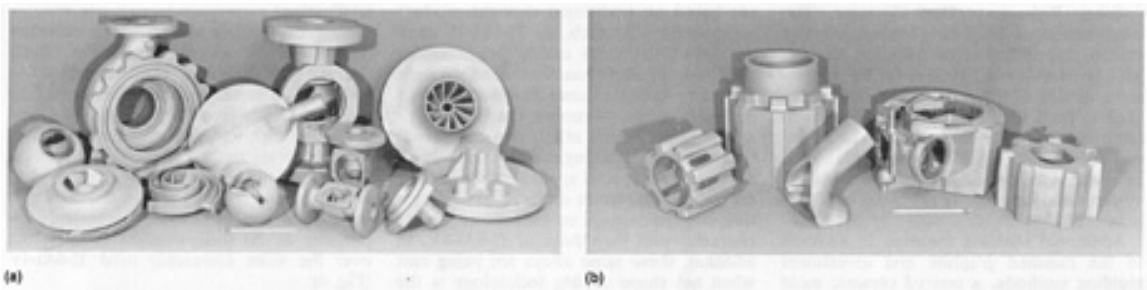

Fig. 3 Typical titanium parts produced by the rammed graphite process. (a) Pump and valve components for marine and chemical-processing applications. (b) Brake torque tubes, landing arrestor hook, and optic housing components used in aerospace applications

Molding Methods

Rammed Graphite Molding. The traditional rammed graphite molding process uses powdered graphite mixed with organic binders (see the article "Rammed Graphite Molds" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*). Patterns typically are made of wood. The mold material is pneumatically rammed around the pattern and cured at high temperature in a reducing atmosphere to convert the organic binders to pure carbon. The molding process and the tooling are essentially the same as those used for cope and drag sand molding in ferrous and nonferrous foundries. In the 1970s, derivations of rammed graphite mold materials were developed using components of more traditional sand foundries, along with inorganic binders. This resulted in more dimensionally stable and less costly molds that were capable of containing molten titanium without undue metal/mold reaction and with easier mold removal from the cast parts.

Lost-Wax Investment Molding. The principal technology that allowed the proliferation of titanium alloy castings in the aerospace industry was the investment casting method, which was introduced in the mild-1960s (see the article "Investment Casting" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*). This method, already used at the dawn of the metallurgical age, more than 5000 years ago, for casting copper and bronze tools and ornaments (see the article "History of Casting" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*), was later adapted to enable the production of high-quality steel and nickel-base cast parts. The adaptation of this method to titanium casting technology required the development of ceramic slurry materials that had minimum reaction with the extremely reactive molten titanium.

Refractory Oxide Shell Systems. Proprietary lost-wax ceramic shell systems have been developed by the several foundries engaged in titanium casting manufacture. Of necessity, these shell systems must be relatively inert to molten titanium and cannot be made with the conventional foundry ceramics used in the ferrous and nonferrous industries. Usually, the face coats are made with special refractory oxides and appropriate binders. After the initial face coat ceramic is applied to the wax pattern, more traditional refractory systems are used to add shell strength by means of repeated backup ceramic coatings. Regardless of face coat composition, some metal/mold reaction inevitably occurs from titanium reduction of the ceramic oxides. The oxygen-rich surface of the casting stabilizes the α phase. In β and α+ βalloys, a metallographically distinct α-case layer on the cast surface is usually formed. This α-case layer may be removed later by means of chemical milling using an acid etchant. It should be noted that this α-case layer is not noticeable in 100% α alloys such as commercially pure (C.P.) titanium or Ti-5Al-2 $\frac{1}{2}$Sn alloys.

Foundry practices focus on methods to control both the extent of the metal/mold reaction and the subsequent diffusion of reaction products below the cast surface. The diffusion of reaction products into the cast surface is time-at-temperature dependent. The depth of surface contamination can vary from nil on very thin sections to more than 1.5 mm (0.06 in.) on thick sections. On critical aerospace structures, the brittle α case is removed by chemical milling. The depth of surface contamination must be taken into consideration in the initial wax pattern tool design. Hence, the wax pattern and casting are made slightly oversize, and final dimensions are achieved through careful chemical milling. Metal superheat, mold temperature and thermal conductivity, *g* force (if centrifugally cast), and rapid postcast heat removal are other key factors in producing a satisfactory product. These parameters are interchangeable, that is, a high *g* force centrifugal pour into cold molds may achieve the same relative fluidity as a static pour into heated molds.

Other Refractory Shell Systems. The combination of graphite powder, graphite stucco, stucco, and organic binders has also been used as a shell system for the investment casting of titanium. After dewax, the shell is fired in a reducing atmosphere to remove or pyrolyze the binders before casting. This technology has not been promoted as much as the use of refractory oxide shell systems and is presently primarily of historic interest.

Additional Molding Systems. In addition to the rammed graphite and investment molding methods, a poured ceramic mold has been used to produce large parts that require good dimensional accuracy. This method, developed in the late 1970s, was used to a limited extent for several years.

Semipermanent, reusable molds, frequently made from machined graphite, have been used successfully since the earliest U.S. Bureau of Mines work (Ref 13, 15) but only on relatively simple-shape parts that allow metal volumetric shrinkage to occur without restriction. The method is economical only when reasonably high volumes are required, that is, thousands of parts, because of the high cost of the solid mold material.

A titanium sand casting technique based on conventional foundry moldmaking practices has been under development at the U.S. Bureau of Mines (Ref 17). Because the mold materials are less costly and the cast part is easier to remove from the sand mold than from other methods of titanium casting, this development could lower production costs. However, surface quality problems are restricting the use of this method thus far.

Foundries and Capacities. Table 1 lists the major titanium casting foundries in the industrial western world and summarizes the use and capacities of the various titanium casting practices, including the use of hot isostatic pressing.

Alloys

All production titanium castings to date are based on traditional wrought product compositions. As such, the Ti-6Al-4V alloy dominates structural casting applications. This alloy similarly has dominated wrought industry production since its introduction in the early 1950s, becoming the benchmark alloy against which others are compared. However, other wrought alloys have been developed for special applications, with better room-temperature or elevated-temperature strength, creep, or fracture toughness characteristics than those of Ti-6Al-4V. In addition, these same alloys are being cast when net shape casting technology is the most economical method of manufacture. As with Ti-6Al-4V, other cast titanium alloys have properties generally comparable to those of their wrought counterparts.

Chemistry and Demand. Table 2 lists the most prevalent casting alloy chemistries and the most characteristic attribute of each in comparison with Ti-6Al-4V, plus current approximate market share.

Table 2 Comparison of cast titanium alloys

Specifications. Industrywide specifications, listed in Table 4 for reference, give more detail on mechanical property guarantees and process control features. In addition, most major aerospace companies have comparable specifications. *MIL Handbook V, Aerospace Design Specifications* does not presently include titanium alloy castings, but it is expected that such information will be incorporated in the near future. As with wrought products, commercially pure titanium castings are used almost entirely in corrosion-resistant applications. Commercially pure titanium pumps and valves are the principal components made as titanium castings for corrosion-resistant applications. There are used extensively in chemical and petrochemical plants and in numerous marine applications (seawater pumps, for example, are a very important application).

Table 4 Standard industry specifications applicable to titanium castings

MIL-T-81915	Titanium and titanium alloy castings, investment
AMS-4985A	Titanium alloy castings, investment or rammed graphite
AMS-4991	Titanium alloy castings, investment

AMS-4956	Titanium alloy welding wire Ti-6Al-4V, extra low interstitial

Newer Alloys. As aircraft engine manufacturers seek to use cast titanium at higher operation temperatures, Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-2Sn-4Zr-6Mo are being specified more frequently (see Tables 2 and 3). Other advanced high-temperature titanium alloys for service up to 595 °C (1100 °F) such as Ti-1100 and IMI-834 are being developed as castings. The alloys mentioned above exhibit the same degree of elevated-temperature superiority as do their wrought counterparts over the more commonly used Ti-6Al-4V (Fig. 4).

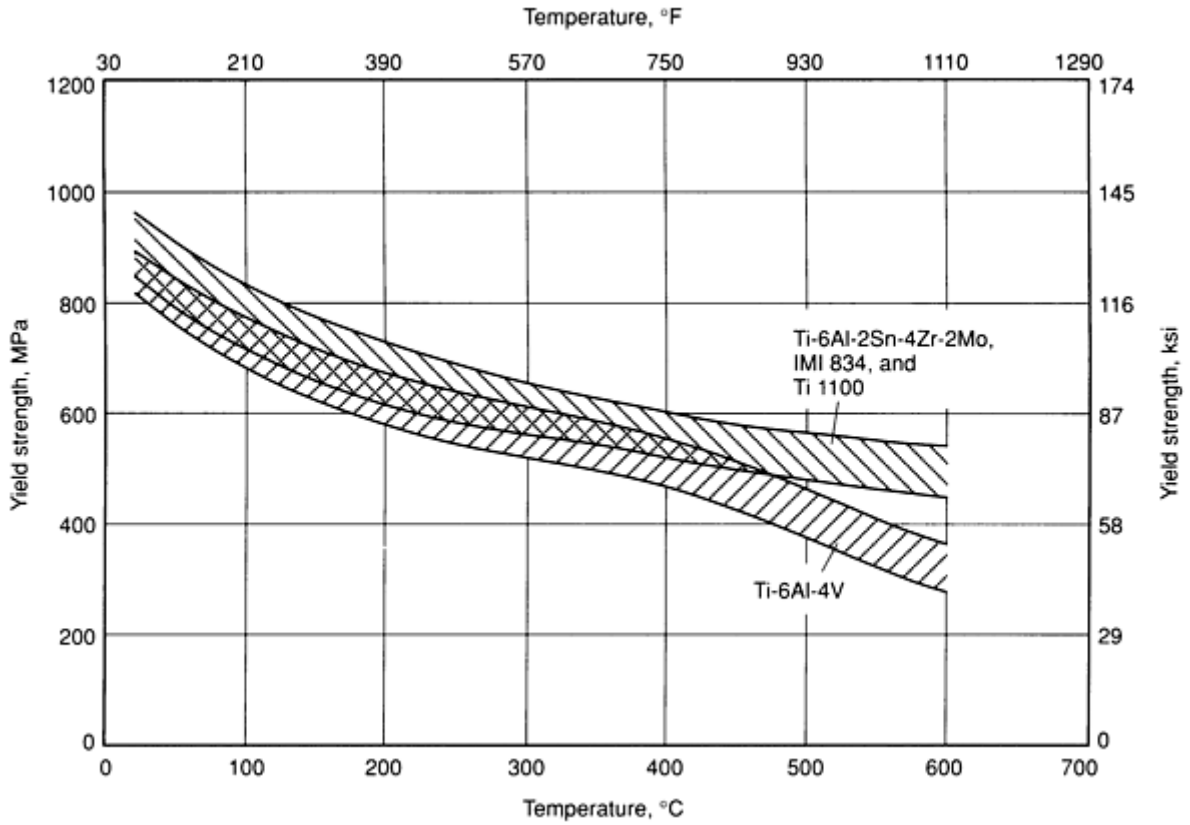

Fig. 4 Plot of yield strength versus temperature to compare elevated-temperature properties of cast Ti-6Al-2Sn-4Zr-2Mo, IMI 834, and Ti 1100 alloys with standard cast Ti-6Al-4V alloy

Extra low interstitial (ELI) grade Ti-6Al-4V has been used for critical cryogenic space shuttle service where fracture toughness is an important design criteria. The most recent alloy to receive attention in the casting industry is the metastable β alloy Ti-15V-3Al-3Cr-3Sn (Ti-15-3) (see Tables 2 and 3). Originally developed as a highly cold-formable and subsequently age-hardened sheet material, this alloy is highly castable and readily heat treated to a 1275 MPa (185 ksi) tensile strength level, making it a serious candidate for the replacement of high-strength precipitation-hardening (PH) stainless steels such as 17-4 PH. The full density advantage of titanium of about 40% is preserved because strength levels are comparable in both materials. Figure 5 shows typical room-temperature tensile data following several simple aging cycles. The data show excellent 25% elongation at 700 MPa (100 ksi) yield strength in the solution-annealed (as hot isostatically pressed) condition, and subsequent aged tensile strength capability of as much as 1400 MPa (200 ksi) with 3 to 4% elongation.

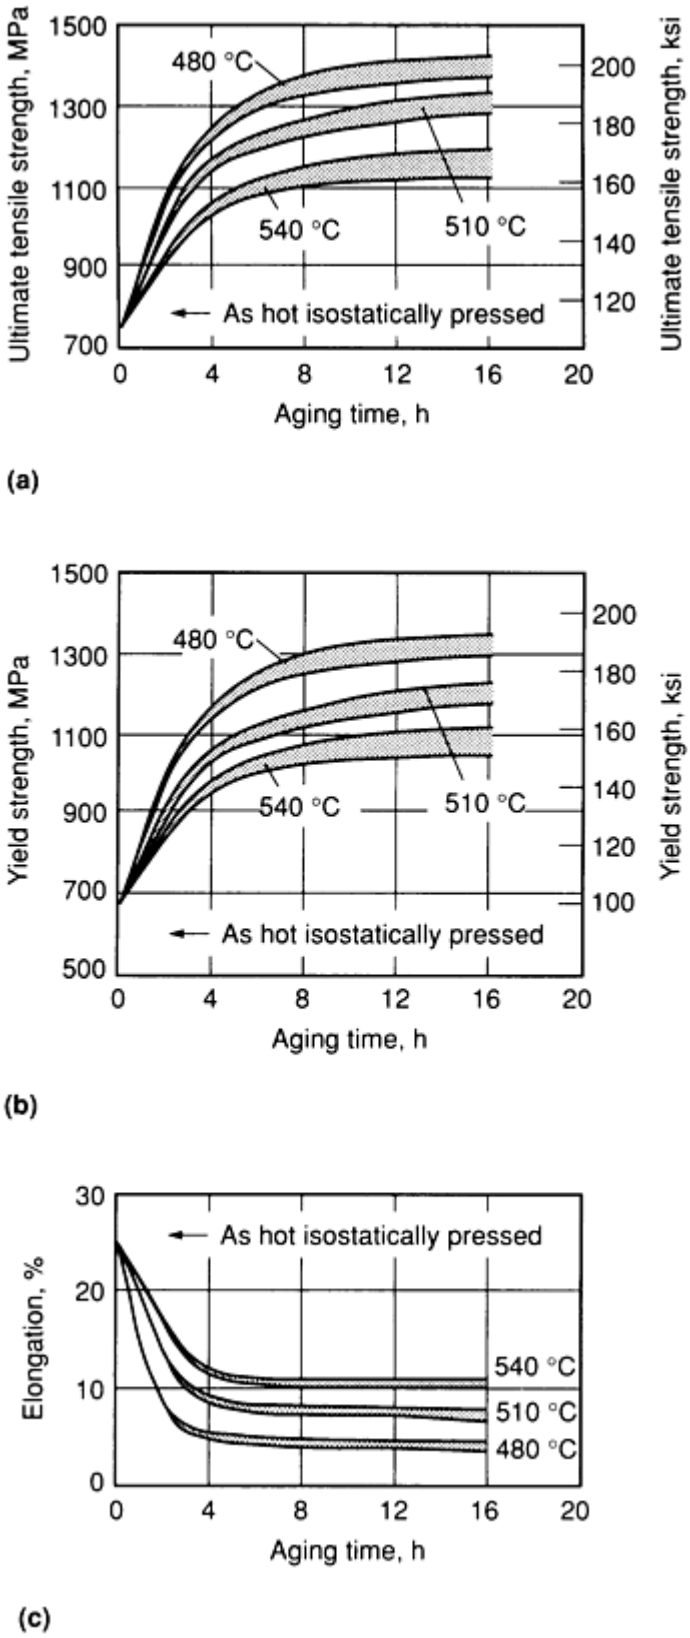

Fig. 5 Aging curves showing typical room-temperature tensile properties of HIP and aged Ti-15V-3Al-3Cr-3Sn (Ti-15-3) castings. (a) Ultimate tensile strength. (b) Yield strength. (c) Elongation

Titanium-aluminide castings are being developed for application in the compressor sections of aircraft gas turbine engines subjected to the highest temperatures. Compositions based on both the α_2 (Ti_3Al) and γ(TiAl) ordered phases have been cast experimentally, with the former being closer to limited-production status. The low ductility of these alloys at room

temperature has been the major producibility challenge. It is anticipated that the service potential for titanium aluminides in the 595 to 925 °C (1100 to 1700 °F) temperature range will eventually be realized. The difficulty in machining shapes in these brittle alloys may increase the advantage of net shape methods such as castings or powder metallurgy (see the article "Titanium P/M Products" in this Volume).

Because Ti-6Al-4V dominates the industry, much more metallurgical and mechanical test data are available on this alloy. These data are discussed in the section "Microstructure of Ti-6Al-4V" below.

Microstructure of Ti-6Al-4V

Cast Microstructure. To understand the relatively high mechanical property levels of titanium alloy castings and the many improvements made in recent years, it is necessary to understand the microstructures of castings and their influence on the mechanical behavior of titanium. The phase transformation from βto α+ β leads to the elimination of the dendritic cast structure. The existence of such dendrites during the solidification stage is evident in the surface morphology of shrinkage pores (Fig. 6). The phase transformation, which in the alloy Ti-6Al-4V is typically initiated at 995 °C (1825 °F), results in the microstructural features shown in Fig. 2(a). This microstructure, which will be discussed in details, is very similar to a β-processed wrought microstructure and therefore has similar properties. Thus, in the study and development of titanium alloy castings, it is possible to draw much information from the vast knowledge of conventional titanium ingot metallurgy.

Fig. 6 Dendritic structure present in the surface shrinkage porosity of an as-cast Ti-6Al-4V component

Hot isostatic pressing is now becoming almost a standard practice for all titanium cast parts produced for the aerospace industry (Table 1). As a result, cast + HIP microstructure also needs to be considered (Fig. 2b). Because the HIP temperature is typically well below the βtransus temperature, where there is no growth of the β grains, α plates, or their colonies, the ascast (Fig. 2a) and the cast + HIP (Fig. 2b) microstructures look very much alike, except for the lack of porosity in the latter.

As-Cast and Cast + HIP Microstructures. Because most castings for demanding applications are produced with Ti-6Al-4V alloy (Table 2), only microstructures of this α+ βalloy will be reviewed here.

Beta Grain Size. Beta grains (A, in Fig. 2a) develop during the solid-state cooling stage between the solidus/liquidus temperature and the β transus temperature. As a result, large and thick sections, which cool at a slower rate, show larger β grains. The size range of the β grains is from 0.5 to 5 mm (0.02 to 0.2 in.). As will be further discussed, large β grains may lead to large α plate colonies. This is beneficial for fracture toughness, creep resistance, and fatigue crack propagation resistance (Ref 18, 19) and detrimental for low- and high-cycle fatigue strength and tensile elongation (Ref 20, 21).

Grain Boundary α. This α phase (B, in Fig. 2a) is formed along the β grain boundaries when cast material is cooled through the α+ β phase field (in Ti-6Al-4V this is typically from 995 °C, or 1825 °F, down to room temperature). This phase is plate shaped and represents the largest α plates in the cast structure. The length of these plates can equal the β

grain radius. Because of its long dimension and planar shape, it has been found to be very detrimental to fatigue crack initiation at room temperature (Ref 22, 23) and at elevated temperatures (Ref 23, 24) both in cast and ingot metallurgy (I/M) materials. Many postcast thermal treatments eliminate this phase to improve fatigue life.

Alpha Plate Colonies. Alpha platelets (C, in Fig. 2a) are the transformation products of the β phase when cooled below the β transus temperature. The hexagonal close-packed (hcp) orientation of these plates is related to the parent body-centered cubic (bcc) β phase orientation through one of the 12 possible variants of the Burgers relationship (Ref 25, 26):

$$\{110\}\beta \parallel (0001)\alpha$$

$$\langle 111\rangle\beta \parallel \langle 1120\rangle\alpha$$

When cooling rates are relatively slow, such as in thick-section castings, many adjacent α platelets transform into the same Burgers variant and form a colony of similarly aligned and crystallographically oriented platelets. The large colonies (C, in Fig. 2a) may be associated with early fatigue crack initiation (Ref 21), the result of heterogeneous basal slip across the plates (Ref 27). At the same time, the large colony structure is beneficial for fatigue crack propagation resistance (Ref 28, 29). Because α platelet colonies cannot grow larger than the β grains, titanium castings with large prior βgrains typically have large colonies. The individual α platelets are typically 1 to 3 μm (40 to 120 μin.) in thickness and 20 to 100 μm (0.0008 to 0.004 in.) in length (Ref 30, 31). The typical colony size range in Ti-6Al-4V castings is 50 to 500 μm (0.002 to 0.02 in.) (Ref 22, 30, 31).

As a general rule, slower solid-state cooling rates, such as in thick cast sections, result in microstructures with larger βgrains, a longer and thicker grain-boundary α phase, thicker α platelets, and larger α platelet colonies.

Porosity. Gas (D, in Fig. 2a) and shrinkage voids (E) are typical phenomena in as-cast titanium products. Hot isostatic pressing, however, closes and heals these pores. This is demonstrated by comparing the as-cast microstructure in Fig. 2(a) with the cast + HIP structure in Fig. 2(b). The reactiveness of the titanium at the HIP temperature range of 900 to 955 °C (1650 to 1750 °F) leads to dissolution of all microconstituents deposited on the pore surfaces leading to complete healing of casting porosity. Hot isostatic pressing also causes a degree of α plate coarsening. It should be noted that all aerospace-related titanium alloy cast parts are delivered after hot isostatic pressing (see Table 1).

Modification of Microstructure. Most Ti-6Al-4V titanium castings produced commercially today are supplied in the annealed condition. However, much microstructural modification development work has been done recently, and it can be expected that solution-treated and aged or other postcast thermal processing will eventually become specified on cast parts requiring certain property enhancement such as fatigue or tensile strength. The following section reviews several of these developmental procedures and their results.

The modification of microstructure is one of the most versatile tools available in metallurgy for improving the mechanical properties of alloys. This is commonly achieved through a combination of cold or hot working followed by the heat treatment known as thermomechanical processing. Net shapes such as castings or P/M products cannot be worked, which limits the options for controlling microstructures. A substantial amount of work has been done in recent years to improve the microstructures of titanium alloy net shape products, with an emphasis on Ti-6Al-4V material. Most treatment schemes can be successfully applied to both cast parts (Ref 8) and P/M compacts (see the article "Titanium P/M Products" in this Volume) (Ref 32, 33). In the case of titanium alloy castings, the main goal has been to eliminate the grain-boundary α phase, the large αplate colonies, and the individual α plates. This is accomplished either by solution treatments or by a temporary alloying will hydrogen. In some cases, the hydrogen and solution treatments are combined. The details of these methods, including the appropriate references, are listed in Table 5. The typical resulting microstructures of the α-β solution treatment (ABST), βsolution treatment (BST), broken-up structure (BUS), and high-temperature hydrogenation (HTH) methods are shown in Fig. 7(a), 7(b), 7(c), and 7(d), respectively. As can be seen from the photomicrographs, these treatments are successful in eliminating the large α plate colonies and the grain-boundary α phase. As discussed below, a substantial improvement of both tensile and fatigue properties is achieved with these processes.

Table 5 Thermal and thermochemical methods for modifying the microstructure of α+ βtitanium alloy net shape products

Mechanical Properties of Ti-6Al-4V

Oxygen Influence. Figure 8 is a frequency distribution of tensile properties from separately cast test bars representing hot isostatically pressed and annealed Ti-6Al-4V castings. Oxygen, a carefully controlled alloy addition, is in the 0.16 to 0.20% range, which is common for many aerospace specifications.

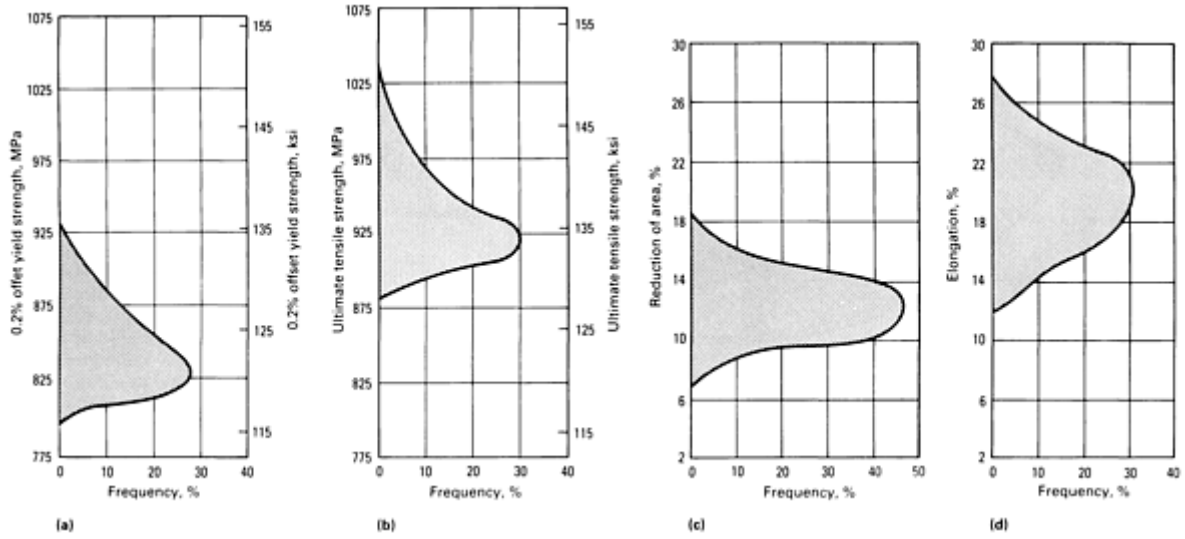

Fig. 8 Frequency distribution of tensile properties of hot isostatically pressed and annealed Ti-6Al-4V casting test bars. Percent frequency is plotted versus (a) 0.2% offset yield strength, (b) ultimate tensile strength, (c) percent reduction of area, and (d) percent elongation. Alloy composition is 0.16 to 0.20% O_2; sample size is 500 heats. Source: Ref 46

Some specifications allow a 0.25% maximum oxygen content. The resultant properties with oxygen in the 0.20 to 0.25% range are typically about 69 to 83 MPa (10 to 12 ksi) higher than those shown in Fig. 8 with slightly lower ductility levels. In this case, it is possible to guarantee 827 MPa (120 ksi) yield strength and 896 MPa (130 ksi) ultimate tensile strength levels with 6% minimum elongation. This strength level is the same minimum guarantee for wrought-annealed Ti-6Al-4V.

Microstructure Influence. Because the microstructure of titanium alloy cast parts is very similar to that of β -processed wrought or I/M material, many properties of hot isostatically pressed castings, such as tensile strength, fracture toughness, fatigue crack propagation, and creep, are at the same levels as with forged and machined parts. Tensile strength and fracture toughness properties of cast, cast + HIP, and cast + HIP + heat-treated material (Table 5) are compared in Table 6 to wrought β-annealed data. To provide a complete review, properties of castings treated by many of the methods listed in Table 5 are also included. At the present time, fracture toughness data are available for only a few of the conditions. As can be seen, some of the treated conditions present properties in excess of I/M β-annealed material. However, it should be noted that tests were done on relatively small cast coupons. Properties of actual cast parts, especially large components, could be somewhat lower, the result of coarser grain structure or slower quench rates. Of special interest are the hydrogen-treated conditions (such as thermochemical treatment, or TCT; constitutional solution treatment, or CST; and HTH, in Table 5) that result in very high tensile strength (as high as 1124 MPa, or 163 ksi) with tensile elongation as high as 8%.

Table 6 Tensile properties and fracture toughness of Ti-6Al-4V cast coupons compared to typical wrought β-annealed material

(a) All conditions (except as-cast) are cast plus HIP.

(b) See Table 5 for process details.

Fatigue and Fatigue Crack Growth Rate. The fatigue crack growth rate (FCGR) behavior of cast Ti-6Al-4V is also, as expected, very similar to that of β-processed wrought Ti-6Al-4V (Ref 50, 51, 52). This is demonstrated in Fig. 9 in which the scatterband of the FCGR of cast and cast-HIP alloys is compared to β-processed I/M (Ref 18, 53).

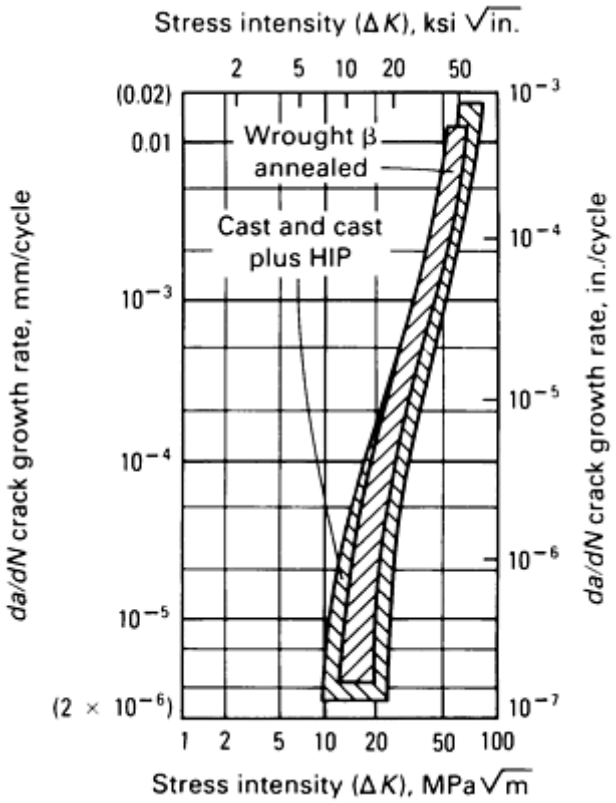

Fig. 9 Scatterband comparison of FCGR behavior of wrought I/M β-annealed Ti-6Al-4V to cast and cast HIP Ti-6Al-4V data

The scatterbands of smooth axial room-temperature fatigue results of cast, cast + HIP (Ref 15, 47, 48, 54, 55, 56, 57), and wrought Ti-6Al-4V are shown in Fig. 10. This figure clearly indicates that the HIP process results in a substantially improved fatigue life well into the wrought-annealed region. The fatigue properties of aerospace quality castings have always been an important issue, because in most other alloy systems this is the property that is most degraded, compared to wrought products. However, because of the complete closure and healing of gas (D, in Fig. 2a) and shrinkage (E, in Fig. 2a) pores by HIP and the inherent β-annealed microstructure, it is possible to obtain fatigue life comparable to wrought material in premium investment cast and hot isostatic pressed parts. As indicated previously (Table 5), substantial work has been done in recent years to modify the microstructure of cast parts to produce fatigue properties either equivalent or superior to the best wrought-annealed products. Figure 11(a) compares the smooth fatigue life of Ti-6Al-4V treated by ABST, BST, BUS, CST, Garrett treatment (GTEC), and HTH (Table 5) to wrought material scatterband. As can be seen, all of these treatments were succesful in improving fatigue life above average wrought levels. The hydrogen treatments (CST and HTH) resulted in the highest improvement in fatigue strength. However, it should be noted that wrought products subjected to the same treatments result in comparable improvements in fatigue strength.

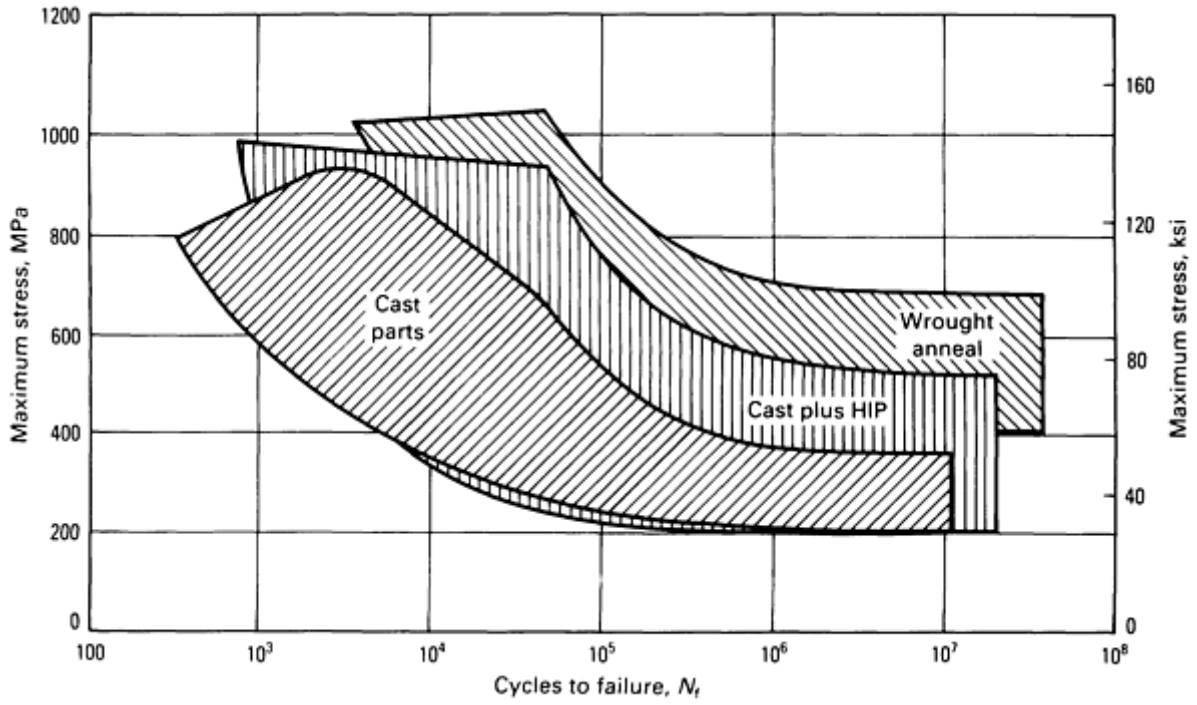

Fig. 10 Comparison of smooth axial room-temperature fatigue rate in cast and wrought Ti-6Al-4V at room temperature with R = +0.1

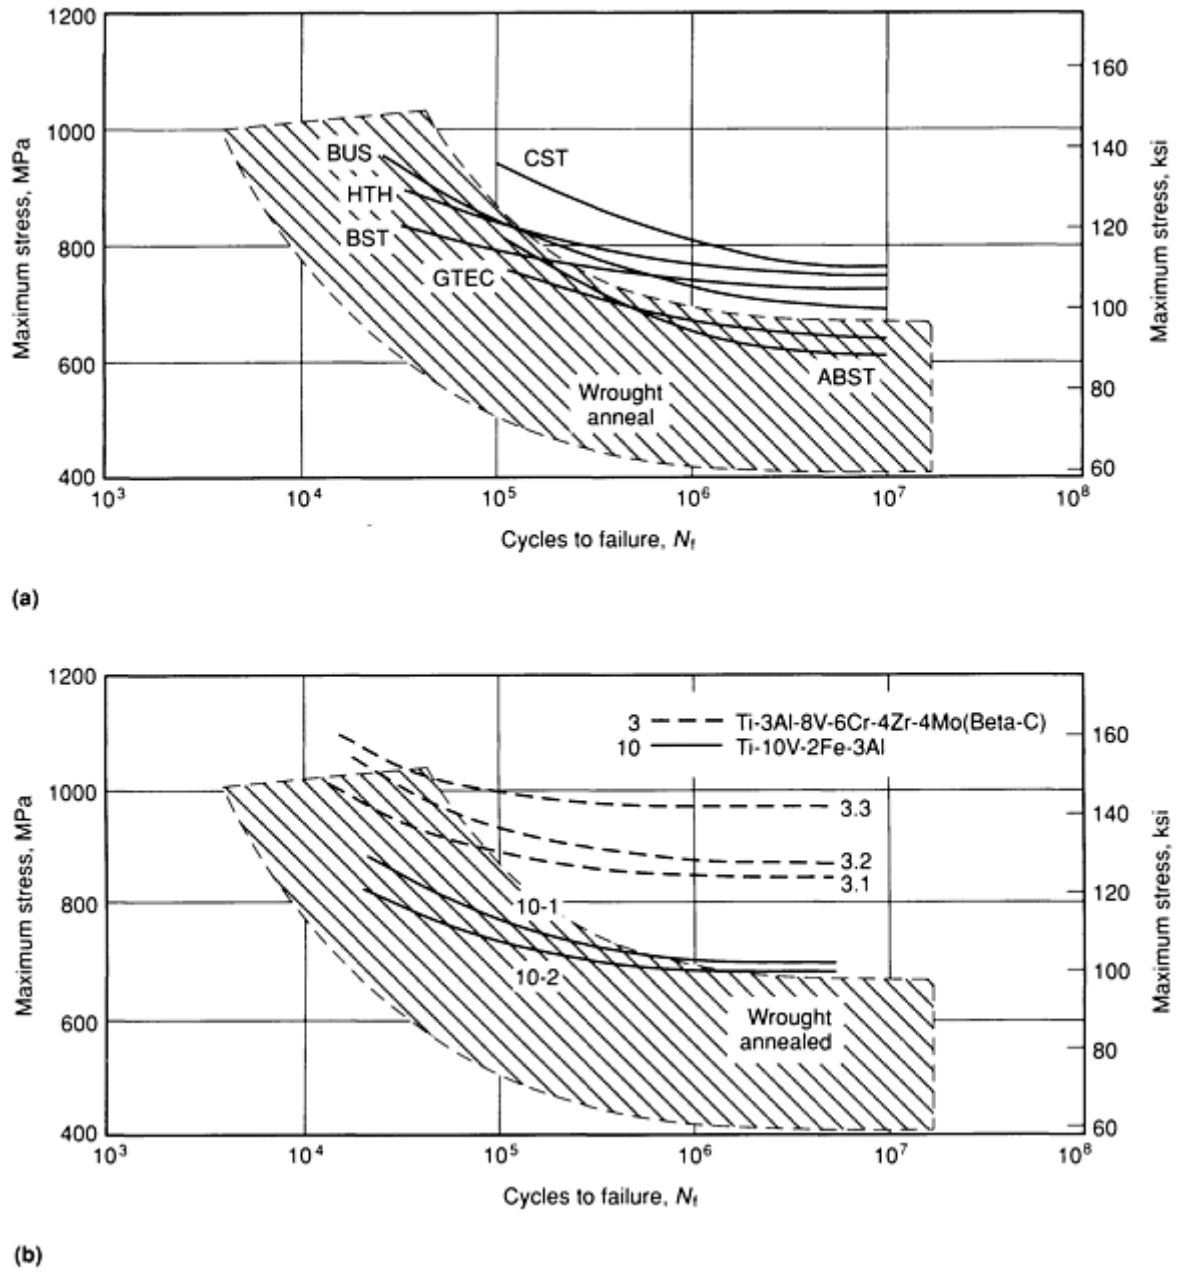

Fig. 11 Comparison of wrought (I/M) annealed Ti-6Al-4V scatterband with (a) Ti-6Al-4V investment castings subjected to various thermal and hydrogen treatments (see Table 5) and (b) heat-treated β titanium alloy castings. For data in (a), smooth axial fatigue measured at room temperature with *R* = +0.1; frequency = 5 Hz using triangular wave form

Another approach to the improvement of fatigue of cast parts is the selection of high-strength cast alloy rather than Ti-6Al-4V. Figure 11(b) compares the fatigue strength of investment cast Ti-3Al-8V-6Cr-4Zr-4Mo (Beta C) and Ti-10V-2Fe-3Al (Ti-10-2-3) in solution-treated and aged (STA) condition to wrought-annealed Ti-6Al-4V (Ref 58). Figure 11(b) shows that fatigue strength in excess of 1000 MPa (145 ksi) can be obtained with high-strength cast alloys.

Casting Design

The best casting design is usually achieved by means of a thorough review by the manufacturer and user when the component is still in the preliminary design stage (see the article "Casting Design" in *Casting*, Volume 15 of *ASM*

Handbook, formerly 9th Edition *Metals Handbook*). Additional features may be incorporated to reduce machining cost, and components may be integrated to eliminate later fabrication. Specifications and tolerances may be reviewed vis-à-vis foundry capabilities, producibility, and pattern tool concepts to achieve the most practical and cost-effective design (see the articles "Dimensional Tolerances and Allowances" and "Patterns and Patternmaking" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). When minimum cast part weight is critical, such as in aerospace components, the capability of the foundry to produce varying wall thicknesses, for example, may be beneficial. Often, cast features that cannot be economically duplicated by any other method may be readily produced.

Titanium castings present the designer with few differences in design criteria, compared with other metals. Ideal designs do not contain isolated heavy sections or uniform heavy walls of large area so that centerline shrinkage cavities and regions with a coarse microstructure may be avoided. From a practical sense, however, ideal tapered walls to promote directional solidification are not usually a reality. The advent of hot isostatic pressing to heal internal as-cast shrinkage cavities has offered the designer much more freedom; however, there still is a practical limit to the size of an internal cavity that can be healed through hot isostatic pressing without contributing significant surface or structural deformation due to the collapse of internal pores.

The lost-wax investment process provides more design freedom for the foundry to feed a casting property than does the traditional sand or rammed graphite approach. It is normal practice to use adequate gates and risers to subsequently hot isostatically pressed investment castings to achieve reasonably good as-cast internal x-ray quality so that hot isostatic pressing will not cause extensive surface or structural deformation.

The usual required minimum practical wall thickness for investment castings is 2.0 mm (0.080 in.); however, sections as thin as 1.1 mm (0.045 in.) are routinely made. Even thinner walls may be achieved by chemical milling beyond that required for α-case removal; however, as cast wall variation is not improved and becomes a larger percentage of the resultant wall thickness. Sand or rammed graphite molded castings have a usual minimum wall thickness of 4.75 mm (0.187 in.), although 3.0 mm (0.12 in.) is not unreasonable for short sections.

Fillet radii should be as generous as possible to minimize the occurrence of hot tears. Although 0.76 mm (0.030 in.) radii are produced, the preferred minimum is 3.0 mm (0.12 in.). A rule of thumb is that a fillet radius should be 0.5 times the sum of the thicknesses of the two adjoining walls.

With proper tool design, zero draft walls are possible. To promote directional solidification, a 3° included draft angle may be preferred. Hot isostatic pressing will close any centerline shrinkage cavities in zero draft walls, making it unnecessary to provide draft. Draft requirements are also dependent on foundry practice, with rammed graphite tooling usually requiring draft, and investment casting typically not requiring draft.

Tolerances. Typically, the major area of concern is the true position of a thin-section surface with respect to a datum. Surface areas of approximately 129 cm^2 (20 $in.^2$) or greater in sections of less than approximately 5.08 mm (0.200 in.) thickness are susceptible to distortion, depending on adjoining sections. The high strength of titanium compared with that of aluminum and low elastic modulus compared with that of steel present challenges in straightening and in maintaining extremely tight, true positions. General tolerance band capabilities for linear dimensions are shown in Table 7.

Table 7 General linear and diametric tolerance guidelines for titanium castings

Size		Total tolerance band[(a)]	
mm	in.	Investment cast	Rammed graphite process
25 to <102	1 to <4	0.76 mm (0.030 in.) or 1.0%, whichever is greater	1.52 mm (0.060 in.)
102 to <305	4 to <12	1.02 mm (0.040 in.) or 0.7%, whichever is greater	1.78 mm (0.070 in.) or 1.0%, whichever is greater
305 to	12 to	1.52 mm (0.060 in.) or 0.6%, whichever is greater	1.0%

<610	<24		
≥ 610	≥ 24	0.5%	1.0%
Examples			
254 mm	10 in	1.78 mm (0.070 in.) total tolerance band or ±0.89 mm (±0.035 in.)	2.54 mm (0.100 in.) total tolerance band or ±1.27 mm (±0.050 in.)
508 mm	20 in	3.05 mm (0.120 in.) total tolerance band or ±1.52 mm (±0.060 in.)	5.08 mm (0.200 in.) total tolerance band or ±2.54 mm (±0.100 in.)

(a) Improved tolerances may be possible depending on the specific foundry capabilities and overall part-specific requirements.

Hot sizing fixtures have been used increasingly to help control critical casting dimensions. This technique typically involves the use of steel fixtures to "creep" the casting into final tolerances in an anneal or stress-relief heat treatment by the weight of the steel or the use of different thermal expansion of the steel relative to the titanium.

Standard casting industry thickness tolerances of ±0.76 mm (±0.030 in.) for rammed graphite and ±0.25 mm (±0.010 in.) for investment cast walls are more difficult to maintain with titanium primarily because of the influence of chemical milling. As mentioned earlier, for critical applications it is necessary to mill all surfaces chemically to remove the α case. This operation is subject to variation because of part geometry and bath variables, and because it is usually manually controlled. Standard industry surface finishes are shown in Table 8.

Table 8 Surface finish of titanium castings

Process	**NAS 823 surface comparator[(a)]**	**rms equivalent[(b)]**	
		µm	**µin.**
Investment			
As-cast	C-12	3.2	125
Occasional areas of	C-25	6.3	250
Rammed graphite			
As-cast	C-30 to 40	7.5-10	300-400
Occasional areas of	C-50	12.5	500

Melting and Pouring Practice

Vacuum Consumable Electrode. The dominant, almost universal, method of melting titanium is with a consumable titanium electrode lowered into a water-cooled copper crucible while confined in a vacuum chamber. This skull melting technique (see the section "Vacuum Arc Skull Melting and Casting" in the article "Vacuum Melting and Remelting Processes" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*) prevents the highly reactive liquid titanium from reacting and dissolving the crucible because it is contained in a solid skull frozen against the water-cooled crucible wall. When an adequate melt quantity has been obtained, the residual electrode is quickly retracted, and the crucible is tilted for pouring into the molds. A skull of solid titanium remains in the crucible for reuse in a subsequent pour or for later removal.

Superheating. The consumable electrode practice affords little opportunity for superheating the molten pool because of the cooling effect of the water-cooled crucible. Because of limited superheating, it is common either to pour castings centrifugally, forcing the metal into the mold cavity, or to pour statically into preheated molds to obtain adequate fluidity. Postcast cooling takes place in a vacuum or in an inert gas atmosphere until the molds can be safely removed to air without oxidation of the titanium.

Electrode Composition. Consumable titanium electrodes are either I/M-forged billet, consolidated revert wrought material, selected foundry returns, or combination of all of these (see Table 1). Casting specifications or user requirements can dictate the composition of revert materials used in electrode construction. Figure 12 shows a typical centrifugal casting furnace arrangement.

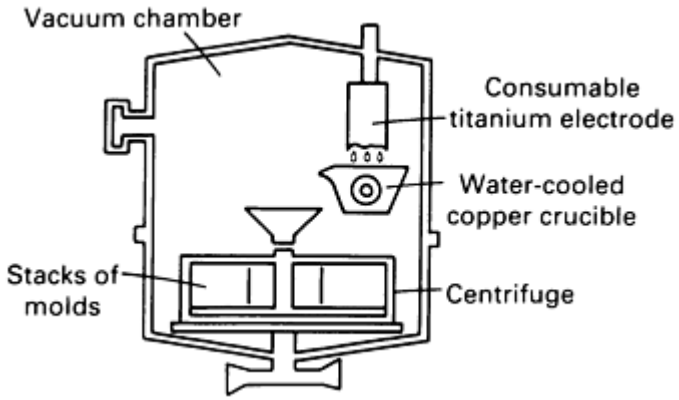

Fig. 12 Schematic of a centrifugal vacuum casting furnace

Chemical Milling

Residual surface contamination, or α case, is typically removed from as-cast aerospace parts before further processing. This is to eliminate the possibility of the diffusion of these contaminants into the part during subsequent HIP or heat treatment. Chemical milling is normally conducted in solutions based on hydrofluoric and nitric acid mixtures plus additives designed to enhance surface finish and control hydrogen pickup. Hydrogen pickup is more likely the higher the β-phase content of the alloy and is also influenced by etch rate and bath temperature. Subsequent vacuum anneals may be used to remove hydrogen picked up in chemical milling. The general objectives are to remove the entire as-cast surface uniformly to the extent of maximum α-case depth and to retain the dimensional integrity of the part.

Hot Isostatic Pressing

Hot isostatic pressing may be used to ensure the complete elimination of internal gas (D, in Fig. 2a) and shrinkage (E, in Fig. 2a) porosity. The cast part is chemically cleaned and placed inside an autoclave, where it is typically subjected to an argon pressure of 103 MPa (15 ksi) at 900 to 955 °C (1650 to 1750 °F) for a 2 h hold time (Ti-6Al-4V alloy) for void closure and diffusion bonding. Recently, an HIP pressure of 206 MPa (30 ksi) has been employed in the hot isostatic pressing of high-temperature titanium alloys to ensure pore closure in these harder-to-deform materials. This practice has been shown to reduce the scatterband of fatigue property test results and improve fatigue life significantly (Fig. 10). HIP temperature may coarsen the α platelet structure, causing a slight debit in tensile strength, but the benefits of HIP normally exceed this slight decrease in strength, and the practice is widely used for aerospace titanium alloy cast parts.

Weld Repair

The weld repair of titanium castings is an integral step in the manufacturing process and is used to eliminate surface-related defects, such as HIP-induced surface depressions or surface-connected pores that did not close during the HIP cycle. Tungsten inert-gas (TIG) welding practice in argon-filled glove boxes is used with weld filler wire of the same composition as the parent metal. Generally, all weld-repaired castings are stress relief annealed. Excellent-quality weld deposits are routinely obtained in proper practice. Weld deposits may have higher strength but lower ductility than the parent metal because of microstructural differences due to the fast cooling rate of the welding process and some oxygen pickup. Those differences may be eliminated by a postweld solution heat treatment, but standard practice is for stress relief or anneal only. Also, welding rods containing lower oxygen-content alloys are commonly used.

Heat Treatment

Conventional heat treatment of titanium castings is for stress relief anneal after any weld repair. The Ti-6Al-4V alloy is typically heat treated at 730 to 845 °C (1350 to 1550 °F). This is done in a vacuum to ensure the removal of any hydrogen pickup from chemical milling and to protect the titanium chemically milled surface from oxidation. As with HIP and weld repair, castings must be chemically clean prior to heat treatment if diffusion of surface contaminants is to be avoided. Alternate heat treatments for property improvement, such as the solution treating and aging (STA) of Ti-6Al-4V alloy castings, are available. Numerous other heat treatments are in various stages of development, as discussed in an earlier section (Table 5).

Final Evaluation and Certification

Titanium castings are produced to numerous quality specifications. Typically, these require some type of x-ray and dye penetrant inspection, in addition to dimensional checks using layout equipment, dimensional inspection fixtures, and coordinate measuring machines. Metallurgical certifications may include HIP and heat treatment run certifications, as well as chemistry, tensile properties, and microstructure examination of representative coupons for the absence of surface contamination.

In the absence of universally accepted x-ray standards, it is common practice to use steel or aluminum reference radiographs (Table 4). Because internal discontinuities in titanium do not necessarily appear the same as they do in other metals, it is necessary to have an expert evaluation of radiographs for proper interpretation. Currently, an industry task force is working on the development of radiographic standards for titanium castings through the American Society for Testing and Materials (ASTM).

Product Applications

The titanium castings industry is relatively young by most foundry standards. The earliest commercial applications, in the 1960s, were for use in pump and valve components requiring corrosion-resistant properties. These applications continue to dominate the rammed graphite production method; however, in more recent years, some users have justified the expense of lost-wax investment tooling for some commercial corrosion-resistant casting applications (see Fig. 13).

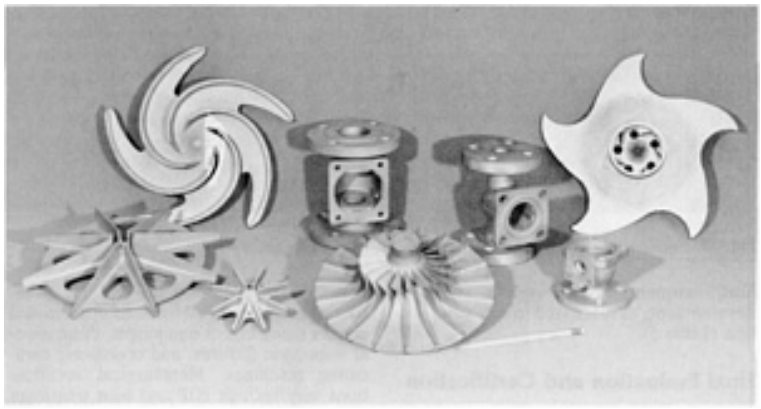

Fig. 13 Investment cast titanium components for use in corrosive environments

Aerospace use of rammed graphite castings became a production reality in the early 1970s for aircraft brake torque tubes, missile wings, and hot gas nozzles. As the more precise investment casting technology developed and the commercial use of HIP became a reality in the mid-1970s, titanium castings quickly expanded into critical airframe (Fig. 14) and gas turbine engine (Fig. 15) applications. The first components were primarily Ti-6Al-4V, the workhorse alloy for wrought aerospace products, and castings were often substituted for forgings, with the addition of some features possible only through net-shape technique. This trend has continued. With continuing experience in manufacturing and specifying titanium castings, applications have expanded from relatively simple, less-critical components for military engines and airframes to large, complex structural shapes for both military and commercial engines and airframes. Today, titanium cast parts are routinely produced for critical structures such as space shuttle attachment fittings, complex airframe structures, engine mounts, compressor cases and frames of many types, missile bodies and wines, and hydraulic housings (Fig. 16). Quality and dimensional capabilities continue to be improved. Titanium castings are used for framework for very sensitive optical equipment because of their relative stiffness, light weight, and the compatibility of the coefficient of thermal expansion of titanium with that of optical glasses (Fig. 17). Applications are evolving for engine airfoil shapes that include individual vanes and integral vane rings for stators, as well as a few rotating parts that would otherwise be made from wrought product. Growth will continue as users seek to take advantage of the flexibility of design inherent in the investment casting process and the improvement in the economics of net and near-net shapes. Also, a great deal of work is currently being done in the area of producing rotating cast parts used for fan blades, vanes, and compressor blades for advanced gas-turbine engines.

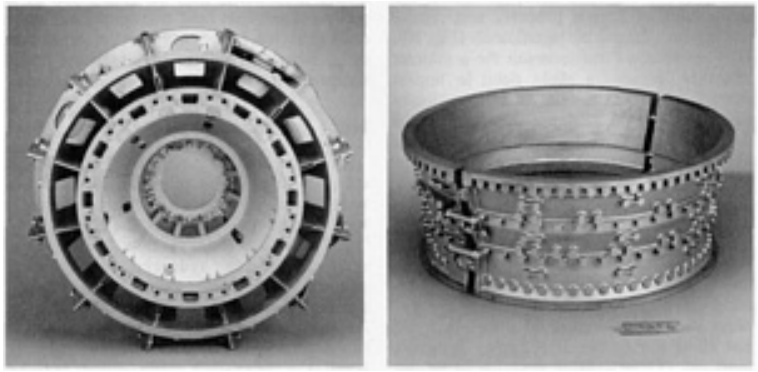

Fig. 15 Typical investment cast titanium alloy components used for gas turbine applications

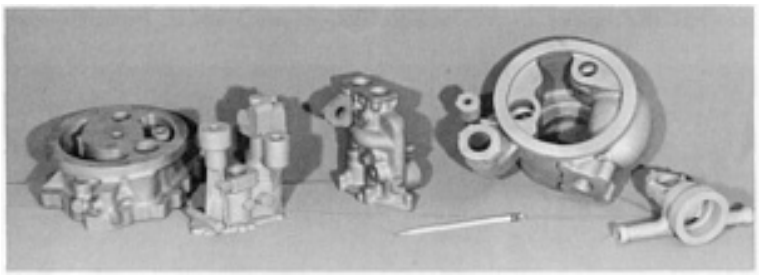

Fig. 16 Titanium hydraulic housings produced by the investment casting process

Fig. 17 Titanium housings for aerospace optical applications produced by the investment casting process.

In spite of the wide acceptance of titanium castings for airframe applications, growth has been somewhat hindered because of the lack of an industry wide data base to establish whether casting factors (derived from early aluminum castings) are, in fact, a necessity for titanium. Such standards are now being considered with the probable elimination of design casting factors (Ref 59).

Foundry size capabilities are expanding to allow the manufacture of larger airframe and static gas turbine engine structures. Widespread routine use of aerospace titanium castings is anticipated as the titanium foundry industry conforms with well-established quality and product standards, and user understanding and confidence continue to be gained from satisfactory product performance.

Concurrent with the above trend, investment cast titanium is increasingly being specified for medical prostheses because of its inertness to body fluids, an elastic modulus approaching that of bone, and the net shape design flexibility of the casting process. Custom-designed knee and hip implant components (Fig. 18) are routinely produced in volume. Some of these are subsequently coated with a diffusion-bonded porous titanium surface to facilitate bone ingrowth or an eventual fixation of the metal implant with the organic bone structure. Of special interest is the use of titanium for a hip joint implant that requires high-fatigue strength properties due to cyclic loading for which Ti-6Al-4V is deadly suited.

Introduction

TITANIUM, the recently introduced member of the family of major structural metals, is the fourth most abundant structural metal in the crust of the earth after aluminum, iron, and magnesium. The development of its alloys and processing technologies started only in the late 1940s (Ref 1); thus, titanium metallurgy just missed being a factor in the Second World War. The difficulty in extracting titanium from ores, its high reactivity in the molten state, its forging complexity, its machining difficulty, and its sensitivity to segregation and inclusions necessitated the development of special processing techniques. These special techniques have contributed to the high cost of titanium raw materials, alloys, and final products. On the other hand, the low density of titanium alloys provides high structural efficiencies based on a wide range of mechanical properties, coupled with an excellent resistance to aggressive environments. These alloys have contributed to the quality and durability of military high-Mach-number aircraft, light helicopters, and turbofan jet engines as well as the increased reliability of heat exchanger units, and surgical body implants.

Despite the combination of low density, high mechanical performance, and excellent corrosion resistance, the high cost of titanium alloys made them a design choice only when lower-cost alloys could not be used. The drive to develop net-shape technologies, such as casting and powder metallurgy (P/M), has been going on for many years. It has been spurred on by the desire to minimize alloy waste and to reduce or eliminate the cost of machining. This article focuses on the properties and applications of titanium P/M compacts. Titanium casting technology, which represents an alternative production method and is a more widely used net-shape technique, is discussed in the article "Titanium and Titanium Alloy Castings" in this Volume.

Because of difficulties encountered with early melting practices, powder metallurgy was used in the beginning stages of titanium technology to produce alloy ingots (Ref 1). Titanium P/M has been developed as a net-shape technique only in the last 15 years (Ref 2, 3, 4, 5). In general, P/M can be divided into two major categories (Ref 6, 7):

- Elemental P/M, in which a blend of elemental powders, along with master alloy or other desired additions, is cold pressed into shape and subsequently sintered to higher density and uniform chemistry
- Prealloyed P/M, which is based on hot consolidation of powder produced from a prealloyed stock

In general, the blended elemental (BE) method produces parts at a low cost, but the parts often are less than fully dense; this technique is typically used for iron (Ref 8), copper (Ref 9), and heavy-metal (Ref 10) alloys. The prealloyed (PA) method is used for making fully dense high-performance components from aerospace alloys such as nickel (Ref 11, 12), aluminum (Ref 13), and beryllium (Ref 14). Titanium P/M has incorporated both methods: BE is used to produce lower-cost parts that are less-than-fully dense, and PA is used for higher-cost, high-performance, full-density compacts (Ref 15). Recent developments in powder selection, compaction techniques, and postcompaction treatments have made it possible to obtain full density in titanium BE P/M. Properties exceeding those of ingot metallurgy (I/M) products have been achieved in BE and PA products. This article highlights the properties and applications of both BE and PA titanium P/M compacts. It includes major recent developments that have led to improved performance in BE and PA products, but it does not cover the developments in titanium rapid solidification alloys that have not yet reached the commercialization stage. Detailed discussions of powder production methods and shape-making techniques are available in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook.* (Ref 6, 7). These processes are briefly described here in only enough detail to rationalize properties and applications.

Mechanical Properties of Titanium P/M Products

The mechanical properties of titanium P/M products depend on alloy composition and on the density and final microstructure of the compact. The compact density and microstructure depend on the nature of the powder, on the specific consolidation technique employed, and on postcompaction treatments such as secondary pressing or heat treatment. To date, most components produced by the various P/M methods have been made from Ti-6Al-4V, the most common aerospace titanium alloy. As a result, the majority of the P/M data available in the literature is for this alloy. However, these technologies are also very well suited for other alloys, such as the high-strength β alloys and the high-temperature near-α alloys. This article includes data on a wide variety of alloys to highlight the range of potential applications available for titanium P/M.

Blended Elemental Compacts

The blended elemental method, which is basically a pressing and sintering P/M technique, involves cold pressing or cold isostatic pressing (CIP) a blend of fine elemental titanium and master alloy powders that have been sintered. Titanium sponge fines (-100 mesh) are the most common elemental powder used in this process; these particles are obtained as by-products of the Hunter or Kroll reduction processes (Ref 4). The metallic titanium sponge produced by these processes is vacuum arc melted into ingots. The titanium sponge fines that are too small to be used in the melting process are available at a relatively low cost. This powder has an irregular shape (Fig. 1a), which makes it easy to cold press into green shapes. The powder is sintered at temperatures in the range of 1150 to 1315 °C (2100 to 2400 °F) in a vacuum to prevent gas contamination that can severely degrade compact properties. The high sintering temperature is needed to provide particle bonding and to homogenize the chemistry. It is well above the β transus (that is, the lowest equilibrium temperature at which the material is 100% β) of all common titanium alloys, and as a result the compact microstructure in α+ β alloys consists of colonies of similarly aligned coarse α plates (Fig. 1b). The plates are about 8 μm (320 μin.) wide and 25 μm (1000 μin.) long. The colonies are about 50 μm (0.002 in.) in diameter. The prior β grains are about 80 μm (0.0032 in.) in diameter. This microstructure is much finer than ingot material treated at the same temperature because of the inherent porosity of the powder compact (Ref 16). The porosity is the result of sodium chloride residues (Kroll process) in the sponge from the reduction process (Ref 4). The sponge fines contain from 0.12 to 0.15% Cl, and, as can be seen in Fig. 1(a), the resulting porosity cannot be entirely closed, even after secondary operations such as hot pressing or hot isostatic pressing (HIP) (Ref 17).

(c) Crushed hydrogenated-dehydrogenated titanium ingot or machine turnings. (d) Microstructure of a fully dense, pressed and sintered , and hot isostatically pressed Ti-6Al-4V compact. (e) Microstructure of a Ti-6Al-4V compact treated to produce a broken-up structure. (f) Microstructure of a Ti-6Al-4V compact treated with thermochemical processing

BE compacts have a green density of 85 to 90% after 415 MPa (60 ksi) cold pressing. After vacuum sintering, they have a density of 95 to 99%. Control of particle size and size distribution can produce compacts that are 99% dense. In ferrous, copper, and heavy-metal P/M alloys, 99% is considered to be full density; however, in titanium alloy compacts, such a level of residual porosity (Fig. 1a) will degrade both fatigue and fracture properties. A substantial effort has been made to entirely eliminate the porosity so that BE P/M parts can be used for fatigue-critical aerospace applications. Postsintering HIP densification can lead to 99.8% density and improved properties (Ref 4, 5). However, it is impossible to entirely eliminate the porosity with postsintering hot-pressing operations. During hot pressing, the chlorides present in the compact becomes volatile and create pockets of insoluble gas. Under the HIP pressure, these relatively large pressurized cavities (Fig. 2a) will break up into a multitude of submicron voids (Fig. 2b) (Ref 16, 17, 18) with sodium chloride in the center of the cavity (Fig. 2c). Both macrovoids and microvoids have an approximate hexagonal shape that is associated with basal-plane facets, which are the most energetically stable planes of the hexagonal close-packed structure (Ref 19). During cooling to room temperature, the gas in the voids transforms into cubic chloride crystals, as can be seen in the transmission electron microscopy image in Fig. 2(b).

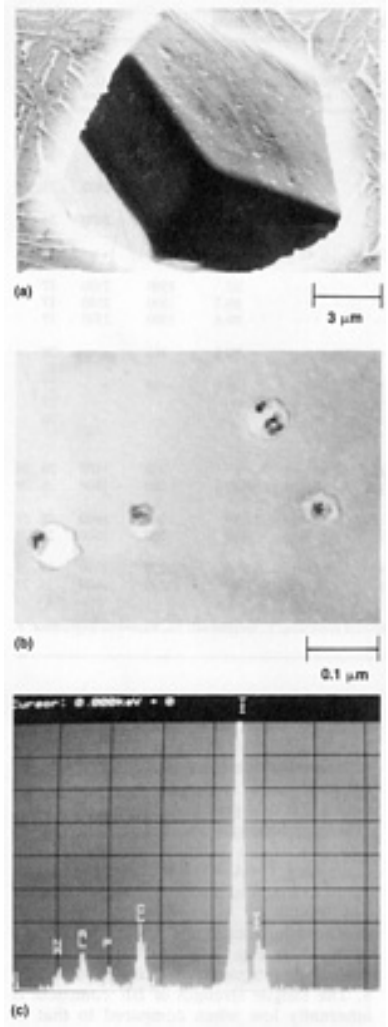

Fig. 2 Chlorine-induced porosity in a titanium BE compact. (a) Scanning electron microscopy photomicrograph of large-size residual porosity in a sectioned Ti-6Al-4V BE compact. (b) Transmission electron microscopy photomicrograph of a Ti-6Al-4V BE compact after postsintering HIP at 925 °C (1700 °F). (c) Chemical analysis showing sodium chloride contaminant at the center of a micropore

To obtain pore-free 100% density material such as that produced by ingot metallurgy, the BE method must use chloride-free titanium powder (Ref 20). One source for such powder is commercially pure titanium ingot material or machine turnings embrittled by hydrogenation that are subsequently crushed, and dehydrogenated. This powder is angular (Fig. 1c), and the sintered microstructure is much coarser (Fig. 1d) because of the lack of porosity during sintering.

Tensile Properties and Fracture Toughness. As with data for other titanium technologies, most of the published BE data are on Ti-6Al-4V. Table 1 is a comprehensive listing of tensile properties of Ti-6Al-4V BE compacts processed under a variety of conditions. Table 2 provides the more limited available information on the properties of additional titanium BE alloys.

Blended Elemental Ti-6Al-4V. As indicated in Table 1, most Ti-6Al-4V BE compact conditions exceed minimum MIL-T-9047 specifications. The process details for each condition are in the corresponding references listed in the table. The final shape of the compact can be achieved through a number of process sequences:

- Pressing and sintering
- Pressing and sintering plus HIP
- Pressing and sintering plus rolling
- CIP and sintering
- CIP, sintering, and HIP (collectively designated as cold and hot isostatic pressing, or CHIP)
- CIP, sintering, and rolling
- CIP, sintering, and forging

By controlling the process parameters, it is possible to obtain compacts with densities between 92 and 100% of the theoretical density. The yield and tensile strength of the compacts are proportional to the density (Fig. 3). The fracture toughness also increases with density (Fig. 4). Above 98% density. BE compacts have K_{Ic} values at the level of mill-annealed I/M materials. However, I/M materials with coarse lenticular microstructures similar to those of BE compacts (Fig. 1d) will have much higher K_{Ic} values (70 to 100 MPa $\sqrt{m}$, or 65 to 90 ksi $\sqrt{in}$). The relatively lower K_{Ic} level of the BE compacts is probably the result of higher oxygen levels (Ref 26) and residual porosity.

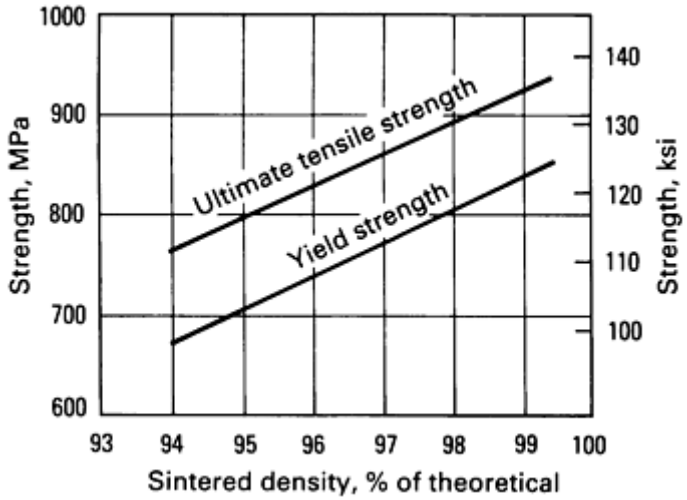

Fig. 3 Effect of sintered density on the yield and tensile strengths of press and sintered Ti-6Al-4V BE compacts. Source: Ref 22

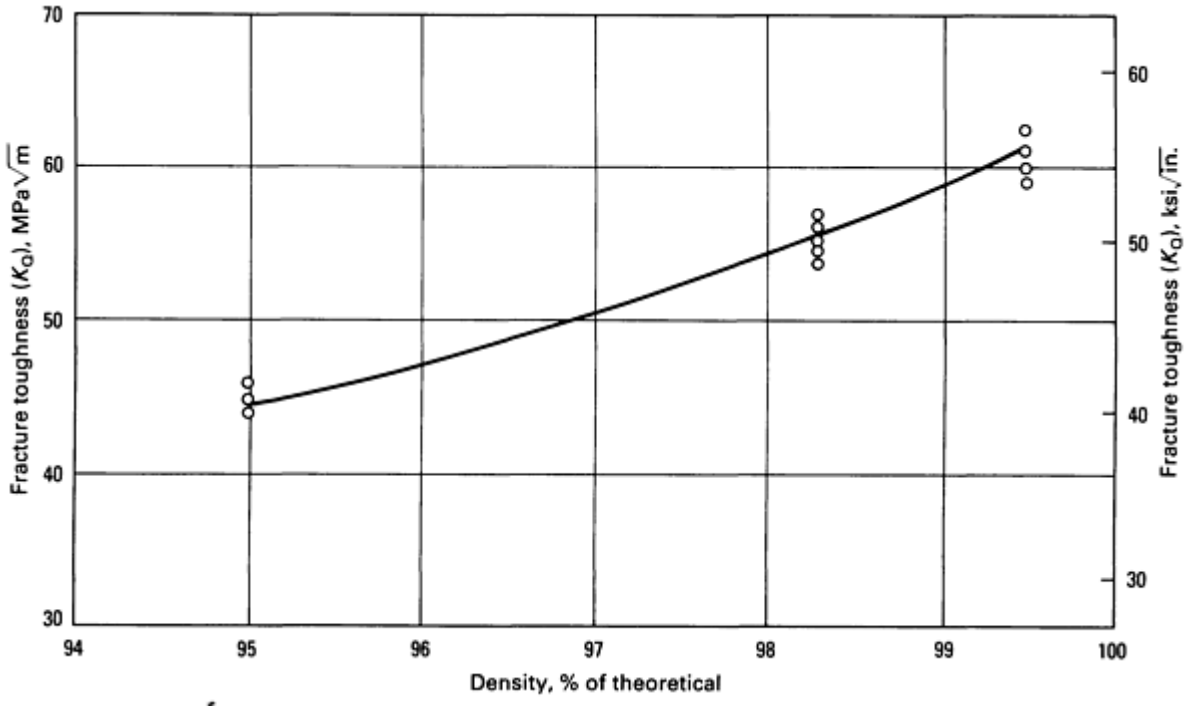

Fig. 4 Effect of density on the fracture toughness of press and sintered Ti-6Al-4V BE compacts. The values are not valid K_{Ic} and thus are labeled as K_Q. Source: Ref 21

Blended elemental compacts can be used as forging preforms (Ref 17). The strong effect of forging deformation on tensile strength and elongation is shown in Fig. 5.

Additional BE Alloys. The limited available mechanical test data for other BE alloys, such as Ti-6Al-2Sn-4Zr-6Mo, Ti-5Al-2Cr-1Fe, and Ti-4.5Al-5Mo-1.5Cr, are listed in Table 2. The most detailed work has been done on the Ti-10V-2Fe-3Al alloy, with some results reported at levels close to those for I/M materials (Ref 33). However, more data are needed for these alloys before reliable parameters for property levels and optimum processes can be established. It is interesting to note that in the case of Ti-10V-2Fe-3Al, a tensile strength of 1268 MPa (184 ksi) with 10% elongation can be achieved with BE methods. The CermeTi, listed in Table 2, is essentially a metal-matrix composite with a Ti-6Al-4V base and titanium carbide particulate reinforcement (10 to 15% TiC is typical) that is produced with a BE P/M process.

Fatigue Strength and Crack Propagation. The fatigue life scatterband of chloride-containing Ti-6Al-4V BE compacts is compared in Fig. 6 to a mill-annealed I/M alloy. The effect of low chloride levels and postsintering treatments on fatigue strength is shown in Fig. 7. The effect of compact density on fatigue strength is shown in Fig. 8. The fatigue strength of BE compacts is inherently low when compared to that of mill-annealed I/M products because of the inherent chloride and related porosity of BE materials. This limits the use of the lower-cost pressing and sintering or CIP and sintering processes to applications that are not fatigue critical, such as missile components. By increasing density through secondary pressing operations and through the use of chloride-free titanium powder, it is possible to further

improve fatigue strength (Fig. 8). However, this increases the cost of these products, thereby negating one of their primary advantages (Ref 15, 35).

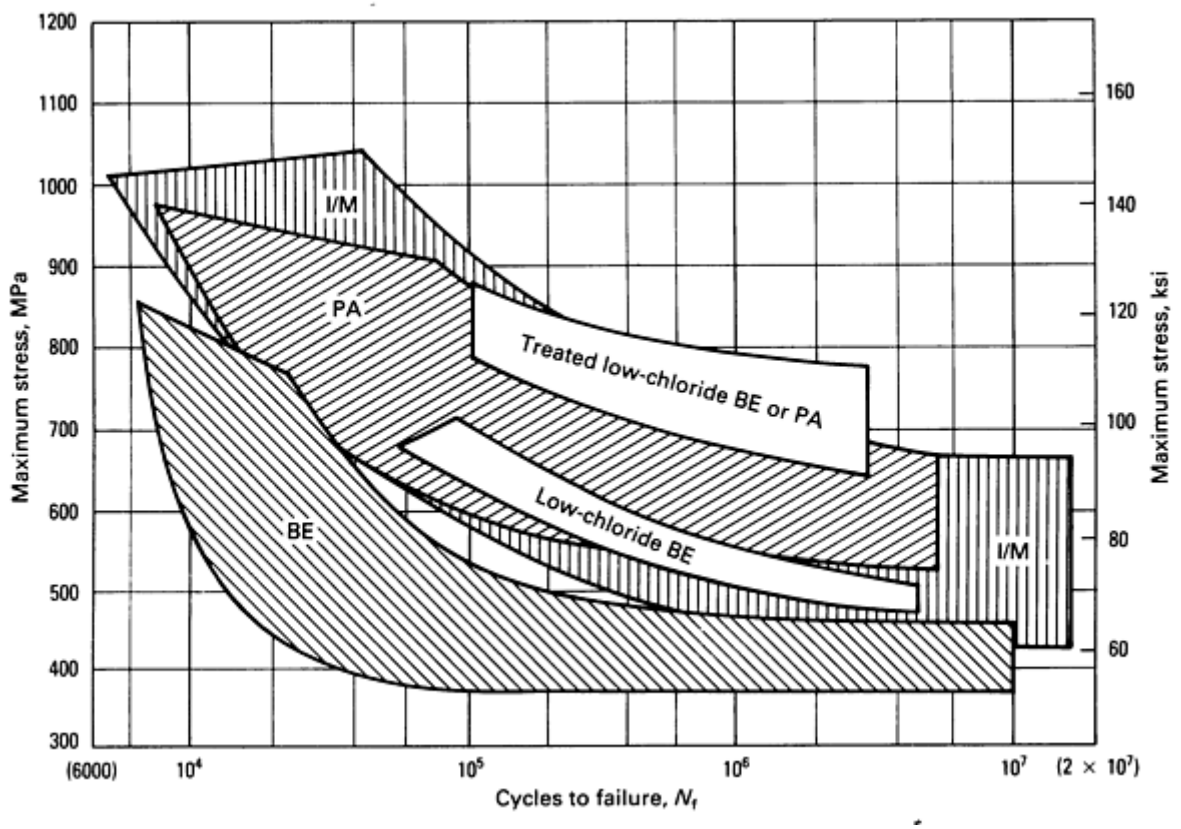

Fig. 6 Comparison of the room-temperature fatigue life scatterbands of BE and PA Ti-6Al-4V compacts to that of a mill-annealed I/M alloy

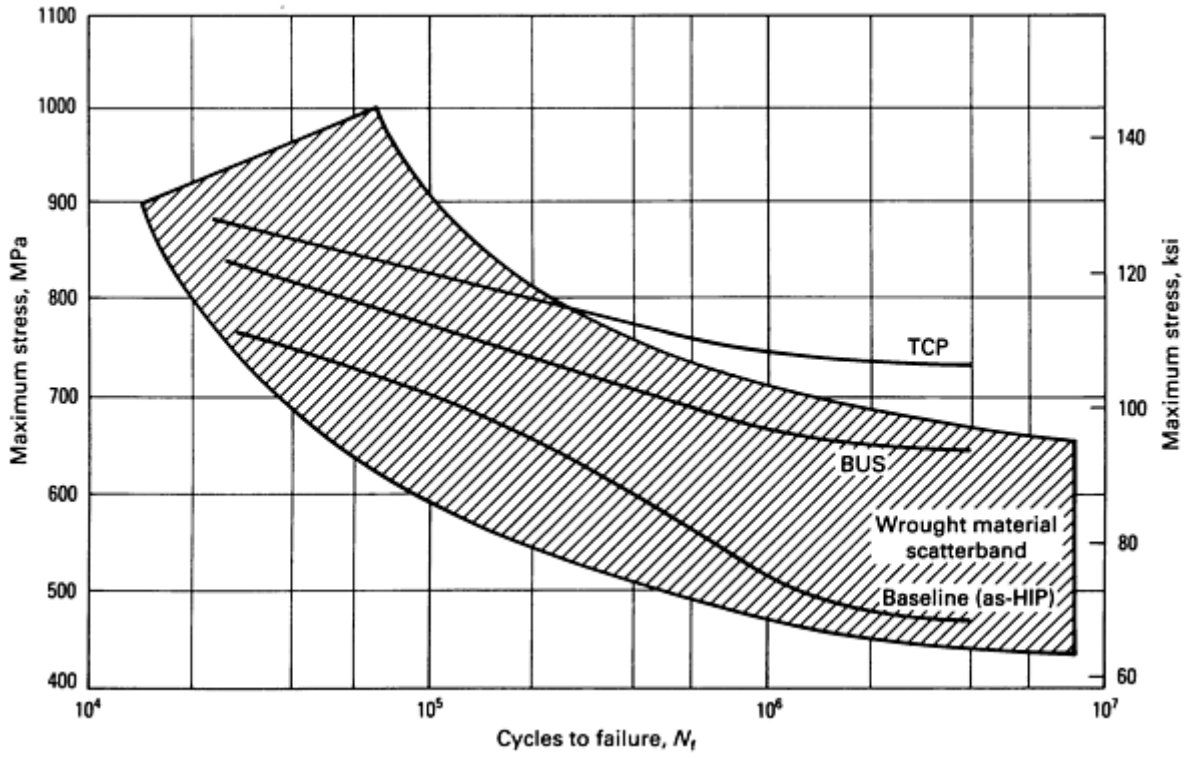

Fig. 7 Comparison of the fatigue strengths of fully dense extra-low chloride Ti-6Al-4V BE compacts with the scatterband for an I/M alloy. The BE compacts were tested in the as-HIP, broken-up structure (BUS), and thermochemically processed (TCP) conditions. Smooth axial fatigue data were obtained at room temperature. Stress ratio (*R*), 0.1; frequency (*f*), 5 Hz with triangular waveform. Source: Ref 27

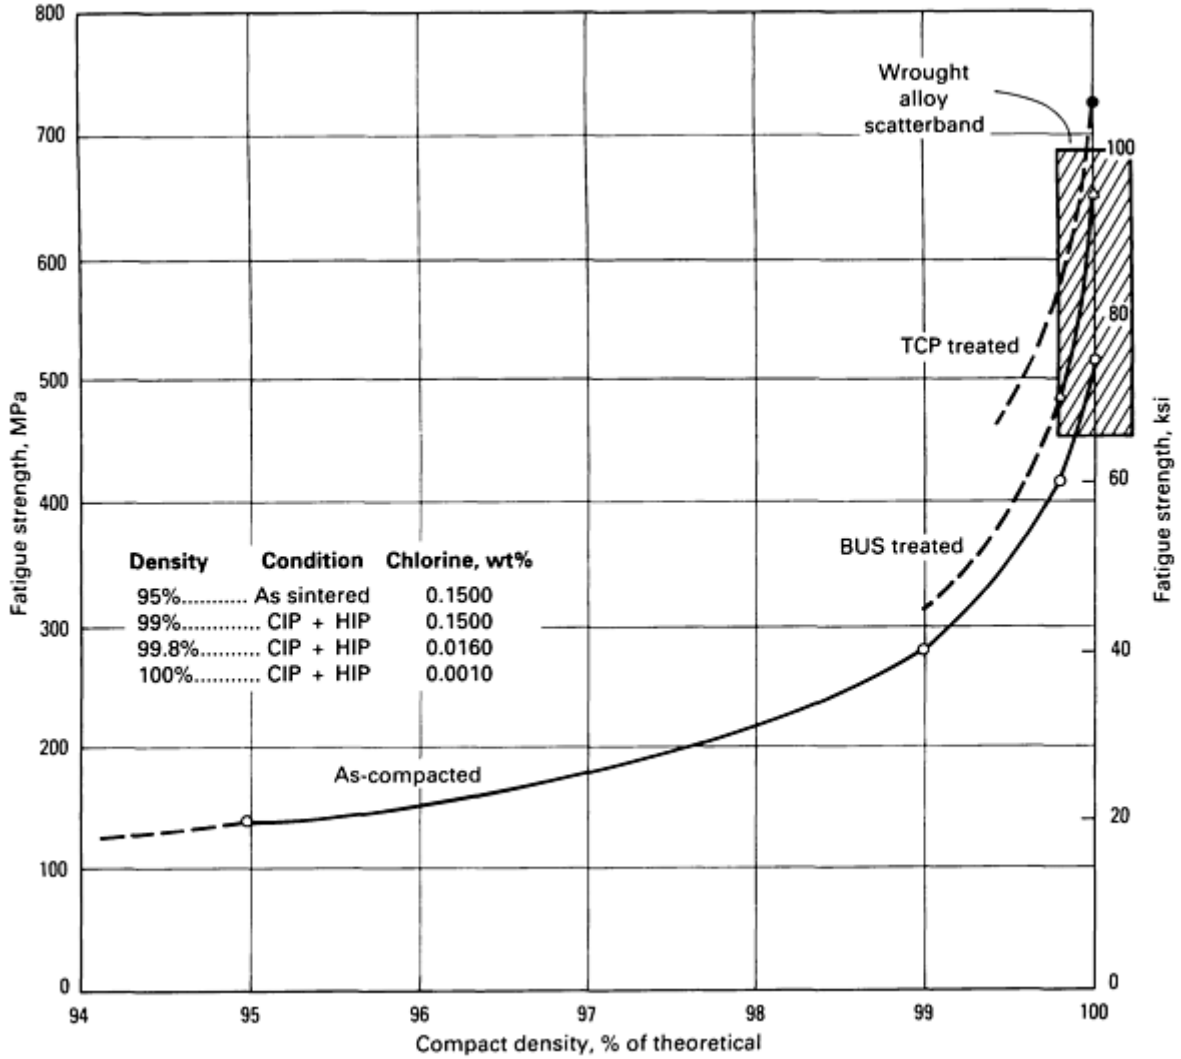

Fig. 8 Effect of compact density on fatigue strength of CIP and sintered Ti-6Al-4V BE compacts. Note that the higher densities are only possible in the low-chloride material. BUS, broken-up structure; TCP, thermochemical processing. Source: Ref 15

Very limited data is available on the fatigue crack growth rate of Ti-6Al-4V BE compacts. Figure 9 shows that the fatigue crack growth rate of this material is between that of a β-annealed materials and that of a mill-annealed I/M material (Ref 26). The BE material tested had a porosity of 1 to 2 vol%, which at this level seems not to adversely influence the fatigue crack growth rate.

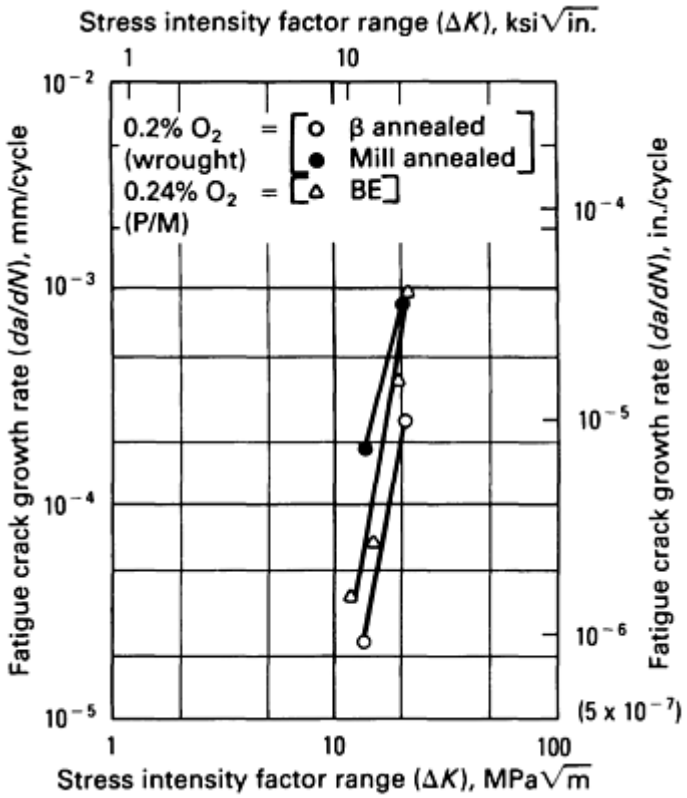

Fig. 9 Comparison of fatigue crack propagation rates of BE and I/M Ti-6Al-4V as a function of the stress intensity factor range at room temperature in air. Stress ratio (*R*), +0.1 (*R* = $\sigma_{min}/\sigma_{max}$, where σ_{min} is the minimum stress and σ_{max} is the maximum stress); frequency (*f*), 5 Hz. Source: Ref 26

Prealloyed Compacts

While BE compacts are produced and used in a wide range of densities, PA P/M parts are acceptable only at 100% density (Ref 2, 3, 4, 5, 15, 35). The titanium PA powders are commercially available as spherical particles that have high tap density (65%) and good powder flow and mold fill characteristics. Two main production methods are used for making clean PA powder:

- Gas atomization (Ref 36)
- Plasma rotating-electrode process (PREP) (Ref 37), a modification of the older rotating-electrode process (REP) (Ref 38)

It is also possible to produce PA powders by comminution (Ref 39) and coreduction (Ref 40, 41) methods. However, because of insufficient mechanical property data, these techniques will not be discussed in this article.

Hot isostatic pressing is the primary compaction method for PA powders (Ref 2, 3, 4, 5, 15, 35), but vacuum hot pressing (VHP) (Ref 42, 43), extrusion (Ref 44), and rapid omnidirectional compaction (ROC) (Ref 45, 46, 47, 48) have also been successfully used. The shape-making step is achieved by containing the powder in a shaped, evacuated mild-steel can. The compaction is typically carried out at a temperature below the β transus to minimize reaction with the can. Processing in the α + β phase field results in a coarse low-aspect-ratio α structure (Fig. 10a). This material is most commonly compared to mill-annealed I/M material because of its microstructure and full density.

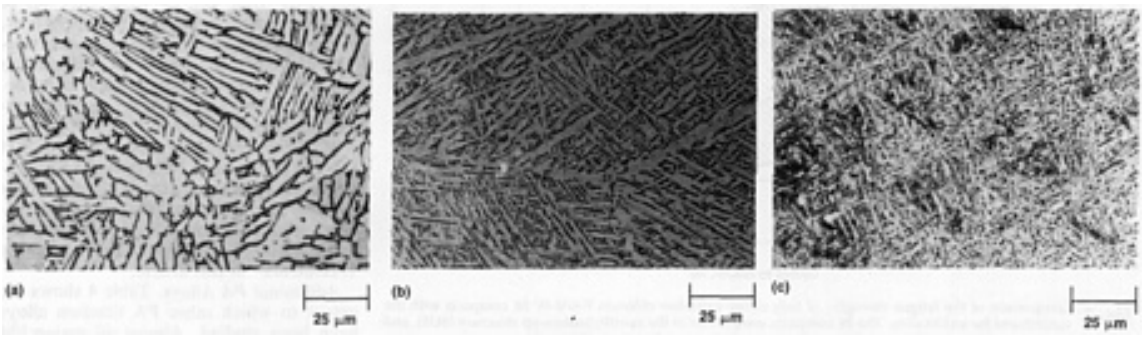

Fig. 10 Microstructure of Ti-6Al-4V PA compacts. (a) As-HIP. (b) Treated to produce a broken-up structure. (c) Thermochemically treated

Powder cleanliness is one of the main factors governing the quality of PA compacts. Because of the full compact density, even a low level of contamination with foreign particles will lead to a substantial loss of inherent properties such as fatigue strength (Ref 49). As a result, only data obtained from clean powders are considered in this article. Also, because fully dense PA compacts are considered for more demanding applications than are the less-dense BE compacts, more mechanical test data have been developed within the aerospace industry on PA P/M than on BE P/M compacts. Only data considered to be typical are reviewed in this article. The majority of PA work has been done on Ti-6Al-4V.

Tensile Properties and Fracture Toughness. Table 3 is a comprehensive listing of the tensile properties of Ti-6Al-4V PA compacts processed under various conditions. Table 4 provides limited information on the properties of additional alloys. When the alloy compacts are produced using HIP (Ref 55), VHP (Ref 42), or ROC (Ref 48) at higher pressures but at lower temperatures, higher strength levels without losses in ductility are achieved. This is the result of the substantial microstructure refinement developed during high-pressure low-temperature powder processing. Similarly, postcompaction hot work, such as rolling (Ref 57) or forging (Ref 58), results in microstructural refinement that improves tensile strength and ductility. Property improvement after postcompaction treatments are discussed in the section "Postcompaction Treatments" in this article.

Additional PA Alloys. Table 4 shows the extent to which other PA titanium alloys have been studied. Almost all major I/M alloys have been evaluated in the PA P/M form. These include the high-strength metastable β alloys (Ref 33, 52, 65, 66, 67, 68), the versatile α + βalloys (Ref 63, 64, 66), the high-temperature near-α alloys (Ref 59, 60), and the ordered titanium aluminide alloys (Ref 70, 71, 72). Of special interest is the alloy Ti-1.3Al-8V-5Fe (Ref 67, 68, 69): This alloy has a remarkable tensile strength of 1516 MPa (220 ksi) with 8% elongation. With conventional I/M methods, the high iron content of this alloy results in segregation problems. Powder metallurgy, on the other hand, produces fine-grain, homogeneous, and segregation-free products. Such alloys have the potential of expanding the market for titanium P/M technology.

Fatigue Strength and Crack Propagation. The smooth-bar fatigue life scatterband of Ti-6Al-4V PA compacts is compared to that of a mill-annealed I/M alloy in Fig. 6 (Ref 4). The P/M data were obtained by testing high-cleanliness REP and PREP compacts that had undergone hot isostatic pressing; some of the compacts received a postcompaction heat treatment. The data for the PA compacts are at equivalent levels to the best I/M results. Powder contamination must be

avoided to maintain a high fatigue strength in these materials. The effect of 50, 150, and 350 μm (0.002, 0.006, and 0.014 in.) diam contaminants on the fatigue strength of Ti-6Al-4V PA compacts is shown in Fig. 11 (Ref 49). Even 50 μm (0.002 in.) contaminant particles are sufficient to noticeably reduce fatigue strength. Fatigue 12 compares the fatigue characteristics of an actual P/M component to those of an I/M material: Figure 12(a) shows results for smooth-bar high-cycle fatigue, Fig. 12(b) covers notched-specimen high-cycle fatigue, and Fig. 12(c) shows data for strain-controlled low-cycle fatigue. In general, high-cycle fatigue results are in the range of 10^6 to 10^8 cycles to failure, and low-cycle fatigue results fall below 10^5 cycles to failure. For all three tests, the P/M alloy performance was comparable to or exceeded that of the I/M material. The component tested is an actual Ti-6Al-4V P/M part used in military airframes (Ref 61).

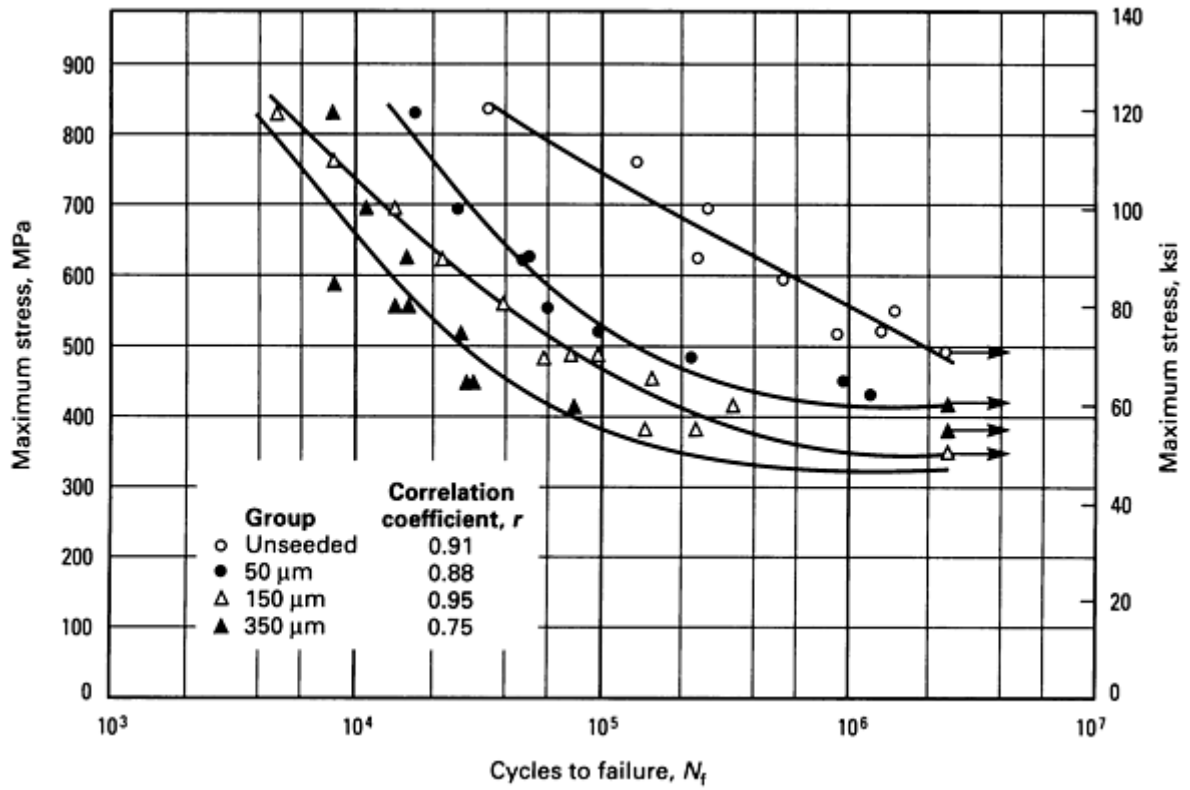

Fig. 11 Effect of contaminant particles on the room-temperature fatigue strength of Ti-6Al-4V PA compacts. Unseeded compacts are compared with SiO_2-seeded PREP compacts. Stress ratio (*R*), +0.1; frequency (*f*), triangular waveform load/time cycle at 5 Hz. Source: Ref 49

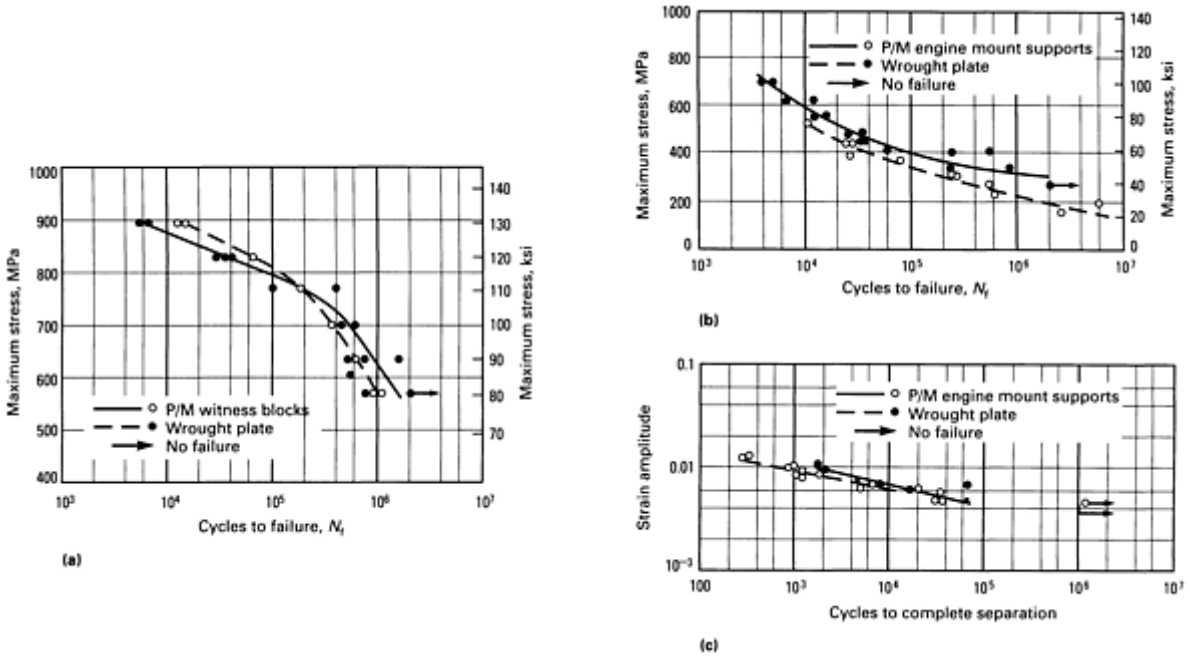

Fig. 12 Comparison of the fatigue strengths at room temperature in air of PREP HIP Ti-6Al-4V P/M components to those of I/M products. (a) Load-controlled smooth-specimen high-cycle fatigue for large bars (13 mm, or $\frac{1}{2}$ in., in diameter). Stress ratio (*R*), 0.1. (b) Load-controlled notched-specimen high-cycle fatigue. Stress concentration factor (K_t), 3; stress ratio (*R*), 0.1 (c) Strain-controlled low-cycle fatigue for small specimens (6.4 mm, or $\frac{1}{4}$ in., diameter). Stress ratio (*R*), -1. Source Ref 73

Figure 13 compares the fatigue crack growth rate of Ti-6Al-4V PA compacts to that of an I/M material with a similar composition and microstructure. Rates are at equivalent levels for both materials, even in PA material with a low level of contamination (Ref 74).

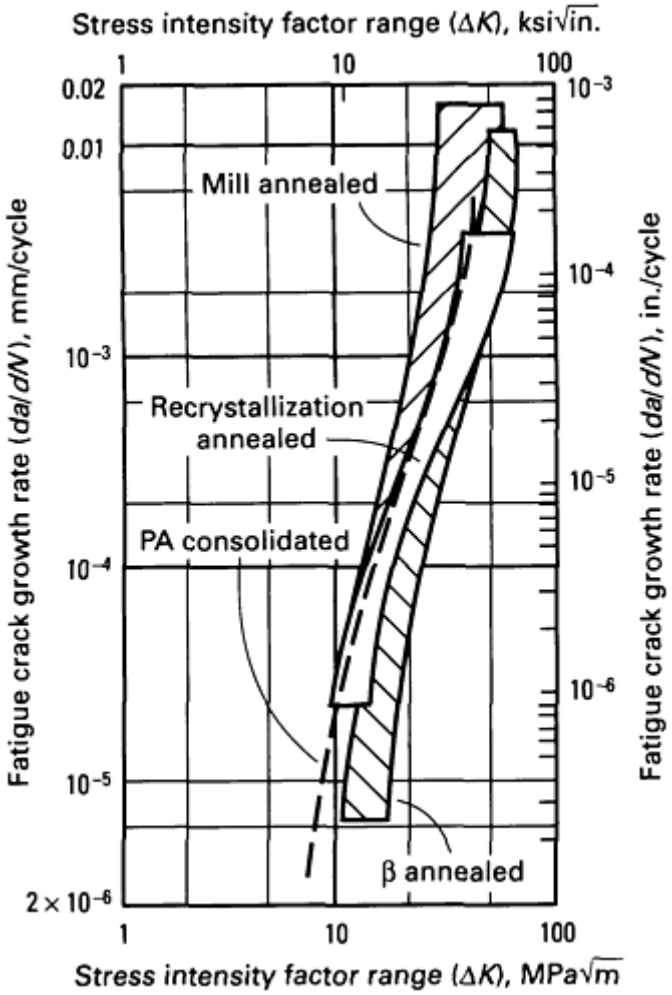

Fig. 13 Comparison of the fatigue crack growth rate at room temperature in air of Ti-6Al-4V PA compacts with that of an I/M alloy material. Stress ratio (*R*), 0.1; frequency (*f*), 5 to 30 Hz (5 Hz for a PA compact). Source: Ref 74

Postcompaction Treatments

Most P/M alloys that are subjected to postcompaction working or to lower-temperature consolidation display improved tensile and fatigue strengths as a result of microstructure refinement. However, in most cases, process economics do not allow subsequent working because it nullifies the objectives of a true net-shape technology. Therefore, only those postcompaction methods leading to microstructure refinement without the use of working will be considered in this article. Two approaches that meet this requirement are heat treatment and thermochemical processing (TCP).

Heat Treatment. In the case of BE Ti-6Al-4V, the only successfully used heat treatment has been the broken-up structure (BUS) treatment in which a β quench is followed by 850 °C (1560 °F) long-term annealing (Ref 27). After such treatment, the microstructure of the alloy is showing broken-up α phase in a matrix of β(Fig. 1e). This microstructure provides a significant improvement in both tensile and fatigue strengths (Fig. 7).

The BUS method is an improvement over standard heat treatments, which typically provide higher tensile properties but no increase in fatigue strength properties.

In the case of Ti-10V-2Fe-3Al BE compacts, β solution treatment and subsequent aging resulted in materials with good combinations of tensile strength and ductility (Ref 33). However, the K_{Ic} was found to be too low (Table 2), possibly because of the high chloride levels and the associated porosity. The Ti-6Al-4V PA compacts responded well to the BUS treatment (Ref 51) (Fig. 10b), as well as to solution treatment and aging (Ref 52). Figure 6 shows the improvement in fatigue strength of both BE and PA Ti-6Al-4V compacts as a result of a microstructure refinement brought about by heat treatment.

Thermochemical Processing. The TCP method (Ref 75) involves the use of hydrogen as a temporary alloying element to refine the microstructure of titanium alloys. This method is very suitable for net-shape products because no hot or cold work is needed to refine the microstructure. An example of the refinement obtained in Ti-6Al-4V P/M products can be seen by comparing Fig. 1(d) with Fig. 1(f) and Fig. 10(a) with Fig. 10(c). This microstructural refinement provides slightly higher strength levels than those typically obtained in I/M or conventional P/M materials (Table 3); more significantly, it substantially enhances the fatigue behavior of the P/M products (Fig. 6, 7, 8).

Applications of Titanium P/M Products

The two distinctively different titanium P/M technologies, the blended element and the prealloyed methods, not only produce compacts with different sets of properties, but also with two different price ranges. The relative low cost of titanium sponge fines and the volume production capability of the pressing and sintering technology allow the production of BE complex-shape aerospace alloy parts at a cost of under $100/kg ($45/lb). Prealloyed powders, on the other hand, require an expensive melt stock, ultraclean handling, and expensive compaction tools. As a result, the higher-performance fully dense PA parts are currently priced above $2000/kg ($90/lb), Although it is projected that volume production will bring this price down substantially. The differences in density, property, and price target these two technologies to different application markets. Because of their lower cost, more BE components than PA parts are currently in use. The introduction of gas-atomized powder (Ref 36) is expected to lower powder costs and make PA products more cost competitive.

Blended Elemental Products

On the low end of the density scale (20 to 80%), commercially pure (CP) titanium filters are produced for electrochemical and other corrosion-resistant applications (Fig. 14a). Higher-density pressed and sintered CP titanium parts, such as the assorted nuts shown in Fig. 14(b), are made commercially for the chemical-processing industry.

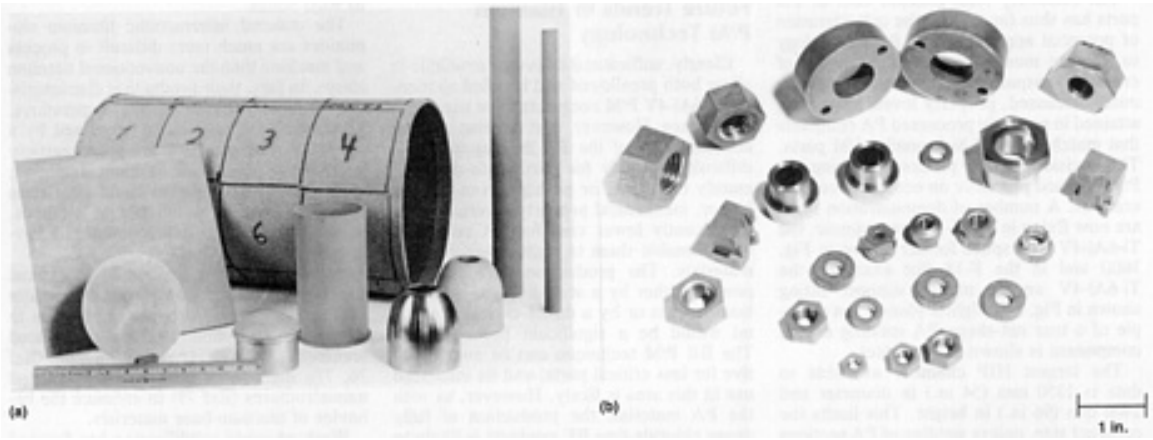

Fig. 14 Commercially pure titanium BE parts. (a) Assortment of porous filters for electrochemical processes. (b) Assortment of parts for the chemical industry. Courtesy of Clevite Industries

For more demanding applications, Ti-6Al-4V BE components with densities from 98% to close to 100% are produced by the CIP and sintering and by the pressing and sintering methods. Very complex shapes, such as the impeller shown in Fig. 15(a) or the McDonnell-Douglas F-18 pivot fitting shown in Fig. 15(b), can be produced by CIP using elastomeric molds (Ref 7). Part size is currently limited to a maximum length of 610 mm (24 in.) by the availability of CIP equipment. The possible dimensional tolerances for small parts are ±0.5 mm (±0.02 in.). The missile housing (Fig. 15c) and the lens housing (Fig. 15d) are production run parts made by the CIP method. The airframe prototype part (Fig. 15e) is made out of chloride-free powder and is fully dense.

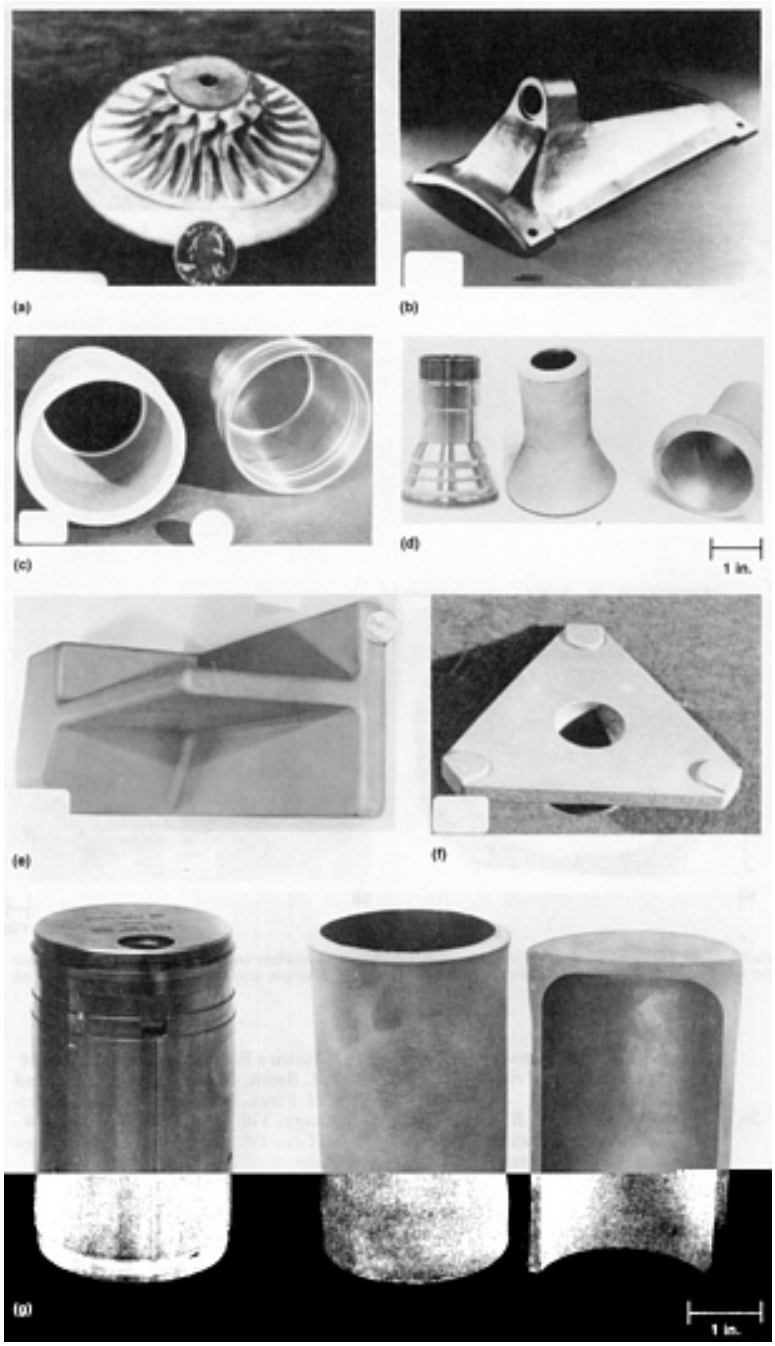

Fig. 15 Aerospace and automotive Ti-6Al-4V components produced by the BE method. (a) Impeller. (b) F-18 higher plane pivot fitting. (c) Missile housing. (d) Lens housings. (e) Prototype for a 100% dense airframe component. (f) Net-shape 35 mm ($1\frac{3}{8}$ in.) diam mirror hub. (g) Automotive cylinder. Courtesy of Dynamet Technology (a, c, and e), Metal Powder Industries Federation (b), Clevite industries (d,g), and Valform (f)

The pressing and sintering method is more volume oriented. The mirror hub (Fig. 15f) is an example of such a production part. Recently, Ti-6Al-4V BE parts are being considered for use in the automotive industry in an effort to increase performance at a moderate cost; the cylinder in Fig. 15(g) is an example of a BE automotive component.

Prealloyed Products

The relatively high product cost of PA parts has thus far limited the consideration of potential applications of PA technology to, for the most part, the manufacture of critical aerospace components. As previously discussed, property levels have been attained in properly processed PA compacts that match those of high-quality I/M parts. The decision-

making process for using PA P/M is based primarily on economic considerations. A number of demonstration parts are now flying in the F-15 (for example, the T-6Al-4V keel splice former shown in Fig. 16(a) and in the F-18 (for example, the Ti-6Al-4V engine mount support fitting shown in Fig. 16b) fighter planes. An example of a true net-shape PA rotating engine component is shown in Fig. 16(c).

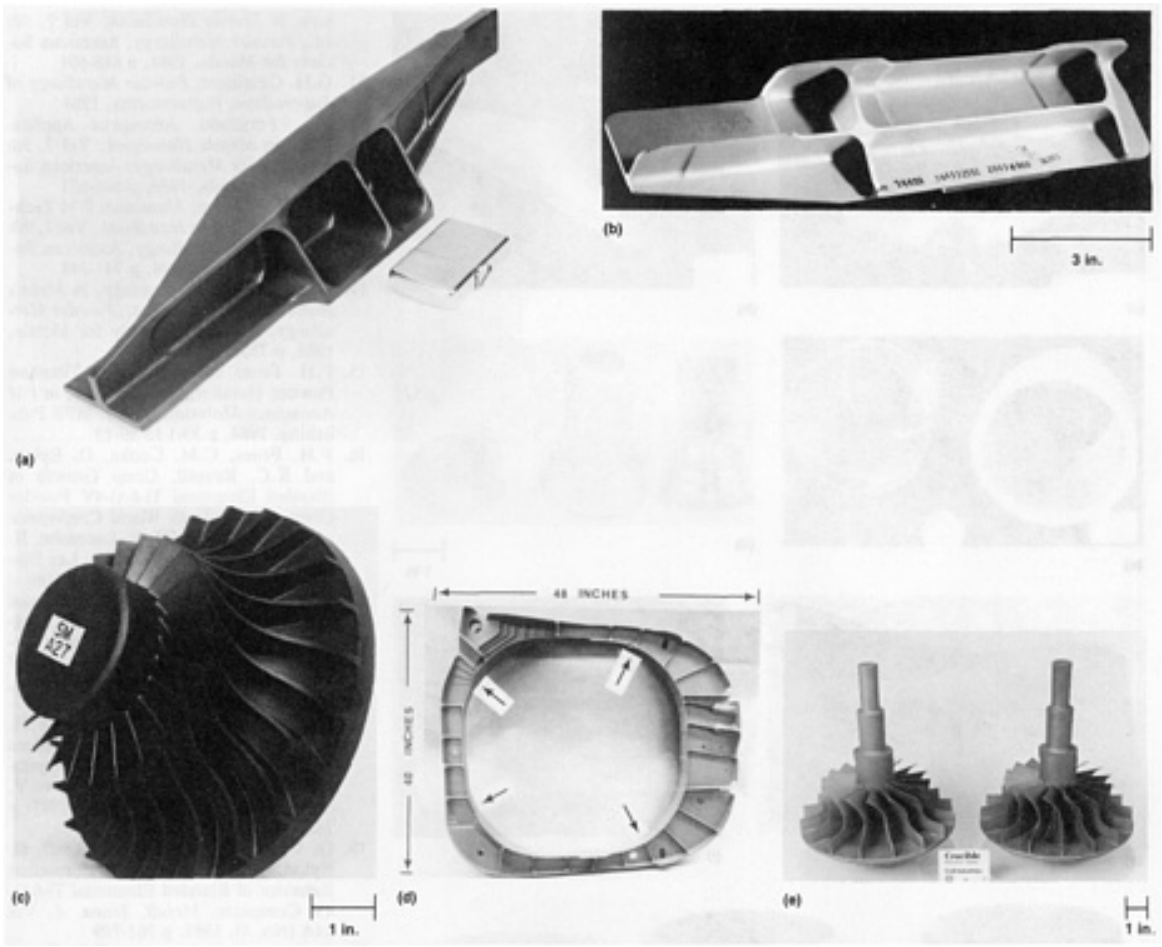

Fig. 16 Prealloyed HIP Ti-6Al-4V aerospace parts produced by the Crucible ceramic mold method. (a) F-14 fighter plane fuselage brace. (b) F-18 fighter plane engine mount support fitting. (c) Cruise missile engine impeller. (d) Four-section welded nacelle frame structure. (e) Titanium aluminide demonstrator impeller. All courtesy of Crucible Research Center

The largest HIP chamber available to date is 1350 mm (54 in.) in diameter and 2400 mm (96 in.) in height. This limits the compact size, unless welding of PA sections is used as it is for the part shown in Fig. 16(d). The increased demand for the brittle and hard-to-machine titanium aluminides, which are used for higher-temperature applications, is creating a new interest in titanium PA P/M technology. A demonstrator impeller made out of titanium aluminide PREP powder is shown in Fig. 16(e). All of the above-mentioned PA parts were made by the Crucible ceramic mold process (Ref 7).

Future Trends in Titanium P/M Technology

Clearly, sufficient data is now available to allow both prealloyed and blended elemental Ti-6Al-4V P/M compacts to be used with confidence. However, cost remains a major concern: Use of the PA P/M approach is difficult to justify for parts with approximately the same, or perhaps even slightly higher, mechanical property levels. Only a significantly lower cost for PA compacts would enable them to replace reliable I/M materials. The production of a low-cost powder either by a scaled-up gas atomization process or by a direct chemical method would be a significant breakthrough. The BE P/M technique can be cost effective for less critical parts, and its increased use in this area is likely. However, as with the PA material, the production of fully dense chloride-free BE products is likely to be stymied by cost unless a breakthrough occurs.

The trend with other conventional titanium P/M alloys is likely to follow that described above for the Ti-6Al-4V alloy. An exception is the high-strength Ti-1.3Al-8V-5Fe (Ti-185) alloy (Ref 67, 68, 69), which cannot be satisfactorily made by the I/M approach because of the segregation of the iron. This alloy should be strictly classified with rapid solidification alloys (discussed below) that require rapid transformation from the liquid to solid states.

The ordered intermetallic titanium aluminides are much more difficult to process and machine than the conventional titanium alloys. In fact, their production characteristics approach those of the superalloys. Thus, the cost benefits to be gained by a net-shape P/M approach are great (particularly for the equiatomic titanium aluminide, TiAl), and these benefits could accelerate the acceptance of titanium P/M methods, particularly with the development of a lower-cost powder.

Research is being conducted to expand the boundaries of conventional titanium P/M technology. Efforts are in progress to evaluate the possibility of using advanced techniques such as rapid solidification (Ref 76, 77), mechanical alloying (Ref 78), and nanostructures (Ref 79) to enhance the behavior of titanium-base materials.

Work on rapid solidification has focused on increasing the temperature capability of both terminal alloys and intermetallic compositions by dispersion strengthening. However, while some improvements have been made, they are not considered to be significant enough to warrant the extra cost and concern over product quality assurance associated with a P/M method. The rapid solidification technique has two major drawbacks. The first is that it has been unable to produce more than about 6 vol% of second-phase particles. The second drawback is that rapid solidification results in a β grain size that is much smaller than is desirable and that there is a lack of elongated α phase, which would be formed on cooling into the α-β phase field after a β anneal. Unfortunately, a β anneal, which corrects the second drawback, results in unacceptable coarsening of the dispersoids.

Mechanical alloying of titanium alloys is at a very early stage, but it does exhibit the potential to increase the volume percentage of dispersoids for elevated-temperature applications. In addition, there are indications that the normally immiscible titanium and magnesium can be combined by mechanical alloying to produce a low-density titanium alloy.

Very preliminary results on the mechanical alloying of titanium-magnesium and titanium-eutectoid formers such as nickel and copper suggest that a very fine nanoscale microstructure (~10^{-9} m scale) can be obtained; such a microstructure could have novel physical and mechanical properties.

Zirconium and Hafnium

R. Terrence Webster, Teledyne Wah Chang Albany

Introduction

ZIRCONIUM was discovered by Klaproth in 1789, but it was not isolated as a metal until 1824, when Berzelius prepared an impure zirconium metal powder. In 1925, VanArkel and DeBoer developed a purified metal using the iodide decomposition process. This process is still used today to purify zirconium and hafnium metal extracted from their ores. In 1947, the magnesium reduction method for extracting the metal from zirconium tetrachloride was developed at the U.S. Bureau of Mines in Albany, OR by W.J. Kroll.

The properties of zirconium established by the U.S. Bureau of Mines indicate that it is ductile and has useful mechanical properties similar to those of titanium and austenitic stainless steel (see the article "Wrought Stainless Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook*). Zirconium has excellent resistance to many corrosive media, including superheated water, and it is transparent to thermal energy neutrons. These properties prompted the U.S. Navy to use zirconium in water-cooled nuclear reactors as cladding for uranium fuel. In 1958, zirconium became available for industrial use and began to supplant stainless steel as a fuel cladding in commercial power station nuclear reactors. Also, the chemical-processing industries began to use zirconium in several severe corrosion environments.

Today, a high proportion of zirconium is used in water-cooled nuclear reactors; the next largest use is in chemical-processing equipment. Additional uses are in flashbulbs, incendiary ordnance, and gettering contaminating gases in sealed devices such as vacuum tubes.

Hafnium was discovered in 1922 by Coster and DeHevesy. It was shown to occur in the same minerals with zirconium in quantities of 1.5 to 4%. Development programs at Oak Ridge National Laboratory produced a liquid-liquid separation process for separating the hafnium fraction from zirconium.

Hafnium has a high-capture cross section for thermal energy neutrons and has consequently found use in nuclear reactor control rods. Previously, the principal application of hafnium was as a neutron absorption material; currently, however, more hafnium is used in superalloys than in reactor applications. Both zirconium and hafnium are essential alloying metals in other metal systems such as aluminum, copper, magnesium, and titanium alloys and the superalloys.

Metal Processing

Zirconium, hafnium, and titanium are produced from ore that generally is found in a heavy beach sand containing zircon, rutile, and ilmenite. Zircon, which is also a gemstone, is a zirconium-hafnium silicate (Zr-Hf, SiO_4) with a zirconium-to-hafnium ratio of 50 to 1. The zircon is separated from rutile, ilmenite, and other minerals by standard ore dressing methods.

The manufacturing of purified zirconium and hafnium metals is a complicated process (Fig. 1). Extraction is accomplished by mixing the zircon with carbon in the form of coke; the mixture is then chlorinated to produce a high-temperature gas stream containing silicon tetrachloride in addition to zirconium and hafnium tetrachlorides. The zirconium-hafnium tetrachloride is selectively condensed, and the silicon tetrachloride is collected and sold as a by-product.

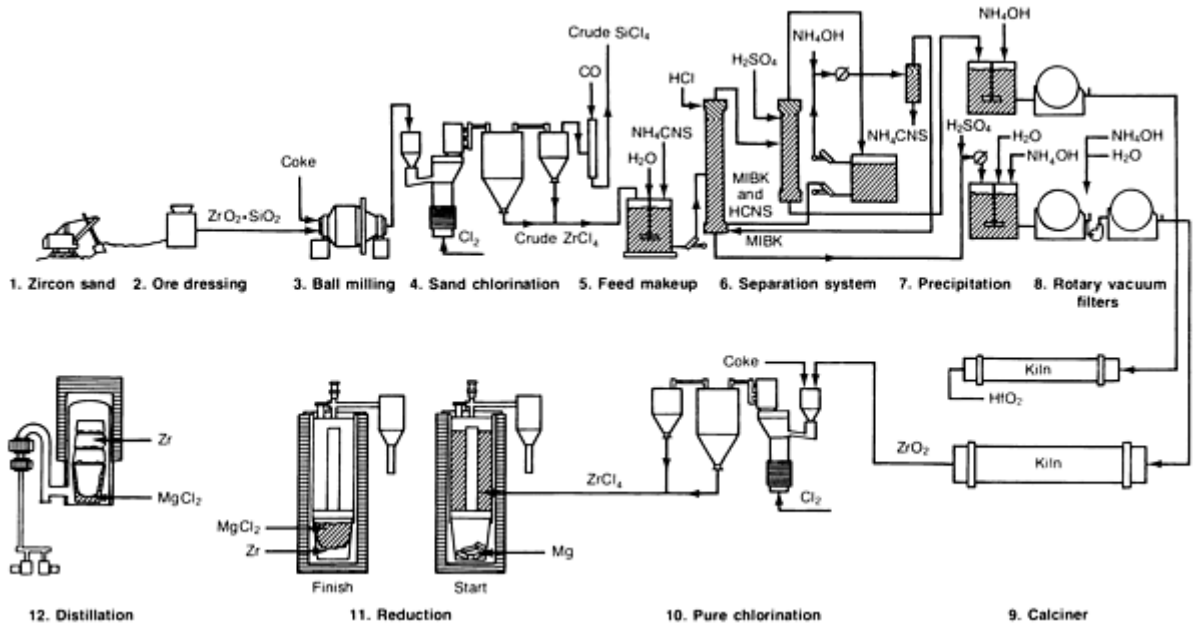

Fig. 1 Flow diagram of the 12 steps required to extract and separate zirconium and hafnium from raw material zircon ore

To produce the industrial grades of zirconium, the crude zirconium-hafnium tetrachloride can be sublimated and reduced to the metal with magnesium. Zirconium for nuclear applications must be separated from hafnium. This is accomplished by one of two processing methods, a liquid-liquid separation process or a distillation process.

Liquid-Liquid Separation Process (Ref 1)

The crude zirconium-hafnium tetrachloride ($ZrCl_4$, $HfCl_4$) is dissolved in water and hydrochloric acid, the zirconium cores are complexed with ammonium thiocyanate (NH_4CNS), and the hafnium is extracted by methyl isobutyl ketone (MIBK). The hafnium content is reduced after many extraction phases to less than 100 ppm. The hafnium is stripped from the solvent and leaves the system in a separate stream from the zirconium stream. The two streams are treated in similar fashion to produce the pure metals (Fig. 1 from step 9 forward).

The aqueous zirconyl chloride is treated first with sulfuric acid and then heated to precipitate basic zirconium sulfate. The basic zirconium sulfate is recovered by filtration and treated with ammonia solution to produce zirconium hydroxide, which is calcined to produce a finely powdered zirconium oxide. The oxide is blended with carbon and then chlorinated to hafnium-free zirconium tetrachloride. This product is further purified by sublimation; it is then reduced to the metal with magnesium by the Kroll process. The resulting porous metal is called sponge metal.

Distillation Separation Process

In the distillation separation process (Ref 2), the crude product obtained after chlorinating the zircon sand is purified by sublimation. The pure tetrachloride vapors are continuously fed into the middle of a separating column containing a solvent made of melted KCl-$AlCl_3$ that is flowing from top to bottom. The chlorides are fed at a rate of about 900 kg/h (2000 lb/h), and the column is maintained as consistently as possible to a temperature of about 350 °C (660 °F) (Fig. 2).

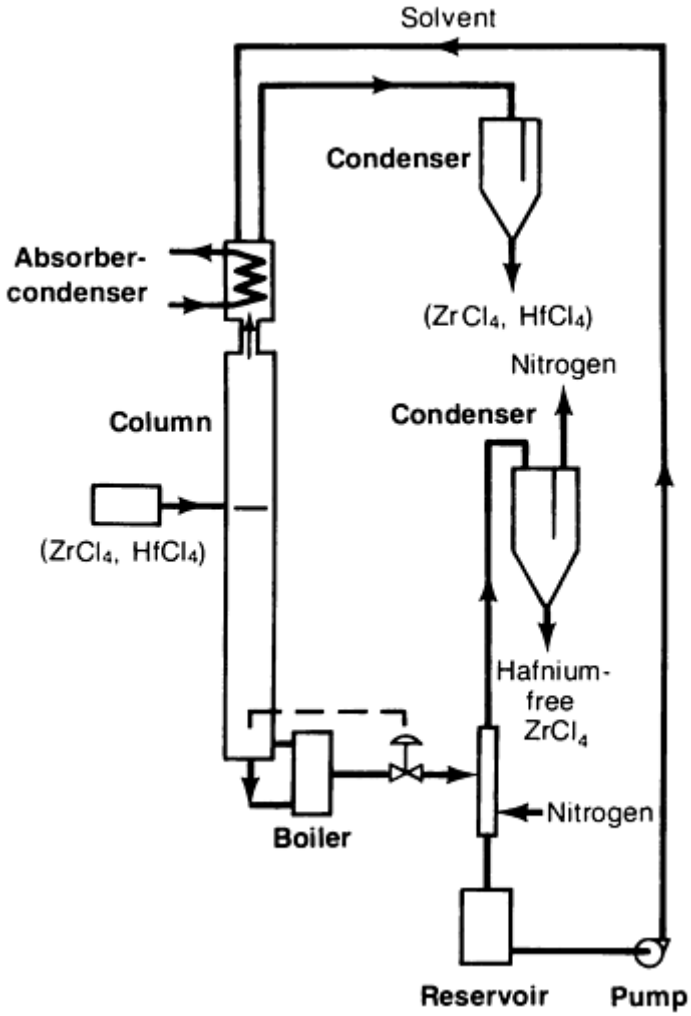

Fig. 2 Flow diagram for hafnium extraction by distillation from molten salt

The vapors of the zirconium tetrachloride, generated in a reboiler at about 500 °C (930 °F), rise in a counterflow against the descending solution of potassium chloroaluminate saturated with zirconium and hafnium chlorides. The rising vapor flow is progressively enriched with hafnium chloride, while the stream of liquid going downward progressively loses its hafnium chloride.

The solvent leaving the reboiler at a temperature of about 500 °C (930 °F) still contains a small percentage of zirconium chloride. This remaining content is completely removed with a stripping column, and the solvent can be recycled to the top of the column through the absorber-condenser. The zirconium tetrachloride stripped in the nitrogen stream (flowing at a rate of 50 m^3/h, or 1800 ft^3/h) is cooled and condensed. This tetrachloride is used directly in the Kroll reduction.

The solvent, stripped of the zirconium tetrachloride and pumped to the top of the column, is fed to an absorber-condenser at a temperature of about 350 °C (600 °F). The solvent dissolves many of the vapors coming out of the column. A small amount of these vapors, enriched in hafnium tetrachloride (30 to 50% $HfCl_4$ content), is not dissolved but instead is condensed by cooling (Fig. 2). This small amount of product has to be reprocessed with the same equipment, but with distinct adjustments, in order to obtain pure hafnium tetrachloride.

Refining

Hafnium sponge metal contains too much oxygen to be ductile and consequently needs to be further refined. For a few applications, zirconium also requires additional refining. The most commonly used method is the iodide decomposition process. In this process, the sponge metal is reacted with iodine in an evaluated and sealed vessel; the resulting metal

iodide is decomposed on an electrically heated wire, forming large metal crystals. The other refining methods are electron beam melting, molten salt electrorefining, and zone refining.

Melting

Zirconium and hafnium are consolidated by electric arc melting in a vacuum or under an inert gas atmosphere using the consumable electrode, cold mold technique.

Zirconium. Zirconium sponge, recycled material from processing, and alloying elements are combined into an electrode for vacuum arc melting. Zirconium alloys are melted at least twice, with the first ingot becoming the electrode for the second melting. Ingots are about 760 mm (30 in.) in diameter and weigh about 6 tonnes (6.6 tons).

Hafnium ingots are usually melted from a mixture of crystal bar, sponge, and scrap selected to meet the required oxygen content. Hafnium ingots are melted in a similar fashion to that of zirconium but are smaller, generally 230 mm (9 in.) in diameter and 500 kg (1100 lb) in weight.

Primary Fabrication

Forging. Hot forging of zirconium ingots is performed starting at 1050 °C (1920 °F), with reheating if the temperature falls below 550 °C (1022 °F). The billets are usually solution annealed in the β-phase region above 1000 °C (1830 °F); solution annealing is followed by a water quench. This last step is performed to homogenize the composition and to improve the ductility and corrosion properties of the zirconium wrought products. Hafnium is forged at temperatures between 1100 and 650 °C (2010 and 1200 °F), with frequent reheats and light reductions.

Hot Rolling. Zirconium and hafnium are hot rolled in the 800 to 550 °C (1470 to 1020 °F) temperature range. Hot-rolled products are annealed at 760 °C (1400 °F).

When heated above 650 °C (1200 °F), zirconium and hafnium form a very refractory white or tan oxide that overlays a black, tenacious adherent oxide layer. These oxide layers are mechanically removed by blasting with metal or abrasive grit, followed by pickling with a solution containing 30% nitric acid and 3 to 5% hydrofluoric acid.

Cold rolling requires strong stiff mills to obtain good reductions and maintain good shape. Lubrication is required to produce a smooth surface finish and to avoid the pickup of the metals on the mill rolls. Reductions vary widely with grade, thickness, and mill configuration. Reductions between anneals are generally 25 to 75% for zirconium and slightly less for its alloys. Hafnium, unless very low in oxygen, can be reduced only 15 to 25% between annealing heat treatments.

Annealing is usually done in a vacuum to preserve the cold-rolled surface. Argon or helium atmospheres can also be used. Annealing is conducted at a temperature of about 705 °C (1300 °F) for several hours to ensure recrystallization. The strip must be clean prior to annealing because rolling lubricants and most soils will break down and cause discoloration and contamination of the metal during heat treatment.

Extrusion of Tubing. Zirconium is extruded at temperatures ranging from 800 to 675 °C (1470 to 1245 °F). Hafnium is extruded at temperatures above 960 °C (1760 °F).

Most tubing is seamless and made from extruded hollows. Bare zirconium will adhere to extrusion tooling, running along both the tools and the extrusion when conventional lubricants are used. Zirconium is currently extruded using either a metal cladding, a proprietary solid film lubricant, or the Ugine-Sejournet glass lubrication technique. Extrusion conditions

and ratios vary widely for producing tube hollows. Some large pipe sizes are extruded to size, but most tubes are cold reduced from larger extrusions.

The primary method for the cold reduction of zirconium tubing is pilgering, also called rocking or tube reducing. The most common machines employ a set of reciprocating grooved rolls and a tapered mandrel. As the larger tube is fed into this device, it is rolled in small increments to the smaller size. Very large reductions of 70% or more can be made in a single pass. Plug and mandrel die drawing are also possible; however, these processes are no longer in wide use because of lubrication problems and because they produce only small reductions of about 15% per step.

The manufacture of zirconium tubing for nuclear fuel cladding requires careful manipulation of the cold reductions so that the correct crystallographic texture or preferred orientation is developed. It is desirable to have high ratios of wall thickness reduction to tube diameter reduction. This ratio is called the *Q*-factor.

Rod and Wire. Hafnium is not fabricated into tubing. Hafnium and zirconium are hot swaged at 800 to 550 °C (1470 to 1020 °F) and cold drawn to rod and wire.

Casting. Zirconium castings for valves, pumps, and other parts are cast in both rammed and machined graphite molds or in molds made by the investment technique. The metal is usually melted by consumable arc skull-melting methods. Additional information is available in the article "Zirconium and Zirconium Alloys" in *Casting,* Volume 15 of *ASM Handbook,* formerly the 9th Edition *Metals Handbook.*

Secondary Fabrication

Machining. Three basic machining parameters should be used for all operations involving zirconium and hafnium alloys:

- Slow speeds
- Heavy feeds
- A flood coolant system using a water-soluble oil lubricant

Zirconium and hafnium exhibit a marked tendency to gall and work harden. Therefore, higher-than-normal clearance angles on tools are needed to penetrate the previously work-hardened surface and cut a clean, coarse chip.

Good results can be obtained with both cemented-carbide and high-speed tools. However, cemented carbide usually provides a better finish and higher productivity. Zirconium and hafnium alloys machine to an excellent finish, and the operation requires relatively light horsepower compared with that for alloy steel. Fine chips should not be allowed to accumulate on or near the machining equipment because they can be easily ignited. The chips should be continually removed and stored, preferably under water in remote and isolated areas that are far removed from the production site. Additional information is available in the article "Machining of Reactive Metals" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Grinding. The grinding methods used for zirconium and hafnium involve standard grinding machine equipment. The grinding characteristics of zirconium and hafnium alloys are similar to those of other metals, and both wheel and belt grinding can be used. The use of straight grinding oil or oil coolant produces a better finish and higher yields; these substances also prevent ignition of dry grinding swarf. Conventional grinding speeds and feeds can be used. Both silicon carbide and aluminum oxide can be used as abrasives, but silicon carbide generally gives better results. Additional information is available in the article "Machining of Reactive Metals" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition of *Metals Handbook.*

Tube Bending. The same techniques and equipment used to cold form stainless steels are also used on zirconium tube. Spring-back caused by work-hardening behavior may be encountered, and provisions for this should be made for any bending operation. For cold forming, a minimum bend radius of approximately three times the outside diameter is advisable. Hot forming at temperatures from 200 to 425 °C (390 to 795 °F) or the use of special bending techniques is required for bends of smaller radius. To prevent buckling and wall thinning, both the inside and outside tube surfaces at the bend area must be in tension during any bending operation.

Drawing and Spinning. In spite of the work-hardening characteristics of zirconium, it has good hot and cold formability. Designs that eliminate severe or abrupt section changes and that allow generous radii are essential. Dies of nongalling material with tolerances and clearances comparable to those of the dies used for austenitic stainless steels should be employed. As in the case of tube bending, die design should allow for the springback tendency of the material.

Welding. Zirconium and hafnium have a better weldability than some more common construction materials, provided that the proper procedure is followed. Proper shielding from air with inert gases such as argon or helium is very important when welding these metals. Because of the reactivity of zirconium and hafnium to most gases at welding temperatures, welding without proper shielding will allow the absorption of oxygen, hydrogen, and nitrogen from the atmosphere and thus embrittle the weld.

Zirconium and hafnium are most commonly welded by the gas tungsten arc welding (GTAW) technique. Other welding methods used for these materials include gas metal arc welding (GMAW), plasma arc welding, electron beam welding, and resistance welding.

Zirconium and hafnium have low coefficients of thermal expansion and thus experience little distortion during welding. Inclusions are not usually a problem in the welds because these metals have a high solubility for their own oxides, and because no fluxes are used in welding, flux entrapment is eliminated. Zirconium and hafnium both have a low modulus of elasticity; therefore, residual stresses are low in a finished weld. However, stress relief of these welds has been found to be beneficial. A stress-relief temperature of 550 °C (1020 °F) should be used for both zirconium and hafnium.

Zirconium and hafnium are subject to severe embrittlement by relatively minute amounts of impurities, especially nitrogen, oxygen, carbon, and hydrogen. They have a high affinity for these elements at the welding temperature. Because of this high affinity for gaseous elements, zirconium and hafnium must either be welded using arc welding processes with inert shielding gases, such as argon or helium, or be welded in a vacuum. Hafnium ductility is affected to a greater degree by oxygen absorption than is zirconium ductility.

Arc welding in an inert blanket using either a tungsten electrode or consumable electrodes of zirconium gives the best results. The weld puddle, the bead just behind the weld puddle, and the backside of the weld must all be protected from the atmosphere in some manner. The weld puddle and the bead just behind the weld puddle can be protected by secondary shielding, such as a trailing shield.

The most common techniques used for welding zirconium and hafnium are the inert gas GTAW and GMAW methods. This equipment can be set up and used in the manual or automatic welding modes. Alternating current or direct current can be used for gas tungsten arc welding. Straight polarity is preferred for welding with a consumable electrode filler wire because it results in a more stable arc. Additional information is available in the article "Welding of Zirconium Alloys" in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Metallurgy of Zirconium and Its Alloys

Zirconium and most of its alloys exhibit strong anisotropy because of two characteristics of the metal: Zirconium has a hexagonal close-packed (hcp) crystal structure at room temperature, and it undergoes allotropic transformation to a body-centered cubic (bcc) structure at about 870 °C (1600 °F). The strong anisotropy profoundly influences the engineering properties of zirconium and its alloys and must be taken into account when selecting and processing a zirconium metal. The most common alloys are rather dilute α alloys with characteristics generally similar to those of unalloyed zirconium.

The Allotropic Transformation

In zirconium, the low-temperature α phase has a hcp crystal structure. This phase transforms to a bcc structure at about 870 °C (1600 °F). Small amounts of impurities, particularly oxygen, strongly affect the transformation temperature (Table 1).

Table 1 Variation in allotropic transformation temperature with oxygen content for unalloyed zirconium

Temperature		Phases present at oxygen content of:		
°C	°F	1640 ppm	1370 ppm	970 ppm
955	1750	β	β	β
930	1710	α+ β	β	β
925	1700	α+ β	β	β
920	1690	α+β	β	β
915	1680	α	α+ β	β
910	1670	α	α+ β	β
905	1660	α	α+ β	β
895	1640	α	α+ β	α+ β
890	1630	α	α	α+ β
885	1625	α	α	α+ β
865	1590	α	α	α
855	1575	α	α	α

The transformation on cooling generally results in a Widmanstätten structure of α zirconium; β phase cannot be retained even by rapid quenching (Fig. 3). The more rapid the cooling rate, the finer the platelets of the Widmanstätten structure. The phase stability of zirconium is influenced by α- and β-stabilizing elements and by low-solubility intermetallic compound formers.

Fig. 3 Zirconium cooled from 950 °C (1740 °F). Cooling transformation resulted in a Widmanstätten structure. 75×

Alpha-stabilizing elements raise the temperature of the allotropic α-to-β transformation. These elements include aluminum, antimony, tin, beryllium, lead, hafnium, nitrogen, oxygen, and cadmium. Phase diagrams for many of the binary alloy systems formed between these various elements and zirconium exhibit a peritectic or a peritectoid reaction at the zirconium-rich end.

Beta-stabilizing elements lower the α-to-β transformation temperature. Typical β stabilizers include iron, chromium, nickel, molybdenum, copper, niobium, tantalum, vanadium, thorium, uranium, tungsten, titanium, manganese, cobalt, and silver. For binary alloy systems between zirconium and these elements, there usually is a eutectoid reaction, and often a eutectic reaction as well, at the zirconium-rich end of the phase diagram.

Low-solubility intermetallic compound formers such as carbon, silicon, and phosphorus have very low solubility in zirconium, even at temperatures in excess of 1000 °C (1830 °F). They readily form stable intermetallic compounds that are relatively insensitive to heat treatment.

Impurities such as iron and chromium are soluble in β zirconium but relatively insoluble in α zirconium, where they exist primarily as intermetallic compounds. The size and distribution of these secondary phases are largely governed by reactions that take place during the last transformation from β to α and by subsequent mechanical working at lower temperatures.

Heating at temperatures near the α -β transition, or in the α + β region, causes migration of many impurities to grain boundaries. This migration impairs ductility and corrosion resistance, particularly in zirconium alloys (Fig. 4). However, it is beneficial in some instances for unalloyed zirconium.

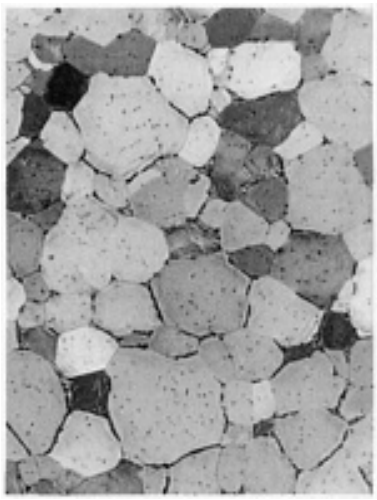

Fig. 4 Zirconium heated at 880 °C (1615 ° F) showing impurities deposited in the grain boundaries. 450×

Cold Work and Recrystallization

The degree to which unalloyed zirconium can be cold worked depends both on metal purity and on the method of reduction. Zirconium work hardens rapidly, reaching maximum hardness and strength after cold reduction of only about 20%. However, reductions of about 50% are common during cold rolling, and reductions of 80% can be accomplished in some instances. Reductions of 90% or more can be obtained by starting with very soft metal and using machines that feature multiaxial loading (such as cold Pilger machines or Sendzimir rolling mills). Reductions during cold drawing are generally about 15 to 30%. Initially, deformation results in twinning, which reorients the lattice for slip; slip is the primary mechanisms for cold working.

Recrystallization is a function of the amount of cold work, temperature, and time, with time playing a relatively small role. In heavily cold-worked material, recrystallization commences at about 510 °C (950 °F). Process annealing of such material is usually conducted at 620 to 790 °C (1150 to 1450 °F). Recrystallization will occur in times, as short as 15 min, but much longer times are normally used to ensure that the entire furnace load reaches temperature. Grain growth is nearly nonexistent at the usual annealing temperatures; times of 100 h or more are required to produce grain growth of 2 to 3 ASTM sizes (Fig. 5).

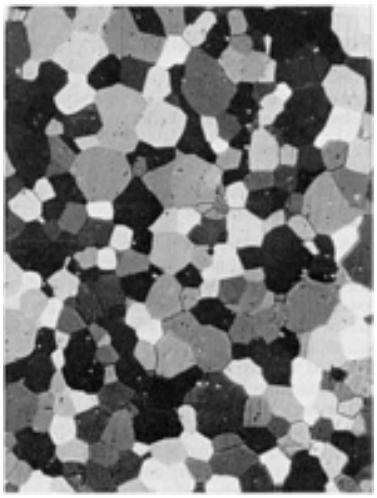

Fig. 5 Recrystallized α zirconium. 300×

Large grains can be grown by annealing after cold reduction of about 5 to 8%. The most common source of large grains is reannealing after a straightening or forming operation that imparts only a small amount of cold work.

Anisotropy and Preferred Orientation

The relationships among the preferred orientation of zirconium crystal structure, the working practice that caused it, and the properties that result from it are complex and have been studied in great detail. For most engineering applications, it is important to understand that wrought forms of zirconium and its alloys have different tensile properties in the rolling direction (or longitudinal direction) than they have in the transverse direction. Yield strength is higher in the transverse direction; tensile strength is slightly higher in the rolling direction.

When the crystallographic texture of zirconium is discussed, it is usually presented in the form of a stereographic basal pole figure of the type shown in Fig. 6(a), or as an inverse pole figure of the type shown in Fig. 6(b).

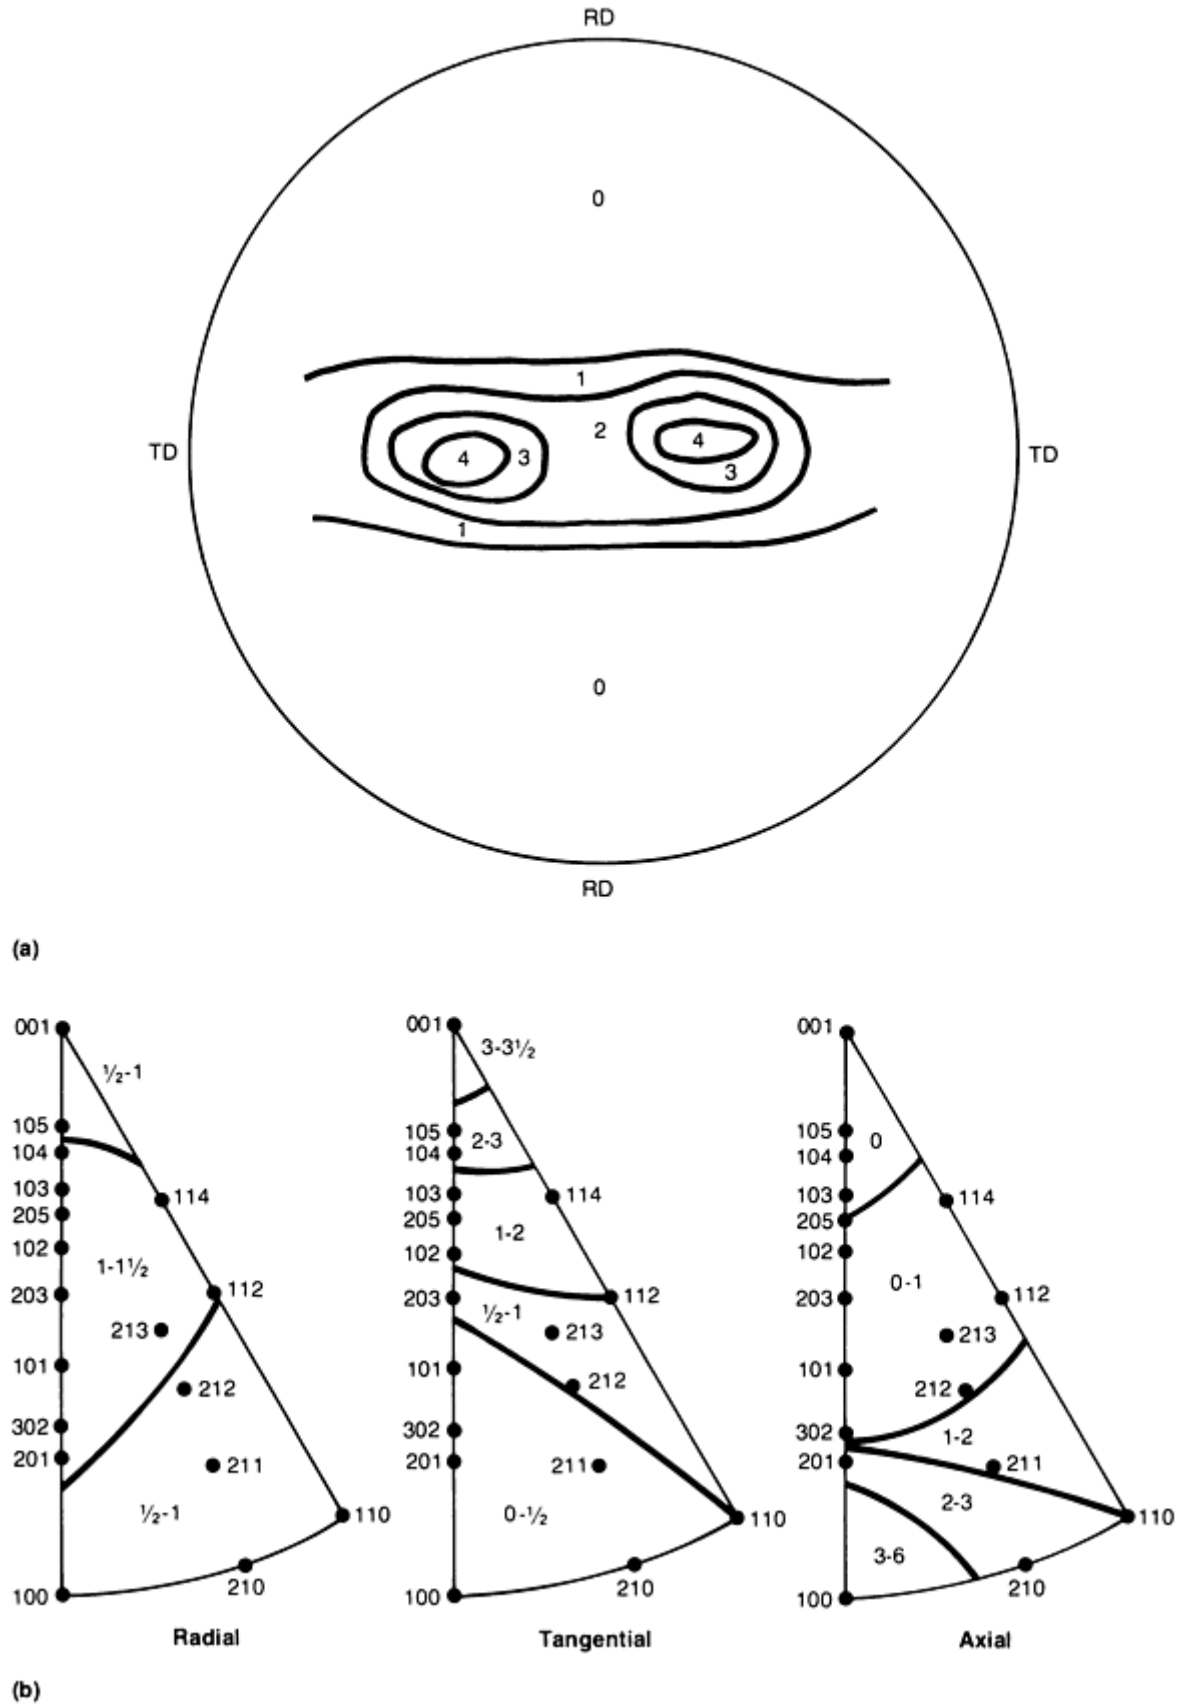

Fig. 6 Typical pole figures for showing anisotropy in zirconium. (a) Stereographic basal pole figure for hot-rolled Zircaloy-2 plate. Numbers indicate the relative densities of the poles in multiples of random occurrence. RD, rolling direction; TD, transverse direction, (b) Inverse pole figure for a typical Zircaloy-2 tubing sample

The Role of Oxygen

Oxygen was originally considered a troublesome impurity in zirconium, and considerable effort was devoted to its elimination. But when oxygen levels were finally reduced below 1000 ppm, it was found that required strength levels in Zircaloy could no longer be met. The status of oxygen then changed to one of a controlled solid-solution alloying agent. Early methods for determining oxygen content were crude and relatively imprecise, so hardness (which is roughly related to oxygen content but much easier to measure) became the controlling attribute and is still widely used to express the purity or grade of both unalloyed zirconium and zirconium alloys.

The oxygen content of Kroll process sponge varies from about 500 to 2000 ppm, depending on the number of purification steps and the effectiveness of each step. A hardness of 125 HB indicates soft sponge with an oxygen content of about 800 ppm, whereas 165 HB is considered hard and indicates an oxygen content of about 1600 ppm. Crystal bar zirconium generally has a hardness level of below 100 HB and contains less than 100 ppm oxygen.

Oxygen is a potent strengthener at room temperature, but much of its effectiveness is lost at elevated temperature.

Zirconium Alloys

The most common zirconium alloys, Zircaloy-2 and Zircaloy-4, contain the strong α stabilizers tin and oxygen, plus the β stabilizers iron, chromium, and nickel. There is an extensive α + β field from about 790 to 1010 °C (1450 to 1850 °F). Iron, chromium, and nickel form intermetallic compounds, and the distribution of these compound phases is critical to the corrosion resistance of the alloys in steam and hot water. These alloys are generally forged in the β region, then solution treated at about 1065 °C (1950 °F) and water quenched. Subsequent hot working and heat treating is done in the α region (below 790 °C, or 1450 °F) to preserve the fine, uniform distribution of intermetallic compounds that results from solution treating and quenching.

Except for being somewhat stronger and less ductile than unalloyed grades, the Zircaloys are quite similar to unalloyed zirconium in metallurgical behavior.

The only other zirconium alloy that has significant commercial importance is Zr-2.5Nb. In zirconium, niobium is a mild β stabilizer; eutectoid reaction is induced when the niobium content exceeds about 1%. (The eutectoid point occurs at 20% Nb.) The mechanical and physical properties of Zr-2.5Nb are very similar to those of the Zircaloys; however, its corrosion resistance is slightly inferior to that of the Zircaloys.

Applications According to Alloy Grades

Nuclear Applications. A high corrosion resistance to high-temperature water and steam in combination with a transparency to thermal energy neutrons (Table 2) make zirconium a highly desirable material for uranium nuclear fuel cladding and other reactor internal structures. Zirconium alloys are used in pressurized-water reactors and boiling-water reactors in the United States, and in Canadian deuterium uranium (CANDU) reactors.

Table 2 Thermal neutron capture cross section of various materials

Element or alloy	Thermal neutron cross section, b[(a)]
Beryllium	0.009
Magnesium	0.059
Lead	0.17
Zirconium	0.18

Zircaloy-4	0.22
Aluminum	0.22
Tin	0.65
Niobium	1.1
Iron	2.4
Molybdenum	2.4
300 series stainless steel	3.1
Nickel	4.5
Titanium	5.6
Hafnium	113
Cadmium	2.4×10^3
Gadolinium	44×10^3

(a) b, barns

The high corrosion resistance of zirconium alloys results from the natural formation of a dense stable oxide on the surface of the metal. This film is self healing, it continues to grow slowly at temperatures up to approximately 550 °C (1020 °F), and it remains tightly adherent. Additional information is available in the section "Corrosion of Zircaloy-Clad LWR Fuel Rods" of the article "Corrosion in the Nuclear Power Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Hafnium has the same high corrosion resistance to high-temperature water and steam as does zirconium, but it also has a very high thermal neutron cross section (see Table 2) and consequently is used as a control rod material, mainly in naval reactors.

Zirconium Alloy Grades. Four reactor grades of zirconium and zirconium alloys are available:

- Reactor grade zirconium (UNS R60001) is highly purified unalloyed zirconium currently used as an inner lining of zirconium alloy fuel cladding tubes. Its resistance to corrosion by hot water and steam is highly variable
- Zircaloy-2 (UNS R60802) is a zirconium-tin alloy with small amounts of iron, chrome, and nickel that is highly resistant to hot water and steam. It is widely used in nuclear reactor service
- Zircaloy-4 (UNS R60804) is a variation of Zircaloy-2, but it contains no nickel and has a higher, more closely controlled iron content. This alloy is also used in nuclear service; it absorbs less hydrogen than Zircaloy-2 when exposed to corrosion in water and steam
- Zr-2.5Nb (UNS R60901) has high corrosion resistance to superheated water, and it is heat treatable to a

higher level of strength than that which can be achieved with the Zircaloys. It was developed for use in pressure tubes of heavy water reactors (such as the CANDU reactors)

The compositions and mechanical properties of the nuclear alloys are summarized in Table 3.

Table 3 Compositions and tensile properties for nuclear grades of zirconium

Designation		Nominal composition, wt%						Minimum tensile strength		Minimum 0.2% yield strength		Elongation in 50 mm (2 in.), %

(a) Typical content

Hafnium is used in control rods in the purified unalloyed form. Hafnium products contain approximately 250 ppm O_2 for fabrication ductility. Available product forms are plate, sheet, foil, rod, and wire. The ASTM specifications B 737, for both hot-rolled and cold-finished hafnium rod and wire, and B 776, for hafnium and hafnium alloy flat-rolled products, relate to these applications. The physical properties of hafnium are listed in Table 4; Table 5 gives the mechanical properties of hafnium products.

Table 4 Physical properties of hafnium

Industrial Applications. Generally, zirconium alloys are less resistant to chemical solutions than in unalloyed zirconium. Zirconium has excellent corrosion resistance to acids, alkalies, organic compounds, and salt solutions. The few media that will attack zirconium include hydrofluoric acid, ferric or cupric chloride, aqua regia, concentrated sulfuric acid, and moist chlorine gas (see the article "Corrosion of Zirconium and Hafnium" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

Zirconium industrial alloys are the hafnium-containing commercial grades of zirconium. They are used in nonnuclear applications such as chemical processing equipment, but they are similar in properties to the nuclear-grade alloys (Table 6). The industrial alloy grades of zirconium are:

- Grade 702 (UNS R60702)--commercial pure zirconium that is similar to reactor-grade zirconium
- Grade 704 (UNS R60704)--a Zr-1.5Sn alloy that is similar to Zircaloy-2 and Zircaloy-4
- Grade 705 (UNS R60705)--Zr-2.5Nb, a higher-strength alloy that is similar to nuclear-grade R60901
- Grade 706 (UNS R60706--an alloy that differs from grade 705 only in having lower oxygen content, lower tensile and yield strength properties, and greater elongation

Table 6 Typical properties and mechanical properties of zirconium alloys

Uranium and Uranium Alloys

K.H. Eckelmeyer, Sandia National Laboratories

Introduction

URANIUM is a moderately strong and ductile metal that can be cast, formed, and welded by a variety of standard methods. It is used in non-nuclear applications primarily because of its very high density (19.1 g/cm^3, or 0.690 lb/in.^{3}; 68% greater than lead). Uranium is frequently selected over other very dense metals because it is easier to cast and/or fabricate than the refractory metal tungsten and much less costly than such precious metals as gold and platinum. Typical non-nuclear applications for uranium and uranium alloys include radiation shields, counterweights, and armor-piercing kinetic energy penetrators.

Natural uranium contains approximately 0.7% of the fissionable isotope U-235 and 99.3% U-238. Ore of this isotopic ratio is processed by mineral beneficiation and chemical procedures to produce uranium hexafluoride (UF_6). Isotopic separation is performed at this stage. This produces both enriched UF_6, which contains more than the natural isotopic abundance of U-235 and is subsequently processed and used for nuclear applications, and depleted UF_6, which typically contains 0.2% U-235. Access to enriched UF_6 is tightly controlled, but depleted material can be purchased for industrial applications. The UF_6 is reduced to uranium tetrafluoride (UF_4), commonly called green salt, by chemical reaction with hydrogen. The UF_4 is then reduced with magnesium or calcium in a closed vessel at elevated temperature, producing 150 to 500 kg (330 to 1100 lb) ingots of metallic uranium commonly referred to as derbies. These derbies are typically vacuum induction remelted and cast into the shapes required for engineering components or for subsequent mechanical working. Alloying elements can also be added during this melting step. Ingot breakdown and primary fabrication processes, such as forging, rolling, and extruding, can be readily carried out between 550 and 640 °C (1020 and 1180 °F) or between 800 and 900 °C (1470 and 1650 °F). The 650 to 780 °C (1200 to 1435 °F) range is avoided because cracking commonly occurs at these temperatures. Secondary fabrication processes such as rolling, swaging, and straightening are commonly done between room temperature and 500 °C (930 °F). Following heat treatment, machining to final dimensions can be carried out by most conventional cutting and grinding techniques, but uranium and its alloys are generally considered difficult to machine. Therefore, special tools and conditions must be applied.

This article presents an overview of the processing and properties of uranium and uranium alloys. Each section includes a few key references, but additional information can be found in previously published reviews (Ref 1, 2, 3, 4, 5, 6, 7, 8) and reports dealing with specific alloys and/or topics referenced in these reviews.

Environmental, Safety, and Health Considerations

While depleted uranium can be melted, fabricated, and machined using conventional metallurgical practices, its mild radioactivity, chemical toxicity, and pyrophoricity require that special precautions be taken in its processing. This section gives a brief overview of the principal hazards and precautions associated with processing depleted uranium. More complete information is available in Ref 9, 10, 11, and information on health and safety considerations in processing other metals is available in the article "Toxicity of Metals" in this Volume. Organizations that process depleted uranium should have their facilities and procedures regularly reviewed and approved by an occupational health and safety organization for compliance with current guidelines and statutory regulations. Personnel and work areas should also be tested and inspected regularly.

Radioactivity. Depleted uranium is only mildly radioactive and is listed as a "low specific activity" (LSA) material in shipping regulations. The primary radiological hazards associated with this material are beta (β) and alpha (α) emission. The β-ray dose rate at the surface of a uranium slug is 0.23 rad/h. The dose rate of this modestly penetrating radiation decreases dramatically with distance from the source, due to absorption in the air and geometric effects. As a result, working near depleted uranium and normal handling of this material does not result in excessive exposures to β radiation. Nonetheless, significant β exposures could result from continuous very close contact, so unnecessary contact (such as carrying material in pockets) should be avoided. In addition, it has recently been shown that during melting and casting operations U-238 daughter products such as Th-234 and Pa-234 tend to float to the surface of the molten uranium and are left as residue in the crucible and on the surface of the casting. These daughter products have much higher activities and produce more energetic β rays. They have half-lives of 1.17 min (Pa-234) to 24.1 days (Th-234). Hence, they result in substantially increased β doses in the vicinities of recently melted materials and warrant greater precautions in areas where such materials are being handled.

Alpha radiation is also emitted by depleted uranium, but this nonpenetrating radiation is almost totally absorbed in 10 mm (0.4 in.) of air or in the 0.07 mm (0.003 in.) thick protective layer of skin and therefore presents no external health hazard. If finely divided particles become airborne and are inhaled, however, they can result in damaging α irradiation of delicate lung tissue. Hence, it is important to ensure that airborne uranium concentrations remain below the Occupational Safety and Health Administration standard of 0.25 mg/m^3 of air.

Toxicity. Depleted uranium is about as chemically toxic as other heavy metals, such as lead. Ingestion of excessive amounts of dust or fumes from these metals can cause problems such as kidney damage. Worker ingestion problems can best be avoided by careful control of any finely divided material and by good personal hygiene practices such as washing hands after handling uranium and avoiding eating in areas where uranium is being processed.

Pyrophoricity. Finely divided uranium is pyrophoric; therefore, machining chips and grinding residue must be handled carefully to avoid the danger of fire. Sparking frequently occurs during cutting and grinding operations, and these sparks can ignite even coarse machining chips such as lathe turnings. More finely divided waste, such as grinding residue, can ignite spontaneously due to the heat produced by natural oxidation. These fire hazards can be minimized by using liberal amounts of machining fluid, keeping machining waste submerged in water or oil, removing chips from tools and work areas frequently, and avoiding mixed metal chips. In addition, dry powder fire extinguishers should be readily available in the event that dry chips ignite. Water should not be used on uranium fires because it reacts with the hot metal and generates hydrogen, adding to the combustion.

As can be seen from the previous paragraphs, the danger associated with the radioactivity, toxicity, and pyrophoricity of large pieces of depleted uranium is minimal, but it increases substantially as the material becomes more finely divided. As a result, operations that produce uranium fumes or finely divided particulates must be carefully vented and the exhausts passed through well-monitored filtering systems. In addition, work areas should be checked regularly for the presence of excessive levels of airborne material or residue on floors, furniture, and equipment. Workers should also change footwear and clothing when entering or leaving areas where finely divided residue is likely to be present, such as areas where uranium is being machined or where hot-worked uranium (with its powdery oxide surface) is handled. Finally, personnel who work with uranium should have their radiation exposures monitored by dosimeters and their ingestion levels checked by periodic urinalyses.

Because of uranium's radioactivity and toxicity, disposal of uranium residue and release of uranium-containing effluents are strictly regulated. Facilities that process uranium must be equipped with the appropriate air- and liquid-handling systems and must monitor their effluents regularly to ensure that regulatory standards are being met.

Processing and Properties of Unalloyed Uranium (Ref 1, 2, 3, 4, 5, 6, 7, 8, 12, 13, 14, 15, 16)

Unalloyed uranium is typically induction melted and poured into molds to produce either engineering components or ingots for subsequent mechanical working. Uranium is a highly reactive metal, so all melting operations must be done in a vacuum. Uranium also reacts with many common crucible materials. To avoid such reactions, vacuum induction furnace crucibles and molds are usually made of graphite with zirconia or yttria washes applied to their interior surfaces to minimize carbon pickup by the molten metal. Unalloyed uranium castings are frequently used in applications such as counterweights and radiation shields, where mechanical properties are not primary design concerns.

Hot and cold fabrication techniques are frequently used to improve ductility and produce forms such as sheets, rods, and hollow cylinders of unalloyed uranium. Solid uranium exhibits three polymorphic forms: gamma (γ) phase (body-centered cubic) above 771 °C (1420 °F), β phase (tetragonal) between 665 and 771 °C (1229 and 1420 °F), and α phase (orthorhombic) below 665 °C (1229 °F). The effects of crystal structure and temperature on mechanical properties are shown in Fig. 1. The high-temperature γ phase is very soft and ductile, and dynamic recrystallization occurs when the metal is worked in this temperature range. Unfortunately, however, oxidation also occurs very rapidly at these temperatures. This results in poor surface quality and a substantial amount of finely divided oxide debris. Hence, relatively little γ-phase metalworking is done except in instances where severe deformation requirements and/or limitations in the tonnage of the available processing equipment demand maximum ductility and/or minimum flow stress. The intermediate-temperature β phase is brittle in polycrystalline form and is unsuitable for metalworking processes. The low-temperature α phase deforms by a number of slip modes, but slip becomes more restricted and increasing amounts of twinning occur as the temperature decreases. The combination of low flow stress, high ductility, and dynamic recrystallization make the high α region (550 to 640 °C; 1020 to 1180 °F) ideal for many primary metalworking operations, such as forging, rolling, and extrusion. The oxidation rate at this temperature is only one-third that in the γ

region, and heating in preparation for hot working can be done in molten salt baths so the hot material is exposed to air for only a short time, resulting in substantial reductions in oxidation and improvements in surface quality. The material continues to be quite ductile and workable at temperatures down to 150 to 200 °C (300 to 390 °F), but the absence of recrystallization below about 500 °C (930 °F) results in substantial work hardening when secondary metalworking processes such as rolling and swaging are carried out in the 150 to 500 °C (300 to 930 °F) range. The α phase becomes less ductile below 100 to 150 °C (212 to 300 °F), but secondary fabrication processes such as swaging, drawing, spinning, and straightening can be done at room temperature if only modest deformations are required.

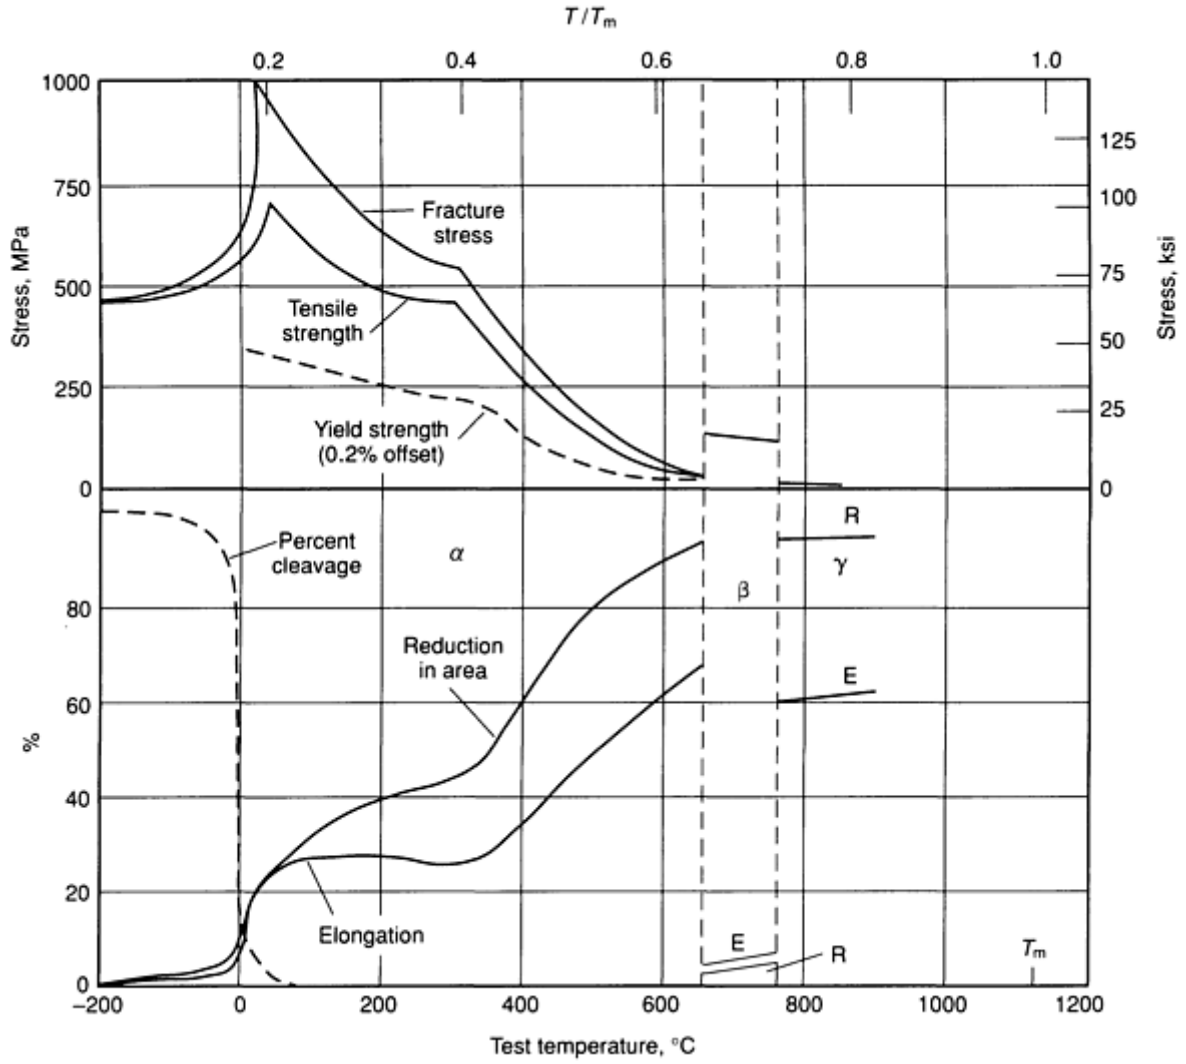

Fig. 1 Effect of temperature on the tensile properties of unalloyed uranium. T_m, melting temperature. Source: Ref 12

The mechanical properties (particularly ductility) of α uranium near room temperature vary substantially depending on processing history and impurity content (Table 1). This variability is largely the result of a ductile-to-brittle transition that occurs at about room temperature, as shown in Fig. 1. The ductile-to-brittle transition temperature is sensitive to various metallurgical variables, but in particular can be suppressed to lower temperatures (thus increasing room-temperature ductility) by decreasing hydrogen content and grain size and by leaving some residual warm work in the material. Thus, as-cast material, which typically contains a moderate amount of hydrogen (1 to 3 ppm, by weight) and exhibits very large grains, has low room-temperature ductility (~6% elongation). Ductility can be substantially improved by lowering hydrogen content via vacuum heat treatment (~1 Pa, or 10^{-2} torr) in the high α region (550 to 640 °C, or 1020 to 1180 °F). The time required for hydrogen outgassing depends on temperature and section thickness, as shown in Fig. 2. Hydrogen outgassing can be done more quickly in the γ region (~800 °C, or 1470 °F), but due to the higher solubility of hydrogen in the γ phase, a substantially better vacuum is required (~ mPa, or 10^{-4} torr). Additional improvements in the ductilities of castings can be obtained by refining the grain size via βphase heat treatment and quenching.

Table 1 Effect of heat treatment on tensile properties of uranium

Form	Heat treatment	Yield strength, MPa (ksi)	Tensile Strength, MPa (ksi)	Elongation, %
Cast	None	205 (30)	450 (65)	6
Cast	500 °C (930 °F), 1 h in salt	215 (31)	460 (66)	8
Cast	650 °C (1200 °F), 2 h in vacuum + 630 °C (1165 °F), 24 h in vacuum[(a)] (hydrogen outgassed)	185 (27)	560 (81)	13
Cast	720 °C (1330 °F) in vacuum quench, 550 °C (1020 °F), 24 h in vacuum[(a)] (β quenched and hydrogen outgassed)	295 (43)	700 (101)	22
600 °C (1110 °F) rolled	550 °C (1020 °F), 1 h in salt (α-rolled)	270 (39)	575 (83)	12
600 °C (1110 °F) rolled	630 °C (1165 °F), 2 h in vacuum[(a)] (α-rolled and hydrogen outgassed)	270 (39)	720 (103)	31
300 °C (570 °F) rolled	630 °C (1165 °F), 2 h in vacuum[(a)(b)] (warm rolled and hydrogen outgassed)	220 (32)	750 (109)	49

(a) Properties dependent on adequate time for hydrogen outgassing.

(b) Several sequences of warm rolling and annealing; final anneal at 550 °C (1020 °F)

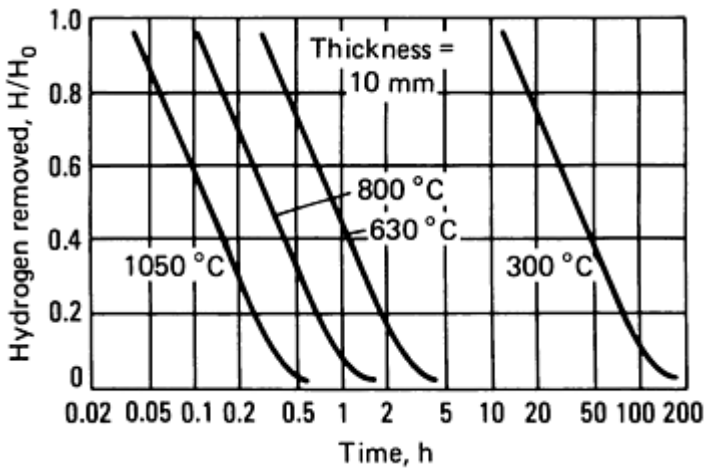

Fig. 2 Time required for hydrogen outgassing at the center of 10 mm thick plate at various temperatures. Times for hydrogen removal vary as thickness is squared; for example, the time required for 90% hydrogen removal (H/H_0 = 0.1) in 3.0 cm thick plate at 630 °C (1165 °F) is 3.0^2 × 2.5 h, or 22.5 h. Source: Ref 16

Rolling or other forms of hot working carried out in the high α region (550 to 640 °C, or 1020 to 1180 °F) cause recrystallization to much finer grains than are typical of castings; thus wrought products typically have higher ductilities than do castings. Preheating in salt to the deformation temperature, however, frequently introduces hydrogen into the material, with limits the ductility gains imparted by working and grains size refinement. Vacuum heat treatment in the high α region, after rolling, removes this hydrogen, resulting in additional improvements in ductility. Optimum ductility can be obtained by warm rolling at about 300 °C (570 °F) with vacuum anneals at 630 °C (1165 °F) as required; after the final warm rolling increment a 550 °C (1020 °F) vacuum anneal is performed. This provides a very fine-grained low-hydrogen material with outstanding room-temperature ductility. Eliminating the final annealing step and leaving some warm work in the material decreases this ductility but suppresses the ductile-to-brittle transition temperature by about 40 °C (70 °F), thus resulting in increased low-temperature ductility.

Impurity elements generally have very low solubilities in uranium, so when present they contribute to increased densities of inclusions and second-phase particles. It is generally accepted that these conditions have adverse effects on ductility; however, the extend of many of these effects have not been quantified in careful experiments where the effects of other significant variables, such as hydrogen content, have been controlled or eliminated. Carbon is a particularly notorious impurity because it forms carbide inclusions, which clearly decrease ductility, and because it is introduced to a limited extent during melting in graphite crucibles despite oxide coatings that are applied to the crucibles to minimize this effect. This buildup of carbon is the most serious impediment to recycling uranium scrap. A typical specification for relatively high-purity material is shown below:

Element	**Amount (by weight)**
Uranium	99.85% min
Carbon	100 ppm max
Iron	75 ppm max
Magnesium	5 ppm max
Nickel	50 ppm max
Silicon	75 ppm max
Manganese	35 ppm max
Aluminum	15 ppm max
Calcium	50 ppm max

Unalloyed uranium is readily weldable provided that it is protected from atmospheric oxygen. Electron beam welding in a vacuum is the most commonly used method, but shielded arc welds have also been successful. Coarse grains in the weld region limit the strengths and ductilities of welded parts to those typical of castings.

The susceptibility of uranium of oxidation and corrosion must be seriously considered, particularly in applications of unalloyed uranium. Unalloyed uranium oxidizes rapidly in air, forming a dark coating of uranium dioxide after only a few

hours of exposure. Exposure to water results in rapid corrosion, particularly if the solutions are somewhat acidic or contain even small amounts of chloride (Cl^-) ions. Protective coatings, such as electroplated nickel or ion-plated aluminum, are frequently applied to minimize such environmental effects.

Uranium Alloys

Uranium is frequently alloyed to improve its corrosion resistance and mechanical properties. Alloying results in substantial decreases in density, hence it is desirable to obtain the necessary properties with small amounts of alloying additions. These alloys are produced by vacuum induction or vacuum arc melting and, like unalloyed uranium, can be fabricated hot (gamma and high alpha regions: 800 to 900 °C, or 1470 to 1650 °F; and 500 to 640 °C, or 930 to 1180 °F), warm (150 to 500 °C, or 300 to 930 °F), or cold (room temperature). A wide range of properties can be obtained by post-fabrication heat treatment. More information on the properties and processing of uranium alloys is available in Ref 2, 3, 4, 5, 6, 7, and 17.

Heat treatment of uranium alloys is based on the fact that common alloying elements (molybdenum, niobium, titanium, and zirconium) are highly soluble in the high-temperature phase but substantially less soluble in the lower-temperature β and α phases (Fig. 3). This results in eutectoid or eutectoid-like phase diagrams, such as that for the U-Ti system shown in Fig. 4. Uranium alloys are generally solution heat treated at approximately 800 °C (1470 °F) to put the alloying additions into solid solution in the γ phase, and then cooled at various rates to room temperature. Slow cooling permits the γ phase to diffusionally decompose, as illustratedin Fig. 5. The product of such diffusional decomposition is analogous to pearlite in steels and consists of alternating platelets of essentially alloy-free α uranium and alloy-enriched second phases. Such two-phase structures exhibit somewhat higher strengths than unalloyed uranium, but because they contain high fractions of alloy-free α-phase uranium, little or no improvement in corrosion resistance is obtained. The properties of several alloys in the slowly cooled condition are shown in Table 2. These types of materials are frequently used in applications such as large, thick-walled cylindrical radiation shields for nuclear material shipping casks, where strengths higher than

those of unalloyed uranium are needed but where large size and wall thickness preclude quenching to obtain even higher strengths and ductilities.

Table 2 Mechanical properties of annealed uranium alloys

Alloy	Yield strength, MPa (ksi)	Tensile strength, MPa (ksi)	Elongation, %	Reduction in area, %
Unalloyed U	220 (32)	650 (94)[a]	13-50[a]	12-45[a]
U-0.75 Ti	520 (75)	1070 (155)	10	10
U-2.0 Mo	415 (60)	830 (120)[b]	10[b]	10[b]
U-2.3 Nb	480 (70)	965 (140)	25	31

Note: All with ~50 ppm C and <0.5 ppm hydrogen unless noted.

(a) Varies substantially with prior processing and grain size.

(b) 210 ppm C; UTS, elongation, and reduction in area are expected to be higher with decreased carbon.

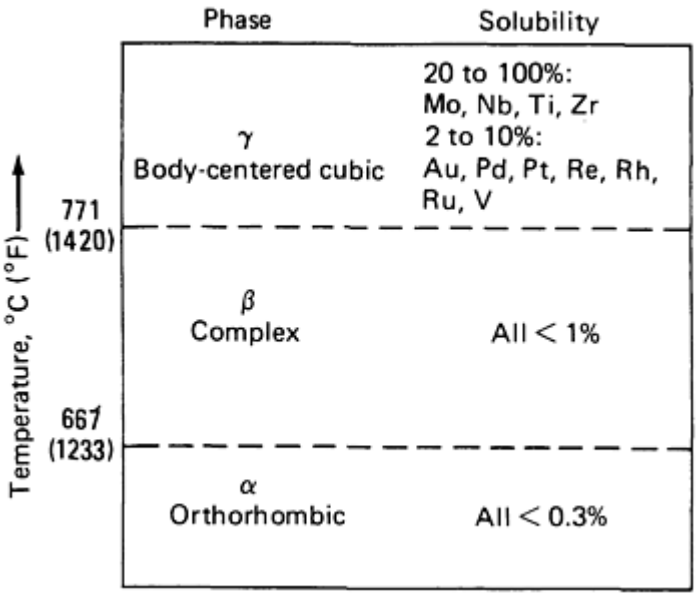

Fig. 3 Solubilities of alloying elements in γ, β, and α polymorphs of uranium. Source: Ref 17

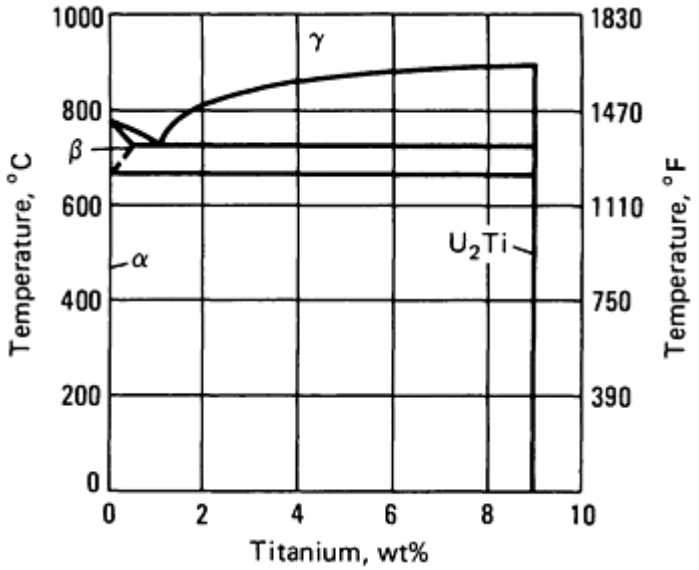

Fig. 4 A portion of the U-Ti equilibrium phase diagram. Source: Ref 17

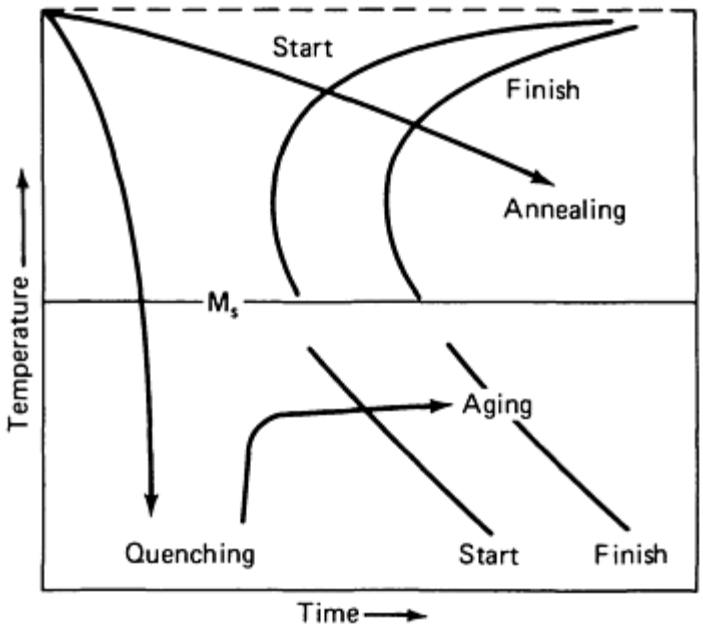

Fig. 5 Generalized time-temperature-transformation diagram showing heat treatments employed with uranium alloys. Slow cooling results in diffusional decomposition of γ phase to coarse dual-phase microstructures. Quenching results in diffusionless transformation of γ phase to supersaturated martensites, which can be subsequently age hardened. M_s, martensite start temperature

Rapid quenching from the high-temperature γ -phase field suppresses diffusional decomposition, resulting in the formation of supersaturated metastable phases, as illustrated in Fig. 5. These phases generally exhibit better combinations of strength and ductility than does unalloyed uranium. In addition, their supersaturation makes them amenable to additional strengthening by age hardening. Finally, the presence of alloying elements in supersaturated solid solution substantially improves their corrosion resistance. The properties of several alloys in various quenched or quenched-and-aged conditions are shown in Table 3. Quenched and aged uranium alloys are commonly used in applications requiring good combinations of strength, ductility, and corrosion resistance, such as kinetic energy penetrators.

Table 3 Properties and applications of heat-treated uranium alloys

Alloy	Density, g/cm^3	Processing	Hardness	Yield strength, MPa (ksi)	Tensile strength, MPa (ksi)	Elongation, %[(a)]	Reduction in area, %[(a)]	Corrosion resistance	Used for applications requiring	Precautions, comments
Unalloyed U	19.1	Cast, β-quenched, hydrogen outgassed	93 HRB	295 (43)	700 (101)	22	. . .	Poor	Complex shapes, low strength requirements	. . .
Unalloyed U	19.1	α-rolled, hydrogen outgassed	94 HRB	270 (39)	720 (104)	31	. . .	Poor	Sheet, rod, formed parts, low strength requirements	. . .

(a) All based on high-purity alloys with low hydrogen contents

Solution heat treatment (Ref 16, 17, 18, 19, 20) is generally done at about 800 °C (1470 °F) for 1 to 8 h in a vacuum. The temperature must be high enough to ensure that the materials is completely transformed to γ phase and that the alloying elements are taken into solid solution. An inert environment is needed to keep the material from rapidly oxidizing at this high temperature. Vacuum heat treatment at about 1 mPa (10^{-4} torr) not only prevents oxidation but removes hydrogen from the material, thus avoiding internal hydrogen embrittlement. The length of the vacuum solution heat treatment is dictated primarily by hydrogen outgassing considerations.

Uranium alloys are most frequently used in either the as-quenched or quenched-and-aged condition. In either case, the material must be cooled from the solution treatment temperature rapidly enough to suppress diffusional decomposition of the γ phase and permit a nonequilibrium supersaturated structure to be obtained. Critical cooling rate varies substantially with alloy composition. Dilute alloys (those containing less than 2 to 3 wt% alloying addition) generally exhibit high critical cooling rates (in the vicinity of 50 to 150 °C/s, or 90 to 270 °F/s). These rates can only be obtained by water-quenching relatively thin sections; thus, quenched or quenched-and-aged dilute alloys cannot be used for heavy section applications. U-0.75Ti, for example, cannot be effectively quenched in sections thicker than about 25 mm (1 in.). More highly alloyed materials generally exhibit lower critical cooling rates (decreased quench rate sensitivity) and can be quenched in thicker sections and/or less severe quenching media, such as oil. Some very highly alloyed materials, such as U-10Mo, have such low critical cooling rates that they do not have to be quenched at all; cooling in an inert atmosphere is sufficient.

Subcritical quenching has a substantial influence on mechanical properties, age hardenability, and corrosion resistance. The effect of quench rate on the tensile properties of U-6Nb is shown in Fig. 6. Quench rates in excess of approximately 10 °C/s (18 °F/s) completely suppress diffusional decomposition and produce a supersaturated variant of the α phase, which is soft and ductile and which exhibits outstanding corrosion resistance. As the cooling rate decreases to below 10 °C/s (18 °F/s), diffusional decomposition occurs to a progressively greater extent. This results in increases in strength and decreases in ductility and corrosion resistance. At 0.2 °C/s (0.4 °F/s), complete diffusional decomposition occurs, resulting in very low ductility and poor corrosion resistance. Further decreases in cooling rate produce coarser two-phase microstructures with lower strengths and somewhat better ductilities but with no improvement in corrosion resistance. Similar trends are observed in other uranium alloys, but with different characteristic quench rates, depending on alloy composition.

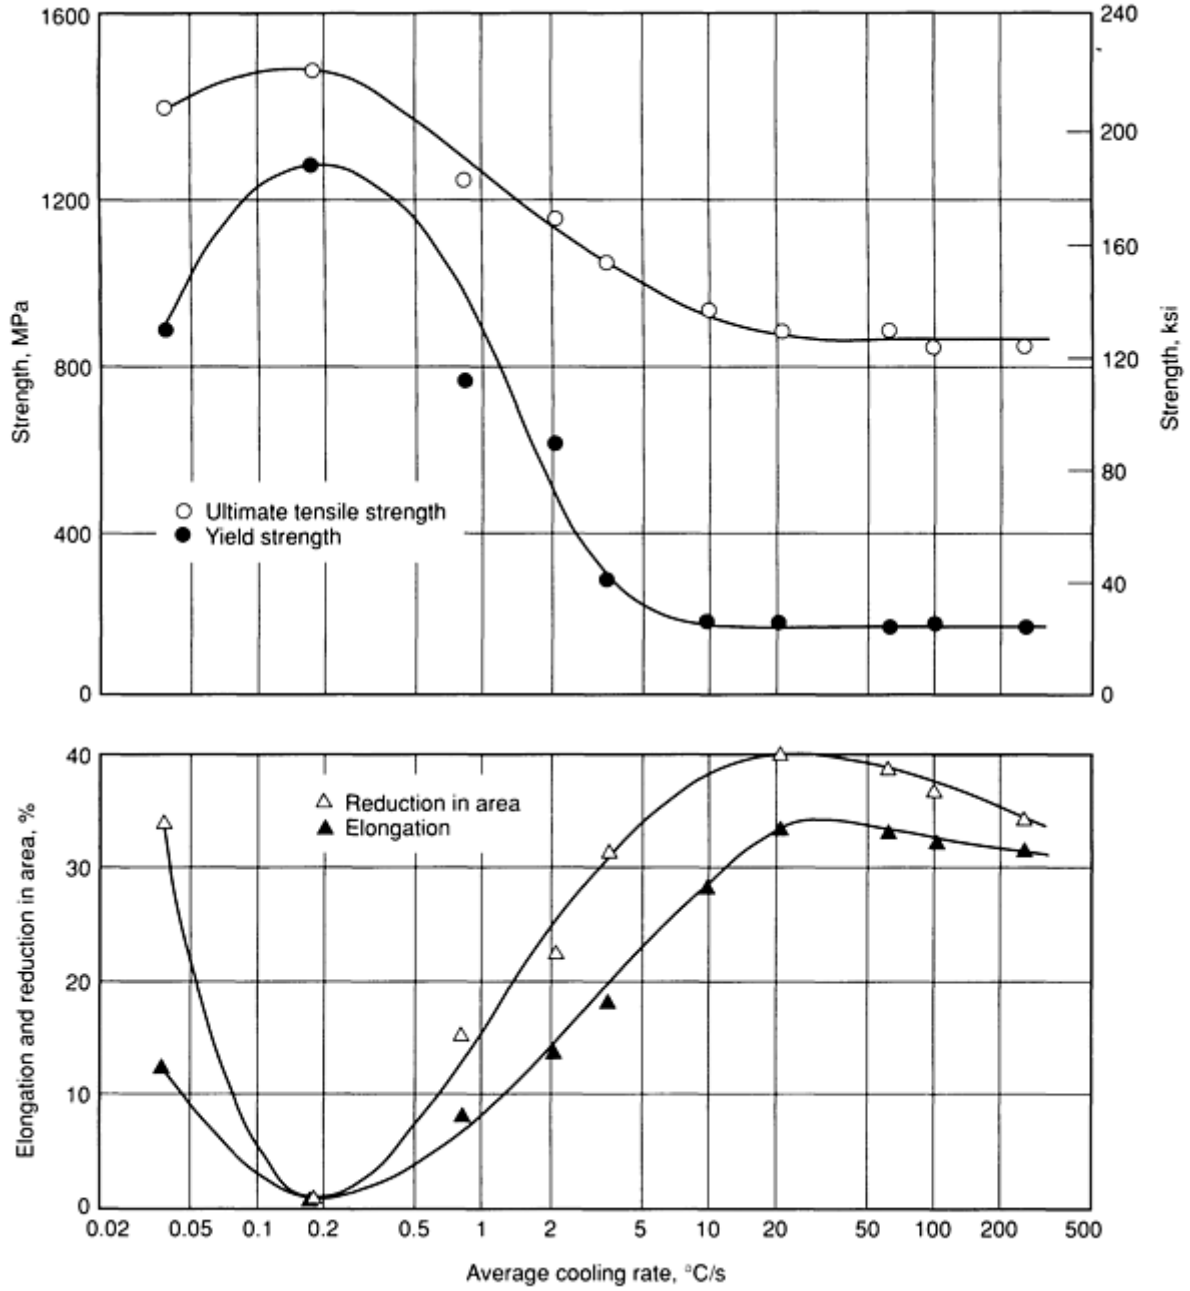

Fig. 6 Effect of cooling rate on tensile properties of U-6.0Nb. Source: Ref 19

Plunge quenching of rods greater than 20 mm (0.8 in.) in diameter into water causes radial heat extraction, which results in sufficiently high triaxial tensile stresses along the centerline and can cause internal fracturing or centerline bursting. This can be avoided by lowering the bar into the quenchbath at a controlled rate, typically 5 to 10 mm/s (0.2 to 0.4 in./s). Such controlled quenching results in more longitudinal heat extraction, thus reducing stress triaxiality and preventing centerline bursting.

Microstructures and Properties of Quenched Alloys (Ref 6, 17, 21, 22, 23). Quenching from the γ-phase field produces a variety of metastable supersaturated phases whose microstructures, crystal structures, and properties vary in a regular manner with alloy content. These variations are illustrated in Fig. 7, and photomicrographs of the various structures are shown in Ref 6.

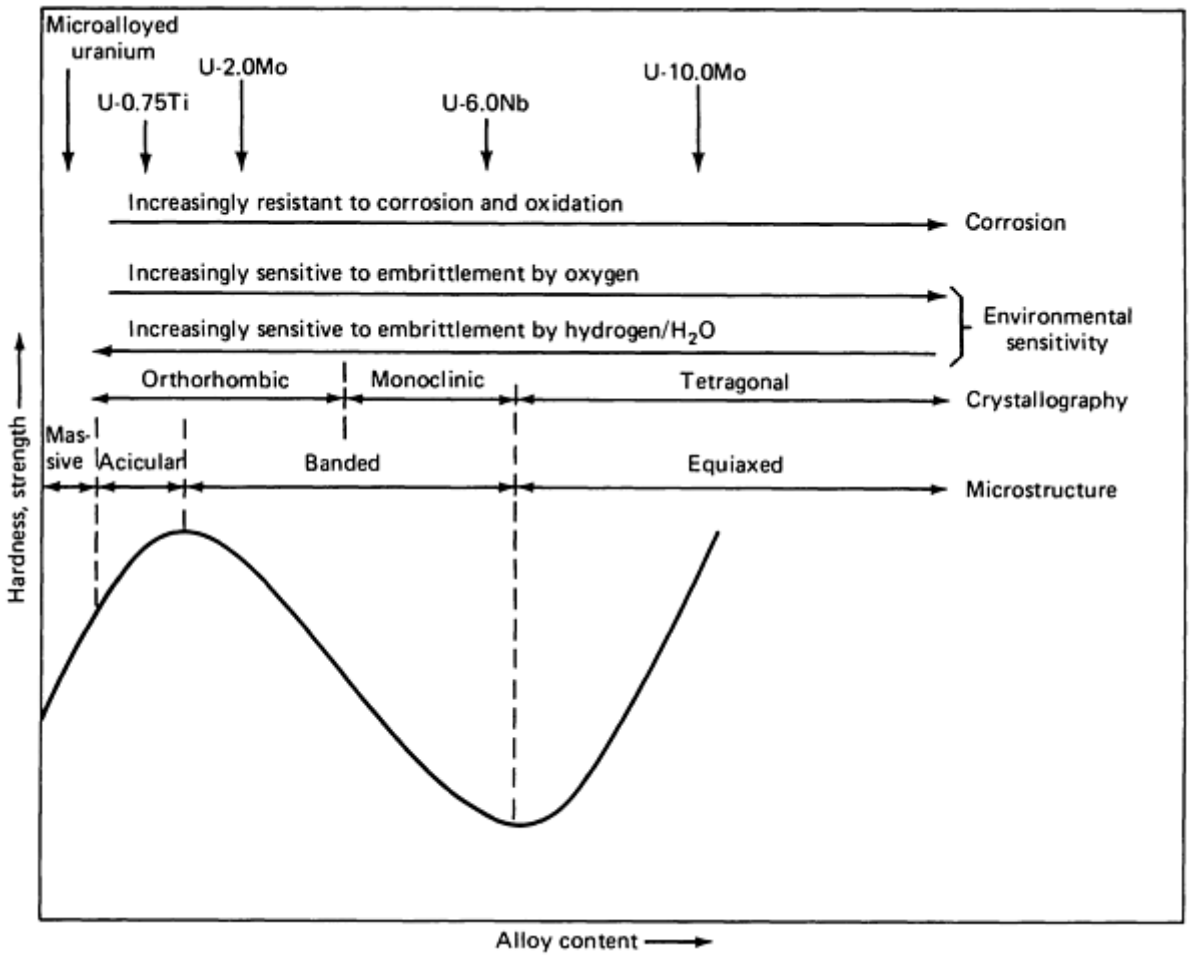

Fig. 7 Effects of alloy composition on microstructure, crystal structure, and properties of quenched uranium alloys

Relatively small alloying additions result in progressive increases in hardness and strength. Very dilute alloys exhibit irregular grain structures typical of those produced by massive transformation and similar to those of unalloyed uranium. Somewhat more concentrated alloys exhibit acicular martensitic microstructures. Both of these phase are orthorhombic, in which the lattice parameters (particularly the *b* parameter) are modified by the presence of alloying atoms in solid solution.

Further increases in alloy content cause a transition to a thermoelastic, or banded, martensite. The hardness and strength of thermoelastic martensites decrease with increasing alloy content, apparently due to increasing mobilities of the boundaries of the many fine twins produced during the transformation. Midway in the thermoelastic martensite composition range, the crystal structure changes from orthorhombic to monoclinic, as one lattice angle departs gradually from 90 deg. This change in crystal structure has little apparent effect on mechanical behavior. The martensitic variants of α-uranium are frequently termed α'_a, α'_b, and α''_b. The subscripts a and b denote the acicular and banded morphologies, respectively, and the prime and double prime superscripts denote the orthorhombic and monoclinic crystal structures, respectively.

Additional increases in alloy content produce a transition to γ°, a tetragonal variant of elevated-temperature γ uranium. The γ° phase exhibits an equiaxed grain structure similar to that of γuranium, but differences in crystal structure can be detected by x-ray diffraction. The hardness and strength of γ° increase with increasing alloy content.

While the microstructures and resulting mechanical properties vary with composition in this complex manner, corrosion resistance is controlled primarily by the amount of alloying addition in solid solution. Hence, corrosion resistance increases progressively with increasing alloy content.

Age Hardening (Ref 24, 25, 26, 27, 28). The phases produced by quenching are supersaturated substitutional solid solutions; therefore, they can be further strengthened by age hardening. The as-quenched phases are relatively soft (hardnesses range from 92 HRB to 35 HRC, with yield strengths from 140 to 700 MPa, or 20 to 100 ksi) and ductile (15 to 32% tensile elongation). Aging increases their hardness and strength and decreases their ductility, as shown in Fig. 8 and 9. Age hardening occurs at temperatures below approximately 450 °C (840 °F) due to fine-scale microstructural changes observable only by transmission electron microscopy or other high-resolution techniques. Hardnesses in excess of 50 HRC and yield strengths over 1200 MPa (175 ksi) can be obtained by full aging, but most alloys exhibit little or no ductility in the fully aged condition. Most applications employ partially aged material in order to obtain an acceptable balance of strength and ductility.

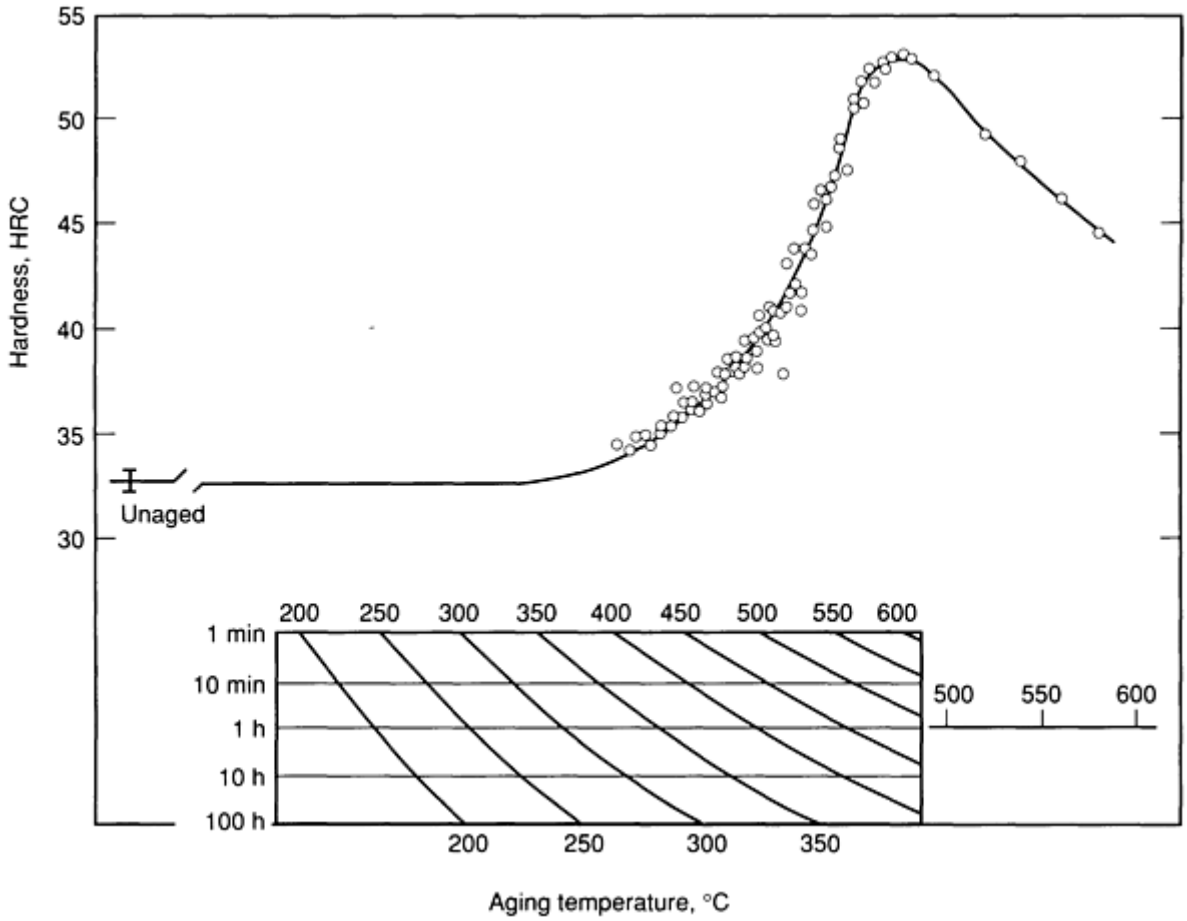

Fig. 8 Effects of aging temperature and time on hardness of U-0.75Ti

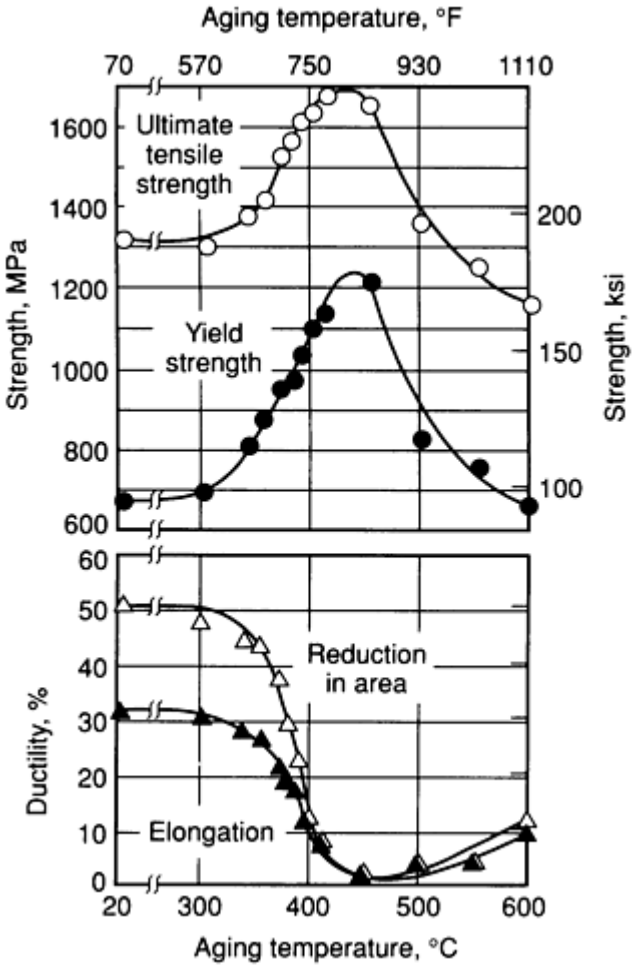

Fig. 9 Effect of aging temperature on tensile properties of U-0.75Ti aged 6 h

Overaging occurs at temperatures in excess of approximately 450 °C (840 °F) by decomposition of the supersaturated metastable microconstituents to the equilibrium phases. This decomposition, which commonly takes place by cellular or discontinuous precipitation, can be easily revealed by optical metallography (Ref 6). Overaging decreases hardness and yield strength and increases ductility (relative to the fully aged condition), but tensile elongations in excess of 10% are not usually obtained until yield strength has decreased below 800 MPa (115 ksi). In addition, most alloy-induced increases in corrosion resistance are lost because the α phase no longer contains the alloying additions in supersaturated solid solution. For these reasons, alloys are infrequently used in the overaged condition, except where only moderate strengths (600 to 800 MPa, or 90 to 115 ksi) are required and low residual stresses are strongly desired. Fully overaged dilute alloys such as U-2Mo and U-2.3Nb offer attractive combinations of properties in these cases, as shown in Table 3.

Residual Stresses and Stress Relief (Ref 20, 29). Residual stresses can be introduced into uranium alloys by cold and warm working operations, by the quenching step inherent in solution heat treatment, and by welding operations. These stresses can be large enough to seriously degrade manufacturability and service life. Common consequences of residual stresses include centerline bursting, when bars greater than approximately 20 mm (0.8 in.) in diameter are plunge-quenched into water; dimensional distortion, when parts containing residual stresses are machined; and delayed cracking in welds in high-strength alloys. Surface tensile stresses are particularly dangerous because they can result in stress-corrosion cracking, which is known to occur when uranium alloys with tensile surface stresses are exposed to environments as benign as moist air.

Residual stresses can be relieved either thermally or mechanically. Thermal stress relief occurs in the same temperature range as age hardening; thus a material that is partially aged is also partially stress relieved, but only fully aged and overaged structures are fully stress relieved. As discussed in the previous section, fully overaged alloys that exhibit good ductility, such as U-2Mo and U-2.3Nb, can be used in applications requiring very low residual stresses and only moderate

strength. It is important that these materials be slowly cooled from the 550 to 600 °C (1020 to 1110 °F) overaging temperatures, as rapid cooling will reintroduce substantial residual stresses.

Mechanical stress relief can be accomplished by imposing a small amount of plastic deformation on a part after quenching. For example, quenched hollow cylinders, which frequently exhibit large compressive stresses near the outer surfaces and tensile stresses near mid-wall, can be upset forged 1 to 3% at room temperature. This results in plastic deformation of both the tensile and compressively stressed regions, and markedly reduces the magnitudes of the residual stresses (Fig. 10). Mechanical stress relieving is frequently used to minimize run-out problems on quenched parts that must be machined to exacting dimensional tolerances.

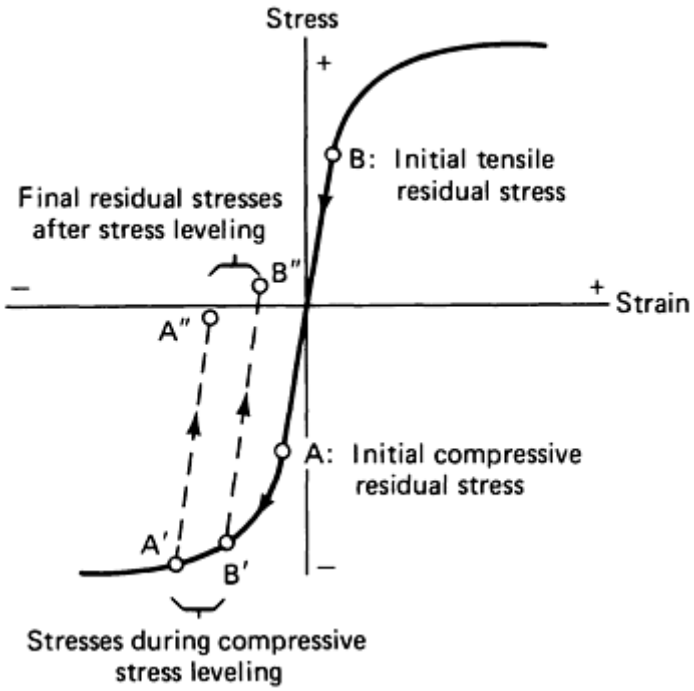

Fig. 10 Stress-strain curve of quenched uranium alloy illustrating initial residual stresses at the surface (A) and interior (B) and how compressive mechanical stress relief reduces residual stress magnitudes

Delayed Cracking (Ref 7, 16, 30, 31, 32). Uranium alloys are very susceptible to delayed cracking. This problem can result either from small amounts of hydrogen impurities in the metal or from external environments as apparently benign as moist or dry air. Aqueous solutions containing as little as a few ppm Cl^- are a particularly notorious cause of stress-corrosion cracking. In all cases susceptibility to delayed cracking increases the increasing strength of the material. Therefore, soft materials such as unalloyed uranium, as-quenched U-6Nb, and fully overaged alloys, are relatively immune, whereas materials that have been quenched and aged to high strength are more prone to delayed cracking.

Susceptibility to hydrogen, either as internally dissolved hydrogen or in the form of atmospheric moisture, is most severe in dilute alloys. The alloy U-0.75Ti, for example, can be severely embrittled by testing at low strain rates in humid air or by the presence of as little as 0.2 ppm of dissolved hydrogen. More concentrated alloys, such as U-6Nb, however, are relatively immune to atmospheric moisture and can tolerate greater than 10 ppm of dissolved internal hydrogen without ductility losses.

Sensitivity to atmospheric oxygen, on the other hand, is most severe in concentrated alloys, such as U-10Mo and U-7.5Nb-2.5Zr. These alloys fail by intergranular fracture when they are highly stressed in oxygen-containing environments such as dry air.

Aqueous solutions containing even low concentrations of Cl^- cause severe cracking in all high-strength uranium alloys. In moderately concentrated solutions (500 ppm Cl^-), cracking has been observed in the absence of an applied stress due to the wedging effect of the lower-density corrosion product.

Because of the sensitivity of high-strength uranium alloys to delayed cracking, it is desirable to minimize the magnitudes of residual stresses. This can be done by mechanical stress relief after quenching in alloys that will be aged to high-strength levels, or by complete overaging in cases where decreased corrosion resistance and only moderate strengths can be tolerated. It is particularly critical to avoid tensile residual stresses at free surfaces in components that are heat treated to high strengths.

Welding (Ref 33, 34). Welding of low-strength uranium alloys in inert environments is relatively straightforward, but delayed cracking frequently occurs in high-strength alloys due to the environmental effects described in the previous section. The relationship between delayed cracking susceptibility and strength is believed to be associated with the magnitudes of the stresses that develop upon cooling the weld metal and heat-affected zone. The magnitudes of these stresses are controlled (limited) by the yield strengths of the material. In low-strength materials, the elastic stresses are lower than those required to cause cracking, so sound welds are obtained. In high-strength materials, much larger residual stresses can be supported, so cracking occurs after the welded structure has been removed from the inert welding environment. Caution must be exercised when welding even normally soft materials, however, because the cooling rates associated with the welding process might not result in the intended microstructure. If hard microconstituents are formed in the weld region due to inadequate quenching, serious cracking problems can result. For example, U-6Nbcan be successfully joined by electron beam welding because heat sinking by the adjacent cold metal provides a sufficient quench rate to produce the soft α''_b microstructure. Cracking could result, however, from the use of alternate welding processes that cause more heating of adjacent material, thus slowing the quench rate and resulting in the formation of harder microconstituents in the weld or heat-affected regions.

Specific Alloys and Classes of Alloys

Microalloyed Uranium (Ref 35, 36). Very dilute alloys (containing less than 0.3 wt% total alloying additions) can be used in applications that require slightly higher yield strength than that available in unalloyed uranium but no improvements in corrosion resistance. Common alloying elements employed include aluminum, iron, molybdenum, silicon, and vanadium, and are added during the vacuum induction melting process. Small amounts of these elements are soluble in the γ and β phases but not in the α phase. Quenching enables these elements to be retained in supersaturated solid solution in the α phase, where they have the greatest effect on strength, as shown in Table 4. The microstructures of these quenched alloys consist of irregular "massive" grains, identical in appearance to unalloyed uranium. Unlike these intentional alloying additions, carbon does not go into solution to any significant extent. Instead, the presence of tramp carbon results in the formation of carbide inclusions that decrease ductility.

Table 4 Effect of composition on tensile properties of β-quenched microalloyed uranium

Composition, ppm[(a)]	Yield strength, MPa (ksi)	Tensile strength, MPa (ksi)	Elongation, %	Reduction in area, %
Unalloyed U	200 (29)	750 (109)	33	37
240 Al	220 (32)	780 (113)	25	21
270 Fe	310 (45)	870 (126)	35	34

570 Fe	325 (47)	955 (138)	31	32
440 Si	305 (44)	860 (125)	31	28
1000 Si, 420 Fe	495 (72)	1005 (145)	18	14
1000 Si, 480 Fe, 150 C	455 (66)	975 (141)	13	11

Source: Ref 36

(a) All materials contain ~50 ppm each of C, Fe, Al, Si unless otherwise noted.

If these microalloyed materials are slowly cooled (or annealed in the high α region) second phases form, apparently during the $\beta \rightarrow \alpha$ transformation. These result in some strengthening, but not as much as when the alloying elements are retained in solid solution. Table 5 compares the properties of γ-quenched, β-quenched, and α-annealed microalloys. As shown in that table, annealing results in decreased strength but improved ductility. Carbon promotes the formation of carbide inclusions that reduce ductility regardless of heat treatment condition.

Table 5 Effect of heat treatment on tensile properties of microalloyed uranium

Composition, ppm	Heat treatment[(a)]	Yield strength, MPa (ksi)	Tensile strength, MPa (ksi)	Elongation, %	Reduction in area, %
1000Si-420Fe-50C	γ-quenched	485 (70)	940 (136)	13	9
1000Si-420Fe-50C	β-quenched	500 (73)	1000 (145)	18	14
1000Si-420Fe-50C	α-annealed (550 °C, or 1020 °F, 4 h)	380 (55)	955 (139)	31	42

(a) All heat treatments in vacuum.

Vanadium additions have been reported to decrease the grain size of cast uranium, resulting in increases in both strength and ductility. As shown in Fig. 11, this effect is maximized at 0.2 wt% V.

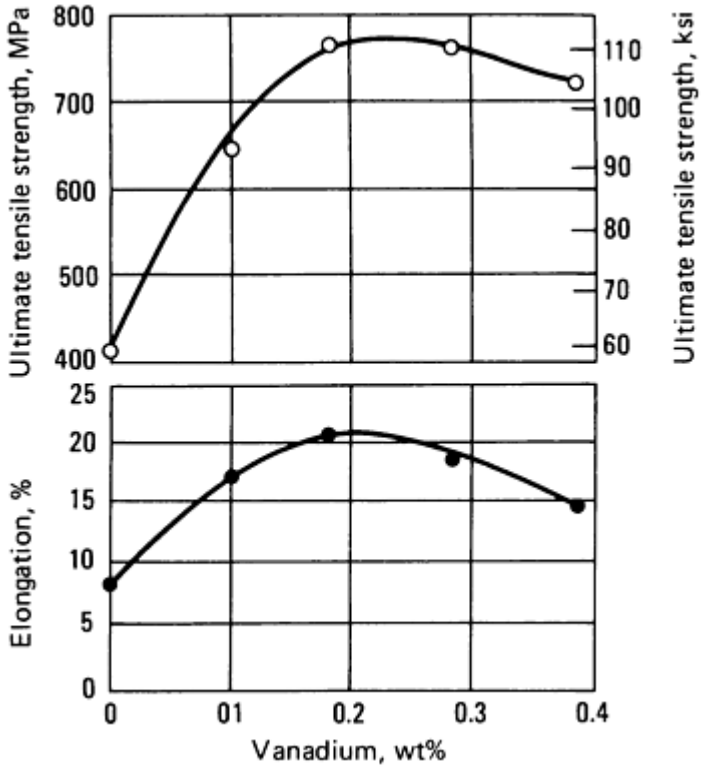

Fig. 11 Tensile properties of cast uranium-vanadium alloys. Source: Ref 35

Little work has been done on topics such as hydrogen cracking, stress-corrosion cracking, and welding of microalloyed uranium. Since these alloys exhibit relatively low strengths and cannot sustain high residual stresses, it seems likely that they would be relatively free from delayed cracking problems. It is probable, however, that the presence of small quantities of dissolved hydrogen and/or low strain rate testing in humid air would cause substantial decreases in tensile ductility.

Uranium-Titanium Alloys (Ref 15, 16, 17, 18, 20, 26, 28, 29, 30, 31, 32). The alloy U-0.75Ti is used for applications that require the highest combinations of strength and ductility. Like unalloyed uranium, this alloy is produced by vacuum induction melting. During the melting process, some of the titanium reacts with tramp carbon to form solid titanium carbides, which float to the surface of the melt and can be removed, rather than uranium and niobium carbides, which form during the solidification process and are dispersed throughout the ingot or casting. Good carbon control and excellent microcleanliness are thus possible with U-Ti alloys.

U-O.75Ti is vacuum-solution heat treated at 800 °C (1470 °F) to remove hydrogen and put the titanium into solution in the γ phase, and then water quenched to room temperature to produce supersaturated α'_a martensite. The quenching process introduces high residual stresses, particularly when the quenched parts are thick. The magnitudes of these stresses are frequently reduced by mechanical stress leveling in order to avoid delayed cracking and/or reduce the amount of distortion that occurs during subsequent machining. The α'_a martensite exhibits a yield strength of 650 MPa (95 ksi) due to the solid solution effect of titanium. Further strengthening can be obtained by age hardening, in the 330 to 450 °C (625 to 840 °F) range, to form fine coherent precipitates of U_2Ti in the α'_a martensite. Overaging occurs at temperatures exceeding 450 °C (840 °F), due to cellular decomposition of the α'_a martensite to the equilibrium α and U_2Ti phases. More complete descriptions of the microstructural changes that occur during heat treatment are given in Ref 3, 5, and 6.

The mechanical properties of quenched and aged U-0.75Ti are summarized in Fig. 8 and 9. Aging results in substantial increases in hardness and strength but decreases in ductility. Overaging reduces strength but produces only modest increases in ductility because a semicontinuous film of brittle U_2Ti forms along the martensite plate boundaries during the

overaging process. Because of this, the material is virtually never used in the overaged condition. Most applications that require a balance of strength and ductility specify aging at about 380 °C (715 °F) for 4 to 6 h.

The ductility of U-0.75Ti can be severely decreased by the presence of small amounts of hydrogen, as shown in Fig. 12. This hydrogen embrittlement phenomenon is strongly strain-rate dependent and is most severe at low strain rates. This problem can be avoided by solution heat treatment in a vacuum of higher than 1 mPa (10^{-4} torr) for periods long enough to reduce the hydrogen content to a low value. The times required for effective hydrogen removal are shown in Fig. 2. Atmospheric moisture has a similar embrittling effect on this alloy, apparently because water vapor reacts with the surface of the metal to produce UO_2 plus atomic hydrogen. Because of this, tensile testing is frequently carried out in a dry environment to avoid scatter in the ductility data due to variations in relative humidity. The tensile properties of U-0.75Ti are also very dependent on test temperature (Fig. 13). Low ductilities are obtained at temperatures below approximately 0 °C (32 °F) regardless of strain rate, hydrogen content, and testing environment.

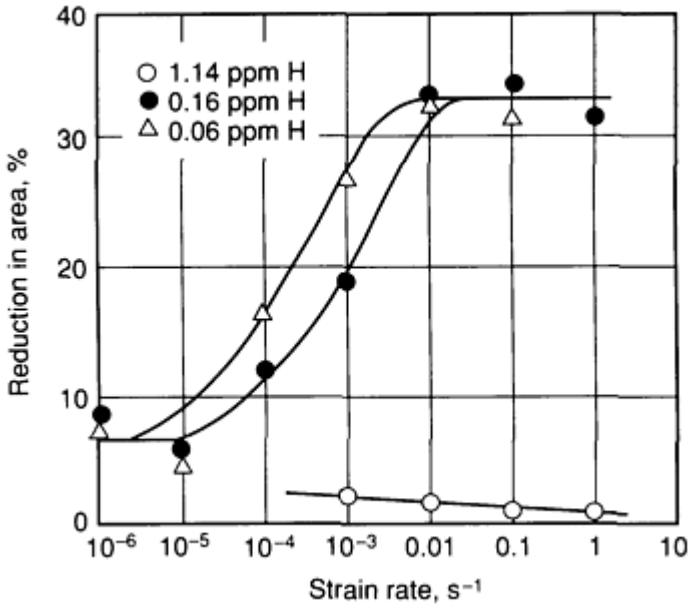

Fig. 12 Effects of hydrogen content and strain rate on ductility of U-0.75Ti with yield strength of 965 MPa. Source: Ref 32

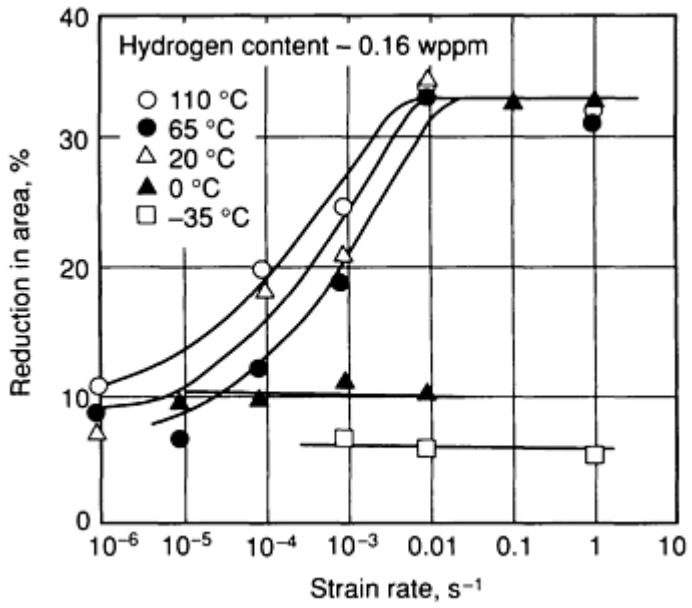

Fig. 13 Effect of temperature and strain rate on ductility of U-0.75Ti with yield strength of 965 MPa. The alloy contained 0.16 ppm hydrogen. Source: Ref 32

The fracture toughness behavior of U-0.75Ti parallels its ductility, as shown in Fig. 14. For the commonly used heat treatment approach (380 °C, or 715 °F, for 6 h), the yield strength and fracture toughness values are approximately 950 MPa (140 ksi) and 45 MPa $\sqrt{m}$ (41 ksi $\sqrt{in}$), respectively. This results in a critical flaw size in the vicinity of 0.7 mm (0.03 in.), which is detectable by nondestructive inspection techniques.

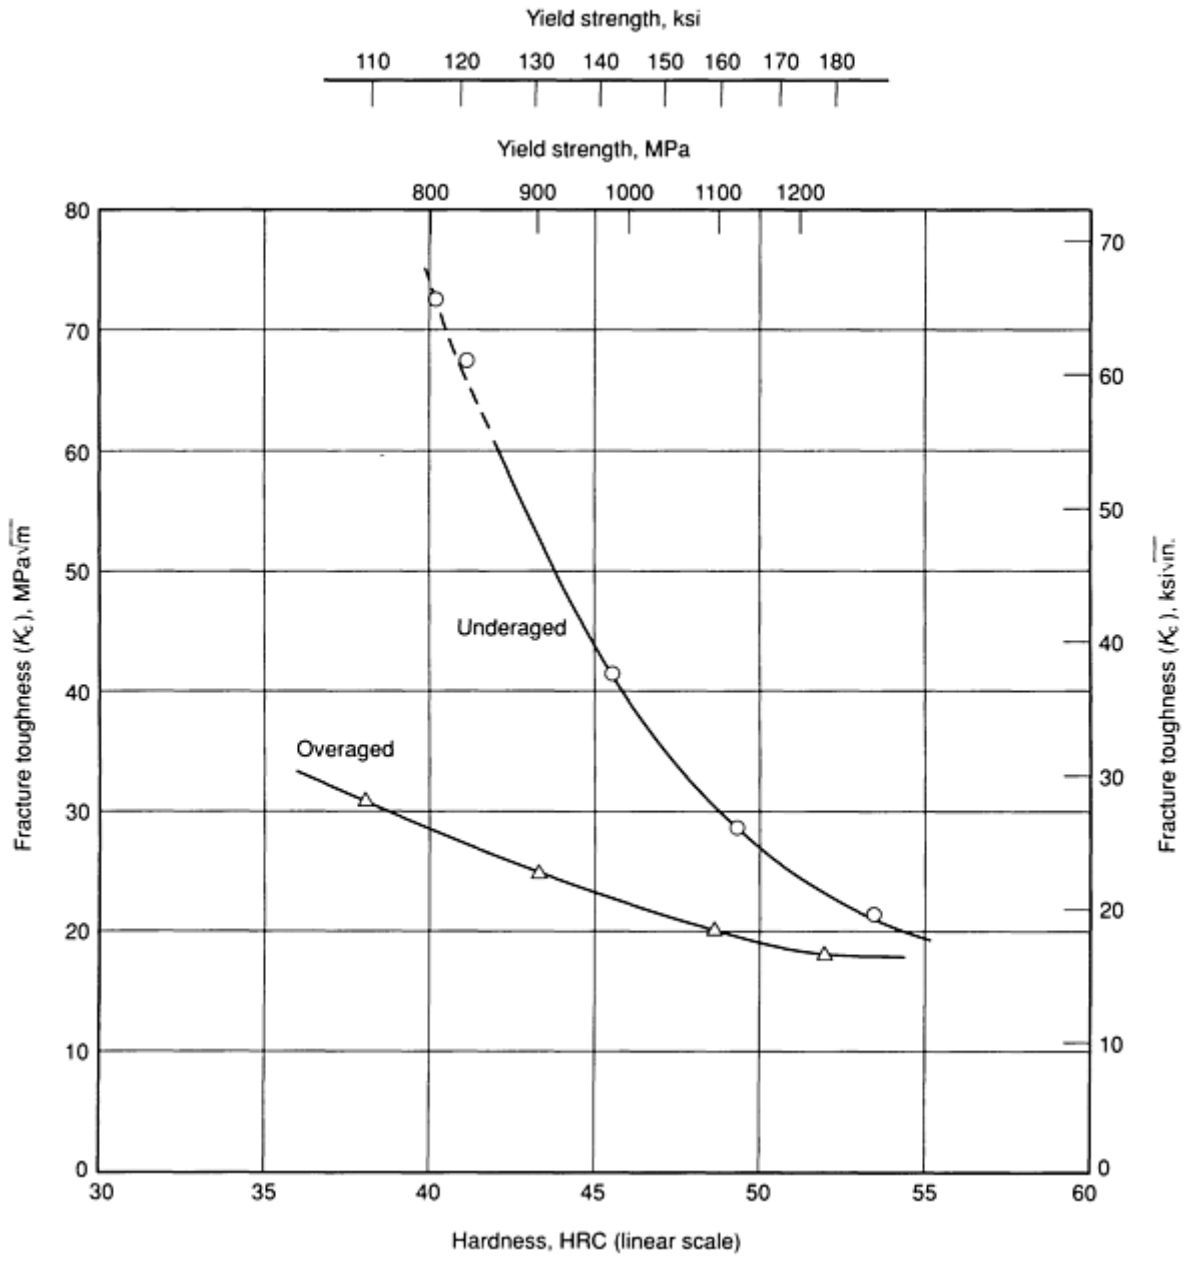

Fig. 14 Effect of aging on fracture toughness of U-0.75Ti. Source: Ref 17

Unfortunately, subcritical flaw growth is possible in U-0.75Ti in environments as benign as humid air. Values of K_{ISCC} in various environments are given in Table 6. This susceptibility to stress-corrosion cracking increases the importance of quench-induced residual stresses. Fortunately, the surface stresses in most parts of simple shape are compressive, but tensile surface stresses can result from machining complex features into such parts. Residual stress magnitudes can be

reduced by both mechanical stress leveling and aging, but aging is of limited utility in this regard because it also reduces K_{ISCC}.

Table 6 K_{ISCC} values for U-0.75Ti

Environment	K_{ISCC}, MPa $\sqrt{m}$ (ksi $\sqrt{in}$)	
	Aged 380 °C (715 °F), 6 h (Yield strength 985 MPa, or 143 ksi)	**Aged 450 °C (840 °F), 6 h (Yield strength 1200 MPa, or 174 ksi)**
Dry air	42 (38)	29 (26)
Air (100% relative humidity)	28 (25)	15 (14)
50 ppm Cl^- solution	18 (16)	. . .
3.5% NaCl solution	18 (16)	10 (9)

Source: Ref 30

U-0.75Ti exhibits substantial quench rate sensitivity. Quench rates of approximately 200 °C/s (360 °F/s) are required to obtain 100% martensite. This can only be achieved by water quenching of plates thinner than about 10 mm (0.4 in.), as shown in Fig. 15. The lower cooling rates that occur during water quenching of thicker parts are insufficient to completely prevent diffusional decomposition of the γ phase. The diffusionally formed transformation products characteristic of these lower cooling rates exhibit substantially lower ductilities than the α'_a martensite, as shown in Fig. 16. In addition, since they are not supersaturated with titanium, they cannot be subsequently age hardened. For most applications, however, acceptable performance can be obtained if approximately 50% martensite is present at mid-thickness. This enables satisfactory processing of U-0.75Ti plates up to about 28 mm (1.1 in.) thick and rods up to about 46 mm (1.8 in.) in diameter.

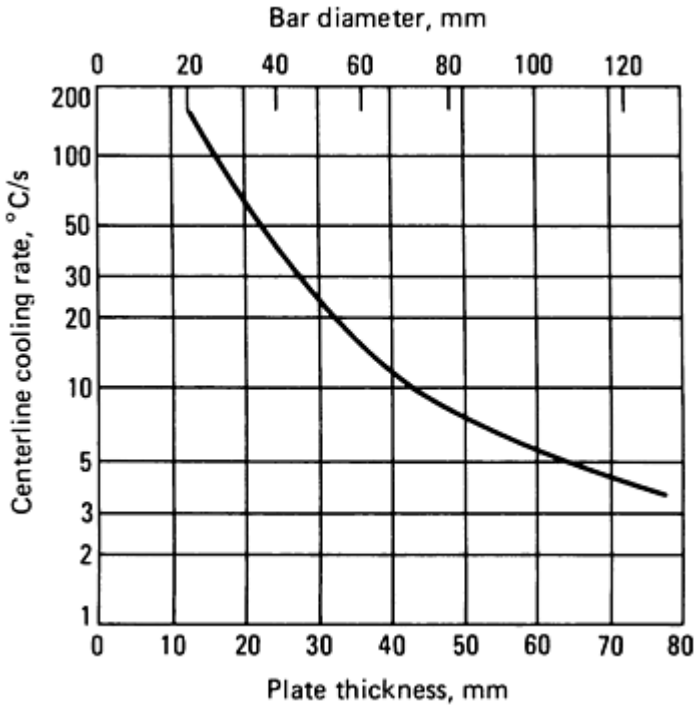

Fig. 15 Centerline cooling rates in plates and bars quenched into 20 °C water

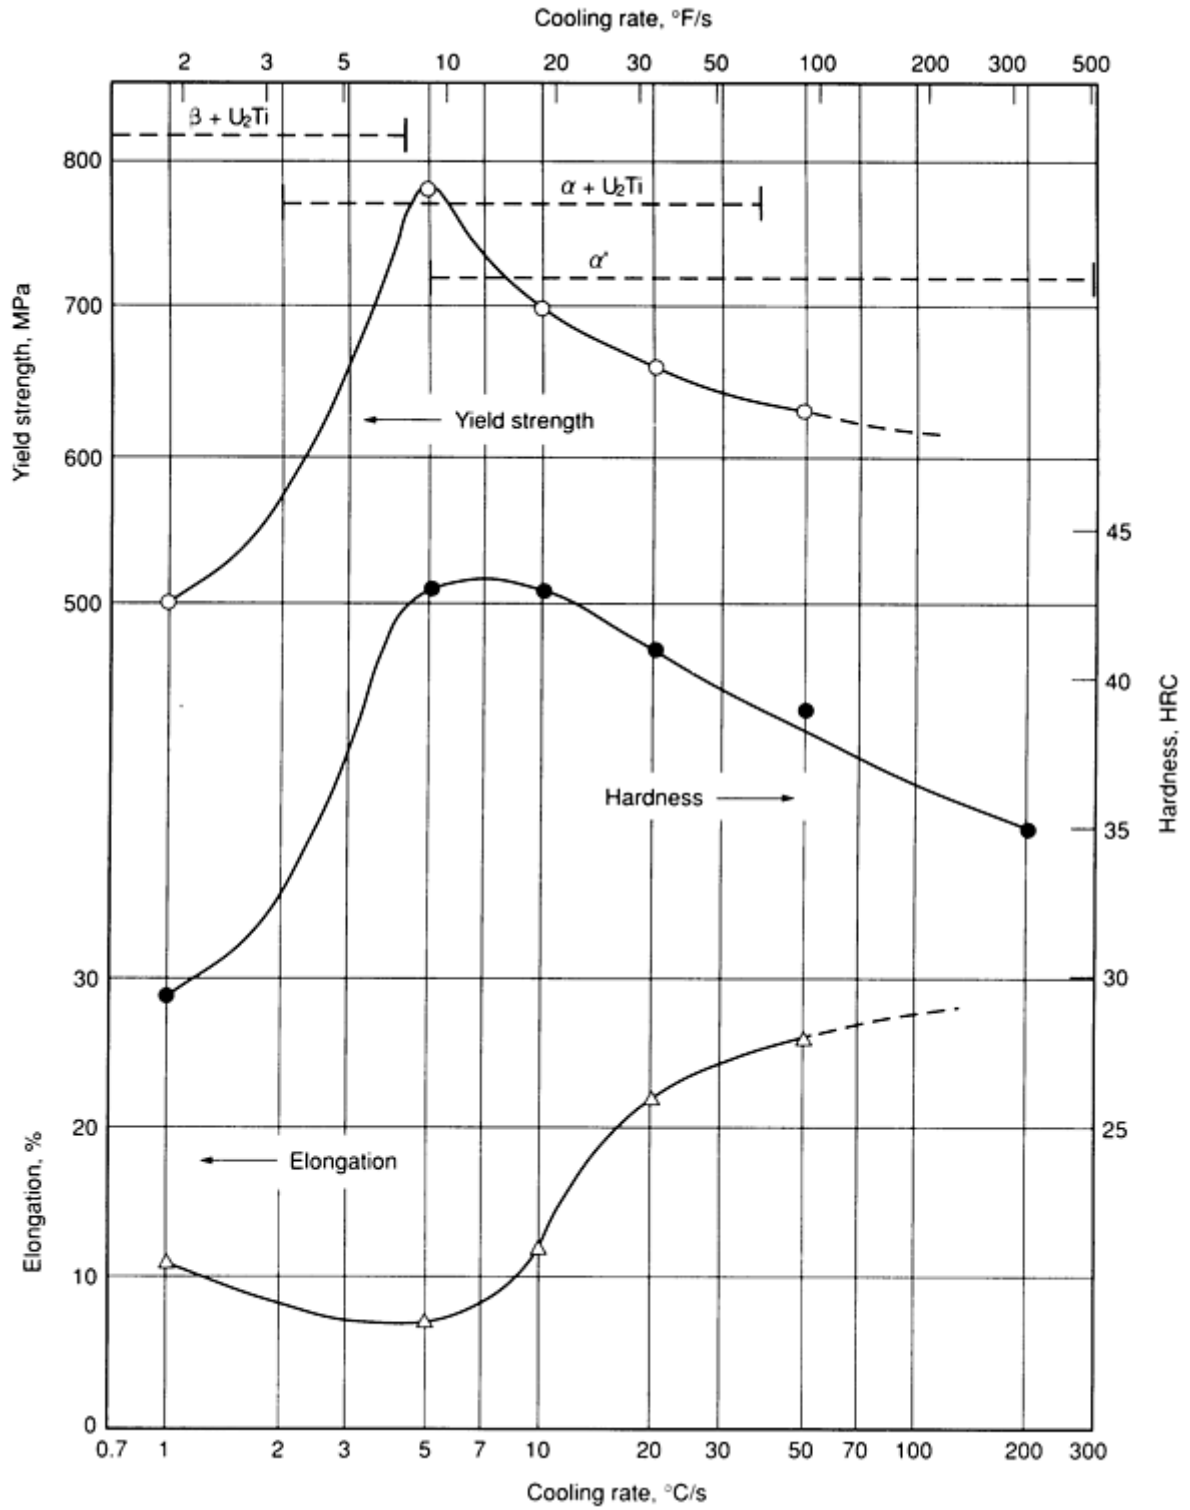

Fig. 16 Effect of quench rate on properties of U-0.75Ti. Dashed lines show approximate microstructural regions. Source: Ref 18

These quench-rate sensitivity limitations in section size can be reduced somewhat by modifying alloy composition. Decreasing the titanium content increases the kinetics of diffusional decomposition of the γ phase, but it also increases the martensite start temperature. These effects interact in a way that reduces the critical quench rate for martensite formation with decreasing titanium content. The effects of titanium content on the sizes of parts that can be effectively heat treated is shown in Table 7. As shown, reducing the titanium content to 0.6 wt% enables larger parts to be effectively heat treated. Such a reduction in titanium content, however, also decreases the yield strength corresponding to any given aging treatment by about 60 MPa (9 ksi). This strength reduction can be overcome by aging at a slightly higher temperature, but

this results in decreased ductility. Optimum properties thus are obtained by keeping titanium content as high as can be tolerated without encountering excessive quench-rate-sensitivity problems. Below about 0.5 wt% titanium, the γ phase no longer transforms to martensite on quenching but undergoes a massive transformation to a variant of α phase that exhibits very little age hardenability. For this reason 0.5 wt% Ti is the lower limit for useful U-Ti alloys. Increases in titanium content, conversely, result in superior combinations of strength and ductility, but increases in the critical quench rate for martensite formation make these alloys difficult to process except in very thin sections.

Table 7 Critical cooling rates and section sizes for 50% martensite at centerline in U-Ti alloys

Titanium content, %	Critical cooling rate, °C/s (°F/s)	Plate thickness, mm (in.)	Bar diameter, mm (in.)
0.60	10 (18)	42 (1.7)	72 (2.8)
0.75	28 (50)	28 (1.1)	46 (1.8)
1.0	40 (72)	24 (0.95)	40 (1.6)
1.5	>100 (>180)	<15 (<0.6)	<25 (<1)

U-Ti alloys are difficult to weld because their high yield strengths permit residual stresses in the vicinity of 650 MPa (95 ksi) to develop in the weld and heat-affected regions. These stresses result in cold cracking when the material is removed from the protective welding environment and exposed to moist air. Because of this, mechanical joints must be made between U-Ti alloy components.

The titanium in solid solution makes U-0.75Ti somewhat less susceptible to oxidation and corrosion than unalloyed uranium. Nevertheless, protective coatings, such as electroplated nickel and ion-plated aluminum, are used in many applications.

Uranium-Niobium Alloys (Ref 16, 17, 19, 23, 25, 27, 30, 31, 37, 38). The alloy U-6Nb is used for applications requiring good corrosion resistance and ductility. This alloy is vacuum arc melted because of its high melting temperature and tendency to segregate during solidification. After forming, the material is vacuum-solution heat treated at 800 °C (1470 °F), to put the niobium into solid solution and to remove hydrogen, and is then quenched to room temperature to produce supersaturated α''_b martensite. The as-quenched material exhibits a yield strength of only 160 MPa (25 ksi) much lower than that of U-0.75Ti. Because of this low yield strength, U-6Nb cannot sustain high residual stresses, hence stress relief in not required. This low yield strength results from the ease with which the many twin boundaries in the α''_a martensite move. This twin boundary movement, coupled with the $\alpha''_b \leftrightarrow \gamma°$ martensitic transformation that occurs slightly above room temperature, results in a shape memory effect that can cause temperature-dependent dimensional instabilities and make it difficult to machine parts to close tolerances. These dimensional instabilities can be overcome by age hardening the martensite slightly, usually at 150 °C (300 °F) for 2 h. This aging treatment increases the yield strength somewhat, but has little effect on ductility.

U-6Nb is most frequently used in either the as-quenched or slightly aged (dimensionally stabilized) condition, where it exhibits good corrosion resistance and high ductility. Aging in the 150 to 400 °C (300 to 750 °F) range produces additional increases in strength and decreases in ductility, as shown in Fig. 17, but the combinations of strength and ductility obtainable in this alloy are not as good as those in U-0.75Ti. Overaging occurs at temperatures in excess of 400 °C (750 °F).

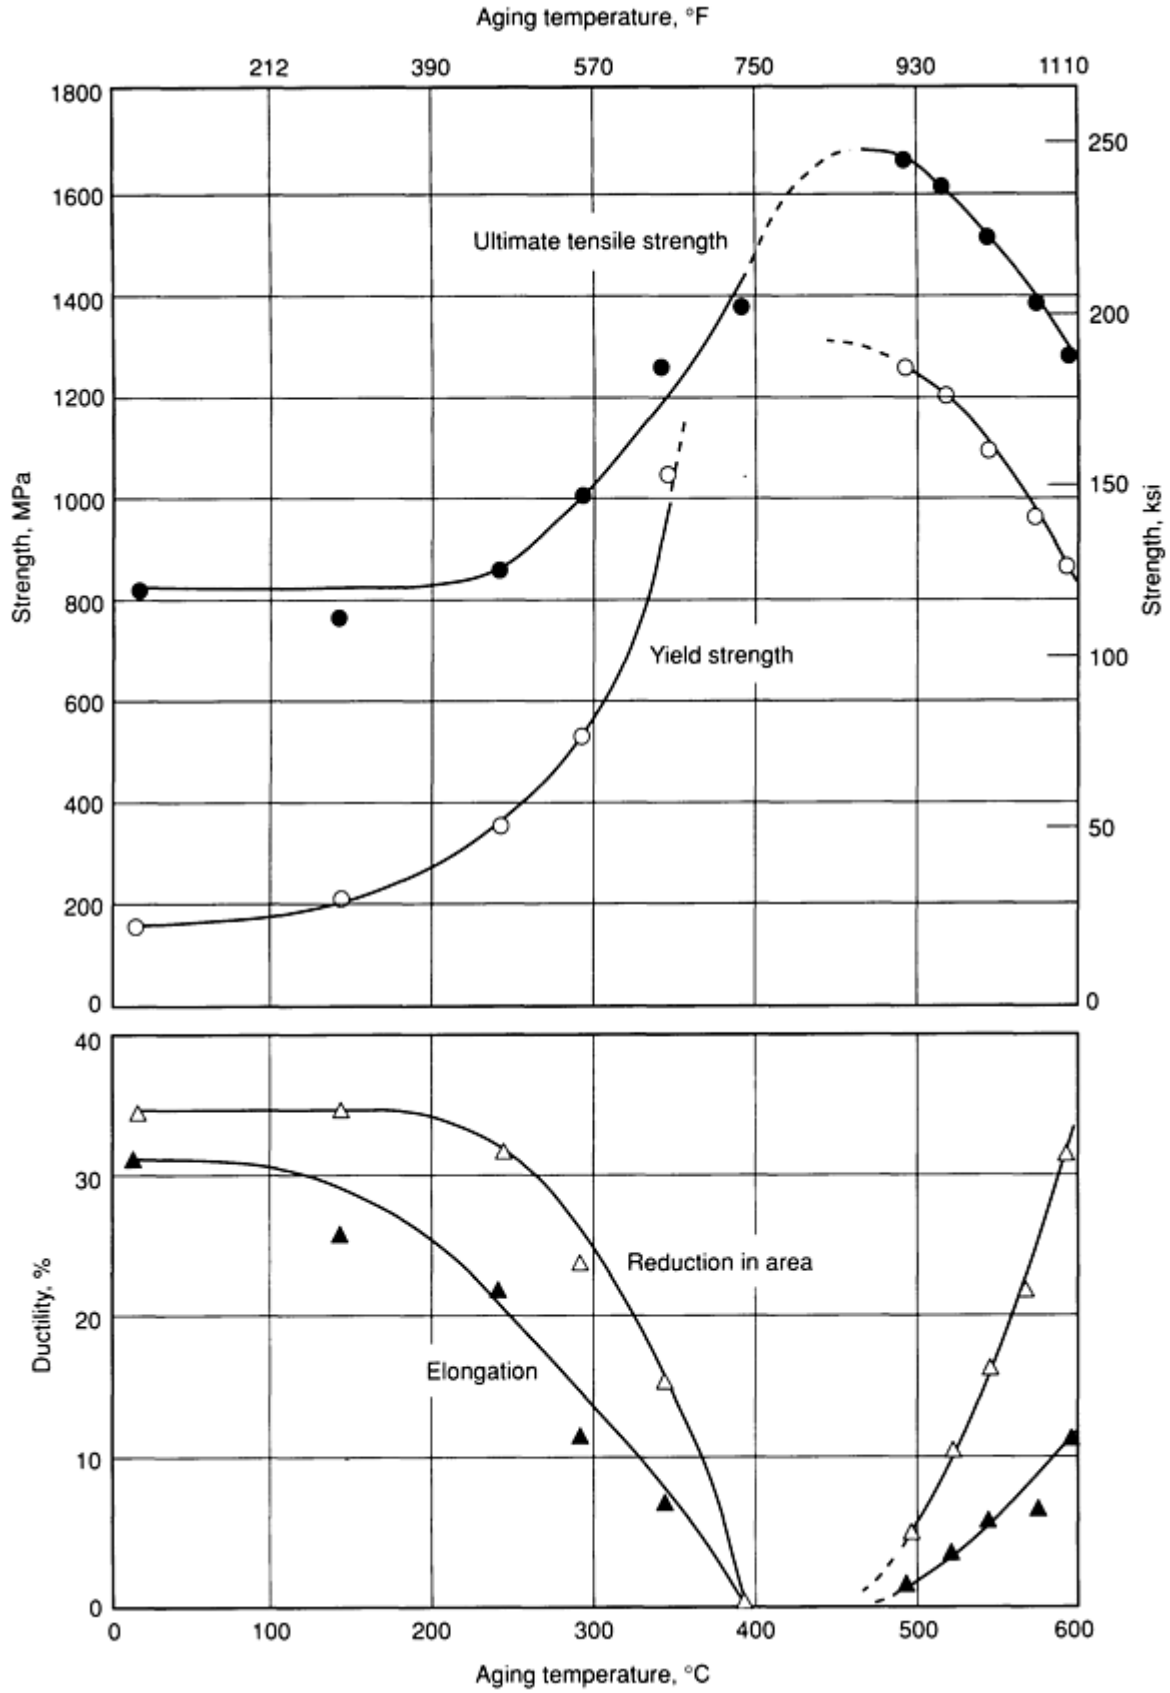

Fig. 17 Effect of aging temperature on tensile properties of U-6.3Nb aged 1 h. Source: Ref 19

U-6Nb is substantially less sensitive to quench rate than U-0.75Ti. Single-phase supersaturated microstructure can be obtained at cooling rates as low as 10 °C/s (18 °F/s), as shown in Fig. 6. This permits plates as thick as 40 mm (1.6 in.)

and bars up to 70 mm (2.75 in.) in diameter to be processed by water quenching to produce 100% martensitic microstructures. Thinner parts can be quenched in less severe media, such as oil.

The properties of U-6Nb are far less influenced by variations in hydrogen content, atmospheric moisture, test temperature, and strain rate than those of U-0.75Ti. In addition, this alloy is less susceptible to stress-corrosion cracking than many other alloys. To some extent, this is due to the materials generally being used in a low-strength condition; when aged to high strength it becomes increasingly prone to stress-corrosion cracking. It is also readily weldable and, since high residual stresses cannot be supported by this low-strength material, welds are generally not prone to delayed cracking. U-6Nb exhibits good resistance to corrosion, so it does not typically require protective coatings.

Other U-Nb alloys have been investigated, with niobium contents ranging from 2 to 12 wt%. Alloys with 2 to 4 wt% Nb exhibit better combinations of strength and ductility when aged to higher strengths, but not as good as U-0.75Ti. These leaner alloys also require more drastic quenches than does U-6Nb, and are more prone to hydrogen cracking when aged to high-strength conditions, particularly the U-2.3Nb alloy. Fully overaged U-2.3Nb, however, exhibits good ductility and resistance to delayed cracking at moderate strength levels, as shown in Table 3. Alloys with 8 to 12 wt% Nb exhibit excellent corrosion resistance but are increasingly susceptible to stress-corrosion cracking due to their higher strengths.

Uranium-molybdenum alloys (Ref 22, 24, 25, 28, 39) have been extensively investigated but are not widely used in high performance applications. U-Mo alloys are similar to U-Nb alloys except they are easier to melt (can be vacuum induction melted), are less resistant to corrosion, and are more susceptible to stress-corrosion cracking. U-2Mo is the most common of these alloys and is used primarily in the as-cast condition for shielding in radioactive material shipping casks. U-2Mo can be solution treated, quenched, and aged, but the resulting strength-ductility combinations are not as good as those obtainable in U-0.75Ti. When slow cooled from 800 °C (1470 °F), this alloy exhibits about twice the yield strength of unalloyed uranium (Table 2). This, plus case of melting and casting, makes it well suited for thick-walled castings, such as those used in radioactive shipping containers. It can also be used in the quenched and fully overaged condition for applications requiring moderate strengths and very low residual stresses (Table 3).

U-10Mo exhibits good corrosion resistance and is very quench rate insensitive, but its relatively high yield strength (~900 MPa, or 130 ksi), permits it to sustain high residual stresses and it stress-corrosion cracks severely. For these reasons, it is rarely used.

Other Alloys (Ref 27, 40, 41). Many ternary, quaternary, and higher-order alloys have also been investigated. In most cases these were relatively highly alloyed materials (α''_b or $\gamma°$ microstructures). Little evidence has been presented indicating that these alloys exhibit better strength-ductility combinations, reduced quench rate sensitivity, or improved resistance to hydrogen or stress-corrosion cracking than their simpler binary counterparts. For this reason, these higher-order alloys have found limited application.

Beryllium

A. James Stonehouse and James M. Marder, Brush Wellman Inc.

Introduction

BERYLLIUM is a metal with an unusual combination of physical and mechanical properties that make it particularly effective in optical components, precision instruments, and specialized aerospace applications. In each of these three general application areas, beryllium is selected because of its combination of low weight, high stiffness, and specific mechanical properties such as a precise elastic limit. It is also useful because it is transparent to x-rays and other high-energy electromagnetic radiation. In addition, beryllium is used as a small additive in some copper-base and nickel-base alloys (see the article "Beryllium-Copper and Beryllium-Nickel Alloys" in this Volume).

Unalloyed beryllium is readily joined by brazing. Fusion welding is not advisable in most situations, although beryllium can be fusion welded with aluminum filler metals when extreme care is exercised. Beryllium can be extruded into bar, rod, and tubing or rolled into sheet. The surface of beryllium can be polished to a very reflective mirror finish, and this finish is particularly effective at infrared wavelengths. Beryllium can be plated with nickel, silver, gold, and aluminum, and the surface also can be anodized or chromate conversion coated to provide a measure of corrosion resistance. Beryllium can be machined to extremely close tolerances; this attribute, in combination with its excellent dimensional stability, allows beryllium to be used for the manufacture of extraordinarily precise and stable components.

Almost all of the beryllium in use is a powder metallurgy (P/M) product. Powder processing is required for a number of reasons. Castings of beryllium generally have porosity and other casting defects that make them unsuitable for use in critical applications. This stems from the high melting point, the high melt viscosity, and the narrow solid-liquid range of beryllium. The high melting point (1283 °C, or 2341 °F) promotes reaction of the molten metal with potential casting mold materials; the high melt viscosity and the narrow solid-liquid range prevent the easy filling of complex castings. If high superheat temperatures are used to reduce viscosity, mold reaction limits the integrity of the component. In addition to the limitation on structural integrity imposed by casting, the grain size of as-cast beryllium is quite coarse (>50 μm, or 0.002 in.). The ductility and strength of beryllium depend primarily on grain size and obey the Hall-Petch relationship; these properties require grain sizes of less than about 15 μm (600 μin.) in structural components. Powder metallurgy processing allows grain sizes as low as 1 to 10 μm to be achieved when required. Consolidation by vacuum hot pressing, hot isostatic pressing, pressing and sintering, or other processes can produce parts with density values in excess of 99.5% of the theoretical value of 1.8477 g/cm^3 (0.067 lb/in.^{3}).

The application of P/M processing to beryllium does impose its own limits on the characteristics of the product. For example, the use of excessively fine powders increases the oxide content because of the increase in specific surface area. The oxide content of beryllium is one of the determinants of physical and mechanical properties; therefore, knowledge and control of the powder process are important to the proper fabrication of a beryllium component. Also, powder shape affects the anisotropy of mechanical properties.

Properties of Importance

Of the mechanical and physical properties given for beryllium in the article "Properties of Pure Metals" in this Volume, the most noteworthy are its density, elastic modulus, mass absorption coefficient, and the other physical properties presented in Table 1. The specific modulus, which is the ratio of the modulus of elasticity to the density, is of particular interest: The specific modulus for beryllium is substantially greater than that of other aerospace structural materials such as steel, aluminum, titanium, or magnesium (Fig. 1). Also, beryllium has the highest heat capacity (1820 J/kg · °C, or 0.435 Btu/lb · °F) among metals and a thermal conductivity comparable (210 W/m · K, or 121 Btu/ft · h · °F) to that of aluminum (230 W/m · K, or 135 Btu/ft · h · °F). Beryllium thus may prove to be an efficient substrate material for conducting waste heat away from active solid-state electronic components, particularly in aerospace applications.

Table 1 Selected physical properties of beryllium

Property	Amount
Elastic modulus, GPa (10^6 psi)	303(44)
Density, g/cm^3 (lb/in.^{3})	1.8477 (0.067)
Thermal conductivity, W/m · K (Btu/h · ft · °F)	210 (121)

Coefficient of thermal expansion, 10^{-6}/ °C (10^{-6}/°F)	11.5 (6.4)
Specific heat at room temperature, kJ/kg · K (Btu/lb · °F)	2.17 (0.52)
Melting point, °C (°F)	1283 (2341)
Mass absorption coefficient (Cu K-alpha), cm^2/g	1.007
Specific modulus, m (in.)[(a)]	16.7×10^6 (6.56×10^8)

(a) The specific modulus is defined (in inches) from the ratio of the elastic modulus (in psi) and the density (in lb/in.^{3}).

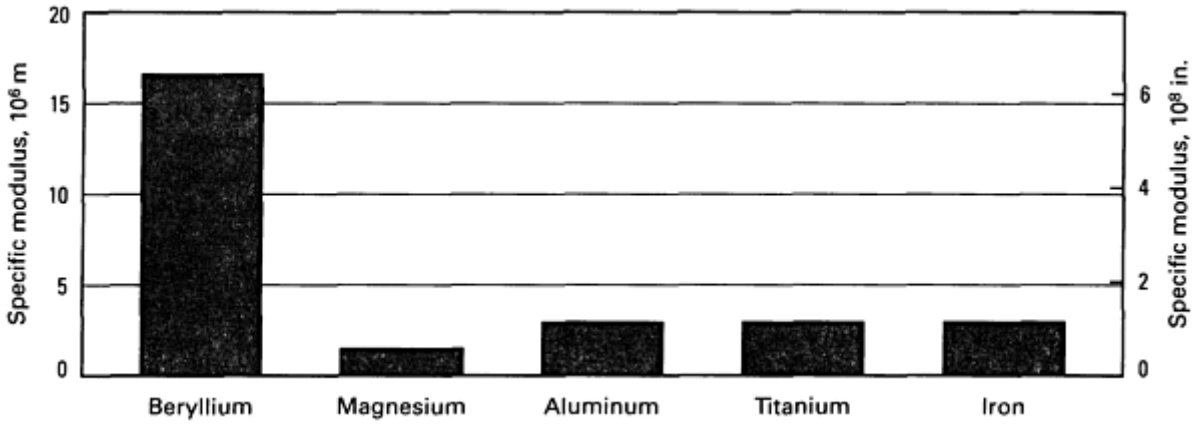

Fig. 1 Specific modulus of lightweight materials

The microyield strength of beryllium is of particular concern in guidance system components for ships, aircraft, and missiles. In a gyroscopic system, permanent errors can be introduced by yielding of the guidance components. A permanent set of 1 part in 10^6 (microyield), as opposed to the common yield criterion of 2 parts in 10^4, is the yield strength value used in evaluating gyroscope materials. Instrument grades of beryllium thus have a microyield strength acceptance criterion.

Infrared Reflectivity. The second important area of application for instrument-grade beryllium is in infrared optics. At long-wave infrared (LWIR) wavelengths, beryllium has a reflectivity in excess of 99% of the incident intensity. This enables beryllium to be used in LWIR surveillance and in deep-space observatories. The mirrors for satellites such as the Infrared Astronomical Satellite often are beryllium because the metal combines infrared reflectivity with light weight and high stiffness.

The low mass absorption coefficient of beryllium makes it practically transparent to x-rays and other high-energy electromagnetic radiation. It is therefore used as a window material in x-ray tubes and detectors such as those used in energy dispersive analysis of x-ray equipment.

Beryllium Mining and Refining

While a number of beryllium-containing minerals have been identified, only beryl ($3BeO\text{-}Al_2O_3\text{-}6SiO_2$) and bertrandite ($4BeO\text{-}2SiO_2\text{-}H_2O$) have been commercially significant to date. Beryl occurs in isolated pockets in pegmatites and, with the possible exception of operations in the Soviet Union and China, is normally recovered as a hand-sorted by-product of

mining operations for other minerals such as feldspar, spodumene, or mica. Commercial beryl normally contains about 10% BeO (3.6% Be). Until Brush Wellman began commercial extraction from a bertrandite-bearing deposit near Delta, UT in 1969, beryl was the only source of beryllium. The Utah deposit consists of mineralization in a water-laid tuff and is mined by open-pit methods. This ore, which averages 0.6% BeO, is the principal source of beryllium for the subsequent extraction process (Fig. 2), although Brush Wellman processes both bertrandite ore and beryl at its extraction facility in Delta, UT. The beryl is purchased from foreign sources as a means of husbanding the available domestic reserves of beryllium-containing ore. The mine and mill at Delta, UT, contain an estimated 50 years of proven reserves of bertrandite ore.

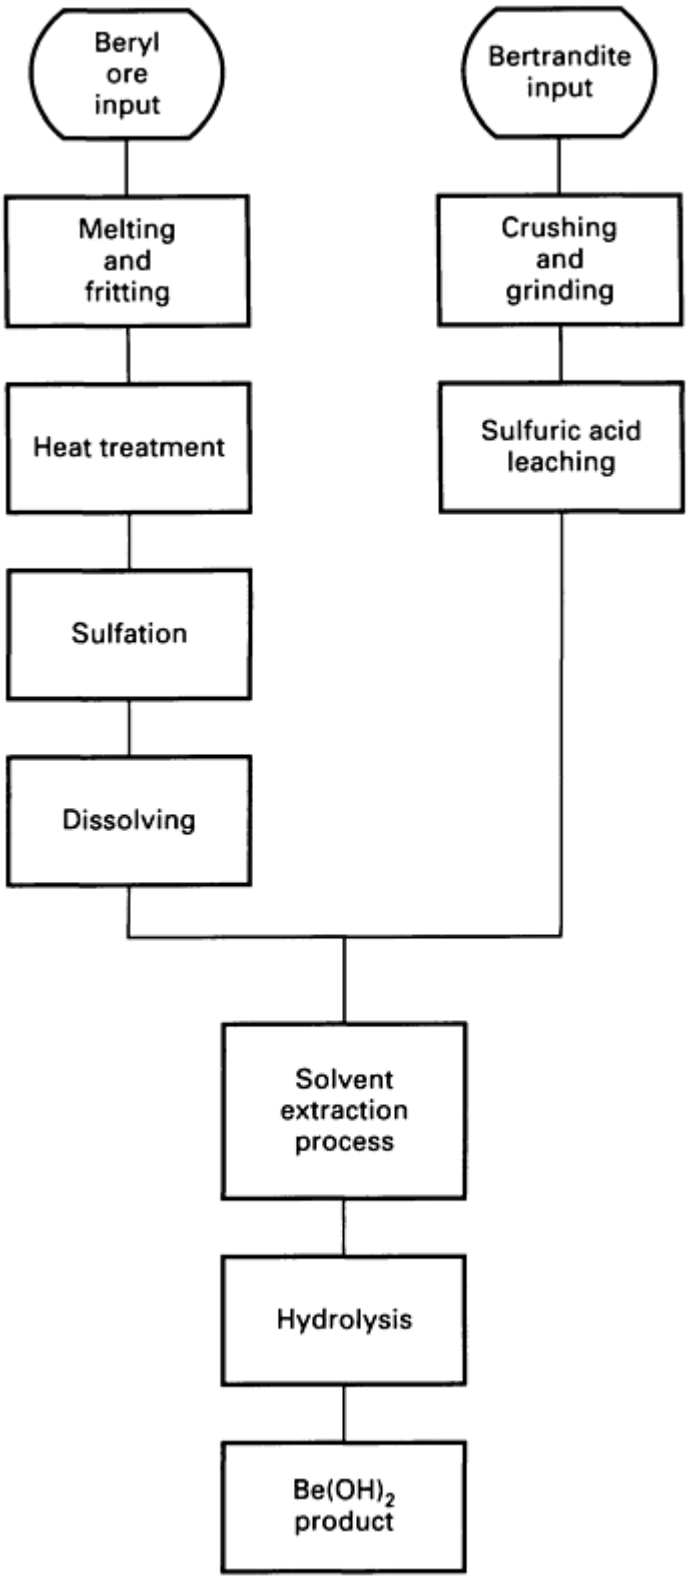

Fig. 2 Beryllium extraction processes used at the Delta, UT, extraction facility

Beryl is treated by arc melting, water quenching, and elevated-temperature sulfating to make the beryllium accessible to the extraction process. The bertrandite mineral is soluble in sulfuric acid without this treatment; this factor, along with the extensive nature of the deposit, provides the advantage of Utah bertrandite over imported beryl. The product of both ore inputs is a crude solution of beryllium sulfate. A purified beryllium hydroxide is obtained by a solvent extraction procedure followed by hydroxide precipitation. For the production of beryllium metal, the hydroxide is dissolved in ammonium bifluoride, purified, and then crystallized from aqueous solution as ammonium fluoroberyllate [$(NH_4)_2BeF_4$]. This salt is thermally decomposed to the anhydrous fluoride (BeF_2) and NH_4F gas. The fluoride is reacted with magnesium to yield beryllium and magnesium fluoride (MgF_2). The primary beryllium is in the form of pea-to-marble-sized pebbles.

The electrowinning of beryllium by fused-salt electrolysis of beryllium chloride ($BeCl_2$) from a variety of low-melting-point baths is possible, as is the electrorefining of beryllium using a bath of KCl-LiCl-$BeCl_2$. However, these procedures are not known to be in commercial operation at this time.

Beryllium pebbles from magnesium reduction are vacuum cast to remove residual reduction slags and any excess magnesium. A similar step is necessary with the electrolytic materials to remove the trapped chlorides from the fused-salt bath. The present commercial practice is to melt the metal in magnesium oxide crucibles and then pour it into graphite molds yielding about 180 kg (400 lb). The vacuum cast ingot is the input for beryllium powder manufacture.

Beryllium Powder Production Operations

Current Industrial Practices. Although ingot castings are not useful as commercial products themselves because of the inherent limitations of cast beryllium (as previously described), the ingot is quite acceptable from the chemical analysis point of view and provides a starting point for subsequent P/M operations. The ingot is converted into chips using a lathe and a multihead cutting tool. The chips are ground to powder using one of several mechanical methods: ball milling, attritioning, or impact grinding. These processes produce powders with varying characteristics, particularly with regard to particle shape.

Ball milling and attritioning are relatively slow processes, and they activate slip and fracture primarily upon the basal planes of the hexagonal close-packed beryllium crystal. This fracture mode gives rise to a flat-plate particle morphology. When the particles manufactured by this process are loaded into a die for consolidation, the flat surfaces align and give rise to areas of preferred orientation.

The impact-grinding process, which relies upon a high-velocity gas stream to accelerate beryllium particles and drive them against a beryllium target, activates fracture upon additional crystal planes other than the basal plane, resulting in a blocky particle. The blocky particles exhibit less tendency to align preferentially during powder loading, thereby reducing the tendency for preferred orientation in the final consolidated product. The reduction in preferred orientation leads to improved overall ductility, a property particularly sensitive to orientation, in all directions in the consolidated component. For this reason, impact grinding has largely replaced attritioning and ball milling as the major powder production technique.

Atomization has recently been introduced as a powder production technique. Atomization has several potential advantages over mechanical comminution methods. Atomization typically produces a spherical particle, and the use of such a particle is logically the most effective means of eliminating property anisotropy resulting from the shape of powder particles. There are also economic factors that favor atomization. The inert-gas atomization process is capable of very high production rates, and the effectiveness of such a process could conceivably reduce production costs significantly.

Three atomization techniques are currently in various stages of developmental investigation. The inert-gas atomization process is furthest along in the development cycle and has shown the capability of producing clean fine-grain powders with excellent flow and packing characteristics. The properties of consolidated billets made from this material have been equal or superior to those made with comparable mechanically comminuted material. Centrifugal atomization, as represented by the plasma rotating-electrode process and the rapid solidification technique is in a less-advanced stage of application development.

Powder Consolidation Methods

Once powder is made, it must be consolidated. This step in the production of beryllium components has effects on the properties of the consolidated material that are as profound as the effects of the size and chemistry of the powder. Until the mid-1980s the predominant consolidation method was vacuum hot pressing of powder into right circular cylinders. This remains the technique with the highest production volume, but net-shape technology is transforming the industry because of the cost advantages associated with greater material utilization.

Vacuum Hot Pressing. Schematic diagrams of the vacuum hot pressing (VHP) and the hot isostatic pressing (HIP) processes are shown in Fig. 3. In the VHP process, the powder is vibratory loaded into a die, and the die is placed into a vacuum furnace. Hydraulically driven punches are inserted into the die cavity, vacuum is established, and the heating and pressing cycle is initiated. Consolidation of beryllium powder is performed in vacuum because of the reactive nature of the powder. Densities in excess of 99% of theoretical are typically achieved. The sizes of vacuum hot presses range from 200 to 1800 mm (8 to 72 in.) in diameter. Pressures up to 8 MPa (1200 psi) and temperatures up to 1100 °C (2000 °F) are used in the consolidation process. The consolidated billets are then machined into components.

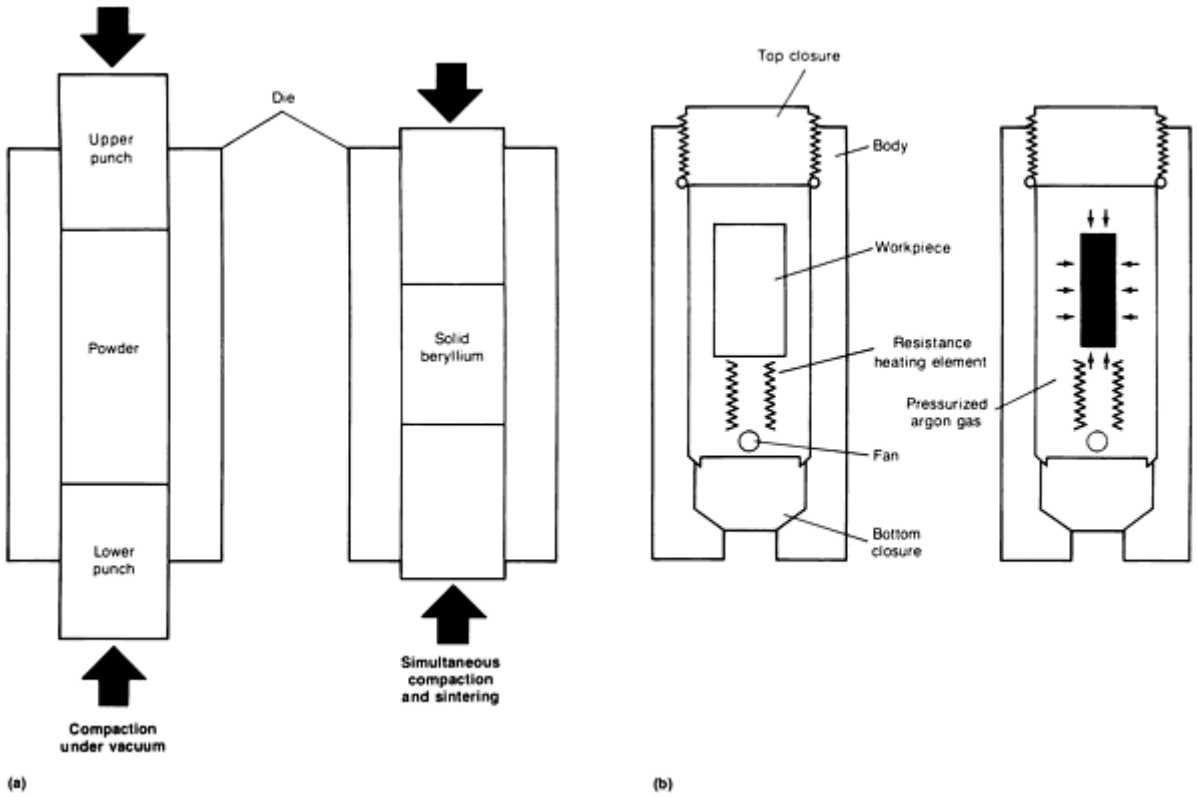

Fig. 3 Schematic diagrams of two powder consolidation methods. (a) Vacuum hot pressing. In this method, a column of loose beryllium powders is compacted under vacuum by the pressure of opposed upper and lower punches (left). The billet is then brought to final density by simultaneous compaction and sintering in the final stages of pressing (right). (b) Hot isostatic pressing. In this process, the powder is simultaneously compacted and sintered to full density inside a pressure vessel within a resistance-heated furnace (left). The powder is placed in a container, which collapses when pressure is exerted evenly on it by pressurized argon gas (right).

Near-net shape processes are being developed that take advantage of various combinations of HIP, cold isostatic pressing (CIP), and sintering. The use of a variety of processes allows parts to be manufactured that meet all design requirements at the lowest manufacturing cost. The use of near-net shape processing is not an entirely new development. Cold pressing of powder followed by vacuum sintering to achieve final density has been used for a number of years to make parts such as brakes for F-14, C-5A, and S-3A aircraft. In recent years, however, the implementation of HIP technology has fostered a more aggressive development effort.

Sintering of beryllium to achieve high densities requires temperatures in excess of 1200 °C (2200 °F); these elevated temperatures cause grain growth and a resultant reduction in mechanical properties. Hot isostatic pressing allows powders to be consolidated at temperatures as low as 650 to 725 °C (1200 to 1340 °F), although 1000 °C (1830 °F) is a more common consolidation temperature. Very high strength is achieved with the lower-temperature cycle, but with a loss of ductility. A temperature of 1000 °C (1830 °F) gives an excellent combination of strength and ductility. In addition, if HIP is employed as a final densification step, 100% theoretical density can be achieved. This density level is not possible with either sintering or the VHP process.

There are several variations on the net-shape processes that rely on HIP to provide final densification. The most straightforward of these is the direct-HIP process, in which powder is loaded into a shaped mild-steel can. The can is then degassed in a vacuum at about 600 to 700 °C (1100 to 1300 °F) in order to remove both air and the gasses that are adsorbed onto the powder surface. The can is then hermetically sealed and isostatically pressed. After HIP consolidation, the can is removed by either machining or acid leaching. If the can is properly designed, the shape of the beryllium part can be used with a minimum of machining or secondary processing. The direct-HIP process yields the greatest control over grain size--and therefore over properties--because it permits consolidation with the greatest temperature latitude.

Another variant of the net-shape process combines cold isostatic properties with hot isostatic pressing. In this method, powder is loaded into an elastic (for example, neoprene or latex) bag and isostatically pressed by means of a liquid at room temperature to produce a green compact of about 80% theoretical density. The compact can then be vacuum sintered to achieve a density of 98% or more. At this density level, a can is not necessary for further densification by HIP because the porosity is isolated rather than interconnected. The expense of fabricating a complex disposable can is thus eliminated, and the bag that is used in place of the can has a relatively low cost and is reusable. The trade-off is that the high sintering temperature used in the bag method results in grain growth. However, this is offset somewhat by the elimination of residual porosity. Also, the CIP process permits the production of parts with complex, three-dimensional complexity that cannot be made by the uniaxial cold-pressing route.

Beryllium Grades and Their Designations

The distinctions among grades of beryllium are generally made according to mechanical properties, which vary with grain size and specimen orientation. Physical properties generally do not vary greatly among grades. In view of these considerations, it is obvious that the specifications of a grade of beryllium must identify the consolidation techniques as well as powder characteristics.

Beryllium grades, as opposed to alloys, are nominally beryllium with beryllium oxide as the only other major component. Although oxide inclusions are regarded as undesirable contaminants in many systems, the oxide in beryllium is desirable as a grain-boundary pinning agent. The finer the powder, the greater the oxide content. When very fine-grain sizes are required, the high oxide content of the powder acts to stabilize the grain size during consolidation. Beryllium oxide contents of commercial grades vary from an allowed maximum of 0.5% in O-50, an optical grade, to a required minimum of 4.25% in I-400, an instrument grade. Table 2 presents chemical compositions of currently available commercial grades of beryllium.

Table 2 Chemistry of commercial grades of beryllium

Beryllium grade	Beryllium components, %		Maximum impurities, ppm					
	Be, min	BeO, max	Al	C	Fe	Mg	Si	Other, each
Structural grades								
S-65B	99.0	0.7	600	1000	800	600	600	400
S-200F and S-200FH	98.5	1.5	1000	1500	1300	800	600	400

Instrument grades								
I-70A	99.0	0.7	700	700	1000	700	700	400
O-50	99.0	0.5	700	700	1000	700	700	400
I-220B	98.0	2.2	1000	1500	1500	800	800	400
I-400B	94.0	4.25 min	1600	2500	2500	800	800	400

Structural grades of beryllium are indicated by the prefix S in their designations. Property requirements for commercially available structural grades are presented in Table 3. In general, these grades are produced to meet ductility and minimum strength requirements. S-200F, an impact-ground powder grade, is the most commonly used grade of beryllium. This grade evolved from S-200E, which used attritioned powder as the input material. Recently, S-200FH has been introduced to the marketplace; the suffix H designates consolidation by HIP. The properties of S-200F include a minimum ductility of 2% elongation in all directions within the vacuum-hot-pressed billet, an increased of 1% over its predecessor, S-200E. In addition, S-200F has yield and ultimate strengths that are somewhat higher than those of S-200E, reflecting the general improvements in powder-processing techniques and consolidation methods.

Table 3 Mechanical property requirements for structural grades of beryllium

Grade	0.2% yield strength		Ultimate strength		Elongation, %
	MPa	ksi	MPa	ksi	
S-65B	207	30	290	42	3.0

Grade S-65 also is an impact-ground powder product. This grade was formulated to meet the damage tolerance requirements for use in the Space Shuttle. Grade S-65 sacrifices some strength for improved ductility. The 3% minimum ductility requirement is achieved by using impact-ground powder in combination with tailored heat treatments. The heat treatments produce a desirable morphology of iron-aluminum-beryllium-base precipitates.

Low levels of iron and aluminum are present in commercial grades of beryllium (see Table 2). Although these elements cannot be eliminated economically, they can be balanced, and heat treatments can be applied to form discrete grain-boundary precipitates of $AlFeBe_4$. This minimizes the iron in solid solution or in the compound $FeBe_{11}$, either of which is embrittling. The precipitates also eliminate aluminum from the grain boundaries, thus precluding hot shortness at elevated temperatures.

At moderate temperatures, beryllium develops substantial ductility. At 800 °C (1470 °F), for example, the elongation of S-200F is in excess of 30%. Yield strength and ultimate strength decrease with increasing temperature, but usable strength and modulus are maintained up to approximately 600 to 650 °C (1100 to 1200 °F). The changes in strength and ductility of S-200F with temperature are shown in Fig. 4.

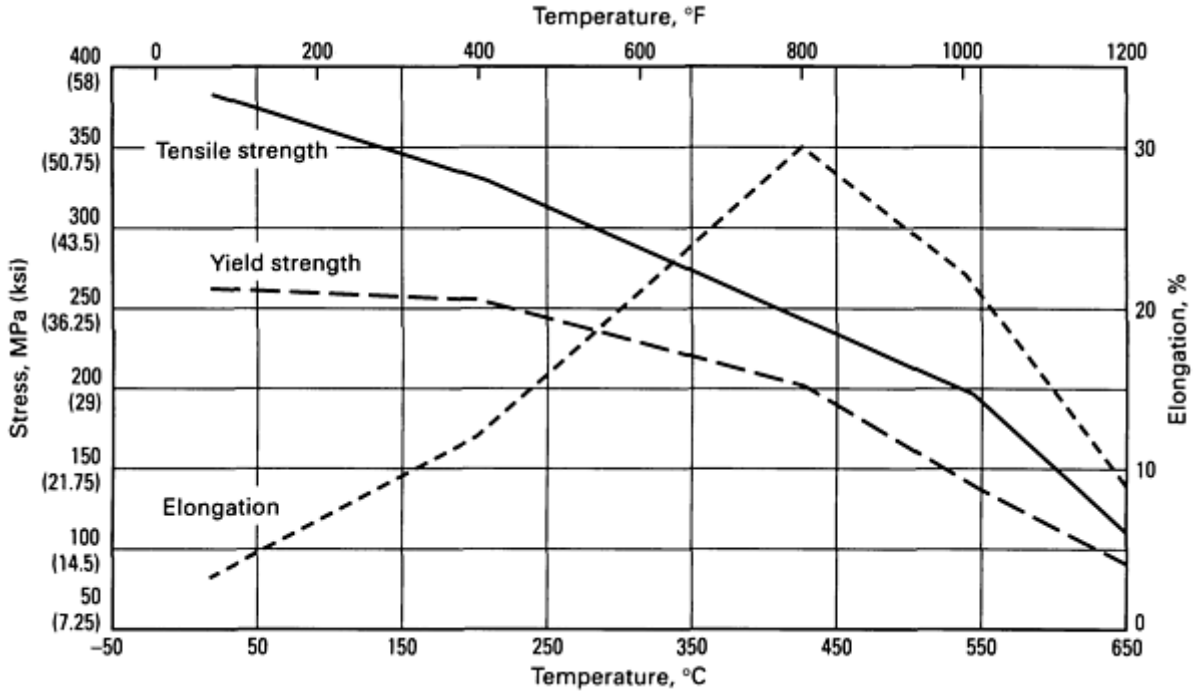

Fig. 4 Tensile properties of S-200F beryllium at elevated temperatures

Instrument grades of beryllium, which are designated by the prefix I, were developed to meet the specific needs of a variety of precision instruments. These instruments generally are used in inertial-guidance systems where high geometrical precision and resistance to plastic deformation on a part-per-million scale are required. The resistance to deformation at this level is measured by microyield strength.

In addition to those grades developed to meet the needs of inertial guidance systems, grade I-70 was developed specifically for optical components is satellite imaging systems. Because the large mirrors used in aerospace optics must retain precise geometry throughout complex loading spectra, no differentiation was drawn between grades used for optical instruments and those used for inertial-guidance instruments. Recently, however, O-50, a grade developed specifically for the qualities of infrared reflectivity and low scatter has initiated the use of the prefix O to indicate an optical grade. The property requirements for commercially available instrument grades are given in Table 4.

Table 4 Mechanical property requirements for instrument grades of beryllium

Instrument grade	0.2% yield strength		Tensile strength		Elongation, %	Microyield strength	
	MPa	ksi	MPa	ksi		MPa	ksi
I-70A	172	25	240	35	2.0	. . .	. . .
O-50	172	25	240	35	2.0	. . .	. . .
I-220B	275	40	380	55	2.0	34.5	5

The property requirement that differentiates instrument grades from structural grades is microyield strength. In I-400, ductility has practically been ignored in order to attain microyield strength values of 60 to 70 MPa (9 to 10 ksi). Grade I-220 strikes a balance between ductility and microyield strength, with a 2% elongation requirement and a microyield strength of 35 to 40 MPa (5 to 6 ksi). As greater insight into the relationship between properties and powder processing, composition, and heat treatment is obtained, further property improvements should be made possible.

Wrought Products and Fabrication. Consolidated beryllium block can be rolled into plate, sheet, and foil, and it can be extruded into shapes or tubing at elevated temperatures. At present, working operations typically warm work the material, thereby avoiding recrystallization. The strength of warm-worked products increases significantly as the degree of working increases. The in-plane properties of sheet and plate (rolled from a P/M material) increase as the gage decreases, as shown in Table 5. As with most hexagonal close-packed materials, it develops substantial texture as a result of these working operations. The texture in sheet, for example, generally results in excellent in-plane strength and ductility, with almost no ductility in the short-transverse (out-of-plane) direction. Similar property trade-offs resulting from the anisotropy caused by warm working are inherent in extruded tube and rod. Sheet can be formed at moderate temperatures by standard forming methods. For some special applications, there has been interest in the improved formability of ingot-derived rolling stock as opposed to material rolled from a block of P/M materials. The ingot-derived stock has improved weldability and formability, primarily because of its reduced oxide content.

Table 5 In-plane properties of beryllium products rolled from a P/M source block

Thickness		0.2% yield strength		Ultimate strength		Elongation, %
mm	in.	MPa	ksi	MPa	ksi	
11-15	0.45-0.60	275	40	413	60	3
6-11	0.25-0.45	310	45	448	65	4

In many instances, complex components must be built up from shapes made from sheet and foil. For example, beryllium honeycomb structures have been made by brazing formed sheet, as have complex satellite structural components. Beryllium tubing made by extrusion has also been used in satellite components. Space probes such as the Galileo Jupiter explorer have used extruded beryllium tubing to provide stiff lightweight booms for precision antenna and solar array structures.

Health and Safety Considerations

Beryllium has been commercially produced for more than 50 years, and its toxicity has been recognized and successfully controlled for the last 30 years. Information on the toxicity of beryllium is contained in the article "Toxicity of Metals" in this Volume.

The main concern associated with the handling of beryllium is the effect on the lungs when excessive amounts of respirable beryllium powder or dust are inhaled. Two forms of lung disease are associated with beryllium: acute berylliosis and chronic berylliosis. The acute form, which can have an abrupt onset, resembles pneumonia or bronchitis. Acute berylliosis is now rare because of the improved protective measures that have been enacted to reduce exposure levels.

Chronic berylliosis has a very slow onset. It still occurs in industry and seems to result from the allergic reaction of an individual to beryllium. At present, there is no way of predetermining those who might be hypersensitive. Sensitive individuals exposed to airborne beryllium may develop the lung condition associated with chronic berylliosis.

Exposure Limits. Two in-plant exposure limits have been set by the Occupational Safety and Health Administration to prevent beryllium disease. The first is a maximum atmospheric concentration of 2 μg/m^3 of air averaged over an 8-h day. The second is a short-exposure limit of 25 μg/m^3 of air for a duration of less than 30 min. The U.S. Environmental Protection Agency (EPA) has set a nonoccupational limit of 0.01 μg/m^3 of air averaged over a 1-month period outside of a beryllium facility. The EPA limits the emission of beryllium into the environment to 10 g in any 24-h period. To meet these requirements, beryllium producers must adhere to industrial-hygiene standards and use air pollution control measures when dusts, mists, and fumes might be created. Historically, these control measures appear to have been effective in preventing chronic beryllium disease.

Precious Metals and Their Uses

A.R. Robertson, Englehard Corporation

THE EIGHT PRECIOUS METALS, listed in order of their atomic number as found in periods 5 and 6 (groups VIII and Ib) of the periodic table, are ruthenium, rhodium, palladium, silver, osmium, iridium, platinum, and gold. Atomic, structural, and physical properties of the precious metals, which are also referred to as the noble metals, are listed in Table 1. Additional property data can be found in the articles "Properties of Precious Metals" and "Properties of Pure Metals" in this Volume.

Table 1 Selected properties of precious metals

Property	Value for indicated metal							
	Platinum	**Palladium**	**Iridium**	**Rhodium**	**Osmium**	**Ruthenium**	**Gold**	**Silver**

Precious metals are of inestimable value to modern civilization. Their functions in jewelry, coins, and bullion, and as catalysts in devices to control auto exhaust emissions are widely understood. But in certain other applications, their functions are not as spectacular and, although vital to the application, are largely unknown except to the users. Many facets of daily life and influenced by precious metals and their alloys. For example, precious metals are used in dental restorations and dental fillings (see the section "Precious Metals in Dentistry" in this article). Precious metal solders are used in dentistry and in the jewelry and electronics industries. Thin precious metal films are used to form the electronic circuits. Much of our clothing today is produced with the aid of precious metals that are used in spinnerettes for producing synthetic fibers. Precious metals perform as catalysts in various processes; for example, widely used agricultural fertilizers are produced with the aid of a platinum-rhodium alloy catalyst woven in the form of gauze, and auto emissions are reduced through the use of platinum-group alloy catalysts. Electrical contacts containing palladium are essential to telephone communications. Certain organometallic compounds containing platinum are significant drugs for cancer chemotherapy.

Resources and Consumption

Metal specialists at the U.S. Bureau of Mines continually survey the market in silver, gold, and platinum-group metals to determine present availability and usage and to forecast future trends. *Mineral Commodity Profiles* and *Mineral Industry Surveys* covering these metals are issued periodically.

Much of the information in this section was obtained from Ref 1, 2, 3, 4, 5, 6, 7, and 8. For the latest available information concerning these metals, it is recommended that the most recent issues of these publications be consulted.

Silver. In recent years, the United States has been a net importer of silver. Imports, including unrefined silver, supplied about 89 million troy ounces of silver to the U.S. supply in 1988. Domestic mine production added 53 million troy ounces to this total, and refining of old scrap increased the U.S. silver level to a total of approximately 217 million troy ounces

during this same period. The U.S. supply is obtained from primary and secondary sources. About 25% of primary silver is obtained from predominantly silver ores; the remaining primary silver is a by-product of the refining of copper, lead, zinc, and other metals. In addition, significant quantities of silver are derived as a by-product of gold mining. The top states for mine production are Idaho, Nevada, Montana, Arizona, and Utah.

Five smelting and refining companies produce the major portion of domestic primary silver. The smelters and refineries treat ores, concentrates, residues, and precipitates from company mines and plants in addition to materials purchased from other sources. Silver scrap is recycled by several primary smelters and a considerable number of small secondary refineries. In addition, secondary silver is recovered by several trading and fabricating companies and is recycled by end-product manufacturers.

In recent years, government regulations relating to the environment and to control of emissions of hazardous compounds have limited the operation of some base metal smelters that recover silver as a by-product. Silver in its ionic form, as in waste discharged from electroplating plants, is considered a potential source of pollution and a health hazard. Because of increasing concerns about environmental matters, governmental agencies can be expected to step up their efforts to minimize discharges from processing plants.

The following table presents primary statistics for U.S. silver demand in 1987. A general indication of the annual demand pattern for silver can be drawn from this data:

End use	**Demand, troy ounces × 10^6**
Electroplated ware	2.5
Sterling ware	3.8
Jewelry and arts	4.2
Photography	60.2
Dental and medical supplies	1.3
Brazing alloys and solders	5.6
Mirrors	1.0
Batteries	2.5
Contacts and conductors	22.7
Bearings	0.3
Coin, medallions, and commemorative objects	4.2

Catalysts	2.5
Other	4.5
Total U.S. demand	**115.3**

Several factors can affect the supply and demand of silver. One factor is the appreciable amount of silver required for monetary purposes; another is the speculative or investor market in refined silver bars and sacks of domestic coins. In addition, there has been some interest in the collection of commemorative medallions and limited-use objects fabricated from silver. Whether the latter end use will continue to grow or will decline in the future is a matter of considerable interest. In any event, depending on prices, a large potential secondary supply of silver is available in the form of coins, silverware, jewelry, and commemorative objects.

Gold. Because of its aesthetic beauty and enduring physical properties, gold is important not only to industry and the arts, but also as a commodity having long-term value. In the past, gold was considered to be mainly a monetary metal. However, starting in the late 1950s, more gold was used by manufacturers and investors than was used for monetary purposes. Since 1968, gold has become, to a considerable extent, a free-market commodity, with prices free to adjust to supply and demand. Despite this open market, almost half of the total world supply of gold, estimated at 2.4 billion troy ounces, is in various government vaults tied down by agreements among large industrial nations.

About 1.7 million troy ounces of gold per year are mined and reclaimed from old scrap in the United States (see, for example, the section "Recycling of Electronic Scrap" in the article "Recycling of Nonferrous Alloys" in this Volume). This amount falls far short of the amount required by U.S. industry. The requirements for bullion and coins are almost equal to those of industry. Because of this general demand for gold, the net inflow of this metal from foreign sources is large. In 1988, for example, 3.0 million troy ounces were imported, mostly in the form of refined metal.

About 50% of U.S. refinery production comes from gold ores, and the remainder from by-products of the refining of copper and other base metals. Refinery production in the United States includes gold from domestic mines, from imported ores and base bullion, and from domestic and foreign scrap. In recent years about 5 to 10% of U.S. refinery production has been derived from foreign ores, base bullion, and scrap.

About 5 to 10% of the total U.S. supply of gold comes from old scrap, which is defined as metal discarded after use. New scrap, which is generated during manufacturing, is usually reclaimed by the fabricator and is not considered part of the market supply.

The United States has appreciable gold resources, some of which are marginally profitable to recover. The price is now high enough to encourage growth of production at a modest rate, but environmental restraints on placer mining and the high cost of developing lode deposits currently dictate that the United States will continue to import most of its gold.

The largest foreign producer of gold, the Republic of South Africa, produced about 20 million troy ounces of the estimated 1988 total world production of 59 million troy ounces. Other important gold producers are the Soviet Union, Canada, South America, Asia, and Oceania. According to the U.S. Bureau of Mines, world resources are adequate to meet the forecast demand for this metal to the year 2000.

Data for U.S. gold demand in 1988 illustrates the general pattern of consumption of gold in fabricated products:

End use	**Demand** **troy ounces × 10^3**

Jewelry and arts	1774.0
Dental supplies	247.0
Industrial products	1176.0
Total U.S. demand	**3197.0**

Source: U.S. Bureau of Mines

The use of gold for jewelry accounts for approximately 55% of the gold consumed. Dental uses generally amount to 7 to 8% of annual demand. Industrial requirements are generally centered in the electronics industry. However, even though the total number of end uses for gold in electronics continues to be high, considerable emphasis has been placed on reducing the use of gold in present applications because of its increasing cost. Bars, medallions, coins, and related products amounted to less than $\frac{1}{4}$ of 1% of the total U.S. gold consumption in 1988.

Platinum-Group Metals. The six closely related metals in the platinum group commonly occur together in nature. These transition elements are near neighbors in periods 5 and 6 of group VIII in the periodic table. Ruthenium, rhodium, and palladium each have a density of approximately 12 g/cm^3, osmium, iridium, and platinum each have a density of about 22 g/cm^3 (see Table 1).

The platinum-group metals are among the scarcest of metallic elements, and for this reason their cost is high. They occur as native alloys or in mineral compounds in placer deposits, sometimes together with gold; they also occur in lode deposits in basic or ultrabasic rocks, where they may be found together with nickel and copper. Most of the world supply of platinum-group metals is currently extracted from lode deposits in the Republic of South Africa, the Soviet Union, and Canada.

Another major source of platinum-group metals is old scrap obtained from obsolete equipment, spent catalyst, and discarded jewelry. This source is increasing in importance with the broadening industrial applications of these metals. Material of each type can be concentrated by a number of different methods, then refined by any of several chemical processes that conclude with a heating step to convert precipitates to metal in a porous, somewhat powdery form called sponge. Sponge is the most common form in commercial metal transactions, although ingots and shot are also traded.

In lode deposits, platinum-group metals are often associated with nickel and copper sulfide, which may be the principal products of mining (as in Canada and the Soviet Union) or important coproducts (as in the Republic of South Africa). In the ores, the proportions of the six platinum-group metals vary from one lode deposit to another. Canadian deposits in the Sudbury District contain approximately equal amounts of platinum and palladium; South African deposits contain more than twice as much platinum as palladium. Generally, platinum and palladium together account for about 80 to 85% of the platinum-group metals present in any given ore, followed by (in order of decreasing presence) ruthenium, rhodium, iridium, and osmium.

The composition of placer deposits differs somewhat from that of lode deposits. Placer deposits are characterized by the nearly complete absence of palladium and the common presence of gold. It appears the palladium and, to a certain extent, platinum, rhodium, and ruthenium are dissolved away during placer formation; in the well-established placer deposit in Witwatersrand, South Africa, only osmium and iridium are present (as the alloy osmiridium). At present, the only economically important placers are found in Colombia, South Africa, and the Soviet Union; together they account for about 2% of total world production.

The United States depends almost entirely on foreign sources for platinum-group metals. In 1988, net import reliance as a percentage of apparent U.S. consumption was approximately 93%. Apparently U.S. consumption during 1988 is estimated at 2.7 million troy ounces. The sources of U.S supply between 1984 and 1987 were the Republic of South Africa, 44%; the United Kingdom, 16%; the Soviet Union, 9%; all others, 31%.

One company in Texas recovers platinum-group metals as by-products of the copper-refining process. In addition, about 24 smaller refineries located mostly on the East and West Coasts, handle or in some way process domestic scrap. However, most of them treat only platinum and palladium, and only three or four refine all six metals.

At present, U.S. mine production and reserves of platinum-group metals are small; untapped domestic resources appear to be large but are not well explored. The heavy dependence the United States places on foreign sources for these critical metals has strategic implications as well as a substantial impact on the U.S. balance of payments. The need for exploration and development of U.S. resources is apparent.

The U.S. demand for platinum-group metals is projected to grow at an annual rate of about 2.5%, with an estimated 1990 demand of 3.3 million troy ounces. Demand in the rest of the world is forecast to grow more slowly than in the U.S.; it is expected to reach a level of about 9.7 million troy ounces in the year 2000. World reserves and resources appear to be more than adequate to meet this demand.

The U.S. demand patterns in 1988 for three of the most-used platinum-group metals were:

End use	**1988 Demand, troy ounces × 10^3**		
	Platinum	**Palladium**	**Rhodium**
Automotive	609,000	160,000	65,000
Chemical	61,976	81,343	3,091
Dental and medical	10,871	227,747	142
Electrical	108,660	386,710	3,508
Glass	19,896	350	2,748
Jewelry and decorative	11,932	7,356	5,254
Petroleum	36,730	26,111	45
Miscellaneous	76,394	135,581	22,787

The United States and Japan currently use about 60% of the platinum-group metals produced. Western Europe and the Soviet Union essentially divide the remaining 40%. Automotive emission requirements (which require the use of a platinum-palladium catalyst) began in 1974 in the United States and presently are substantial (this application alone accounted for 43% of total consumption in 1987). In Japan, about three-fourths of the platinum goes into jewelry, whereas in the United States and Western Europe, about 5 to 15% of this metal is used in jewelry. Substantial increases in the use of platinum-group metals can be expected in the European Economic Community with the gradual implementation of restrictions on automobile emissions from 1988 through 1993.

Trade Practices

Precious metals are bought and sold in troy ounces or, in markets where the metric system is used, in kilograms. One kilogram is equal to 32.15 troy ounces. The troy system of weights is based on the troy ounce of 480 grains, 31.1 grams, or 20 pennyweight. One troy ounce is equal to 1.097 avoirdupois ounces.

Silver and Gold. The term fineness refers to the weight portion of silver or gold in an alloy, expressed in parts per thousand. For example, 1000 fine silver (also called fine silver) is pure silver, or 100% silver, and 1000 fine gold is 100% pure gold. Gold bullion that is commercially traded is at least 995 fine or higher. Sterling silver is 925 fine, or 925 parts (also 92.5%) silver and 75 parts (or 7.5%) copper. Until 1964 the U.S. coin silver was an alloy of 90% Ag (900 fine) and 10% Cu. Silver bullion that is traded has a silver content ranging from 999 fine to 999.9 fine. Gold and copper are silver impurities in any fineness of silver bullion.

Another way of indicating gold purity is by the karat, which is a unit of fineness equal to the $\frac{1}{24}$th part of pure gold. In this system, 24 karat (24 k) gold is 1000 fine or pure gold. The most popular jewelry golds in the United States are:

Karat designation	Gold content
24 k	100% Au (99.95% min)
18 k	$\frac{18}{24}$ths, or 75% Au
14 k	$\frac{14}{24}$ths, or 58.33% Au
10 k	$\frac{10}{24}$ths, or 41.67% Au

Each category differs from the others in number, type, and proportions of the base metal additions. Gold alloys used in jewelry are always specified by karats, whereas those used in dentistry and for electronic purposes are designated by percentage.

Jewelry golds range from light yellow through deep yellow to reds and greens, and also include a family of whites. Each alloying element has a different effect on the color of gold:

- *Silver:* As the proportion of silver increases, gold changes in hue from yellow to greenish-yellow to white
- *Copper:* As copper content increases, gold becomes redder in appearance
- *Nickel:* Nickel has the effect of whitening gold. The so-called white golds substitute nickel for silver
- *Zinc:* Zinc is considered a decolorizer. Some red golds (copper-containing alloys) are converted to a substitution of zinc for some of the copper and silver

Trade practice rules for the jewelry industry in the United States, set by the Federal Trade Commission, require that any article labeled gold contain at least 10 k gold, with a tolerance of $\frac{1}{2}$ k. In gold cladding (gold adhered to base metal stock), the ratio of the weight of the material is indicated, together with the karat of the cladding. For example, one-tenth 12 k gold filled stock is a base metal surfaced with a layer or layers of 12 k gold alloy that make up 10% of the weight of the composite article. Such an article, if assayed into, would be found to contain 5% gold.

The designation gold filled is limited by stamping regulations to articles in which the weight of the coating is at least $\frac{1}{20}$ th of the total. Lower ratios may be stamped rolled gold plate. The quality mark cannot be applied to articles surfaced with an alloy of less than 10 k. In the cases of the gold-filled and rolled gold plate materials, the karat gold is bonded to the base metal substrate by soldering, brazing, welding, or mechanical means.

Platinum-Group Metals. Platinum and palladium are traded on the New York Mercantile Exchange in respective lots of 50 and 100 troy ounces; on the Chicago Mercantile Exchange, they are traded in units of 100 troy ounces. On the New York Exchange, the metals can be in the form of bar or sheet.

The required purity of platinum may vary according to the end use or application. Although commercial-grade platinum must be at least 99.8% pure, platinum with a purity of at least 99.9% is required for alloying, laboratory ware, and contacts. Platinum of even higher purity, sometimes with controlled impurities, is used for other specialized applications such as thermocouples and resistance thermometers. The present U.S. thermometric standard platinum, designated Pt 67, is 99.999% pure.

Federal regulations stipulate that an article of trade can be marked platinum only if it contains at least 98.5% platinum-group metals, of which no more than 5% may consist of platinum-group metals other than platinum; that is, the material must contain a minimum of 93.5% Pt. Special stamping provisions cover some jewelry alloys. All platinum jewelry sold in the United Kingdom must be hallmarked.

Alloys used for dental purposes are rather complex in composition, and metallurgical considerations are the dominant factors in their design. Various specifications have been established by the American Dental Association and by the federal government, but these do not cover all of the dental alloys (see the section "Precious Metals in Dentistry" in this article).

Special Properties

The precious metals have unusual combinations of properties that often are superior to those of other materials. In some cases, these property combinations make them the only materials that can meet the specialized requirements of an advanced technology or industrial application. The initial investment in these metals or their alloys may be high, but it is offset by long, reliable service and by ease of refining. Also, the refining process is marked by a high recovery rate because the precious metals are virtually indestructable. This high rate of recovery can make their use, for many applications, economical as well as efficient.

The precious metals share a number of properties that distinguish them from other metals or alloys, including corrosion resistance, good electrical conductivity, catalytic activity, and excellent reflectivity. However, each of these metals also has distinctive individual characteristics.

Silver, a bright white metal, is very soft and malleable in the annealed condition. It does not oxidize at room temperature, but it is attacked by sulfur. Nitric, hydrochloric, and sulfuric acids attack silver, but the metal is resistant to many organic acids and to sodium and potassium hydroxide.

In commercial applications, the special chemical properties, superior thermal and electrical conductivity, high reflectivity, malleability, ductility, and/or corrosion resistance of silver justify its high initial cost. In addition, uses have been established in photography, brazing, batteries, medicines, dentistry, mirror backings (silver-backed mirrors may become a more significant use as solar energy technology is developed), bearings, catalysts, coinage, and nuclear control rods.

The use of silver in photography is based on the ability of exposed silver halide salts to undergo a secondary image amplification process called development. In silver solders, the controlling factor is the rather low melting temperature of the alloys and their ability to wet various base metals at temperatures below the melting points of the metals to be joined. Such alloys do not dissolve or attack steel in normal usage, are ductile, have sufficient strength over a wide range of temperatures, and are capable of joining a wide variety of materials. Silver alloys are finding more and more use as replacements for the lead-tin solders traditionally used in residential plumbing.

Silver that contains varying amounts of dispersed cadmium oxide (≤20% CdO) is used in medium- and heavy-duty electrical contacts (see the article "Electrical Contact Materials" in this Volume). In this composite material, silver imparts its good electrical and thermal conductivity as well as its low surface contact resistance, and the dispersed cadmium oxide improves resistance to sticking and welding and provides good resistance to arc erosion (good arc quenching). The susceptibility of fine silver contacts to sulfidation precludes their use in low-current, low-voltage, and low-contact-force applications. In general, they should not be used below 10 V (except at high currents) or in situations where a voltage drop of 0.2 V will be troublesome; in addition, they are not suitable for application in low-level audio circuits because of the electrical noise they would introduce.

Silver is used in engine bearings because it has good lubrication properties as well as moderate hardness, good thermal conductivity, and low solubility in iron.

The good mechanical properties of certain silver-tin-mercury and silver-tin-copper-mercury alloys, and the small dimensional changes that occur during setting of these alloys, are the basis for the extended use of silver in dental amalgams (see the discussion of dental amalgams in the article "Properties of Precious Metals" that follows).

Sterling silver (silver-copper alloy) retains its long-established position in uses where elegant appearance is of paramount importance. For jewelry and tableware, high reflectivity makes silver particularly attractive. Much work has been done in developing a nontarnishing sterling silver, but no such alloy has yet been produced. Various thin protective coatings, such as rhodium, have been used on silver objects that are not likely to scratch.

Silver-clad copper, brass, nickel, and iron are produced for a variety of uses, ranging from electrical conductors and contacts to components for chemical equipment. Silver is also used in various chemical processes, including catalytic applications such as the production of formaldehyde or the oxidation of ethylene.

Silver coatings are applied to glass and ceramics by spreading a special silver paste on the material and then warming it to red heat. These coatings are widely used in electronic devices and automotive applications. Chemical methods for applying conductive coatings to plastics and glass are also used as the base for electroplate. Organometallic solutions containing silver are applied and fired in the production of conductors, electrical grounds and shields, resistance heaters, electrode terminals, and conductive bases for electroplating.

The rapid diffusion of oxygen through silver at elevated temperatures can be an advantage or disadvantage depending on the application. This phenomenon has been used to advantage in the internal oxidation of base metal alloying constituents (such as cadmium, rare earths, cerium, or calcium) in silver alloys. The resulting silver composite containing fine, well-dispersed oxide particles has been used in electrical contact applications (see the article "Electrical Contact Materials" in this Volume).

Electrodeposited silver is used widely for electrical, electronic, industrial, and decorative applications. Heavy electrodeposits can be used for surfacing chemical equipment and for bearings.

Gold is a bright, yellow, soft, and very malleable metal. Its special properties include corrosion resistance, good reflectance, resistance to sulfidation and oxidation, freedom from ionic migration, ease of alloying with other metals to

develop special properties, and high electrical and thermal conductivity. Because gold is easy to fashion, has a bright pleasing color, is non-allergenic, and remains tarnish free indefinitely, it is used extensively in jewelry. For much the same reasons, it has long been used in dentistry in inlays, crowns, bridges, and orthodontic appliances (see the section "Precious Metals in Dentistry" in this article).

Gold is used to a considerable extent in electronic devices, particularly in printed circuit boards, connectors, keyboard contactors, and miniaturized circuitry (see *Packaging*, Volume 1 of the *Electronic Materials Handbook* published by ASM INTERNATIONAL). Because electronic devices employ low voltages and currents, it is important that the coated components remain completely free from tarnish films and that they remain chemically and metallurgically stable for the life of the equipment.

Gold is a good reflector of infrared radiation; for this reason, gold films are used in radiant heating and drying devices as well as in thermal barrier windows for large buildings. A much publicized use of gold reflective coatings has been for protecting space vehicle components and space suits from excessive solar radiation that could raise temperatures substantially.

Fired-on gold organometallic compounds are used to decorate porcelain and glassware. Chemically inert gold rupture discs are used in chemical process equipment. Because of its good resistance to corrosion and wear, the gold alloy 70 Au-30Pt has been used in the perforated spinnerettes through which cellulose acetate fibers are extruded. Gold has also been used in other industrial applications, such as sliding electrical contacts, fine-wire gold connectors for the semiconductor industry, vacuum and sputter-deposited films or coatings for interconnecting links in thin-film integrated circuits, gold brazing alloys for joining jet engine components, and gold alloys in thermocouples for both cryogenic service down to liquid helium temperature and high-temperature use up to 1300 °C (2370 °F).

Among the gold alloys, the Au-Ag-Cu-Pt-Pd alloys are used in dentistry because of their good mechanical properties, response to age-hardening treatments, nobility, and moderate melting points. The Au-Ag-Cu (yellow) golds and Au-Ni-Cu-Zn (white and suntan) golds have a relatively good resistance to tarnishing and corrosion, and adequate mechanical properties; these attributes, along with social custom and the available colors of the materials, account for their use for jewelry, eyeglass frames, and rings. These alloys are also used for certain rubbing contacts in small electrical devices. Gold-silver alloys containing about 70% Au, generally with a few percent platinum, resist both oxidation and sulfidation, and have other properties useful for low-current electrical contacts.

Pure gold is readily electrodeposited and it, as well as rhodium and palladium, is used for surfacing certain high-frequency conductors for service in environments where silver corrodes. A substantial quantity of electrodeposited gold is used for surfacing plug-type electrical connectors. Platinum metals may be required at higher temperatures to minimize diffusion and adhesion (sticking). Gold alloys are also electrodeposited on jewelry and other items where appearance is important. For some pieces, several layers of gold and other metals are deposited successively, and the article is subsequently heated to produce an alloy by diffusion.

Pure gold has high reflectivity in the red and infrared spectral ranges and therefore is sometimes used for surfacing infrared reflectors. Although pure gold resists nitric, sulfuric, and hydrochloric acids as well as many other corrosives, its applications are limited because of its susceptibility to attack by halogens, its softness and relatively low melting point, and, to some extent, its cost. However, gold sometimes is used as a lining for small calorimeter bombs and as a corrosion-resistant solder. The hard 70Au-30Pt alloy has been used for rayon spinnerettes, but it generally has been replaced in this application by Pt-10Rh.

Platinum-Group Metals. All six platinum-group metals are closely related and commonly occur together in nature. Their most distinctive trait in the metallic form is their exceptional resistance to corrosion. Of the six metals, platinum has the most outstanding properties and is the most used. Second in industrial importance is palladium, which is the lightest metal of the group.

Rhodium occasionally is fabricated in the unalloyed form, but it is more commonly used as an alloying element with platinum, and to a lesser extent, with palladium. In the unalloyed form, iridium is fabricated into large crucibles that are used in the production of single crystals of yttrium-aluminum garnet and gadolinium-gallium garnet, a substrate for bubble memory devices. It also finds considerable use as an alloying element for platinum and rhodium. Ruthenium is mainly used as an alloying element for platinum and palladium. When alloyed with platinum and palladium, rhodium, iridium, and ruthenium (in order of increasing effectiveness) act as hardening agents. Osmium forms a toxic oxide at ambient temperature and is therefore a difficult metal to utilize. A naturally occurring alloy of osmium and iridium called

osmiridium is very hard and has been used for fountain pen tips and phonograph needles. The important properties of the platinum-group metals are outlined below.

Platinum is a white, very ductile metal that remains bright in air at all temperatures up to its melting point. Platinum has the following engineering characteristics:

- High melting point (1769 °C, or 3216 °F)
- Readily strengthened by alloying with compatible precious metals
- Can be electroplated
- Virtually nonoxidizable
- Resists molten glass and molten salts in oxidizing atmospheres
- Low vapor pressure
- Low electrical resistivity and, conversely, a high temperature coefficient of electrical resistivity; this combination makes it eminently suited for measuring elements in resistance thermometers
- Stable electrical contact resistance
- Stable thermoelectric behavior (the Pt-10Rh versus Pt thermocouple is the defining instrument on the International Practical Temperature Scale of 1968)
- High thermionic work function
- Special magnetic properties when alloyed with cobalt
- High thermal conductivity
- High resistance to spark erosion (hence its use in spark plugs)
- Excellent catalytic activity
- Coefficient of thermal expansion matching that of common glass

Platinum resists practically all chemical reagents and is soluble only in acids that generate free chlorine, such as aqua regia.

Palladium is a white, very ductile metal with properties similar in many respects to those of platinum. Palladium has the following engineering characteristics:

- A density of 12.02 g/cm^3, which is approximately 56% that of platinum and 63% that of gold. It can be used in place of lower-cost gold alloys without sacrificing the good corrosion resistance of gold
- High melting point (1554 °C, or 2829 °F)
- Excellent ductility
- Easily cold worked
- Outstanding ability to form extensive ductile solid solutions with other metals
- Can be electroplated, electroformed, and deposited via electroless methods
- Effective whitener for gold
- Good catalytic activity

Palladium resists tarnishing in ordinary atmospheres, but it does tarnish slightly upon outdoor exposure to sulfur-contaminated environments. When palladium is heated in air to 400 to 800 °C (750 to 1475 °F), a thin oxide film is formed; this film decomposes at higher temperatures, leaving the metal with a bright appearance. Hydrochloric acid and sulfuric acid attack palladium slightly; nitric acid, ferric chloride, and most halogens attack it readily. Palladium absorbs hydrogen, which will diffuse at a relatively rapid rate when the metal is heated. This reaction is the basis for laboratory apparatus for purifying hydrogen. Palladium has found increasing use in dental porcelain fused to metal alloys (for example, Au-Pt-Pd-Ag alloys).

Rhodium is a hard white metal. It is fairly ductile when hot. Rhodium is the whitest platinum-group metal and remains bright under all atmospheric conditions at ordinary temperatures. It resists hot aqua regia. High oxidation resistance and a high melting point (1963 °C, or 3565 °F) permit rhodium to be used for fabricating items for use at high temperature. Rhodium has high specular reflectivity and the highest electrical and thermal conductivities of any platinum-group metal.

Iridium is a white metal that has limited malleability at room temperature; however, it can be worked at elevated temperatures. Iridium oxidizes visibly when heated in air (to temperatures of 600 to 1000 °C (1100 to 1850 °F), but it remains bright at higher temperatures. Acids or aqua regia do not attack it, but molten salts do. Iridium has exceptional corrosion resistance, and this property coupled with a high-temperature (≤ 1650 °C, or 3000 °F) strength comparable to that of tungsten and a high melting point (2447 °C, or 4437 °F) permit its use in crucibles for melting nonmetallic substances at temperatures as high as 2100 °C (3800 °F). Iridium has a high modulus of elasticity (517 GPa, or 75×10^6 psi). It is the only known metal that can be used for short periods of time at temperatures up to 2000 °C (3650 °F) in air without undergoing catastrophic failure. Iridium is catalytically active and is the heaviest of all metals (22.65 g/cm^3).

Ruthenium is a very hard white metal that cannot be worked cold. It can be worked after being heated to a failure high temperature, but only with extreme difficulty. Ruthenium resists common acids, including aqua regia, at temperatures up to 100 °C (212 °F). Ruthenium has a high resistance to contamination by lead. Like iridium, it is principally used as a hardener for platinum and palladium. Ruthenium has a high melting point (2310 °C, or 4190 °F), is exceptionally hard, and has a high elastic modulus (414 GPa, or 60×10^6 psi). In the absence of oxygen, ruthenium exhibits good resistance to attack by molten lithium, sodium, potassium, copper, silver, and gold. It has low electrical contact resistance at temperatures up to 600 °C (1100 °F) and resists any tendency of the contacts to weld together at these temperatures.

Osmium is a white hard metal that is not malleable at room or elevated temperatures. It forms a toxic oxide at ambient temperatures. Osmium is used as an alloying element to provide other precious metals with extreme hardness and resistance to corrosion. Osmium has the highest melting point of all the platinum-group metals (3045 °C, or 5513 °F) and the second-highest density (22.61 g/cm^3).

Commercial Forms and Uses

Semifinished Products. Silver, gold, platinum, palladium, and rhodium can be drawn to rod and wire as small as 25 μm (0.001 in.) in diameter. Iridium can be drawn to diameters as small as 75 μm (0.003 in.). Some of the platinum alloys containing iridium or rhodium can be drawn to diameters of 7.5 μm (0.0003 in.).

Sheet, strip, ribbon, and foil in a broad range of alloys, sizes, and thicknesses can be produced. Silver, gold, platinum, and some of its alloys can be rolled to thicknesses as small as 2.5 μm (0.0001 in.), but tolerances cannot be guaranteed. Clad materials can be obtained as wire, sheet, strip, and formed parts, with a great variety of substrate materials.

Tube is manufactured in a wide range of sizes and in round, half-round, and square sections. Seamless tube made of platinum, palladium, gold, and most alloys of these metals is manufactured in sizes ranging from 0.4 mm (0.016 in.) outside diameter × 0.1 mm (0.004 in.) wall thickness up to 44 mm (1.750 in.) outside diameter × a 55 mm (0.200 in.) wall thickness. Tube in larger sizes or made of less ductile materials such as platinum alloyed with rhodium (≥25% or iridium (>25%) is manufactured only as seamed tube with a 3 to 75 mm ($\frac{1}{8}$ to 3 in.) inside diameter × a 0.25 to 2.5 mm (0.010 to 0.100 in.) wall thickness. Pure rhodium and pure iridium are usually furnished as seamed tube with a 3 to 40 mm ($\frac{1}{8}$ to $1\frac{1}{2}$ in.) inside diameter × a 0.25 to 0.6 mm (0.010 to 0.025 in.) wall thickness and as single lengths about 150 mm (6 in.) long. Base metal tube is available with an outer cladding or an inner lining of platinum, gold, silver, or any of the commercial precious metal alloys.

Precious metal powders are produced for a wide range of electronic and industrial applications. Electronic powders are chemically precipitated to produce particle sizes of less than 10 μm and tend to be high in surface area. They are used as inks in hybrid circuits. Flake powders tend to produce shinier, smooth films; spherical particles more often result in dull-appearing surfaces. Platinum, palladium, 40Pt-20Pd-40Au, 10Pt-20Pd-70Au, 7.5Pt-22.5Pd-70Au, and 75Au-25Pd powders have been used for electronic purposes. Trials are usually necessary to determine the most suitable powder from the standpoint of both cost and performance.

Powders intended for industrial uses are composed of mixtures of particles that range in size from about 2 to 3 μm to as large as 840 μm (20 mesh), depending on the size required. These powders are suitable for use in powder metallurgy parts, as protective coatings against hostile industrial environments, as raw materials in alloy manufacture, and for various other uses.

Industrial Uses. Requirements and materials for more than 65 industrial applications of precious metals are cited in Table 2. Additional information on selection and application of precious metal contacts is included in the article "Electrical Contact Materials" in this Volume.

Table 2 Industrial applications of precious metals

Application	Special requirements	Metal or alloy
Electrical and electronic devices		
Spark plug electrodes	Resistance to corrosion and erosion	Thoriated Pt-4W, Ir, ODS Pt, Pd-Au
Jet engine glow plugs	Relight on flameout	Rh-Pt
Leads for thermistors	Freedom from oxidation	Pt and Ag plus binder
Transistor junctions	Doping contact	Au and doping alloy
	Nondoping contact	Ir-Pt
Resistors and potentiometers	High resistivity, low temperature coefficient, and low contact resistance	8W-Pt, 5Mo-Pt, 10Ru-Pt, Au-Pd-Fe, dental-type alloys
Resistance wire and resistance film	High resistivity, low temperature coefficient, and low contact resistance	Au-Pd-Pt
Electrodes for ceramic condensers	Applicability, nonoxidizing, solderability	Ag or Pt, with bonding agent
Electrodes for air condensers	Corrosion resistance	Ag and Au
Conductors in printed circuits	Corrosion resistance, solderability, wear resistance (Rh)	Ag, Au, Rh, Pd (Ag may lead to ionic shorting)
Connectors (such as terminals, lugs, and tabs)	Low contact resistance, solderability	Ag, Au; Pd electro- or electroless plate
High-temperature wiring	Conductivity, oxidation resistance, low contact resistance	Pt-clad base metal, solid Ag, Ag-Mg-Ni
Fuses	High conductivity and oxidation resistance	Ag-Au
Solid leads in mercury contact devices	Negligible solubility, freedom from oxidation	Pt where wetting required; also 10Ir-Pt. Ir where no wetting desired. Rh-plated steel for collector rings

Bonding in vacuum devices requiring vacuum-tight low-vapor-pressure seals	Desired melting point and low vapor pressure	28Cu-72Ag, 20Cu-80Au, 40Ni-60Pd, Au-Pd
Brazing alloys for tungsten	Ductility, high melting point, vapor pressure	Platinum
Instrument applications		
Sensing elements for resistance thermometers	Stable and known resistance, high temperature coefficient	Ultrapure Pt
Thermocouples	Stable temperature relation	10Rh-Pt vs Pt, 6Rh-Pt vs 30Rh-Pt, 13Rh-Pt vs Pt, 5Rh-Pt vs 20Rh-Pt, Au-Pd vs Rh-Pt, Au-Pd vs Ir-Pt
	For sensing ultrahigh temperature in oxygen-free atmosphere	Ir-Rh vs Ir
	High electromotive force	Au-Pd vs Rh-Pt, Au-Pd vs Au-Pd-Pt
Thermocouple connectors	Low-resistance joints with base metal wires	Platinum plate
Galvanometer suspensions	Corrosion resistance, strength, and conductivity	40Cu-60Pd (slow cooled), 14 k Au, Ag-Cu
Galvanometer pivots	Hardness and corrosion resistance	60 Os-Ru alloy
Contact parts in low level switches	Low electrical contact resistance, good wear resistance	Rh electroplate; 69 Au-6Pt, 25Ag; Pt, Pd, and hard dental alloys
Slip rings, brushes for selsyns	Low contact resistance, good wear resistance, and minimum friction	18 k Au, dental alloys, 60Pd-40Cu, Ag, Au electroplate, Rh electroplate
Sensing elements for gas analyzers	Catalytic action proportional to gas content	Pd-Pt, platinum metal
Glass and ceramics industries		
Tanks and crucibles for optical glass	Insolubility, high melting point, noncontaminating	Pure platinum
Bushings and valves for fiberglass	Insolubility, high strength	10Rh-Pt, 20Rh-Pt ODS Pt-Rh
Crucibles for continuous melting glass frit	Noncontaminating	Platinum

Crucibles for melting optical salt crystals	Insolubility, high melting point, noncontaminating	Platinum
Metallized glass and ceramics, metal film bonded to ceramic by heat	Nonoxidizing, desired color	Liquid-bright Au and Pt pastes
Metallized glass and ceramics, metal film produced by vacuum sublimation	Desired properties	Au, Pd, Rh, Ag, and alloys
Heater windings for glass, ceramic, and ferrite research	Nonoxidizing, high melting point, low vapor pressure	Pt, 20Rh-Pt, and 40Rh-Pt
Chemical industry		
Septum in a hydrogen purification system	Selective transmission	Pd, 60Pd-40Ag
Catalyst for removal of oxygen from H_2	Activity at low temperature	Pd on alumina
Septum in an oxygen purification system	Selective transmission	Pure silver
Catalyst for production of nitrogen or nitrogen-hydrogen heat-treating atmosphere from ammonia	Activity and long life	Platinum metal
Catalyst for production of formaldehyde from methanol	Activity	Silver
Catalyst for production of ethylene oxide from ethylene	Activity	Silver
Catalyst for destruction of odoriferous or hazardous contaminants	Activity	Platinum metal
Catalyst for ammonia plus air to yield HNO_3	Long life, high efficiency	Rh-Pt
Catalyst for ammonia, air and methane to yield HCN	Long life, high efficiency	Rh-Pt
Rayon spinnerettes	Corrosion resistance, strength, ductility	Rh-Pt, Pt-Au
High-temperature HCI containers	Corrosion resistance	Platinum
Electrochemical applications		

Insoluble anode for electrolytic protection	Non-film-forming, high corrosion resistance	Platinum, 20Pd-Pt, and 50Pd-Pt
Insoluble anode for production of persulfates and perchlorates, and for electroplating	Corrosion resistance in chlorides, sulfates; proper anodic reaction	Platinum and 5Ir-Pt
Positive plates in primary and secondary batteries	Corrosion resistance, conductivity, and depolarization	$Ag\text{-}Ag_2O_2$
Fuel cell electrodes	Catalytic activity, corrosion resistance	Platinum metals
Container for tantalum capacitors	Corrosion resistance, high conductivity	Silver
Aerospace applications		
Brazing alloys in stainless steel systems for handling rocket fuels and oxidizers	Corrosion resistance, compatibility	Au-Cu-Ni, Au-Ni-Cr
Special uses		
Crucible for molten lead	Insolubility and high melting point	Ir under oxygen-free atmosphere
Crucible for molten bismuth	Insolubility and high melting point	Ru under oxygen-free atmosphere
Crucible for molten NaOH	High corrosion resistance	Silver
Container for high-temperature sulfur and sulfur gases	High corrosion resistance	Gold
Container for high-temperature SO_2	Corrosion resistance, ductility	Pure Pt, pure Au, Au-Pt alloy
Container for high-temperature (1000 °C, or 1830 °F) H_2S	Corrosion resistance, ductility	Gold, platinum
Container for S and H_2S (<1000 °C, or <1830 °F)	Corrosion resistance, ductility	Gold
Neutron absorber	High absorption cross section	Iridium
Intense gamma ray source	Radiation energy; moderate half-life	Iridium
Magnet	Highest known energy product and corrosion resistance, ductility	23Co-Pt

Laboratory ware	Corrosion and heat resistance	Platinum, 0.6Ir-Pt, 3.5Rh-Pt
Reflectors		
Visible and infrared reflecting surface	High efficiency	Ag where protected; Rh where exposed
Ultraviolet and infrared reflecting surface	High and uniform reflectivity	Rhodium
Red and infrared reflecting surface	High long-wave reflectivity	Gold
Safety devices		
Over-pressure protector (frangible disk)	Reproducible tensile properties, corrosion resistance	0.6Ir-Pt, Ag, Au
Fuse wire for temperature-limiting fuse	Required and constant melting point oxidation resistance	Gold

Coatings. Several cladding or coating processes are used to produce composite articles with precious metal surfaces. Table 3 lists the most important coating processes for precious metals, with characteristics, common thickness ranges, and typical applications of each.

Table 3 Precious metal coatings

Method	Characteristics	Thickness range	Examples of applications
Mechanical and thermal bonding (cladding)			
Brazing, hot pressing, hot and cold rolling, puddling, casting	100% density, good adhesion, high wear resistance, uniform thickness	≥2.5 μm (≥0.1 mil)	Precious-metal-clad base metals for jewelry, electrical contacts, chemical apparatus, or other industrial uses; applicable for all malleable precious metals and alloys
Vacuum coating			
Vacuum metallizing	Fairly uniform coating, transparent layers, good adhesion	0.025-12.5 μm (1-500 μin.)	For decorative purposes, reflectors (rhodium on glass), condensers for electronic devices (mostly metals on paper, plastic, or lacquered surfaces); applicable for Ag and Au. Nucleation with Ag required prior to applying Zn on plastic condensers
Cathode sputtering	Very even coating, good adhesion, high density	1.2-125 μm (0.05-5 mils)	For improved corrosion resistance, silver in surgical gauzes, gold on thin Al alloy foils, diaphragms, mirrors

Electrochemical and chemical coating			
Electroplating	Reasonably dense and usually well-adhering deposits; mechanical and physical properties depend greatly on plating conditions	0.15-125 μm (6-5000 μin.)	Decorative uses, improved corrosion and wear resistance, electrical contacts; applicable to a wide range of elemental precious metals and some of their alloys
Fired-on films			
Formulated organometallic solutions, thermal decomposition	Thin, well-adhering film	0.05-0.25 μm (2-10 μin.)	Ceramic and electronic uses, printed circuits, decorations; applicable to bright Au, Ir, Pt, Pd, and Ag, mostly on nonmetallic surfaces
Resins containing very fine suspended metal particles with a low-melting inorganic glass flux	Thick, adhering films	12-40 μm (0.5-1.5 mils)	Electronic applications
Chemical decomposition coating	Thin, well-adhering film	Usually very thin	Mirrors

Jewelry. Gold, the first jewelry metal, still is the most popular. The popularity of gold is maintained by tradition, its distinctive color, and the karat mark. Color and karat are the primary factors to be considered in the selection of a particular gold. Yellow is the most popular color, but red, green, and white karat golds are also available. The 14 k golds are the most popular in the United States, although significant quantities of all kinds of jewelry are made of 18 k gold. At the same time, there is significant use of 10 k gold, especially for rings set with synthetic colored stones. Gold-plated jewelry generally is produced for mass market jewelry lines rather than for fine jewelry lines.

Hand crafting is usual where only a few exclusive creations are made, but where many duplicates will be required, die forming or casting is appropriate. For simple rings, mechanical forming methods are justified where more than a thousand units are required; casting is more cost effective for smaller quantities. When complex shapes such as watchcases are produced from clad or filled stock, intricate and expensive dies are required to maintain uniformity of the cladding.

Platinum is frequently used to make settings for the finest jewelry. In addition to its high intrinsic worth, the workability and strength of platinum ensure reliable retention of jewels, and its white color enhances the brilliance of diamonds. Manufacturers use Pt-10Ir for either wrought or cast items; in some instances, Pt-5Ru may be used. The 15 and 20% Ir alloys are preferred for some of the more delicate pieces, such as small chain.

Where any excess weight is objectionable, as in earrings, palladium is preferred to platinum because of its lower density. Palladium has platinumlike characteristics that have led to its increased use, particularly in quality jewelry.

All of the white metals--platinum, palladium, and white gold--are frequently finished with rhodium plate for whiteness and wear resistance. Sterling is the standard silver jewelry alloy in spite of its tendency to tarnish.

Precious Metals in Dentistry

THE CHANGES IN THE USE of precious metals in dentistry over the last two decades has been dramatic. The use of gold has declined substantially; it has been replaced in many dental applications by palladium or by nonmetallic dental

materials. Reference 9 provides information on the materials science specific to the dental industry. Reference 10 is a comprehensive review of the multidiscipline approach involved in considering materials for the oral environment.

This section is a brief review of the dentistry materials presently in use, with an emphasis on the applications of precious metals. The corrosion characteristics of dental alloys are thoroughly reviewed in the article "Tarnish and Corrosion of Dental Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,* and reference is made to this article in several tables.

Classification of Dental Alloys

A variety of alloys are available for dental applications:

- Direct filling alloys
- Crown and bridge alloys
- Partial denture alloys
- Porcelain fused to metal (PFM) alloys
- Wrought wire alloys
- Implant alloys
- Soldering alloys

Of these categories, precious metals are used in direct filling alloys, crown and bridge alloys, PFM alloys, and soldering alloys. Figures 1 and 2 show a number of typical restorations fabricated from some of these alloys.

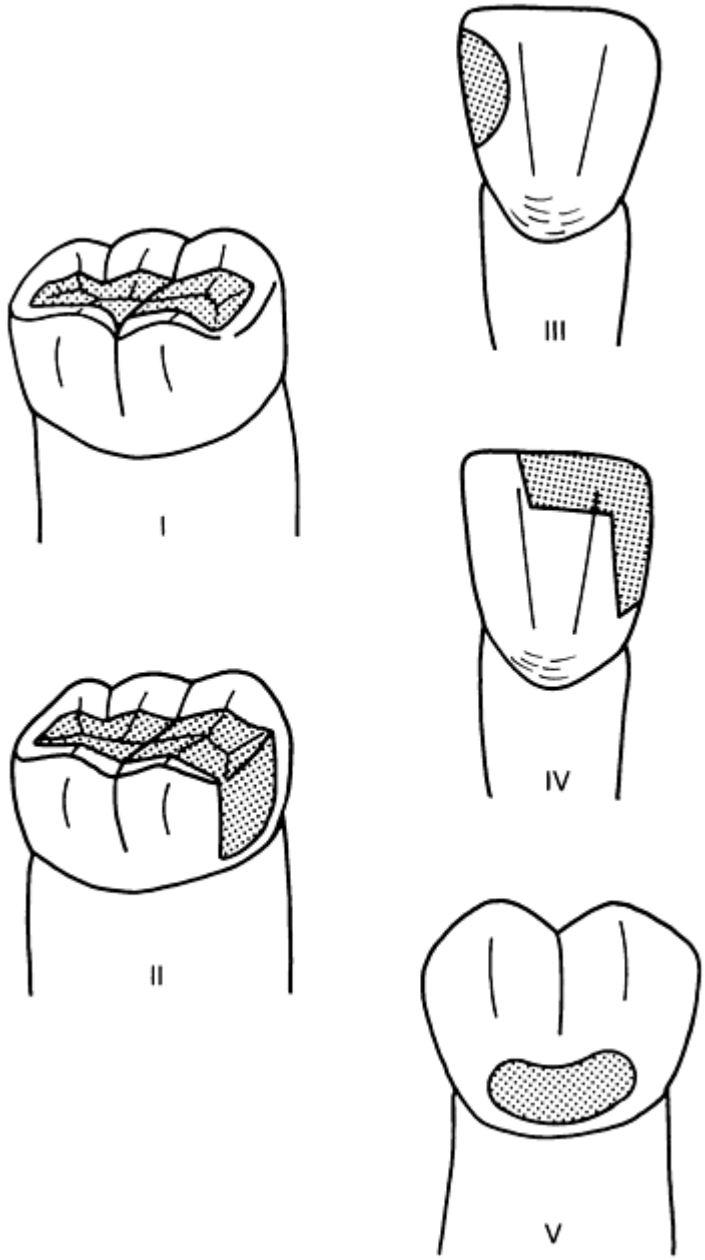

Fig. 1 Different classes of inlay preparation. Classes I and II involve one or two surfaces of a posterior tooth. The restorations can be made of a soft gold alloy (80Au-10Ag-9Cu-1Pd), but are usually made of silver amalgam. Alternate materials are either composite resin or dental porcelain bonded onto the remaining tooth. Classes III, IV, and V inlays are generally made of composite resin. Source: J.F. Jelenko & Company

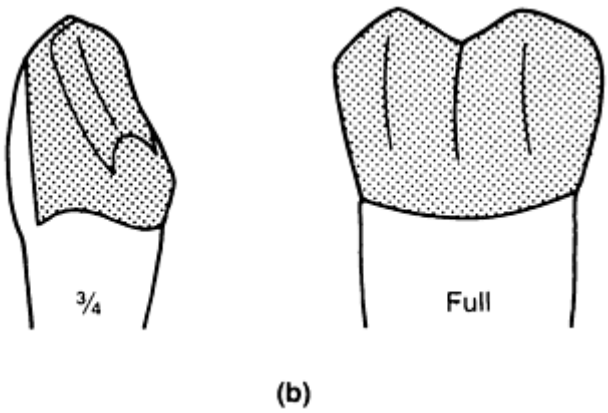

Fig. 2 Gold alloy dental crowns. (a) Three-quarter crown, which covers three surfaces of a tooth. (b) Full crown, which covers the entire tooth. These types of restorations as well as bridgework (multiple crowns) are made from gold alloys containing 40 to 78 wt% Au. Source: J.F. Jelenko & Company

Direct Filling Alloys. Compositions for direct filling restorations usually consist of silver-tin-copper-zinc alloy amalgams. Pure gold in the form of cohesive foil, mat, or powder is used only in very limited applications.

Amalgams are produced by combining mercury with alloy particles by a process referred to as trituration. About 42 to 50% Hg is initially triturated with the high-copper types; increased quantities of mercury are used with the low-copper types. High-speed mechanical amalgamators mix the materials in a matter of seconds. The plastic amalgam mass after trituration is inserted in the cavity by a condensation process. This is accomplished by pressing small amalgam increments together until the entire filling is formed. For amalgams using excess mercury during trituration, the excess mercury is condensed to the top of the setting amalgam mass and scraped away. Table 4 presents compositions for a number of different amalgam alloys.

Table 4 Compositions of selected dental amalgam alloys

Alloy[(a)]	Composition, wt%			
	Ag	Sn	Cn	Zn
Low-copper amalgam				
1	75.0	24.6	0.1	0.3
2	72.0	26.0	1.0	1.0
3	72.8	26.2	2.4	1.0
4	69.0	26.6	3.5	0.9
5	68.0	26.0	5.1	0.9
High-copper amalgam

Crown and Bridge Alloys. Alloys for all-alloys cast crown and bridge restorations are usually gold-, silver-, or nickel-base compositions, although iron-base and other alloys have also been used. The gold-base alloys contain silver and copper as principal alloying elements, with smaller additions of palladium, platinum, zinc, indium, and other precious metals such as ruthenium and iridium as grain refiners.

Table 5 lists compositions of precious metal crown and bridge alloys. Physical and mechanical properties for dental alloys that contain precious metals are provided in Table 6.

Partial Denture Alloys. This type of restoration consists of an alloy substructure upon which a pink acrylic resin and plastic teeth are placed. A cobalt-chromium alloy is almost always used in place of gold.

Porcelain Fused to Metal Alloys. Alloys for porcelain fused to alloy restorations are gold-, palladium-, or nickel-base compositions. The gold-base alloys are divided into gold-platinum-palladium, gold-palladium-silver, and gold-palladium types. The palladium-base alloys are palladium-silver alloys or palladium-gallium alloys with additions of either copper or cobalt. The nickel-base alloys are alloyed primarily with chromium and with minor additions of molybdenum and other elements (about 40% of PFM alloys are made from Ni-15Cr-3Mo-2Be). In contrast to alloys for crown and bridge use, alloys fused to porcelain contain low concentrations of oxidizable elements such as tin, indium, iron, and gallium for the precious-metal-containing alloys; and aluminum, vanadium, and others for the nickel- and cobalt-base alloys. During the heating cycle, these elements form oxides on the surface of the alloy and combine with the porcelain at the firing temperatures to promote chemical bonding.

Stringent demands are placed on the alloy system meant to be used as a substrate for the baking on or firing of a porcelain veneer. The thermal expansion coefficients of alloy and porcelain must be matched so that the porcelain will not crack and break away from the alloy as the material is cooled from the firing temperature to room temperature. Thermal expansion coefficients of porcelains are in the range of 14×10^{-6} to 15×10^{-6} in./in. · °C. Selection of an alloy with a slightly larger coefficient by about 0.05% is recommended so that the alloy will be under slight compression.

The alloy must have a high melting point so that it can withstand the firing temperatures involved with the porcelain. However, excessively high temperatures will preclude the use of conventional dental equipment; therefore, a temperature of 1300 to 1350 °C (2370 to 2460 °F) is about maximum. The porcelain firing procedures require an alloy with high hardness, strength, and modulus so that thin sections of the alloy substrate can support the porcelain, especially at the firing temperatures. Compositions and properties of precious metal PFM alloys are given in Tables 6 and 7.

Table 7 Compositions of precious metal porcelain fused to metal alloys

(a) Numbers are provided for reference purposes only; they are not alloy designations.

Wrought orthodontic wires are composed of stainless steel, cobalt-chromium-nickel, nickel-titanium, and β titanium alloys. The superelastic nickel-titanium alloys are described in the article "Shape Memory Alloys" in this Volume.

Implant Alloys. Alloys that have found applications in support structures implanted in the lower or upper jaws are composed of cobalt-chromium, nickel-chromium, stainless steel, and titanium and its alloys.

Soldering Alloys. Gold-base and silver-base solder alloys (Table 8) are used for the joining of separate alloy components. Base alloy solders with high fusing temperatures are also used for the joining of nickel-chromium and other alloys. In many cases, the term brazing would be more appropriate than joining, but the former term is seldom used in dentistry. The gold-containing solders are used almost exclusively in bridge-work because of their superior tarnish and corrosion resistance. The use of silver-base solders is mainly limited to the joining of stainless steel and cobalt-chromium wires in orthodontic appliances.

Table 8 Compositions of selected silver- and gold-base dental solders

Type	Composition, wt%						
	Au	Pd	Ag	Cu	Sn	In	Zn
Silver	. . .	. . .	52.6	22.2	7.1	. . .	14.1
Gold	45.0	. . .	20.6	28.4	4.3	. . .	2.9
	63.0	2.7	19.0	8.6	. . .	6.5	. . .

Gold-base solders are largely gold-silver-copper alloys to which amounts of zinc, tin, indium, and other elements have been added to control melting temperatures and flow during melting. The silver-base solders are basically silver-copper-zinc alloys to which smaller amounts of tin have been added. The higher-fusing solders to be used with the high-fusing alloys are usually specially formulated for a particular alloy composition because not all alloys have good soldering characteristics.

Properties

The diversity in available alloys exists so that alloys with specific properties can be used when needed. For example, the mechanical property requirements of alloys used for crown and bridge applications are different from the requirements of alloys used for porcelain fused to alloy restorations. Even though crown and bridge alloys must possess sufficient hardness and rigidity when used in stress-bearing restorations, excessively high strength makes grinding, polishing, and burnishing difficult, and it is likely to lead to excessive wear of the occluding teeth. Alloys used with PFM restorations are used as substrates for the overlaying porcelain. In this case, the high strength and rigidity of the alloys more closely match the properties of the porcelain. Also, the higher sag resistance of the alloy at the temperatures used for firing the porcelain results in less distortion and lower levels of retained residual stresses.

Similarly, alloys used for partial denture and implant applications must possess increased mechanical properties for resistance to failures. However, clasps contained within removable partial denture devices are often fabricated from a

more ductile alloy, such as a gold-base alloy, than from cobalt-chromium or nickel-chromium alloys. This ensures that the clasps possess sufficient ductility for adjustments without breakage from brittle fractures.

Other property requirements in specific systems include:

- Matching the thermal expansion coefficients between porcelain and the substrate alloy for PFM restorations
- Negligible setting contractions for direct filling amalgams
- Specific modulus to yield strength ratios for orthodontic wires

Alloy color is often a consideration because high gold prices have led to the use of alloys with lower gold contents. Lighter and pale-yellow gold alloys, as well as white gold alloys, are currently most prevalent.

Table 6 presents some typical mechanical properties for a number of different alloy systems used in dentistry. Additional information on the compositions, properties, and applications of dental alloys can be found in Ref 9 and 10, and in the article "Tarnish and Corrosion of Dental Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Silver and Silver Alloys

Commercially Pure Silver

Compiled by C.D. Coxe (deceased), A.S. McDonald, and G.H. Sistare, Jr. (deceased), Handy & Harman; Reviewed for this Volume by A.M. Reti, Handy & Harman

Applications

Typical uses. The largest single use for commercially pure silver is for photographic emulsions. The second largest use is in the electrical and electronic industries, for electrical contacts in the medium to high current and voltage categories for conductors, and in primary batteries. Silver is deposited on glass to form mirrors, and particles of metallic silver about 1 to 5 μm (40 to 200 μin.) in diameter are used in pastes for metallizing other nonconducting materials. Silver sputtering targets are used for application of transparent thin films to architectural glass, automotive windshields, and microelectronic components. Silver anodes of various shapes are used in the electroplating industry.

In the chemical industry, silver is used as a catalyst for the dehydrogenation of methanol to make formaldehyde, and in the oxidation of ethylene to ethylene oxide. Silver may also be used to line reactors and vessels, particularly caustic evaporators or crystallizers. Silver also is used as a liner in heavy-duty journal bearings.

Mechanical Properties

Tensile properties. Typical: tensile strength, 125 MPa (18 ksi) for 5 mm (0.2 in.) diam wire annealed at 565 °C (1050 °F); yield strength (divider method), 54 MPa (7.9 ksi). See also Fig. 1.

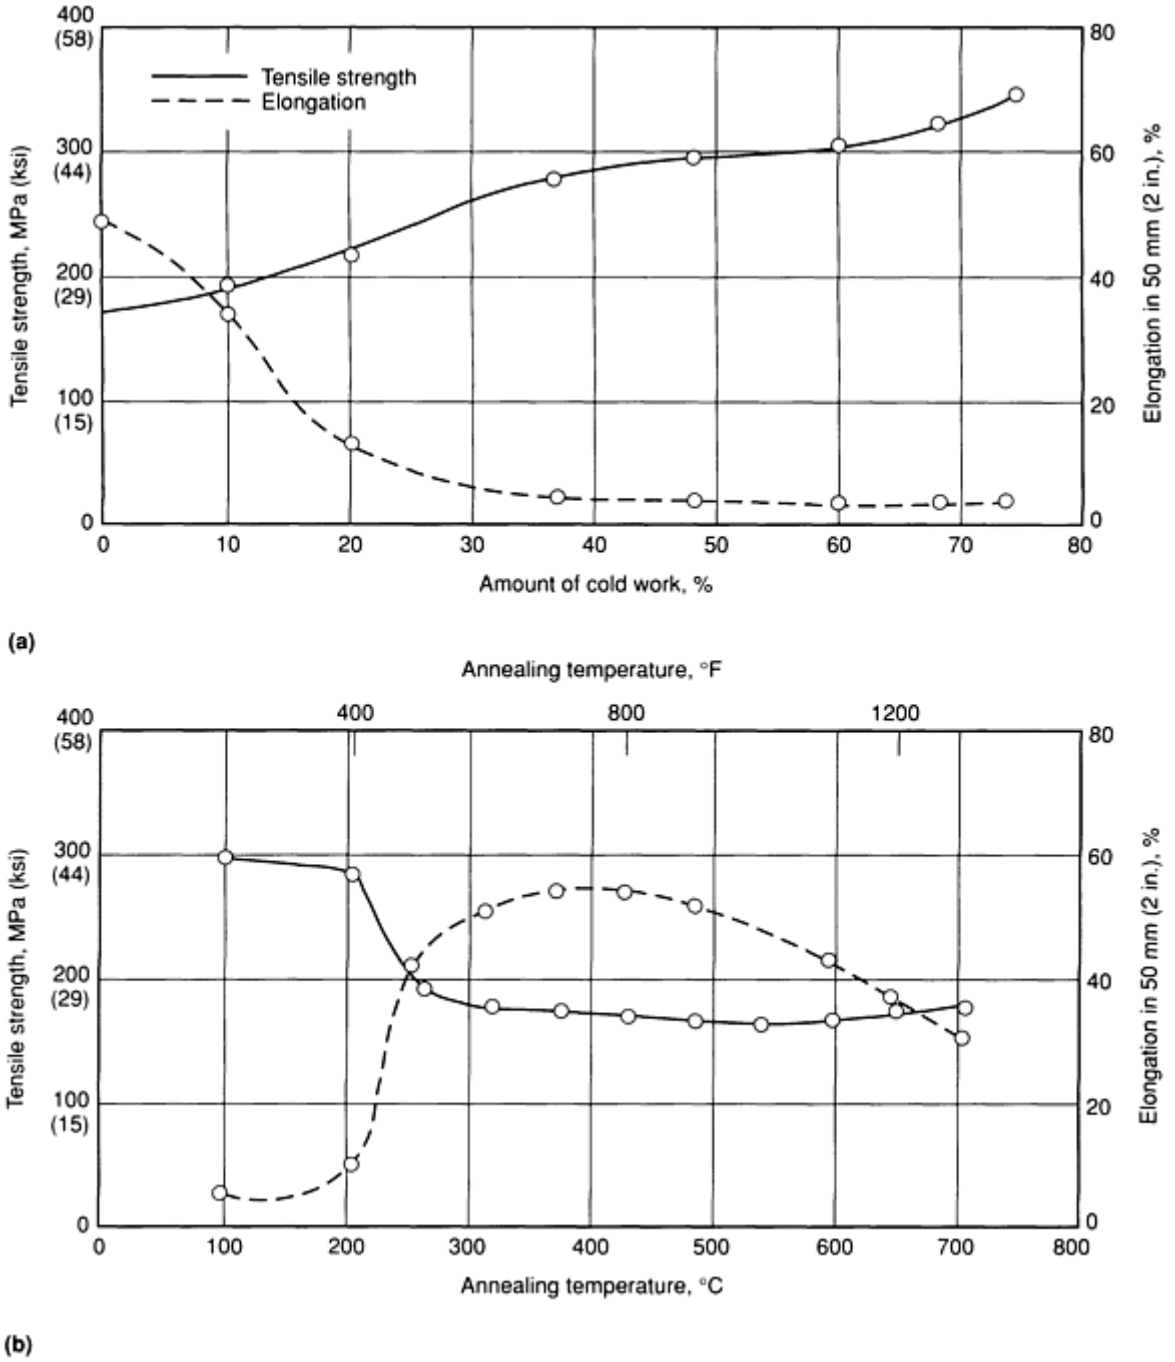

Fig. 1 Tensile properties of commercial fine silver, 2.3 mm (0.091 in.) diam wire. (a) Cold drawn after annealing. (b) Cold drawn 49% before annealing

Hardness. Research on the effect of oxygen on the hardness of annealed silver of various purities indicates that oxidation of impurities during oxidizing anneals generally causes a substantial increase in surface hardness and restrains grain growth, effects that are absent in spectroscopically pure silver. Very pure silver had a hardness of 25 HV after a hydrogen anneal at 650 °C (1200 °F), and 27 HV after annealing in air at 650 °C (1200 °F).

Poisson's ratio. 0.37 for annealed material; 0.39 for hard-drawn material

Elastic modulus. Tension, 71 GPa (10.3×10^6 psi)

Mass Characteristics

Density. 10.49 g/cm^3 (0.379 lb/in.^{3}) or 5.527 troy ounces/in.^{3} at 20 °C (68 °F); density is lowered by cold work and probably by oxygen.

Thermal Properties

Melting point. For oxygen-free silver, 961.93 °C (1763.5 °F)

Coefficient of linear thermal expansion. 19.68 μm/m · K (10.93 μin./in. · °F) at 0 to 100 °C (32 to 212 °F); 20.61 μm/m · K (11.45 μm/in. · °F) at 0 to 500 °C (32 to 930 °F)

Specific heat. 0.234 kJ/kg · K (0.056 Btu/b · °F) at 0 °C (32 °F), 0.237 kJ/kg · K (0.0568 Btu/lb · °F) at 100 °(212 °F)

Thermal conductivity. 418.68 W/m · K (2902 Btu · in./ft^2 · h · °F) at 0 °C (32 °F)

Electrical Properties

Electrical conductivity. Effect of percentage reduction for extremely pure 2.3 mm (0.091 in.) diam wire at 20 °C (68 °F):

Reduction, %	%IACS
Annealed	102.8
10.2	102.2
20.0	101.0
37.0	99.7
48.6	99.5
60.0	99.4
68.5	98.4
74.0	98.1

The electrical conductivity of commercial drawn wire may be much lower than 98 to 99%.

Electrical resistivity. 1.59 μΩ· cm at 0 °C (32 °F); 177 μΩ· cm at 20 °C (68 °F) for annealed 2.3 mm (0.091 in.) diam wire; temperature coefficient, 4.1 × 10^{-3}/°C (6.5 × 10^{-3} μΩ· cm/°C) from 0 to 100 °C (32 to 212 °F)

Chemical Properties

General corrosion behavior. Silver does not appear to oxidize at room temperature in air and thus differs from copper, but it is attacked and blackened by ozone. Silver oxide, however, does exist and has extremely high resistivity. Sulfur attacks silver rapidly, as it does copper, and the rate of tarnishing of silver in indoor atmosphere is determined by the supply of sulfur atoms, because the coating is nonprotective. This sulfide decreases the reflectivity of silver and also increases the electrical contact resistance, particularly at low currents, because it is nonohmic in character. The rate of sulfidation of silver indoors in a large city is of the order of 7 mg/m^2 · d. Much work has been done in searching for a tarnish-resistant high-silver alloy, but it appears that substantial additions of noble metals are required to achieve this goal, about 50% Pd or 70% Au being needed for complete resistance. Various protective plates have been used to protect silver from tarnishing. Of these, rhodium plate applied over a very thin nickel plate is the most successful and maintains a pleasing appearance but is little used.

Resistance to specific corroding agents. Silver is resistant to acetic acid and has been used for condensers handling this acid. It is also resistant to various other organic acids and foods that are free from sulfur. It shows good resistance to phenol and to hydrofluoric and phosphoric acids, provided that these also are substantially free from sulfur.

Silver is attacked by all the low-melting molten metals, such as mercury, sodium and potassium and their mixtures, lead, tin indium, and bismuth; consequently, the use of silver in heat exchangers and other devices that employ liquid-metal heat-transfer mediums should be avoided.

Silver is resistant to sodium and potassium hydroxides, is used in the laboratory for caustic fusions, and has also been considered for large equipment. However, silver creeps at the fusion temperatures of these hydroxides, and its use for large equipment would require supporting vessels. It is attacked by moist bromine, iodine, and chlorine, and vigorously by HC1, HI, and HBr. Alkaline cyanides, in the presence of air or other oxidizing agents, dissolve silver rapidly. Nitric acid that contains traces of nitrous acid attacks silver vigorously, as does hot concentrated sulfuric acid. Hot dilute sulfuric acid also attacks silver.

Fabrication Characteristics

Recrystallization temperature. 20 to 200 °C (68 to 390 °F), depending on purity

Silver-Copper Alloys

Compiled by C.D. Coxe (deceased), A.S. McDonald, and G.H. Sistare, Jr. (deceased), Handy & Harman; Reviewed for this Volume by A.M. Reti, Handy & Harman

Commercial Names

Common names. Sterling silver (92.5 min Ag), coin Silver (90Ag-10Cu)

Chemical Composition

Composition limits. Sterling silver must contain at least 92.5% Ag. The remainder is unrestricted but is normally copper because, in general, other metals have proved less desirable and are less-effective hardeners. Coin silver is 90% Ag and 10% Cu. The eutectic alloy contains 28.1% Cu.

Applications

Typical uses. Silver-copper alloys have been used for thousands of years. Copper is effective in hardening silver, but lowers the melting point considerably and lowers the electrical and thermal conductivities appreciably. Sterling silver is used for flat and hollow tableware and various items of jewelry. Coin silver with 10% Cu and 90% Ag was used for U.S. silver coins and is used for electrical contacts operating under service conditions where pure silver is considered too soft and is more likely to pit. The 28% Cu eutectic alloy finds some use as a brazing or soldering alloy. With heavy cold work, it is quite strong and is used for spring-type electrical contacts.

Mechanical Properties

Tensile properties. See Fig. 2 and 3.

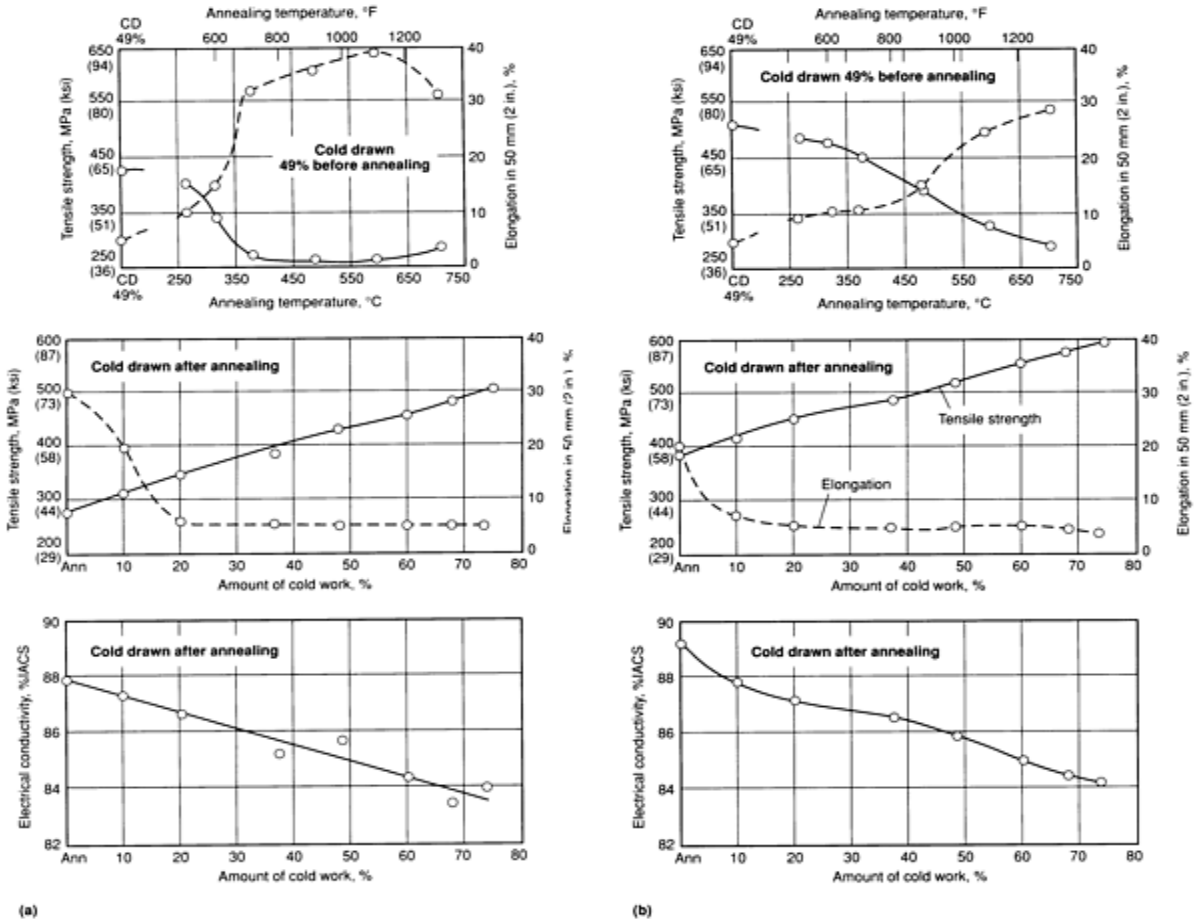

Fig. 2 Tensile properties and electrical conductivity of silver-copper alloys. (a) Sterling silver (92.5Ag-7.5Cu). (b) Eutectic alloy (72Ag-28Cu). Samples are cold-drawn 2.3 mm (0.091 in.) diam wire. CD, cold drawn; Ann, annealed

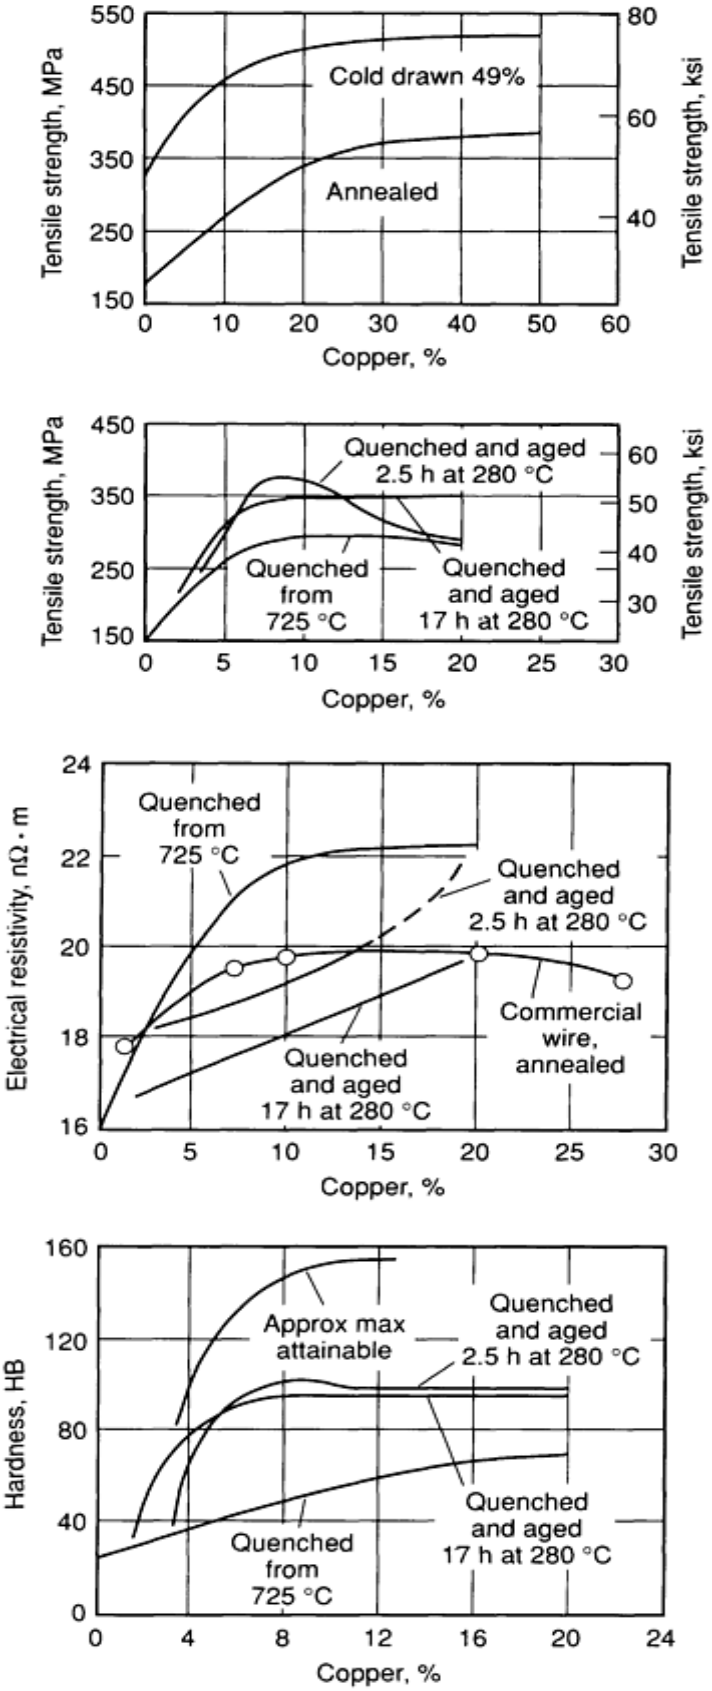

Fig. 3 Effect of copper content on properties of silver-copper alloys

Hardness. See Fig. 3.

Electrical Properties

Electrical conductivity. See Fig. 2.

Electrical resistivity. The addition of copper to silver raises the resistivity to a greater extent if the copper is

held in solution by quenching and to a lesser extent if it is precipitated by aging or slow cooling. In Fig. 3, the curve labeled "Commercial wire, annealed" shows resistivity typical of commercial phosphorus-deoxidized wire, annealed between 480 and 540 °C (900 and 1000 °F) and cooled to room temperature in 1 h. The decrease in resistivity between 20 and 28% Cu is not significant; deviations of this amount can be expected from lot to lot of the same composition.

Chemical Properties

General corrosion behavior. At ordinary temperatures, the presence of copper in solid solution in silver will have effect on the resistance of the metal to corrosion. The presence of small areas of the slightly less noble copper-rich phase might be expected to cause difficulty because of electrolytic effects, but apparently the difference between the potentials is small enough for the duplex alloys to behave satisfactorily in their usual applications. In seawater, however, and in similar electrolytes, some selective attack may be anticipated. At slightly elevated temperatures, copper oxidizes selectively. This behavior is of some consequence in electrical contacts, since it necessitates higher contact pressure. At approximately 595 °C (1100 °F), oxidizing atmospheres will cause rapid oxidation of the copper, and oxygen will diffuse to a considerable depth, forming a substance called fire. One hour of exposure to air at this temperature will oxidize the 7.5% Cu alloy to a depth of 0.08 mm (0.003 in.). This was formerly very troublesome, but with the production of well-deoxidized alloys and the use of nonoxidizing atmospheres, effects from the oxidation of copper have been minimized.

Resistance to specific corroding agents. Because sulfur tarnishes the silver-copper alloys in about the same way it tarnishes silver, sulfur must be excluded, or the silver protected by appropriate coatings or wrappings, if appearance is to be maintained without polishing.

Fabrication Characteristics

Processing. In melting silver-copper alloys, oxygen content should be brought to a low level before pouring at 1050 to 1095 °C (1920 to 2000 °F). Where the electrical conductivity is not important, final deoxidation with 0.025% P is convenient. Cadmium has been used as a partial deoxidizer; 0.5% or more is required. Lithium also is being used with success. Melting the material under a cover of broken graphite and pouring the alloy through a reducing flame during casting also gives good results. The alloy may be reduced approximately 60% in rolling, and short anneals are suitable at 540 to 675 °C (1000 to 1250 °F) in a steam atmosphere or a salt bath. Where the higher temperature is used, quenching is required for producing full softness. Alternation of oxidizing and reducing atmospheres is very damaging. Where light oxidation has occurred, pickling in a hot sulfuric-acid solution (5 to 10%) is suitable. Heavy oxidation, or fire, can be eliminated only by removing considerable metal, either mechanically or chemically.

Heat treatment. Sterling silver can be age hardened without difficulty, and part of the merit of this composition in providing acceptable properties after miscellaneous treatments results from some hardening on cooling in air. The solubility of copper in silver at 650 °C (1200 °F) is about 4%, and at 730 °C (1350 °F) about 6%, so sterling silver processed at these temperatures is duplex with small amounts of the copper-rich phase scattered through the silver-rich matrix. Aging treatments cause precipitation of the copper-rich phase, and if prolonged, increase the electrical conductivity considerably. Coin silver will remain duplex after any annealing treatment and ages in much the same manner as the 7.5% Cu alloy. Both alloys respond to an aging treatment of 2 h at about 280 °C (535 °F) or 1 h at 300 °C (575 °F). The mechanical properties of coin silver are virtually the same as those of sterling silver after the usual annealing treatments at about 650 °C (1200 °F), because the composition of the silver-rich phase will be the same. Alloys containing 20 to 30% Cu have much more of the copper-rich phase and show less age hardening. In practice, relatively little deliberate use is made of the precipitation-hardening phenomenon in the silver-copper alloys. The solution temperature 705 to 730 °C (1300 to 1350 °F) is rather close to the solidus temperature 780 °C (1435 °F) and requires better temperature control than is available to many artisans who work with these alloys. In alloys heavily deoxidized with phosphorus, incipient melting in the grain boundaries may occur at 705 to 730 °C (1300 to 1350 °F), and when this happens the piece is likely to crack during quenching. Furthermore, these alloys are extremely soft at the solution temperature and are easily damaged. On the other hand, when soldering is done, the metal surrounding the joint may be heated to the solution temperature, and air cooling will cause some hardening. This counteracts the softening that would otherwise result from the soldering of work-hardened metal.

Silver-Base Brazing Filler Metals

(a) AWS, American Welding Society.

(b) The brazing alloy shall be analyzed for the specific elements for which values are shown in this table. If the presence of other elements is indicated in the course of this work, the amount of those elements shall be determined to ensure that their total does not exceed the limit specified for other elements.

Applications

Typical uses. Filler metal for brazing copper, nickel, and cobalt alloys, tool steels, stainless steels, and precious metals. Filler metal for brazing carbide tips onto cutting tools, or wear-resisting tips made of tungsten or molybdenum onto copper-alloy resistance welding electrodes

Mechanical Properties

Tensile properties. Typical: tensile strength (approximate range), 275 to 415 MPa (40 to 60 ksi). The strength of silver brazing filler metals declines rapidly at elevated temperatures. Short-time tests on the filler metal 50Ag-15.5Cu-16.5Zn-18Cd indicate that the loss in strength at 205 °C (400 °F) will approximate 20 to 30% of the strength at room temperature and 50% at 260 °C (500 °F). The filler metals that contain 5% or less of zinc and cadmium have better elevated-temperature strengths than those high in zinc and cadmium.

Thermal Properties

Liquidus temperature. See Table 1.

Solidus temperature. See Table 1.

Brazing temperature range. See Table 1.

Electrical Properties

Electrical conductivity. The electrical conductivity of silver brazing filler metals varies from about 10 to 80% IACS. Filler metals with higher silver content and lower zinc content have the highest conductivity. The silver-copper eutectic (72Ag-28Cu) has conductivity of approximately 77% IACS. The high-silver, low-zinc Ag-Cu-Zn filler metals also find some use in electrical contacts.

Chemical Properties

General corrosion behavior. The corrosion resistance of silver-base brazing filler metals is better than that of most of the nonferrous base metal alloys with which they are used.

Fabrication Characteristics

Formability. Silver-base brazing filler metals are malleable and ductile and can be fabricated into sheet and wire with 50% or greater reductions between anneals.

Silver-Magnesium-Nickel Alloys

Compiled by G.M. Wityak, Handy & Harman

Chemical Composition

Composition limits. 0.25 Mg max, 0.25 Ni, bal Ag

Applications

Typical uses. The unique oxidation-hardenable characteristics of this material allow it to excel in applications where stable, high thermal and electrical conductivity are required. This attribute is particularly useful in electromechanical load-carrying devices. This material is generally formed prior to oxidation, and complex shapes in the form of relay springs, sliding contact arms, and severely deformed contact faces can be fabricated without cracking. Once oxidized, the shapes are retained, but for all practical purposes can no longer be plastically deformed. These parts can be easily brazed, cleaned, and plated without a change in hardness since there is no heat-affected zone (HAZ) to be concerned with as is the case with cold-worked material.

Precautions in use. After oxidation, the ductility of this material is limited, particularly in bending. Care should be taken in the design of the device such that service loads and deflections do not exceed the elastic limit of the material. In almost all cases, failure will be in the form of brittle fracture.

Mechanical Properties

Tensile properties. See Table 2.

Table 2 Tensile properties of unoxidized and oxidized silver-magnesium-nickel alloy strips

Alloy designation	Thickness		Temper	Tensile properties[(a)]					
				Ultimate tensile strength		Yield strength (0.2% offset)		Elongation, % (50 mm, or 2 in., gage length)	Reduction, %
	mm	in.		MPa	ksi	MPa	ksi		

Unoxidized	. . .	. . .	Soft	250	36	130	19	28	0
	. . .	. . .	$\frac{1}{2}$ hard	325	47	315	46	4	21
	. . .	. . .	$\frac{3}{4}$ hard	325	47	315	46	3	29
	. . .	. . .	Hard	330	48	285	41	2	37
Oxidized[(b)]	0.15	0.006	. . .	425	62	380	55	9	. . .

	0.30-0.45	0.012-0.018	. . .	400	58	340	49	13	. . .
	0.48-0.61	0.019-0.024	. . .	385	56	325	47	14	. . .

(a) Unoxidized tensile data is typical; oxidized tensile data is minimum.

(b) Modulus of elasticity, 83 GPa (12×10^6)

Fabrication Characteristics

Heat treatment. This silver-magnesium-nickel alloy is unique in that it can be dispersion strengthened via internal oxidation. This is accomplished by heating the alloy in an air or oxygen atmosphere. The magnesium present in solid solution will precipitate to form submicroscopic magnesium oxide particles. The fine dispersion of these hard refractory compounds in the soft, fine silver matrix imparts great strength. The nickel, because of its limited solubility in silver, acts as a grain refiner. This is particularly important during the oxidation operation since the grain boundaries slow the diffusion rate of magnesium outward.

In almost all applications, the oxidation operation is undertaken after forming. Prior to oxidation, this alloy is very ductile, exhibiting forming characteristics very similar to commercial fine silver. After oxidation the strength of the material is about twice that of the unoxidized alloy, and ductility is very limited.

After oxidation this material cannot be restored to its prior ductile condition. Sustained exposure to a reducing atmosphere at a high temperature will soften the material slightly.

It is important to understand that internal oxidation is a diffusion-controlled process. Material thickness, oxygen concentration, temperature, and time are all interrelated variables. Figure 4 shows the oxidation times required as a function of thickness and temperature.

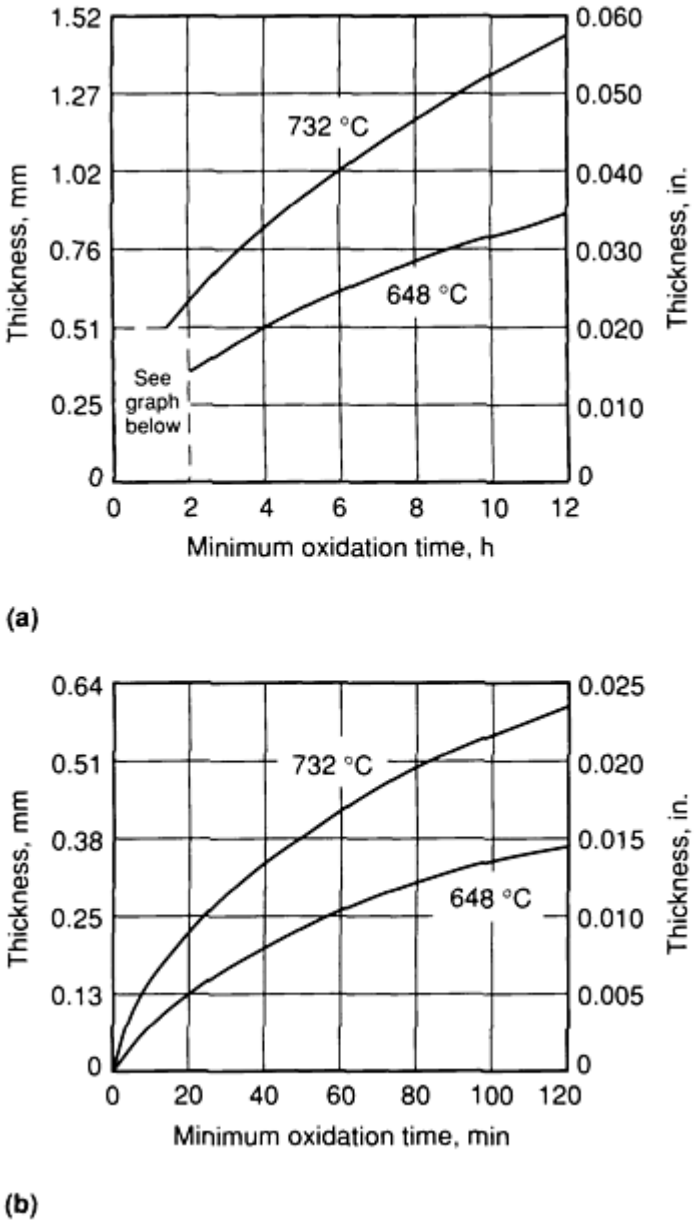

Fig. 4 Effect of strip thickness and temperature on the oxidation times of silver-magnesium-nickel alloy. (a) 0 to 2-h interval. (b) 2 to 12-h interval. Oxidation times given are minimum values obtained by testing in air. Oxidation times for alloys oxidized in pure oxygen are 60% of values shown in figure.

Dental Amalgam

Compiled by R.M. Waterstrat and N.W. Rupp, American Dental Association Health Foundation, Paffenbarger Research Center, National Institute of Standards and Technology

Dental amalgam is a silver-mercury alloy used for restoring lost tooth structure. In this application it is commonly referred to as a silver filling. It is essentially a metallic composite consisting mainly of the intermetallic compounds $\gamma(Ag_3Sn)$ and $\gamma_1(Ag_2Hg_3)$, with smaller amounts of either $\gamma_2(Sn_7Hg)$ or $\eta'(Cu_6Sn_5)$, depending on the copper content. It is prepared in the dental operatory by grinding or milling silver-tin alloy particles with liquid mercury. Small amounts of moisture from the hand or from mixing equipment, if added during mixing, may cause excessive expansion of alloys containing zinc. The alloy mixture remains in a plastic condition for several minutes following its preparation and may be

compacted, shaped, or carved after insertion in a tooth cavity, for example. The mixture hardens by a diffusion reaction in which liquid mercury is replaced by solid mercury compounds such as Ag_2Hg_3 and Sn_7Hg. Excess mercury in the alloy after packing causes the alloy to expand and flow or creep excessively. Excessive working of the mixture during amalgamation or packing reduces or eliminates desired setting expansion. Improper compaction increases the rate of corrosion and decreases physical properties.

Dental amalgam typically contains 40 to 50% Hg, 20 to 35% Ag, 12 to 15% Sn, 2 to 15% Cu, and under 1% Zn. The applicable specifications, however, apply only to the silver-tin alloy particles and liquid mercury used in preparing the amalgam. These are ANSI-MD 156.1 and ISO R1559 for the silver-tin alloy, and ANSI-MD 1556.6 and ISO R1560 for the mercury. Composition limits for the alloy particles are 65% Ag min, 29% Sn max, 6% Cu max, 3% Hg max, 2% Zn max. These limits may be exceeded or other elements added, but if so, the manufacturer must submit the composition and the results of adequate biological and clinical tests to show that the resulting amalgam is safe and effective for use in the mouth, as directed by the manufacturer. Alloys having higher copper content, for example, have been shown to produce improved creep resistance, corrosion resistance, and durability, without producing undesirable biological reactions.

Mechanical Properties

Tensile properties. Tensile strength, 10 to 17% of compressive strength

Compressive properties. Compressive strength, 275 to 345 MPa (40 to 50 ksi) after 5 days

Hardness. 90 HK

Elastic modulus. Tension, 60 GPa (8.7×10^6 psi)

Creep-rupture characteristics. All amalgams flow or creep when subjected to loading. Loads of 10% of the compressive strength may result in a creep rate of 2 μm/m · s (80 μin./in. · s) at room temperature.

Mass Characteristics

Density. 11 g/cm^3 (0.397 lb/in.^{3})

Solidification shrinkage. Expands or contracts 0 ± 0.2% during hardening by a diffusion reaction at room temperature

Thermal Properties

Thermal properties depend to some extent on the copper content. The amalgams containing $\gamma_2(Sn_7Hg)$ compound begin to break down and sweat mercury at about 75 °C (167 °F), whereas amalgams containing $\eta'(Cu_6Sn_5)$ compound are stable up to 120 °C (248 °F).

Coefficient of linear thermal expansion. 22 to 28 μm/m · K (12 to 16 μin./in. · °F) near body temperature

Electrical Properties

Standard electrode potential. The standard electrode potential of dental amalgam is -0.5 V versus gold in normal sodium-chloride solution.

Chemical Properties

Corrosion resistance. The color of dental amalgam is silvery white. Slight tarnishing or corrosion may occur in the oral environment. Electrolytic corrosion and pitting may result from contact with other metals. Dental amalgam is attacked readily by inorganic acids.

Commercial Fine Gold

Compiled by J.A. Bard, Matthey Bishop, Inc.; Reviewed for this Volume by James Klinzing, Johnson Matthey, Inc.

Commercial Names

Common name. Called proof gold if more than 99.99% Au

Applications

Typical uses. The usual grade of refined gold contains from 99.95 to 99.98% Au and is suitable for most purposes, including dental and jewelry alloys. Metal that contains 99.5% Au is acceptable for international exchange and by the U.S. Mint without a refining penalty. Coin gold containing only copper as a hardener with 89.9 to 91.7% Au may also be acceptable.

Gold of high purity is employed for decorative and dental uses, for surfacing china and glass, as a thin film on glass for selective light filters stable over a wide

range of temperature, for thermal limit fuses to protect electric furnaces, as a target in x-ray apparatus, as a freezing-point standard, as a high-melting solder to produce vacuum-tight pressure welds, for the lining of chemical equipment, and clad on phosphor bronze or nickel silver for contact springs in radio-frequency circuits.

Besides decoration and for infrared reflectors, electroplated gold has wide electrical application: in waveguides to provide a coating resistant to corrosion and tarnishing, on grid wires to suppress secondary emission, on variable-resistor terminals to give low-noise internal contact, for adhesion and flexibility of coating on vibrating and flexing components; on contacts for low and stable contact resistance, low cathode-glow discharge and capacitive-current weight loss, and low-rms noise voltage. It is also used as a stop-off in electroplating. Gold is evaporated or sputtered onto selected areas of solid-state electronic devices such as silicon transistors and integrated-circuit chips to provide electrical terminals for these devices, and onto which small-diameter fine gold wires may be thermo-compression bonded for electrical connection to the lead frames or other external circuits. Gold and silicon, or germanium, make low-melting eutectics, and this may be done *in situ* simply by heating pure gold in contact with silicon to produce a solder that bonds the semiconductor to its base or other terminals. The low-melting gold-tin eutectic (prealloyed) is also used for similar purposes. Other solders may include gold with antimony for *n*-type semiconductors and indium for *p*-type semiconductors.

Precautions in use. As of January 1, 1975, a license is not required to buy or sell gold, but future transactions should take into account any changes in federal regulations. In melting, avoid contamination with base metals, particularly lead, bismuth, and the like. Keep atmosphere oxidizing during melting. Avoid contact with hydrochloric acid containing free chlorine; aqua regia; concentrated sulfuric acid containing oxidizing agents; arsenic and phosphoric acids; and alkali cyanides, particularly in the presence of oxygen.

Mechanical Properties

Tensile properties. See Table 3.

Table 3 Mechanical properties of proof gold (≥99.99% Au)

Condition	Tensile strength		Yield strength (0.2% offset)		Elongation[(a)], %	Hardness, HB	Modulus of elasticity	
	MPa	ksi	MPa	ksi			GPa	10^6 psi
Cast	125	18	. . .	. . .	30	33	74.5	10.8
Wrought, annealed	130	19	nil	nil	45	25	79.9	11.6

(a) In 50 mm (2 in.)

Hardness. See Table 3.

Poisson's ratio. 0.42 (form not known)

Elastic modulus. See Table 3.

Fatigue strength. 31.7 MPa (4.6 ksi) at 10^7 cycles of reversed bending

Mass Characteristics

Density. 19.32 g/cm^3 (0.698 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Melting point. 1064 °C (1948 °F)

Coefficient of linear thermal expansion. 14.2 μm/m · K (7.9 μin./in. · °F) at 20 °C (68 °F)

Specific heat. 0.130 kJ/kg · K (0.0312 Btu/lb · °F) at 18 °C (64 °F)

Thermal conductivity. 300 W/m · K (2100 Btu · in./ft^2 · h · °F) at 0 °C (32 °F)

Electrical Properties

Electrical conductivity. Volumetric, 73.4% IACS at 20 °C (68 °F)

Electrical resistivity. 20 to 22 nΩ · m at 0 °C (32 °F), 23.5 nΩ m at 20 °C (68 °F)

Relative attenuation. 1.19 (copper = 1); in waveguide 10.16 × 22.86 mm (0.40 × 0.900 in.) ID (λ = 32 mm), 0.139 dB/m; in waveguide 4.32 × 10.67 mm (0.170 × 0.420 in.) ID (λ = 1.25 mm), 0.6 dB/m. Skin depth: λ= 10 mm (0.4 in.), 0.45 μm (18 μin); λ= 100 mm (4 in.), 1.43 μm (57 μin.); λ= 1 m (40 in.), 4.53 μm (180 μin.). Noise voltage: 0.6 μV rms at 0.5 to 200 Hz (gold ring, graphite brush; pressure, 1.08 kPa (0.157 psi); speed, 0.35 m/s, or 1.2 ft/s). Contact erosion: cathode glow discharge in air: weight loss, 0.886 (platinum = 1). Capacitive current: weight loss, 1.14 (platinum = 1)

Fabrication Characteristics

Formability. Suited to forming by all methods

Weldability. Torch braze with silver solder, no flux, any flame; oxyacetylene weld with gold, no flux, any flame; resistance weld by any method

Annealing temperature. 300 °C (575 °F), but usually no annealing is required

Hot-working temperature. Can be worked at any temperature below the melting point

Casting temperature. 1095 to 1300 °C (2000 to 2370 °F)

Gold-Silver-Copper Alloys

Compiled by G.H. Sistare, Jr. (deceased), and A.S. McDonald, Handy & Harman; Reviewed for this Volume by A.M. Reti, Handy & Harman

Commercial Names

Common names. Green, yellow, and red golds

Chemical Composition

Alloy types. Most of the commercially important colored alloys for jewelry and dental applications are based on the gold-silver-copper system (see Fig. 5)--frequently modified by the addition of zinc, and sometimes of nickel, for jewelry alloys, and of palladium and platinum for dental alloys.

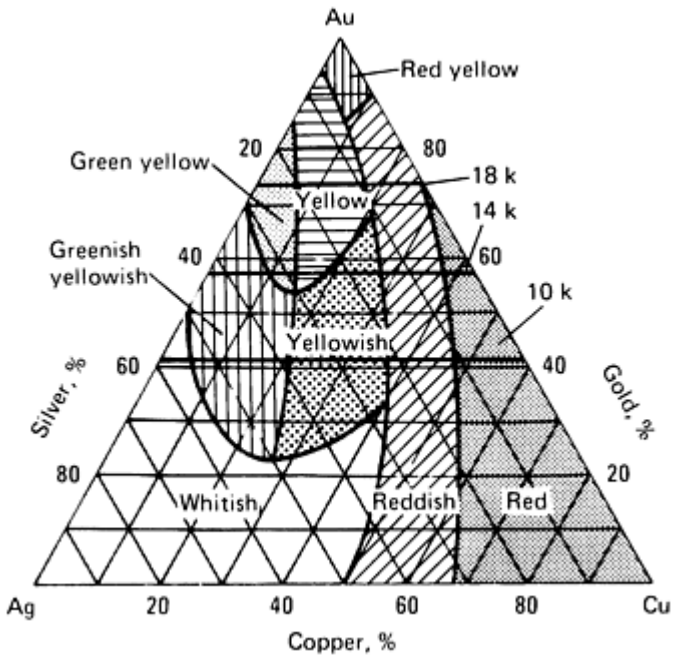

Fig. 5 Color chart for gold-silver-copper alloys for jewelry and dental applications

In the ternary phase diagram, the two-phase field of the silver-copper system extends well in toward the gold corner of the diagram (see Fig. 6). Alloys in the single-phase solid-solution area on both the silver-rich and copper-rich sides are generally soft and not hardenable, except for the order-hardening gold-copper alloys containing approximately 75% Au. Two-phase alloys near the single-phase limit at 370 °C (700 °F) are quite soft when annealed and may be precipitation hardened by solution annealing, quenching, and aging at 260 to 315 °C (500 to 600 °F). Alloys lying farther into the two-phase region are harder in the annealed condition.

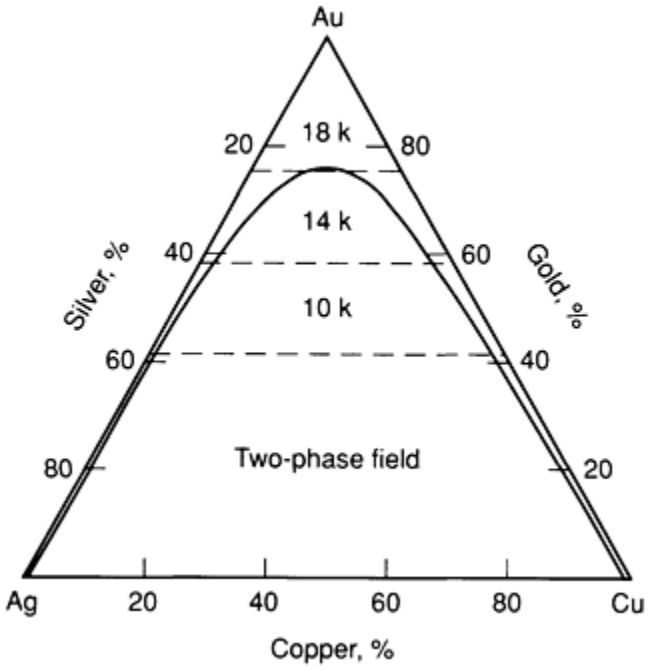

Fig. 6 Isothermal section of the gold-silver-copper ternary phase diagram at 370 °C (700 °F)

Figure 7 shows the effect of composition on hardness of gold-silver-copper alloys at three karat levels. The colors indicated in the triangular diagram may be modified by additions of other metallic elements. Zinc is frequently added to gold-silver-copper alloys:

- As a deoxidizer
- To lighten the color (it makes reddish alloys more yellow)
- To lessen the hardening that may occur on air cooling
- To lower the melting temperature for gold solder

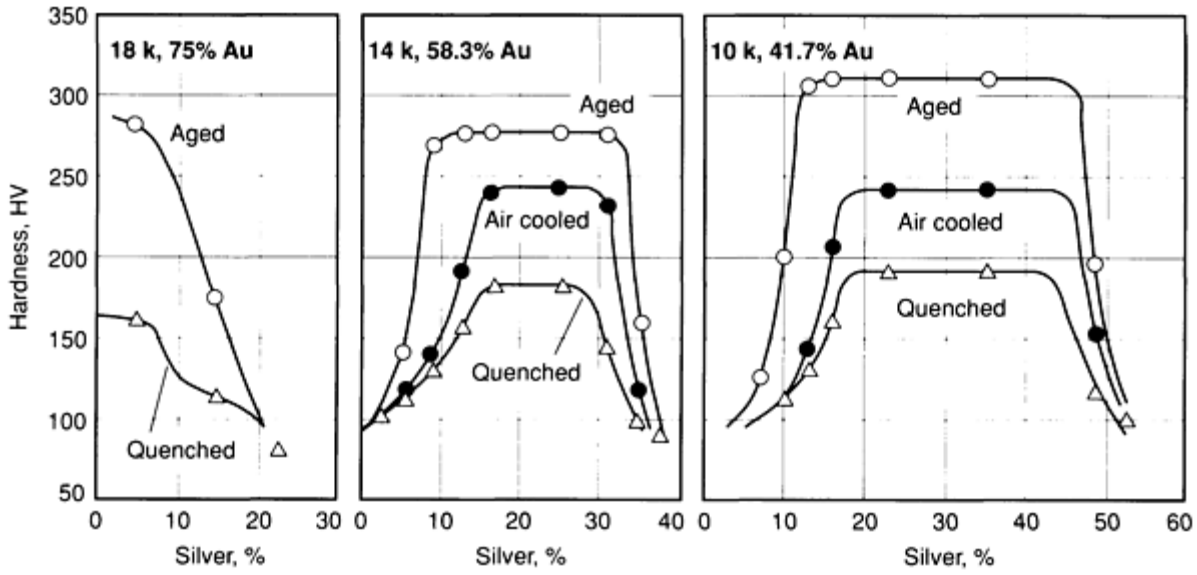

Fig. 7 Variation of hardness with silver content for gold-silver-copper alloys

Where it is desirable to reduce the grain size of cast gold-silver-copper alloys, fractional percentages of iridium or rhodium, plus ruthenium, have been used, particularly in the dental field, to refine the structure. In the wrought jewelry alloys, additions are occasionally desired to reduce the rate of grain growth, and a very small amount of cobalt, or less desirably, iron can be used to accomplish this; nickel has some effect in this direction but its solubility is relatively high, particularly in the low-silver alloys. The addition of considerable percentages of nickel lightens the color and increases the solid-solution hardness. Iron may cause inclusions, and cobalt and nickel will form low-solubility phases with some deoxidizers.

The 18 k gold-silver alloy has a good green color but is too soft for general use, except as a finishing plate, whereas the red 18 k gold-copper alloy is troublesome to work because of ordering transformation in the solid state. The 18 k gold alloys of the gold-silver-copper type are yellow in color. A wider range of colors is available in the 14 and 10 k alloys.

Because the properties of 10 and 14 k alloys are controlled largely by the ratio of silver to copper, regardless of the gold content, alloys can be converted from one gold content to another gold content having similar properties, by addition of pure gold to low-karat alloys or by addition of standard base alloy to high-karat golds.

The metallurgy of gold-silver-copper alloys has been treated in detail (Ref 1) and further contributions were made on the age-hardening and ordering transformation within this ternary system (Ref 2, 3).

Applications

Typical uses. These alloys are used mostly in jewelry but sometimes are used for slip rings and brushes on electrical instruments. Parts may be cast to shape, made from rolled or drawn stock, or made from clad material comprising a layer of gold on one or both sides of a core made of nickel silver, pure nickel, brass, or bronze. Certain of these alloys can be electrodeposited, and sometimes coatings are produced by electrodeposition followed by heating to cause diffusion with the underlying metal.

Gold-Nickel-Copper Alloys

Compiled by G.H. Sistare, Jr. (deceased), and A.S. McDonald, Handy & Harman; Reviewed for this Volume by A.M. Reti, Handy & Harman

Commercial Names

Common name. White gold

Chemical Composition

Alloy types. Historically, white golds developed from a patented gold-nickel-zinc alloy containing about 80% of gold that was offered as a substitute for platinum jewelry. In extending the concept to conventional karat levels, it was immediately discovered that some copper was essential for workability at 18 k. Subsequently, it was found that sizeable amounts of copper were essential if 14 and 10 k alloys were to be worked at all. Modern white golds are based on alloys in the gold-nickel-copper system to which 5 to 12% Zn is added.

The gold-nickel-copper system (discussed in detail in Ref 4) is similar to the gold-silver-copper system in that both are dominated by a two-phase immiscibility gap in the solid-state ternary field. In the gold-nickel-copper system, the immiscibility gap in the gold-nickel binary system extends into the ternary field. In the gold-silver-copper system, the silver-copper binary eutectic generates an immiscibility gap that extends into the ternary. Note however, that in one case (gold-nickel-copper), the two-phase field is opposite the copper corner, while in the other (gold-silver-copper), the two-phase field is opposite the gold corner. Compare the gold-nickel-copper isothermal section in Fig. 8 with the gold-silver-copper isothermal section in Fig. 6. It follows that in constant karat pseudobinary sections (that is, sections at fixed gold content) the two-phase field is asymetrical in the gold-nickel-copper system and symmetrical in the gold-silver-copper system. Thus, white golds based on fixed nickel-copper ratios are dissimilar at different karat levels, whereas yellow golds based on fixed silver-copper ratios, by and large, are readily converted from one karat to another.

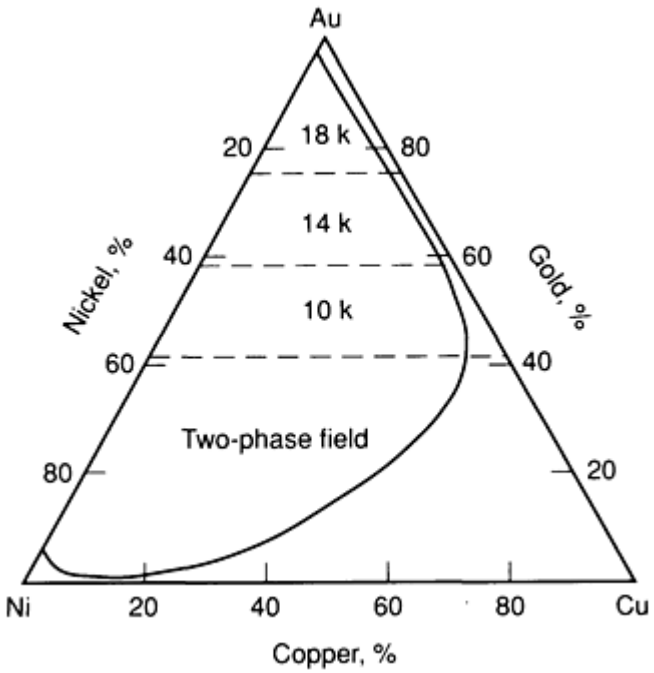

Fig. 8 Isothermal section of the gold-nickel-copper ternary phase diagram at 315 °C (600 °F)

Gold-nickel-copper-base white golds work harden faster and are harder after annealing than gold-silver-copper base yellow golds. All gold-nickel-copper-base white golds lie within the two-phase region at room temperature. The 18 and

14 k alloys can be homogenized at elevated temperatures. The 10 k alloys do not homogenize with any practical heat treatment. The 18 k alloys can be age hardened, but the 14 or 10 k alloys are not age-hardenable modified with an addition of cobalt. It takes about 0.75% Co at 14 k and 1.75% Co at 10 k. In both instances, the cobalt is substituted for copper. These modifications are mostly used as casting alloys and usually can be aged as-cast without first solution annealing.

Gold-nickel-copper-base white golds are very susceptible to firecracking. They fire-crack when they are given a full anneal after light cold working (reductions of less than 50%). Expedients such as stress relieving prior to annealing are ineffective in preventing firecracking. White-gold compositions are the result of a compromise between color and firecracking tendency. Increasing the copper content reduces the firecracking tendency but offsets the whitening effect of nickel. This can be compensated for with the addition of zinc, which tends to decolorize the copper and enhance the whitening effect of nickel. Unfortunately, it also enhances the firecracking tendency. This is illustrated in Table 4, which lists typical compositions of gold-nickel-copper-zinc white golds in order of decreasing karat. At 18 k, little can be done to reduce firecracking tendency; with 75% gold, any significant replacement of nickel with copper would result in an unacceptable color. At 14 k, considerable amounts of copper can be added, and at 10 k, even greater amounts of copper are tolerable. Note in the historical sequence in Table 4 how the increase in copper and decrease in zinc contents have progressively led to a decrease in firecracking tendency, while maintaining an acceptable color.

Table 4 Typical compositions and firecracking tendencies of gold-nickel-copper-zinc white golds

Alloy	Historical sequence	Composition, wt%				Fire-cracking tendency
		Au	Ni	Cu	Zn	
18 k	Early	75	17.30	2.23	5.47	Marked
14 k	Early	58.33	15.17	18.04	8.46	Marked
14 k	Intermediate	58.33	10.82	22.08	8.77	Moderate
14 k	Modern	58.33	12.21	23.47	5.99	Slight
10 k	Early	41.67	21.24	25.25	11.84	Marked
10 k	Intermediate	41.67	15.12	30.96	12.25	Moderate

Gold-Platinum Alloy
70Au-30Pt

Compiled by D.J. Accinno, Engelhard Industries, Inc.; Reviewed for this Volume by James Klinzing, Johnson Matthey, Inc.

Applications

Typical uses. Because of its high corrosion resistance, this alloy is used for spinnerettes in the numerous methods of rayon production that employ high corrosive chemicals. The alloy is also used as a high-melting-point platinum solder.

Mechanical Properties

Tensile properties. Typical: tensile strength, 639 MPa (92.7 ksi); reduction in area, 50%. See also Table 5.

Table 5 Typical mechanical properties of gold-platinum alloy (70Au-30Pt)

Condition	Proportional limit		Yield strength		Hardness[(a)], HB
	MPa	ksi	MPa	ksi	
Annealed[(b)]	200	28.8	245	35.4	130
Annealed[(c)]	. . .	. . .	. . .	. . .	114

(a) AWS. American Welding Society.

(b) The brazing filler metal will be analyzed for those specific elements for which values are shown in this table. If the presence of other is indicated in the course of this work, the amount of those elements will be determined to ensure that their total does not exceed the limit specified.

Applications

Typical uses. Filler metal for brazing stainless steel, tungsten, molybdenum, nickel, and cobalt-base alloys. Filler metal for brazing thin sections due to low rate of interaction with the base metals. Commonly used in applications where strength and corrosion resistance are needed at elevated temperatures, such as in some jet engine components

Mechanical Properties

Tensile properties. Typical: tensile strength (approximate range), 415 to 550 MPa (60 to 80 ksi). The strength of gold-base filler metals is good at elevated temperatures, but it does decline. Short-term tests on filler metal 82Au-18Ni indicate that the loss in strength at 425 °C (800 °F) will approximate 20% of the strength at room temperature and 35% at 650 °C (1200 °F). Those filler metals containing nickel will exhibit higher strength at room and elevated temperatures.

Thermal Properties

Liquidus temperature. See Table 6.

Solidus temperature. See Table 6.

Typical brazing temperature. See Table 6.

Electrical Properties

Electrical conductivity. The electrical conductivity of these filler metals is approximately 5% IACS and up for the various compositions. Those filler metals containing nickel exhibit the lowest conductivity.

Chemical Properties

General corrosion behavior. The gold-base filler metals exhibit excellent oxidation resistance, even at elevated temperature. They also resist attack by water and salt water.

Fabrication Characteristics

Formability. Gold-base filler metals are relatively malleable and ductile. They can be fabricated into sheet and wire form easily.

Platinum and Platinum Alloys

Commercially Pure Platinum
99.95% Pt

Compiled by Edward D. Zysk (deceased), Engelhard Minerals & Chemicals Corp.; Reviewed for this Volume by James Klinzing and Lisa Dodson, Johnson Matthey, Inc.

Applications

Typical uses. Of the platinum group metals, platinum is the least rare, and it is the most widely used because of its general corrosion resistance, high melting point, appearance, and ductility. Platinum of the highest purity is required for use in resistance thermometers and thermocouples. Various alloying elements such as rhodium, ruthenium, and iridium, and for special purposes, other hardeners are employed to develop higher mechanical properties or to protect against special corrosion conditions. Platinum or its alloys are used for the cathodic protection of ship hulls, for electrical contacts, brushes, precision potentiometer wire, chemical production, laboratory ware, spinnerettes for synthetic fibers, anodes in both solid and clad form, and for jewelry. It is also used as a crucible liner for producing high-purity optical glass or as a bushing in the extrusion of fiberglass. A more recently developed application for platinum and its alloys is in cardiac pacemakers and other biomedical specialty items. Platinum is an outstanding catalyst for oxidation, as in the production of H_2SO_4 and HNO_3; for hydrogenation as in the production of vitamins and other chemicals; and in the petroleum reforming process as in the production of high-octane gasolines. Certain organometallic compounds containing platinum have significant antitumor activity.

Mechanical Properties

Tensile properties. Typical: annealed at 700 °C (1290 °F): tensile strength, 125 to 165 MPa (18 to 24 ksi); proportional limit, <13.8 MPa (<2 ksi); elongation, 30 to 40% in 50 mm (2 in.). Hard drawn, 50% cold worked: tensile strength, 205 to 240 MPa (30 to 35 ksi); elongation, 1 to 3% in 50 mm (2 in.)

Effect of low temperature. Coarse grain material: 125 MPa (18.2 ksi) at room temperature; 283 MPa (41.0 ksi) at -195 °C (-317 °F); 565 MPa (82.0 ksi) at -253 °C (-425 °F). Fine grain material: 124 MPa (18.0 ksi) at 21 °C (70 °F) 448 MPa (65.0 ksi) at -195 °C (-317 °F) (Ref 6)

Effect of elevated temperature. Annealed thermocouple quality (about 99.99% pure): 143 MPa (20.7 ksi) at room temperature; 90 MPa (13.0 ksi) at 400 °C (750 °F); 55 MPa (8,0 ksi) at 800 °C (1470 °F); 34 MPa (5.0 ksi) at 1000 °C (1830 °F); 21 MPa (3.0 ksi) at 1200 °C (2190 °F). Tensile strength of 99.98% pure material of two grain sizes is given in Ref 6 for -253 to 827 °C (-423 to 1521 °F).

Hardness. Annealed at 700 °C (1290 °F): 37 to 42 HV; hard drawn, 50% cold work: 90 to 95 HV. Electrodeposited: approximately 600 HV. Effect of rolling and annealing, see Fig. 9 and Ref 7. Effect of alloying, see Fig. 10

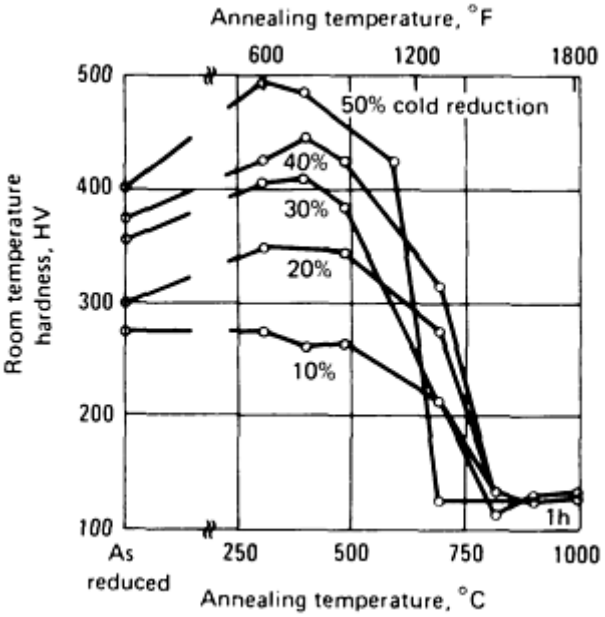

Fig. 9 Room-temperature hardness of commercially pure (99.99%+) platinum after warm rolling and annealing

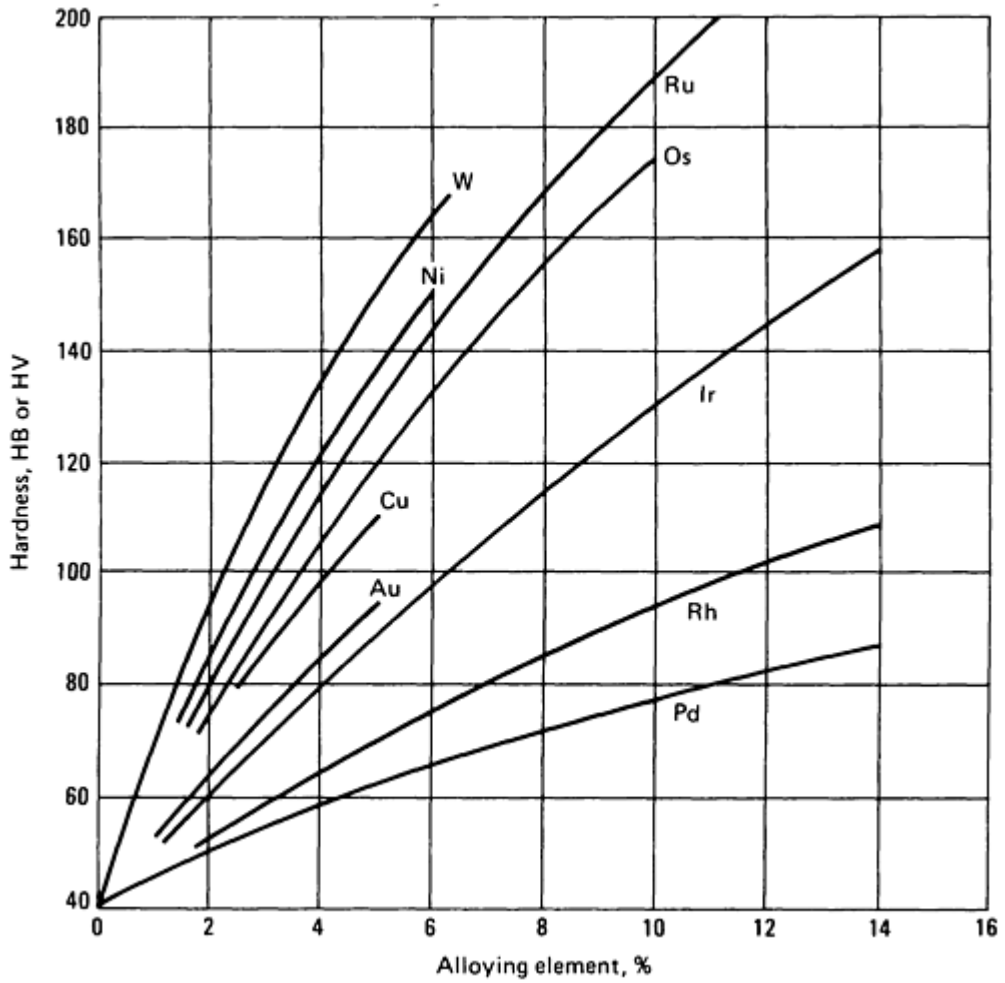

Fig. 10 Effect of various alloying additions on the hardness of annealed platinum

Poison's ratio. 0.39 (Ref 8)

Elastic modulus. At 20 °C (68 °F), annealed at 700 °C (1290 °F). Tension: static, 171 GPa (24.8×10^6 psi); dynamic, 169 GPa (24.5×10^6 psi). Hard drawn, 50% cold work, tension: static, 156 GPa (22.6×10^6 psi)

Creep-rupture characteristics. For platinum and platinum-palladium alloys, see Ref 9.

Mass Characteristics

Density. 21.46 g/cm^3 (0.775 lb/in.^{3}) at 25 °C (77 °F)

Thermal Properties

Melting point. 1769 °C (3217 °F) (Ref 10)

Coefficient of linear thermal expansion. 9.1 μm/m · K (5.1 μin./in. · °F) from 20 to 100 °C (68 to 212 °F) (Ref 11)

Specific heat. 0.132 kJ/kg · K (0.0314 Btu/lb · °F) at 0 °C (32 °F) (Ref 12)

Latent heat of fusion. 113 kJ/kg

Thermal conductivity. 71.1 W/m · K (493 Btu · in./ft^2 · h · °F) at 0 °C (32 °F) (Ref 13)

Electrical Properties

Electrical resistivity. 98.5 nΩ · m at 0 °C (32 °F); 106 nΩ · m at 20 °C (68 °F). Temperature coefficient: 0.0039/K from 0 to 100 °C (32 to 212 °F). Effect of alloying, see Fig. 11

Color. Silver white

Spectral reflectance. Bulk: 70.1% at 589 nm. Electrodeposited: 58.4% at 441 nm; 59.1% at 589 nm; 59.4% at 668 nm (Ref 15, 16, 17)

Chemical Properties

General corrosion behavior. See the article "Corrosion of the Noble Metals" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.* See also Ref 18.

Resistance to specific corroding agents. Resistant to reducing or oxidizing acids at room temperature; attacked by aqua regia (a mixture of nitric and hydrochloric acids); attacked slowly by hydrochloric acid plus other oxidizing agents. Resistant to ferric chloride at room temperature; hydrobromic acid plus bromine attacks at room temperature. All of the free halogens attack at elevated temperatures; hydrochloric acid in the absence of oxidizing agents does not attack, and platinum is useful against this normally active gas up to 1095 °C (2000 °F). Sulfur dioxide does not attack even at 1095 °C (2000 °F) (Ref 19).

As an anode, platinum is outstanding and is used commercially in sulfuric and persulfuric acids, various sulfate-chloride plating electrolytes, and in chlorates with very little corrosion. If electrolyzed with alternating current, chlorides may attack, a characteristic exploited in etching platinum and platinum alloys.

Platinum is highly resistant to acid potassium sulfate, sodium carbonate, potassium nitrate at moderate temperatures, and to sodium carbonate at 800 to 900 °C (1475 to 1650 °F) under nonoxidizing conditions. Although attacked vigorously by molten alkali cyanides and polysulfides, it is quite resistant to the normal sulfides plus alkali. Certain phosphates attack at high temperatures and care must be taken to avoid reducing conditions, particularly when compounds of arsenic,

phosphorus, tin, lead, or iron are present. It is resistant molten glasses, especially to those low in lead and arsenic. Platinum, even in the form of thin leaf, is resistant to corrosion and tarnishing on exposure to the atmosphere, including urban sulfur.

Fabrication Characteristics

Annealing. Annealing temperature depends on the purity of the material and amount of prior cold work. Figure 9 shows the effect of reduction during rolling of 99.99% pure platinum; grain size after annealing platinum of this purity is determined almost entirely by prior reduction; virtually no grain growth occurs on the usual short anneals. It is probable, however, that platinum free from oxygen in solution will show grain growth after recrystallization and may have a still lower annealing temperature.

Air is the preferable atmosphere for annealing platinum; hot-reducing atmospheres, particularly where silica, iron, or easily reduced oxides are nearby, are almost certain to result in contamination. Annealing at too frequent intervals can result in substantial growth, causing the orange peel effect during subsequent working or polishing. To prevent the formation of orange peel, the reduction in cross-sectional area before annealing should not be less than 30%. Annealing for too long a time as well as at too high a temperature can result in thermal etching (grains of metal become clearly visible).

Precautions in working. The maintenance of oxidizing conditions throughout processing is essential to avoid contamination. To remove iron, pickling in hot hydrochloric acid after rolling and before annealing is essential for high-purity wire and sheet.

Platinum-Palladium Alloys

Compiled by J. Hafner and R. Volterra, Metals and Controls Division, Texas Instruments, Inc.; Reviewed for this Volume by James Klinzing and Lisa Dodson, Johnson Matthey, Inc.

Applications

Typical uses. Platinum-palladium alloys are used in place of pure platinum for jewelry in Europe; in the United States, stamping laws do not provide for this type of alloy. Platinum-palladium alloys, with or without additions of other metals, are used for electrical contacts. Platinum with up to 20% Pd is used as an insoluble anode in seawater, and low-palladium platinum alloys are being used in the glass industry.

Mechanical Properties

Tensile properties. See Fig. 12.

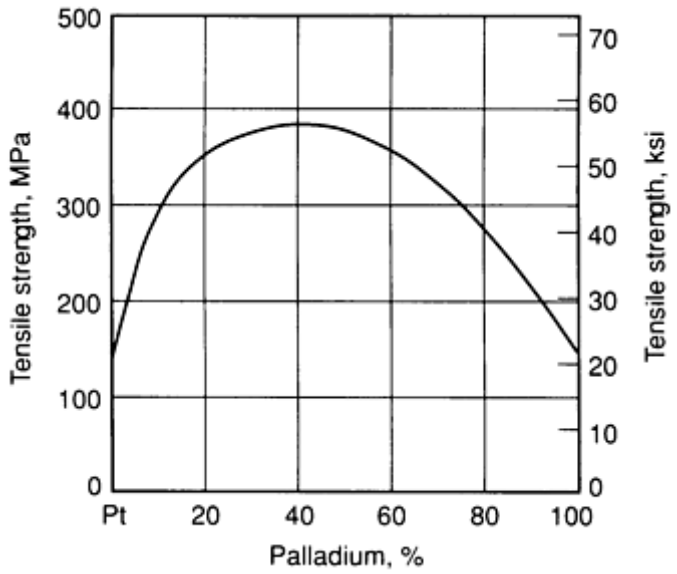

Fig. 12 Tensile strength of annealed platinum-palladium alloys as a function of palladium content

Hardness. See Fig. 13.

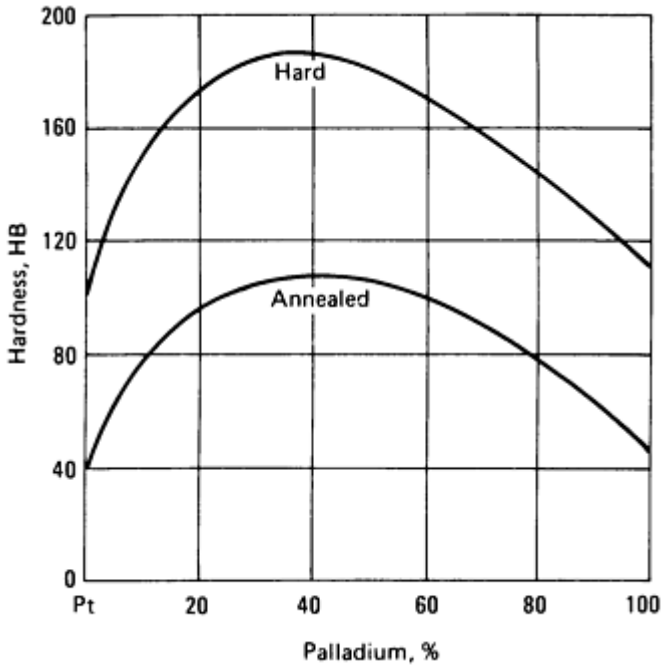

Fig. 13 Hardness of platinum-palladium alloys as a function of palladium content

Structure

Microstructure. Platinum and palladium form a continuous series of solid solutions. Solidus and liquidus curves are close together; the maximum interval between them is about 60 °C (about 110 °F) (50Pt-50Pd). No transformations in the solid state have been reported.

Electrical Properties

Electrical resistivity. See Fig. 14.

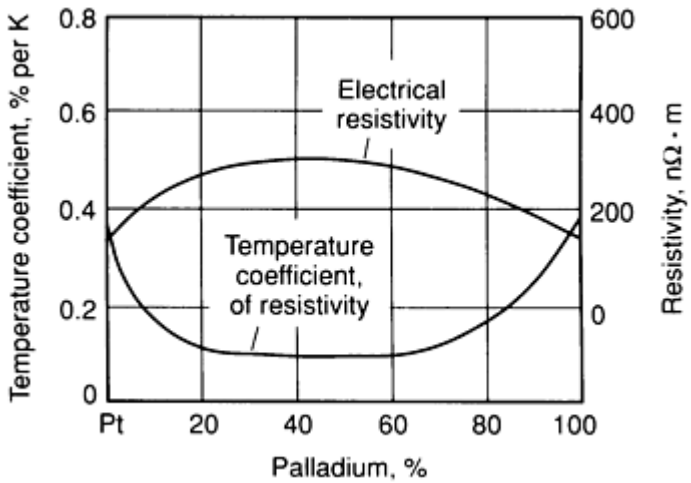

Fig. 14 Electrical resistivity of platinum-palladium alloys as a function of palladium content

Temperature coefficient of resistivity. See Fig. 14.

Chemical Properties

General corrosion resistance. The alloys containing less than 25% Pd perform the same as pure platinum in most chemical mediums. The resistance to nitric acid decreases as the palladium content increases, but an alloy with only 2% Pt is as resistant to this reagent as a 14 k gold alloy. The platinum-rich alloys do not discolor when heated in air, but the palladium-rich alloys darken between 400 and 750 °C (750 and 1380 °F), because of the formation of palladium oxide, which is stable in that interval of temperature but which decomposes at higher temperature. Prolonged heating at high temperature causes slight weight loss by volatilization; however, at 900 °C (1650 °F) in oxygen, the loss in weight is less than that of pure platinum. Presumably, this is caused by the adsorption of oxygen in palladium. The solubility of hydrogen in palladium is reduced significantly by the addition of platinum. At over 34% Pt, only adsorption can be observed. The 90Pt-10Pd alloy has the lowest corrosion rate in seawater.

Fabrication Characteristics

Workability. All platinum-palladium alloys can be cold worked. Those with high palladium content should be annealed in inert or nitrogen atmospheres. Recommended annealing temperature is 950 °C (1740 °F).

Platinum-Iridium Alloys

Compiled by J. Hafner and R. Volterra, Metals and Controls Division, Texas Instruments, Inc.; Reviewed for this Volume by James Klinzing and Lisa Dodson, Johnson Matthey, Inc.

Applications

Typical uses. Platinum-iridium alloys are used in the electrical, electrochemical, chemical, medical, and jewelry fields. The Pt-10% Ir alloys are also used for standards of length and weight because of their permanence. Some applications of different alloys are:

Application	Iridium, %
Laboratory ware	0.4-0.6
Jewelry	5-15
Medical	10
Electrical contacts	10-25
Electrodes for electrochemical processes	10
Tubing for pens, hypodermic needles, spring elements	25-30

Mechanical Properties

Tensile properties. See Table 7 and Fig. 15.

Table 7 Typical properties of platinum-iridium alloys

% Iridium and temper	Tensile strength		Hardness, HB	Density		Electrical resistivity, nΩ · m	Temperature coefficient[a], per °C

(b) By interpolation

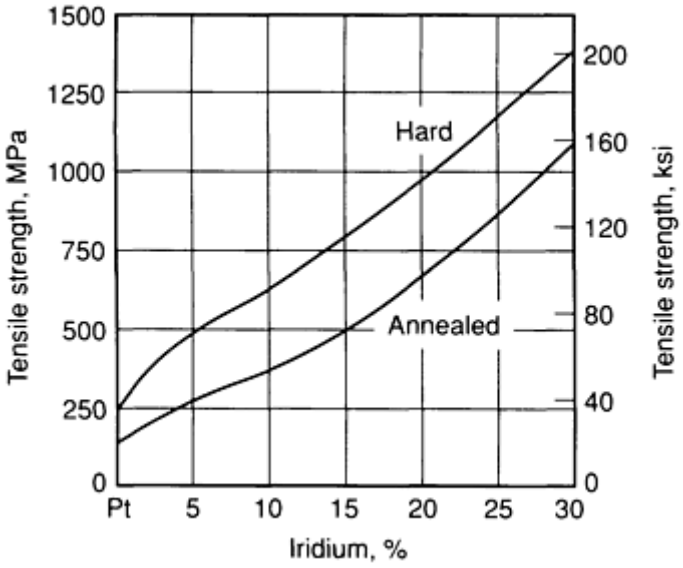

Fig. 15 Tensile strength of platinum-iridium alloys as a function of iridium content

Hardness. See Table 7 and Fig. 16.

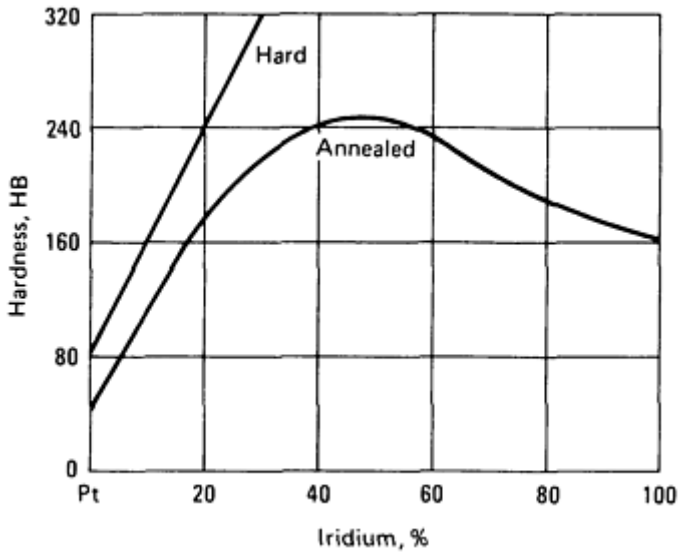

Fig. 16 Hardness of platinum-iridium alloys as a function of iridium content

Structure

Microstructure. The platinum-iridium alloys solidify in a complete series of solid solutions. Below about 995 °C (1825 °F), a very sluggish separation into two solid solutions has been reported. The duplex region ranges from 7 to 99% Ir at 700 °C (1290 °F).

Mass Characteristics

Density. See Table 7.

Electrical Properties

Electrical resistivity. See Table 7 and Fig. 17.

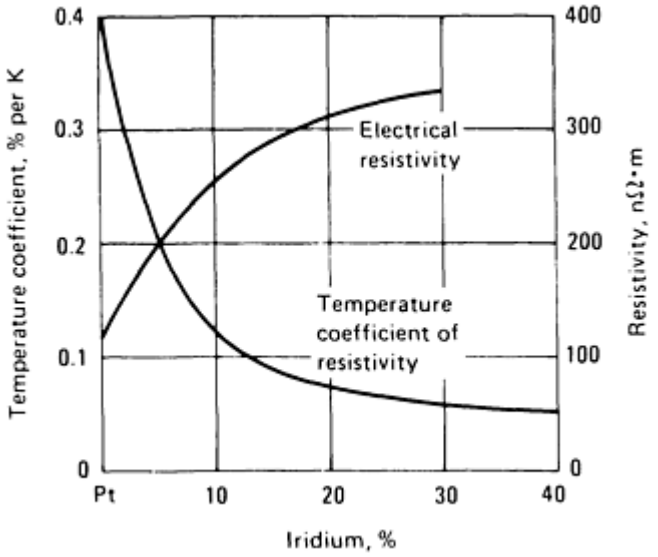

Fig. 17 Electrical resistivity of platinum-iridium alloys as a function of iridium content

Chemical Properties

General corrosion resistance. The resistance to corrosion and tarnishing of the platinum-iridium alloys is excellent. The resistance to aqueous solutions of halogens and aqua regia increases with iridium content. Because iridium forms a volatile oxide at high temperatures, there is a noticeable loss by evaporation when these alloys are annealed in air above 900 °C (1650 °F). The loss by evaporation increases with temperature and iridium content.

Fabrication Characteristics

Workability. The workability of the platinum-iridium alloys decreases with increasing iridium content. The practical limit of workability for cast alloys is about 40% Ir. Alloys with about 25 to 30% Ir can be hot or cold worked. Cold reductions to 75% can be used for alloys with 20% Ir or less; permissible reductions for alloys of higher iridium content are lower. Annealing temperatures between 1000 and 1200 °C (1830 and 2190 °F) are suitable for alloys to 10% Ir. For alloys of higher iridium content, temperatures near 1400 °C (2550 °F) are recommended. Platinum alloys with 10 to 90% Ir have been reported to be susceptible to precipitation hardening. Noticeable changes in physical properties can be obtained by heating at approximately 800 °C (1475 °F) after quenching from about 1700 °C (3090 °F).

Platinum-Rhodium Alloys (3.5 to 40% Rh)

Compiled by R.B. Green, Radio Corporation of America; Reviewed for this Volume by James Klinzing and Lisa Dodson, Johnson Matthey, Inc.

Applications

Typical uses. Rhodium is the preferred addition to platinum for most applications at high temperatures under oxidizing conditions, because unlike most other hardeners, rhodium is not selectively volatilized. The 10% Rh alloy is used more than any of the other alloys in this series. In the production of nitric acid, it is used as a catalyst for the oxidation of ammonia by air. This alloy, with its composition controlled closely, is the positive element in the standard thermocouples (Pt-10Rh versus platinum) that are used to define the International Practical Temperature Scale of 1968 in the range from 630.74 °C (1167.3 °F) to the gold point (1064.43 °C, or 1948.0 °F). Some use is made of the Pt-13Rh versus platinum thermocouple in instruments that are calibrated for it.

The following thermocouples are accepted internationally and standard temperature/electromotive tables are available (for further information see NBS Monograph 125 and latest addition of ASTM Monograph 565):

- Pt-10Rh versus Pt (Type S)
- Pt-13Rh versus Pt (Type R)
- Pt-30Rh versus Pt-6Rh (Type B)

Types R and S thermocouples are generally used to 1400 °C (2552 °F) for extended service, whereas the Type B couple may be used to 1600 °C (2910 °F). The preferred atmosphere for the use of these thermocouples is air. For emf stability, high-purity alumina insulators and protection tubes should be used.

Pt-3.5Rh alloy is used as a crucible and shows very little loss in weight at high temperatures. Platinum-rhodium alloys are used in the glass industry; they stand up well on contact with molten glass. The Pt-10Rh alloy is used for feeder dies and in handling glasses of high melting point. The Pt-10Rh alloy also is used for rayon spinnerettes. Pt-10Rh and Pt-20Rh alloys are used as windings in high-temperature furnaces that operate under oxidizing atmospheres. The 40% Rh alloy has been used as a winding in furnaces operating between 1500 and 1800 °C (2730 and 3275 °F).

Mechanical Properties

Tensile properties. See Table 8.

Table 8 Typical properties of platinum-rhodium alloys

% Rhodium and temper	Tensile strength		Elongation[a], %	Hardness, HB	Density		Electrical resistivity[b], nΩ · m	Temperature coefficient[c], per °C

Hardness. See Table 8.

Mass Characteristics

Density. See Table 8.

Electrical Properties

Electrical resistivity. See Table 8.

Temperature coefficient of electrical resistivity. See Table 8.

Fabrication Characteristics

Workability. These alloys can be worked hot or cold. Alloys containing up to 20% Rh have readily been cold worked. Alloys with a higher rhodium content may require more hot work before they can be cold worked successfully. The hot-working temperature range is between 900 and 1200 °C (1650 and 2190 °F), and the annealing temperature range is between 900 and 1000 °C (1650 and 1830 °F). If proper melting procedures are followed, reductions up to 90% between anneals are possible.

Platinum-Ruthenium Alloys

Compiled by F.E. Carter, Engelhard Industries, Inc., Minerals and Chemicals Corp.; Reviewed for this Volume by James Klinzing and Lisa Dodson, Johnson Matthey, Inc.

Applications

Typical uses. The alloy that contains 5% Ru is used in jewelry and has properties essentially the same as the 10% Ir alloy--the so-called hard platinum of the jewelry trade. The same alloy is also used for laboratory electrode stems and for certain other chemical equipment, but it is not completely suitable for service at high temperature under strongly oxidizing conditions. Platinum-ruthenium alloys are frequently employed as electrical contacts--the 5% Ru alloy in the medium-duty field, the 10% alloy in aircraft magnetos, and the 14% alloy for heavy-duty contacts. Complex platinum-base alloys that contain 4 to 5% Ru are being used to some extent for spark plug electrodes in aircraft. The 10 and 11% Ru platinum alloys are about equally in demand, for electrical contacts and hypodermic needles.

Mechanical Properties

Tensile properties. Tensile strength: 5% Ru: annealed, 415 MPa (60 ksi); hard, 795 MPa (115 ksi). 10% Ru: annealed, 570 MPa (83 ksi); hard, 1035 MPa (150 ksi). Elongation in 50 mm (2 in.): 5% Ru: annealed, 34%; hard, 2%, 10% Ru: annealed, 31%; hard, 2%. See also Fig. 18.

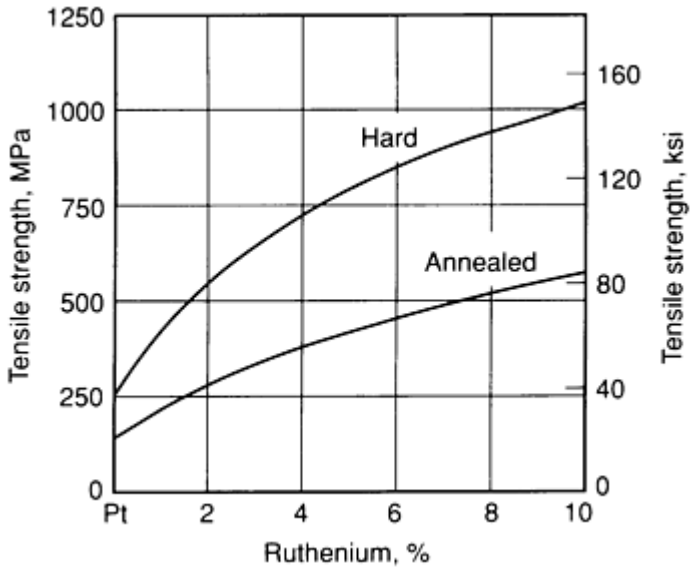

Fig. 18 Tensile strength of platinum-ruthenium alloys as a function of ruthenium content. Initially reduced by 75%, then annealed 15 min

Hardness. 5% Ru: annealed, HB 130, HRB 70; hard, HB 210, HRB 94. 10% Ru: annealed, HB 190, HRB 86; hard, HB 280. 14% Ru, annealed, HV 240

Mass Characteristics

Density. 5% Ru, 20.67 g/cm^3 (0.747 lb/in.^{3}); 10% Ru, 19.94 g/cm^3 (0.720 lb/in.^{3})

Electrical Properties

Electrical resistivity. 5% Ru, 315 nΩ · m; 10% Ru, 430 nΩ · m; 14% Ru, 460 nΩ · m. See also Fig. 19.

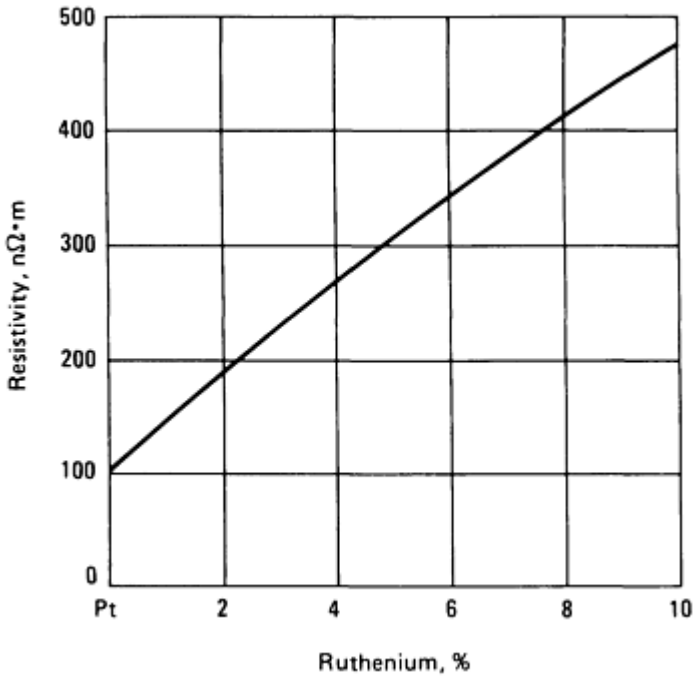

Fig. 19 Electrical resistance of platinum-ruthenium alloys as a function of ruthenium content

Temperature coefficient of resistivity. 5% Ru, 0.0009/°C at 0 to 1000 °C (32 to 1830 °F); 10% Ru, 0.0008/°C at 0 to 1000 °C (32 to 1830 °F); 14% Ru, 0.00036/°C at 0 to 100 °C (32 to 212 °F)

Fabrication Characteristics

Workability. The 5% Ru alloy is hot worked between 900 and 1200 °C (1650 and 2200 °F); and the 10% Ru alloy, between 995 and 1300 °C (1825 and 2375 °F). Annealing temperature for the 5% alloy is about 1000 °C (1825 °F): and for the 10% alloy, about 1095 °C (2000 °F). Maximum reduction between anneals should not exceed 90% for the 5% Ru alloy, or 75% for the 10% alloy. The 14% Ru alloy approaches the practical limit of workability. The atmosphere for high-temperature anneals should be only slightly oxidizing, since excessively oxidizing atmospheres cause loss of ruthenium in the same manner as with iridium alloys.

79Pt-15Rh-6Ru

Compiled by J.D. Mitilineos, Sigmund Cohn Corp.; Reviewed for this Volume by James Cohn, Sigmund Cohn Corp.

Commercial Names

Trade name. Alloy No. 851

Chemical Composition

Composition limits. 78.9 to 80.1 Pt, 14.9 to 15.1 Rh, 5.0 to 6.1 Ru

Applications

Typical uses. This alloy has remarkably high tensile strength and hardness, combined with excellent corrosion resistance, weldability, stability, and shelf life. In solid-solution form, it is used for wire-wound potentiometers, galvanometers, suspension strips, bridgewires, contacts, catalytic glow plugs, and corona wire for copiers.

Mechanical Properties

Tensile properties. Typical: tensile strength, 2070 MPa (300 ksi); yield strength, 1515 MPa (220 ksi); elongation, 2% in 254 mm (10 in.)

Hardness. 371 HK

Elastic modulus. Tension, 205 GPa (30×10^6 psi)

Mass Characteristics

Density. 18.6 g/cm^3 (0.67 lb/in.^{3})

Thermal Properties

Solidus temperature. 1880 °C (3415 °F)

Coefficient of linear thermal expansion. 15.6 μm/m · K (8.69 μin./in. · °F)

Thermal electromotive force versus Cu. 3.24 m V/°C

Electrical Properties

Electrical resistivity. 308 nΩ · m at 0 °C (32 °F); temperature coefficient, 0.06%/°C (0.185 nΩ · m/°C at 0 to 100 °C (32 to 212 °F)

Chemical Properties

General corrosion behavior. Excellent resistance to corrosion

Resistance to specific corroding agents. Very slowly attacked even by aqua regia. Can only be put into solution with a caustic fusion

Fabrication Characteristics

Weldability. Excellent

Platinum-Tungsten Alloys

Compiled by J.D. Mitilineos, Sigmund Cohn Corp.; Reviewed for this Volume by James Cohn, Sigmund Cohn Corp.

Chemical Composition

Nominal compositions. Four platinum-tungsten alloys are commonly used: 2%, 4%, 6%, and 8% W.

Applications

Typical uses. The 4% W platinum alloy was originally developed for spark plug electrodes in aircraft engines. Its resistance to lead contamination is superior in the hard-drawn condition. It was also used for grids in radar tubes because of reduced electron emission. These uses have diminished over the years.

The Pt-8% W alloy has been used for potentiometer wire because it has excellent wear resistance and low electrical noise characteristics. Pt-8% W has been used as a bridgewire and heating element. As with many strong, high-platinum-content alloys, wide use of this alloy is made in the medical community due to its high degree of compatibility with human tissue and excellent fatigue resistance.

Precautions in use. The Pt-8% W alloy is not recommended for use at high temperature under oxidizing conditions because of the selective oxidation of tungsten.

Mechanical Properties

See Table 9 and Fig. 20.

Table 9 Mechanical properties of platinum-tungsten alloys

Condition	Tungsten, %	Tensile strength		Hardness, HV
		MPa	ksi	
Annealed at 1200 °C (2190 °F)	2	570	82	100

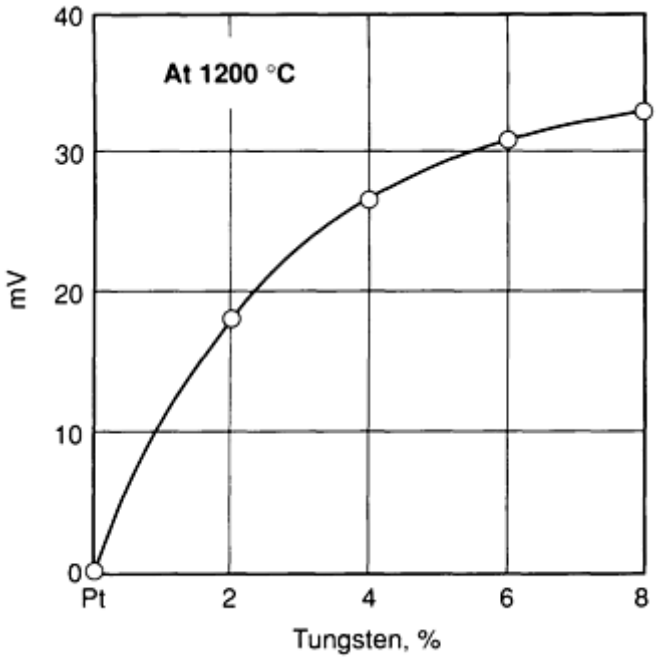

Fig. 22 Thermal electromotive force of platinum-tungsten alloys versus platinum as a function of tungsten content

Platinum-Nickel Alloys

Compiled by J.D. Mitilineos, Sigmund Cohn Corp.; Reviewed for this Volume by James Cohn, Sigmund Cohn Corp.

Chemical Composition

Nominal compositions. Platinum-nickel alloys range in composition from 0 to 20% N.

Applications

Typical uses. These alloys have long been used for their strength at high temperatures. Taut band strips for electrical meters are made from 10% Ni-Pt alloys. In addition to high tensile strength, this alloy is remarkably free of hysteresis.

Precautions in use. Selective oxidation of nickel limits the use of platinum-nickel alloys at high temperature under oxidizing conditions.

Mechanical Properties

Tensile properties. Tensile strength:

Nickel, %	Tensile strength	
	MPa	ksi

Platinum-Cobalt Permanent Magnet Alloys

Compiled by A.R. Robertson, Engelhard Corporation

W.J. Jellinghaus in 1936 discovered that certain platinum-cobalt alloys had an unusually high coercive force, H_c (Ref 20). To date, coercivities up to 540 kA · m^{-1} (6.8 kOe) have been observed in these alloys at room temperature. The most valuable data on these alloys have been published in a series of papers by J.B. Newkirk, R. Smoluchowski, A.H. Geisler, and D.L. Martin; the last of the series is cited below (Ref 21). The platinum-cobalt alloys used for permanent magnets are near the 50 at.% composition (23.3 wt% Co). In this region the alloys are disordered face-centered cubic (fcc) at high temperature and ordered face-centered tetragonal (fct) at low temperature. Alloys near 30 at.% Co form a superlattice similar to Cu_3Au, fcc with cobalt atoms on the corner sites and platinum atoms on the face centers. The strain induced by dimensional change in a rigid alloy when it is ordered results in considerable hardening.

Applications

Typical uses. When an alloy of platinum and cobalt is properly processed, it exhibits extremely high-energy products. For this reason, this material is used in areas where the length-to-thickness ratio of most other magnetic materials would

be unfavorable. In many critical applications that require minimum space or weight and stable temperature performance without fear of attrition, platinum-cobalt magnets may be the best choice. Typical uses include focusing magnets, hearing-aid magnets, magnetic phonograph cartridges, electric watch magnets, rotors in miniature motors, and gyro bearings. Other applications include platinum-cobalt films for use in digital magnetooptic recording, medical implants for atrial stimulation and sensing, as well as in a system for delivery of magnetic emboli via a guided catheter to specific cerebral arteries.

Properties and Fabrication

The magnetic characteristics of the platinum-cobalt alloys can be varied by adjusting composition within the range from 40 to 60 at.% Co, and by varying the heat treatment. Curves of magnetic properties as functions of time and temperature of aging are given in papers by D.L. Martin (Ref 22, 23). According to Martin:

- The disordered phase has a higher saturation $(B_i)_P$ and residual induction B_r than the ordered alloy
- The coercive force, H_c, and the intrinsic coercive force, H_{ci}, and the related maximum energy product $(BH)_{max}$ increase to a maximum and then decrease with additional aging time
- Peak values of H_c, H_{ci}, and $(BH)_{max}$ were obtained in alloys aged at 600 °C (1110 °F). The coercive force reaches its maximum before ordering is complete
- The effect of cobalt on the magnetic properties was not established precisely. However, alloys with 49 to 50 at.% Co have the highest coercive force and the highest $(BH)_{max}$
- Magnetic properties depend not only on time and temperature of aging but also on the temperature at which the alloys are previously heated for disordering and the rate at which they are cooled from the disordering temperature
- The platinum-cobalt alloys can be prepared either by melting or by powder metallurgy; with proper techniques, they can be worked hot or cold, but sulfur content must be controlled to prevent hot shortness. The disordered phase is softer and more ductile than the ordered phase and can be retained at room temperature by quenching

Additional information is available in the article "Permanent Magnet Materials" in this Volume.

Zirconia-Grain-Stabilized Platinum and Platinum Alloys

Compiled by James Klinzing and Lisa Dodson, Johnson Matthey Inc.

The use of platinum and its alloys (up to 25% Rh-Pt) is well established in the automotive, chemical, glass, electrical, and dental industries. However, these applications often mean high-temperature operation of these materials. At high temperatures these materials are weak and subject to creep.

They are also subject to contamination failure.

Zirconia-grain-stabilized (ZGS) platinum materials are produced by incorporating a fine, insoluble phase dispersed uniformly throughout the platinum metal matrix, a process called dispersion strengthening (see the article "Dispersion-Strengthened Nickel-Base and Iron-Base Alloys" in this Volume).

Grain stabilization provides greater resistance to grain growth, dislocation movement, and grain-boundary sliding. These problems normally occur in conventional platinum at high temperatures causing sagging, bulging, and cracking.

Applications

Typical uses. Product applications where high temperature causes creep, distortion, and ultimately failure of unsupported conventional platinum and its alloys. ZGS platinum-rhodium bushings used for the production of continuous filament glass fiber resist creep-induced sagging and eliminate the need for costly platinum supports.

Possible weight reduction in product design is also an advantage of using ZGS platinum. For instance, glass-carrying apparatus can be designed with thinner wall sections and have 50% greater useful life; lightweight thermocouple pockets may be fabricated with walls one-half the conventional thickness; and in stirrers for specialty glasses, ZGS platinum often makes possible the elimination of molybdenum and ceramic cores, doubling of service life, and reduction of running problems.

Physical, Electrical, and Tensile Properties

Table 11 shows the typical properties of ZGS platinum and its alloys at room temperature, and compares the tensile strength of ZGS materials at various temperatures with conventional platinum and its alloys. Figure 26 illustrates the improvement in high-temperature life achieved by grain stabilization.

Table 11 Mechanical and electrical properties of zirconia-grain-stabilized (ZGS) platinum alloys compared with conventional platinum and platinum alloys

Alloy	Density		Specific resistance, μΩ· cm	Temperature coefficient of resistance, per °C	Hardness, HV	Ultimate tensile strength at elevated temperatures													
						20 °C (70 °F) annealed		1000 °C (1830 °F)		1100 °C (2010 °F)		1200 °C (2090 °F)		1300 °C (2370 °F)		1400 °C (2550 °F)		1500 °C (2730 °F)	
	g/cm^3	lb/in.^{3}				MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi
100% Pt	21.4	0.773	10.6	0.0039	40	124	18.0	23	3.4	17	2.4	12.8	1.85	7.86	1.14	3.9	0.57	. . .

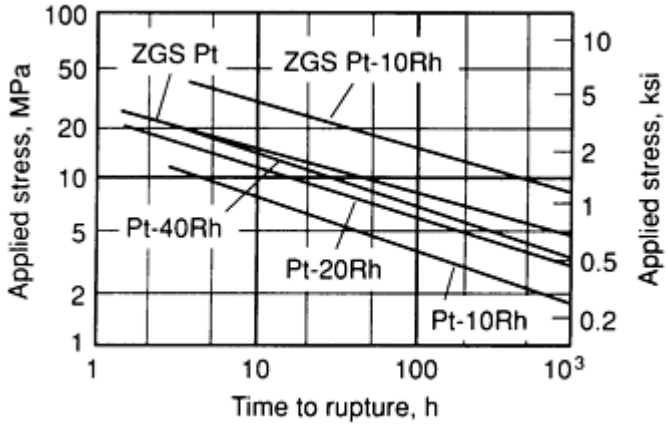

Fig. 26 Stress-rupture properties of ZGS platinum, ZGS Pt-10Rh, and the commercially important conventional alloys. Samples were 1.5 mm (0.060 in.) thick sheets tested in air at 1400 °C (2550 °F).

The time to failure at 1400 °C (2550 °F) under a stress of 9.83 MPa (1.425 ksi) shows that ZGS platinum lasts two or three times as long as the best conventional platinum-rhodium alloy, and ZGS Pt-10Rh lasts more than 10 times as long as ZGS platinum.

Fabrication Characteristics

Machinability. The machining characteristics of ZGS platinum and its alloys are, in general, similar to but somewhat better than those of pure platinum, platinum-rhodium alloys, or pure nickel. ZGS materials gall readily, therefore tools must be kept sharp to minimize galling and pickup on the machining tools. Sulfur-free oils normally are recommended for machining.

Workability. ZGS platinum and its alloys can be hot forged or hot rolled readily in the temperature range of 1200 to 1500 °C (2190 to 2730 °F). It is essential to maintain oxidizing conditions throughout processing to prevent contamination. Before annealing, iron should be removed from the hot-worked surface by pickling in hot hydrochloric acid.

ZGS platinum and its alloys can be cold worked easily by rolling, drawing, and extruding. Wire can be cold drawn with a reduction of 98% or more without intermediate annealing. The material can be easily formed, deep drawn, pierced, punched, spun, and so on.

ZGS platinum work hardens at a rate intermediate between pure platinum and 10% Rh-Pt, making ZGS platinum much easier to fabricate than conventionally melted platinum-rhodium alloys. At the same time, ZGS 10% Rh-Pt work hardens at a rate intermediate between the 10% Rh-Pt alloy and the 20% Rh-Pt alloy. This makes ZGS 10% Rh-Pt easier to fabricate than the 20% Rh-Pt alloy. Cold-worked ZGS platinum and its alloys can be softened by recrystallization at a temperature only slightly higher than that used for pure platinum and its alloys.

Corrosion Resistance

ZGS platinum and its alloys are similar to pure platinum and its alloys in their corrosion-resistant characteristics. It is resistant to corrosion by single acids, alkalies, aqueous solutions of simple salts, and organic materials. Even at elevated temperatures, it is resistant to dry hydrogen chloride and to sulfurous gases. Aqua regia and hydrochloric acid containing an oxidizing agent will attack ZGS materials as will free halogens to some degree at elevated temperatures.

ZGS platinum and its alloys are outstanding in their resistance to oxidation, remaining untarnished on heating in air at all temperatures. It is also essentially inert to many molten salts and it resists the action of fused glasses if oxidizing conditions are maintained. A number of low-melting metals, including lead, tin, antimony, zinc, and arsenic will readily alloy with and attack ZGS materials at their melting temperatures.

Palladium and Palladium Alloys

Commercially Pure Palladium
99.85% Pd

Compiled by E.M. Wise and R.F. Vines, The International Nickel Company, Inc.; Reviewed for this Volume by James Klinzing, Johnson Matthey, Inc.

Applications

Typical uses. Palladium resembles platinum in appearance, ductility, and strength. Its nobility and melting point are somewhat lower than those of platinum, but its lower cost-per-unit weight and lower density provide economic advantages. The major use of palladium is for contacts in light-duty electrical relays, where its freedom from tarnishing provides extreme reliability and noise-free transmission, required in voice circuits. Its effectiveness as a catalyst accounts for its use in the removal of oxygen from atmospheres used for heat treatment, the recombination of hydrogen and oxygen, the hydrogenation of terpines, and also the manufacture of organics such as vitamins. Hydrogen will diffuse selectively through a palladium septum, yielding pure gas. However, the gas must be initially free from sulfur. Palladium hardened with ruthenium provides an all-precious-metal white jewelry alloy that sets off diamonds to advantage. Generally, a solid solution former, palladium is employed as the major or auxiliary element in dental, electrical contact, and special resistance alloys. Palladium is an important constituent in the high-temperature solders that have low vapor pressures, excellent wettability, and minimum penetration into austenitic alloys. Palladium with a minimum purity of 99.8% (UNS P03980) meeting ASTM B 589, and MIL-E-46065 (MR) is available commercially.

Precautions in use. Contamination with low-melting-point metals causes embrittlement, with base metals causes hardening and decreased corrosion resistance, and with silicon causes loss of hot strength.

Mechanical Properties

Tensile properties. Typical: 1.3 mm (0.05 in.) wire. After annealing at high temperature: tensile strength, 145 MPa (21 ksi); elongation, 24%. After annealing at 800 °C (1470 °F): tensile strength, 172 MPa (25 ksi); elongation, 30%. Tensile strength at various temperatures, material annealed at 1095 °C (2000 °F): at room temperature, 193 MPa (28.0 ksi); at 400 °C (750 °F), 125 MPa (18.1 ksi); at 800 °C (1470 °F), 57 MPa (8.3 ksi); at 1000 °C (1830 °F), 26 MPa (3.8 ksi)

The tensile properties of palladium are mildly sensitive to the kind and amount of residual deoxidizing agents present. Palladium containing such residuals may have a tensile strength of 172 to 207 MPa (25 to 30 ksi) as annealed and 324 MPa (47 ksi) after cold drawing 50%. The tensile properties of deoxidized palladium, initially reduced 50% by cold drawing and annealed for 5 min at various temperatures, are shown in Fig. 27. The optimum anneal for this material is about 800 °C (1470 °F).

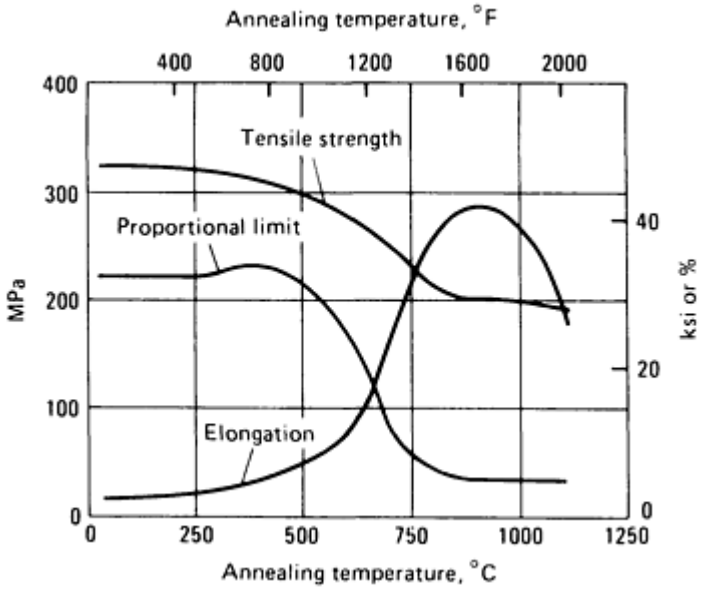

Fig. 27 Tensile properties of cold-drawn deoxidized palladium as a function of annealing temperature. Annealing time was 5 min.

Hardness. Rolled and annealed: 37 to 42 HV. Effect of cold rolling, see Fig. 28. Effect of annealing, see Fig. 29. Electrodeposited palladium is much harder than wrought material, ranging from 190 HV for metal from the chloride bath, to about 400 HV for deposits from the complex nitrite baths. For jewelry and other applications where a stronger material

is desired, palladium usually is hardened with ruthenium. The relative effects of the various additions of the hardness of annealed material are given in Fig. 30.

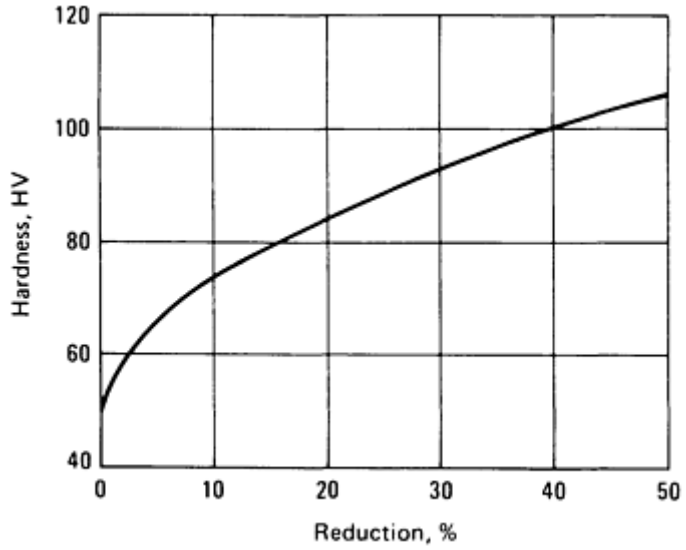

Fig. 28 Hardness of cold rolled palladium as a function of reduction during rolling

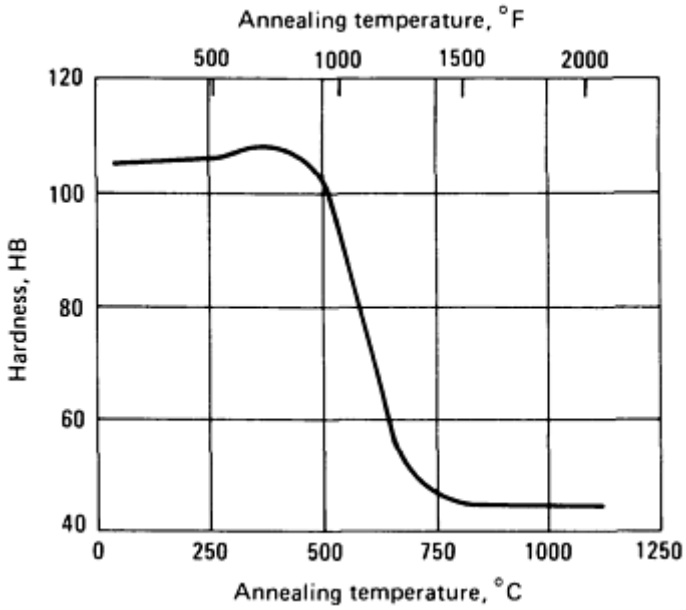

Fig. 29 Hardness of palladium as a function of annealing temperature

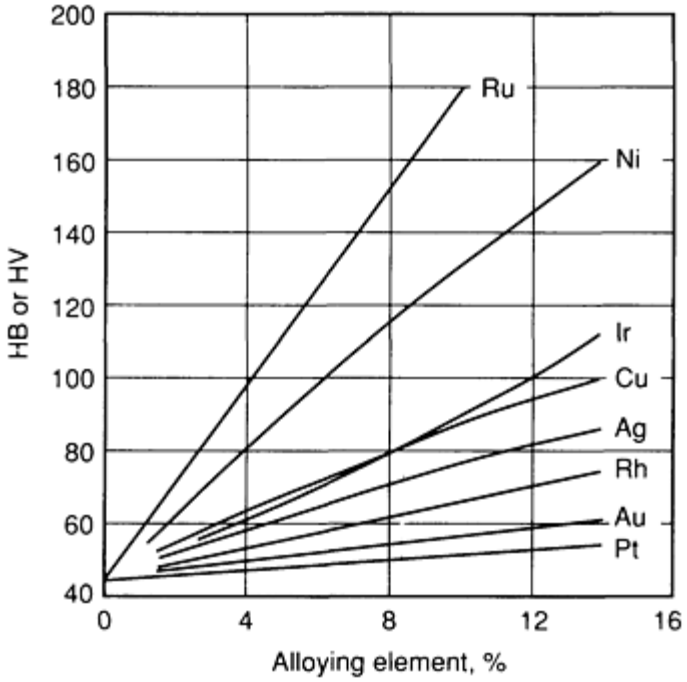

Fig. 30 Effect of various alloying additions on the hardness of annealed palladium

Elastic modulus. Tension: 112 GPa (16.3×10^6 psi)

Mass Characteristics

Density. 12.02 g/cm^3 (0.434 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Melting point. 1552 °C (2826 °F)

Coefficient of linear thermal expansion. 11.76 μm/m · K (6.53 μin./in. · °F) at 20 °C (68 °F)

Electrical Properties

Electrical conductivity. 16% IACS at 20 °C (68 °F)

Electrical resistivity. 108 nΩ · m at 20 °C (68 °F) and 100 nΩ · m at 0 °C (32 °F). Effect of alloying, see Fig. 31

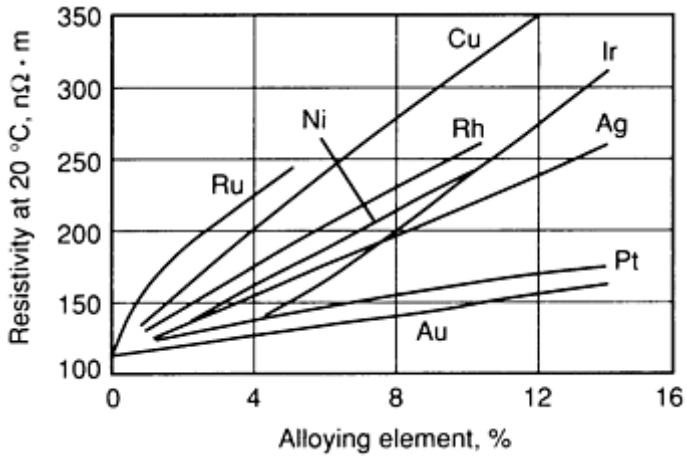

Fig. 31 Effect of various alloying additions on the electrical resistivity palladium

Optical Properties

Reflectance. 62.8% in white light. Increases slightly in going from red to blue (see Fig. 32)

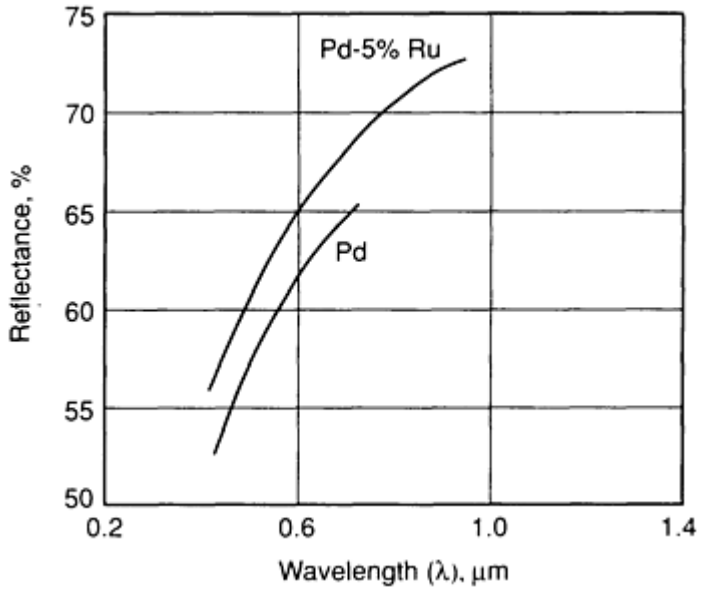

Fig. 32 Reflectance of palladium and Pd-5% Ru as a function of wavelength

Chemical Properties

General corrosion behavior. Generally, palladium is less corrosion resistant than platinum, but more corrosion resistant than silver. In ordinary atmospheres palladium is resistant to tarnish, but some discoloration may occur during exposure to moist industrial atmospheres that contain sulfur dioxide. Adding palladium to gold or silver alloys improve the tarnish resistance.

Resistance to specific corroding agents. At room temperature, palladium is resistant to corrosion by hydrofluoric, perchloric, phosphoric, and acetic acids. It is attacked slightly by sulfuric, hydrochloric, and hydrobromic acids, especially in the presence of air; and it is attacked readily by nitric acid, ferric chloride, hypochlorites, and moist chlorine, bromine, and iodine. Palladium is resistant to molten sodium or potassium nitrate, but not to sodium peroxide, sodium hydrate, or sodium carbonate.

Fabrication Characteristics

Precautions in melting. Torch melting of small lots of palladium alloys is common in jewelry and dental applications. For larger melts, palladium is best inductively melted under an argon or lean hydrogen-nitrogen gas cover with care to prevent contamination with silicon, which causes hot shortness. The melt is deoxidized with 0.05% Al or calcium boride just before pouring.

Hot-working temperature. 760 to 1095 °C (1400 to 2000 °F)

Recrystallization temperature. 595 °C (1100 °F)

Annealing. Nitrogen-hydrogen mixtures, nitrogen, argon, or steam provide suitable annealing atmospheres. The pure metal may be annealed at about 800 °C (1470 °F); 1000 to 1100 °C (1830 to 2010 °F) is required for some of the harder alloys. Slow cooling of palladium from 815 °C (1500 °F) to 425 °C (800 °F) will cause a blue oxide coating to form. To avoid this, the metal should be quenched in water or cooled in a nitrogen atmosphere. Cooling in hydrogen will cause a phase change to occur, with accompanying distortion.

Joining. Palladium can be melted with an oxyhydrogen torch or welded with plasma or gas-tungsten are welding (GTAW) equipment. An oxidizing oxyacetylene flame is desirable for soldering palladium with platinum solders melting from 1095 to 1300 °C (2000 to 2375 °F). A gas-air torch and lower-melting white gold solders are employed for soldering palladium jewelry.

Palladium-Silver Alloys

Compiled by J. Hafner and R. Volterra, Texas Instruments, Inc.; Revised by Robert S. Mroczkowski,* AMP Incorporated

Applications

Typical uses. Alloys with 1, 3, 10 ,40, 50, and 60% Pd are employed for electrical contacts, the lower-palladium alloys showing less transfer than silver, and the higher-palladium alloys providing surety of contact, due to the absence of a tarnish film.

The 60Pd-40Ag alloy, which has electrical resistivity of 42 μΩ· cm (252 Ω· circ mil/ft) at 20 °C (68 °F) and a temperature coefficient of resistivity of only 0.00003/°C (0.00002/°F) between 0 and 100 °C (32 and 212 °F), is used for precision resistance wires.

60Pd-40Ag alloy is also being used as a contact finish for electronic connectors used in low-level dry-circuit applications. A surface layer of gold is used for optimum performance in this applications.

Palladium-silver alloys are used for brazing stainless steel, Inconel, and other heat-resistant alloys; the 90Ag-10Pd alloy has a flow point of 1065 °C (1950 °F) and is much less likely to dissolve or penetrate the base metal than are nickel-base brazing alloys.

Mechanical Properties

Tensile properties. See Fig. 33.

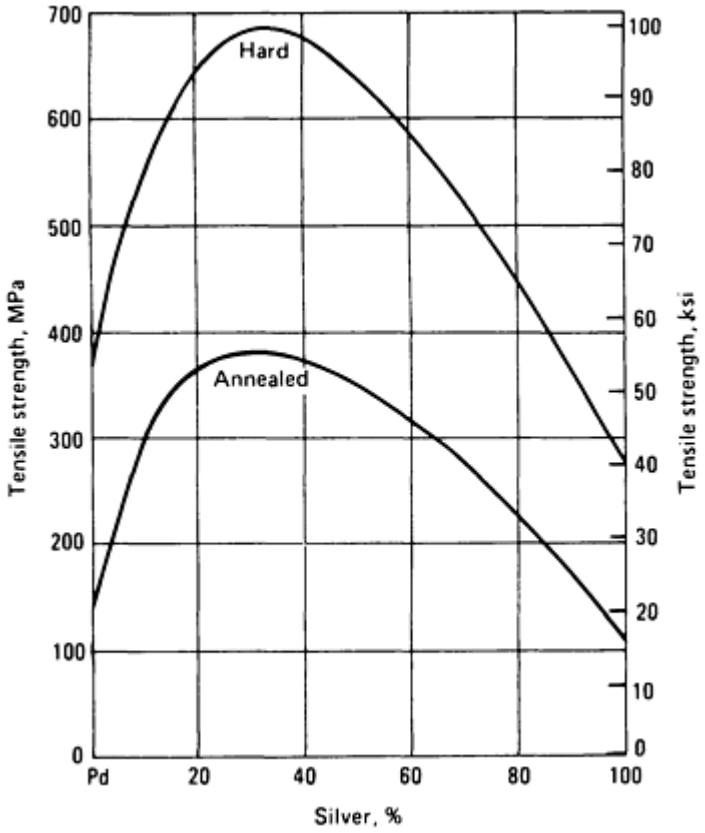

Fig. 33 Tensile strength of palladium-silver alloys as a function of silver content

Hardness. See Fig. 34.

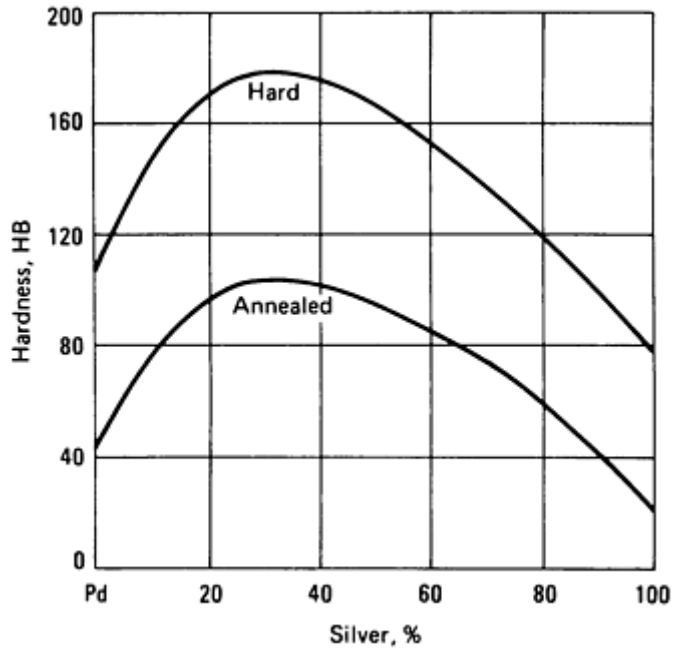

Fig. 34 Hardness of palladium-silver alloys as a function of silver content

Modulus of elasticity. Maximum at about 35% Pd content

Structure

Microstructure. Palladium and silver form a continuous series of solid solutions. Solidus and liquidus curves are close, with a maximum separation of about 60 °C (about 110 °F) for the 30% Pd alloy. No transformations in the solid state have been determined.

Mass Characteristics

Density. Can be calculated from the ratio of the components and the values of the same properties of the unalloyed metals

Thermal Properties

Coefficient of thermal expansion. Can be calculated from the ratio of the components and the values of the same properties of the unalloyed metals

Electrical Properties

Electrical resistivity. See Fig. 35.

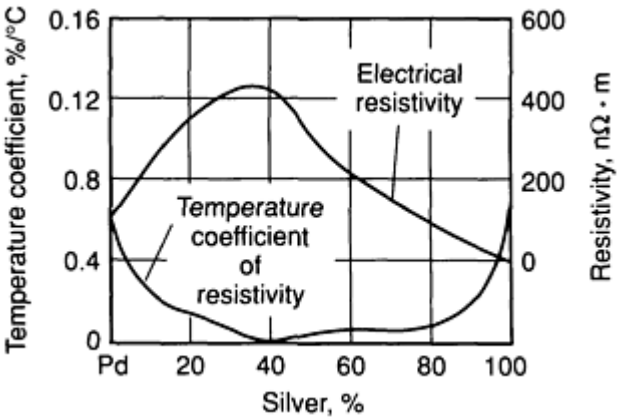

Fig. 35 Electrical resistivity of palladium-silver alloys as a function of silver content

Optical Properties

Color. The color of the alloys varies with palladium content; alloys with as little as 15 to 20% pd have the color of palladium.

Chemical Properties

General corrosion resistance. Alloys with more than about 50% Pd resist tarnishing. Nitric acid dissolves all the alloys, but they are quite resistant to hydrochloric acid, except in the presence of oxidizing agents. Cyanides attack all the alloys, particularly those rich in silver. Metallographic etching can be performed with the Jewett-Wise etch (10% KCN,10% $NH_4S_2O_8$). The high-temperature corrosion in oxygen decreases with increasing palladium content; the 25% Pd alloy has only half as much weight loss as fine silver at 900 °C (1650 °F). Addition of silver to palladium increases the solubility of hydrogen up to 30 to 40% Ag, decreasing it to zero at about 75% Ag. The 60% Pd-40% Ag alloy has been suggested as a selective diffusion septum for the separation of hydrogen from other gases. The separation of high-purity hydrogen also has employed a 75Pd-25Ag alloy (U.S. Patent 2,773,561).

60Pd-40Ag contact systems subject to vibration will catalyze organic vapors resulting in a surface polymer film that degrades electrical contact performance. The 60Pd-40Ag alloy minimizes such film formation. The presence of the silver, however, increases susceptibility to sulfur- and chloride-bearing environments.

Fabrication Characteristics

Workability. All the alloys can be cold worked. Annealing, preferably at 850 °C (1560 °F), must be in inert or nitrogen atmospheres, to prevent oxidation.

In electronic connector applications, the 60Pd-40Ag alloy is primarily used in inlay form.

Note cited in this section

60Pd-40Cu

Compiled by H.T. Reeve, Bell Telephone Laboratories; Reviewed for this Volume by A.R. Robertson, Engelhard Corporation

Applications

Typical uses. 60Pd-40Cu alloy was devised for electrical contacts in the milliampere range, in circuits containing sufficient capacity so that a considerable rush of current occurs on closure. It is also used where a hard material is required for slip rings running against brushes of the same material, and is generally given a final heat treatment to convert it to the ordered, highly conducting condition. This conversion is accelerated greatly by cold work or by the presence of hydrogen in solution.

Mechanical Properties

Tensile properties. Typical: tensile strength: annealed, 515 MPa (75 ksi); hard drawn, 1330 MPa (193 ksi)

Mass Characteristics

Density. 10.6 g/cm^3 (0.383 lb/in.^{3}) at 20 °C (68 °F)

Thermal Properties

Liquidus temperature. Approximately 1224 °C (2235 °F)

Solidus temperature. Approximately 1196 °C (2185 °F)

Electrical Properties

Electrical resistivity. Annealed and quenched, 350 nΩ · m; 35 nΩ · m ordered, which is best produced by heating cold-worked material at 300 °C (570 °F)

Temperature coefficient of electrical resistivity. Annealed, 0.00032/K (0.00018 °F); ordered, 0.00224/K (0.00125/°F) at 20 to 100 °C (68 to 212 °F)

Palladium-Silver-Copper Alloys

Compiled by P.J. Cascone, J.F. Jelenko & Company

Applications

Typical uses. Alloys that contain about 45% Pd with sufficient copper to make them age hardenable to the desired level are used in dentistry, as are variants that contain a small percentage of platinum or gold. These alloys are used also for electrical contacts subjected to sliding wear or for applications that require good spring properties. About 1% Zn may be present, and this, as well as platinum, appears to accelerate age hardening. The alloys containing 10 to 25% Pd are used for high-strength brazed joints.

Mechanical Properties

Hardness. The hardening response of this system is quite good, as shown in Fig. 36. Although the alloy 40Pd-30Ag-30Cu can be readily worked in the quenched condition, upon age hardening it attains a hardness in excess of 450 HV.

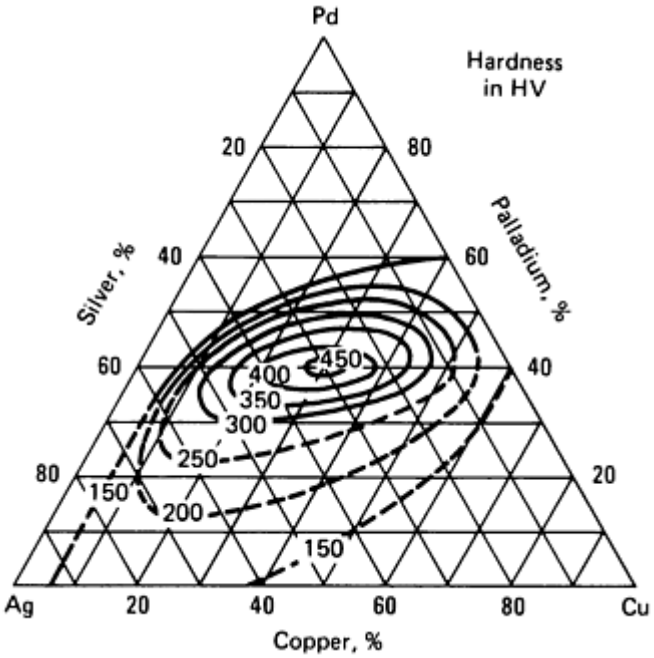

Fig. 36 Maximum hardness of aged palladium-silver-copper alloys

Thermal Properties

The liquidus and solidus features of the palladium-silver-copper system follow the general pattern of the gold-silver-copper system. Palladium increases the liquidus and solidus temperatures of the silver-copper alloys much more rapidly than gold. The silver-copper eutectic persists into the ternary liquidus diagram, terminating at about 30Pd-45Ag-25Cu. The eutectic decomposition on the silver-copper side degenerates into a dome-shape two-phase region in the ternary diagram enabling most of the alloys to be age hardenable (Ref 24). Below 600 °C (1110 °F) the ordered phases $PdCu_5$ and Pd_3Cu_5 appear (Ref 25). These phases extend across the ternary diagram to the silver-rich side of the immiscibility field. Additional sources for phase equilibrium data are available in Ref 26.

Chemical Properties

Resistance to tarnishing. The silver-palladium alloys that contain 50 to 60 wt% or at.% Pd, have good resistance to tarnishing, but that of the corresponding copper-palladium alloys in not quite so good. If substantial age hardening is required, the palladium content should not exceed about 45%, but small amounts of gold or platinum can be added without impairing the hardening, and may actually increase it along with the resistance to tarnishing. As a result, a whole series of useful quaternary alloys exists between the Cu-Ag-Pd and Cu-Ag-Au systems.

Fabrication Characteristics

Melting and working. At high temperatures, most of the ternary alloys are solid solutions and all are workable after quenching. The alloys must be melted in such a manner that oxygen, silicon, and sulfur are low in the metal when it is cast. Final deoxidation with a few hundredths percent of calcium or calcium boride often is useful. Annealing in nitrogen at about 800 °C (1475 °F) is suitable for most of the alloys, and the age-hardenable ones should be cooled fairly rapidly for full softness. If much zinc is present, oil quenching may be required, to prevent partial hardening during cooling. Treatment for $\frac{1}{4}$ to 5 h between 400 and 455 °C (750 and 850 °F) is an effective method for hardening many alloys.

Palladium-Silver-Gold Alloys
40Ag-30Pd-30Au

Compiled by P.J. Cascone, J.F. Jelenko & Company

Applications

Typical uses. The palladium-silver-gold alloys that can be very easily clad to other metals are used when high resistance to chemical corrosion is needed and when other material (for example, tantalum) may present fabrication difficulties. The addition of indium or tin, within solid solubility limits, results in a series of useful dental alloys to which porcelain is fused. The palladium-gold-silver alloys that are made susceptible to precipitation hardening by additions of small amounts of other metals, such as copper, are the base of a group of dental alloys. However, these are heterogeneous two-phase alloys and may be less corrosion-resistant than the solid-solution alloys, which have no such additions.

Mechanical Properties

Tensile properties. 30Pd-40Ag-30Au alloy: typical tensile strength, 640 MPa (92.5 ksi)

Hardness. 30Pd-40Ag-30Au alloy: 130 HB after cold rolling. See also Fig. 37.

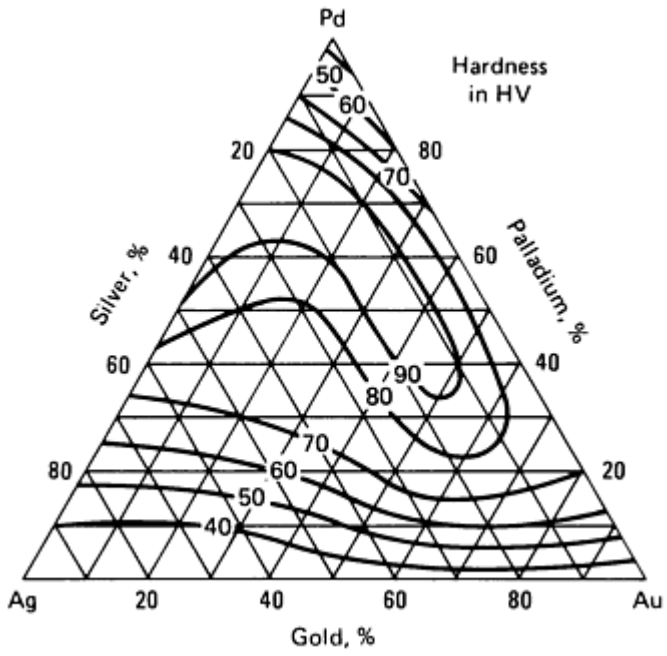

Fig. 37 Hardness of annealed palladium-silver-gold alloys

Thermal Properties

This single-phase system exhibits a narrow melting range throughout. There are no solid-state transformations. Various properties of this system are given in Ref 24.

Chemical Properties

General corrosion behavior. In binary alloys, the addition of 20% Au to palladium or about 60% Au to silver results in substantial resistance to nitric acid, and the ternary alloys from these points to the gold corner of the ternary diagram are very resistant to nitric acid. These alloys are particularly useful where the presence of halogen acids precludes the use of even the best of the corrosion-resistant base metal alloys. The alloy 40Pd-30Au-30Ag shows a loss of 0.06 g/m^2 in the atmosphere formed by boiling 20% hydrochloric acid and air. The alloys containing 50 to 60% Pd or about 70% Au are tarnish-resistant. At high temperatures, the alloys do not oxidize in air but they dissolve oxygen, and any subsequent treatment in a reducing atmosphere will produce surface imperfections.

Fabrication Characteristics

Workability. These alloys can be cold worked without difficulty but must be annealed in an inert atmosphere (for example, nitrogen) with a low dew point to avoid palladium oxidation.

Annealing temperature. 850 °C (1560 °F)

95.5Pd-4.5Ru

Compiled by D.J. Accinno, Engelhard Corporation

Applications

Typical uses. Jewelry, electrical contacts, reduction of nitric oxide by monolithic-supported palladium-ruthenium alloys. This alloy is standard for palladium jewelry in the United States; both wrought and cast forms used. This alloy, including richer ruthenium alloys (containing up to 12% Ru) is used for electrical contacts. The latter percentage is normally accepted as the limit of commercial workability.

Mechanical Properties

Tensile properties. Typical. Annealed: tensile strength, 380 MPa (55 ksi); elongation, 30% in 50 mm (2 in.). Cold drawn: tensile strength, 560 MPa (81 ksi); elongation, 3% in 50 mm (2 in.). See also Fig. 38 and Table 12.

400	750	+5.73
600	1110	+9.00
800	1470	+12.12
1000	1830	+15.30
1200	2190	+18.36

Fabrication Characteristics

Melting and casting. Melting with city gas-oxygen torch and the use of MgO or high-purity Al_2O_3-lined crucibles is common practice, although the use of a zirconia crucible yields superior results and is preferred. To obtain sound castings, deoxidation by 0.05 to 0.1% Al just prior to casting is advised. When using high-frequency induction to melt the charge, magnesia or preferably zirconia-lined crucibles with an argon covering atmosphere are the best approach. Final deoxidation of this melt with a small amount of calcium boride is generally recommended.

Annealing temperature. 900 °C (1650 °F) is suitable for annealing, based on elongation and tensile strength (see Fig. 38). Annealing in nitrogen plus 3 to 7% hydrogen is desirable for high-quality jewelry. Torch annealing should be done in an oxidizing flame.

Joining. Soldering and melting can be readily accomplished with an oxyacetylene torch (oxidizing flame). To avoid hot tearing of cast jewelry, care must be exercised to avoid possible contamination with oxygen or sulfur and particularly silicon and phosphorus.

Rare Earth Metals

K.A. Gschneidner, Jr., B.J. Beaudry, and J. Capellen, Iowa State University*

Introduction

THE RARE EARTH ELEMENTS comprise about one-fifth of the naturally occurring elements of the periodic table. The rare earths include the Group IIIA elements scandium, yttrium, and the lanthanide elements (lanthanum, cerium, praseodymium, neodymium, promethium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, and lutetium) in the periodic table of elements (see the periodic table in the article "Properties of Pure Metals" in this Volume). This definition will be used throughout this article, although many scientists and engineers use the term rare earths to mean the 15 lanthanide elements and do not consider scandium (Sc) and yttrium (Y) to be such.

Introductory textbooks view the rare earth elements as being so chemically similar to one another that collectively they can be considered as one element. To a certain extent this is correct--many applications are based on this close similarity--but a closer examination reveals vast differences in their behaviors and properties. For example, the melting points of the lanthanide elements vary by a factor of almost two between lanthanum (918 °C) and lutetium (1663 °C), the end members of the trivalent lanthanide series. This difference is much larger than that found in many of the groups of the periodic table.

In addition to the normal trivalent state exhibited by most of the rare earth metals, two of the lanthanides (europium and ytterbium) are divalent. This also accounts for vast differences in properties (for example, the vapor pressure of lanthanum at 1000 °C, or 1830 °F, is only *one billionth* that of ytterbium).

The term rare implies that these elements are scarce, but in fact, the rare earths are quite abundant and exist in many viable deposits throughout the world. Of the 83 naturally occurring elements, the 16 naturally occurring rare earths as a group lie in the 50th percentile of the elemental abundances. Cerium (Ce), the most abundant, ranks 28th and thulium (Tm), the least abundant, ranks 63rd.

Note

* *Dr. Gschneidner is affiliated with the Ames Laboratory, DOE, the Department of Materials Science and Engineering, and the Rare-earth Information Center; Mr. Beaudry is associated with the Ames Laboratory, DOE; and Mr. Capellen is on the staff of the Rare-earth Information Center.

Research Grade Versus Commercial Grade

The rare earth metals are extremely reactive elements forming stable oxides, sulfides, hydrides, and other compounds. Thus they are difficult to prepare in a high-purity form without a great deal of effort and cost. For research, generally high-purity materials are necessary to determine the intrinsic properties and behaviors of the metals and alloys. However, for many applications, especially metallurgical ones, such high purities are not needed; therefore, industry makes no effort to prepare high-purity metals, alloys, or compounds.

The major impurities in the rare earth metals (either research grade or commercial grade) are the interstitial impurities hydrogen, carbon, nitrogen, and oxygen (Ref 1). The other rare earth impurity concentrations in a given rare earth metal, and usually most nonrare earth metallic impurities, are low in both grades of metals relative to their interstitial concentrations. Research-grade metals are usually ≥99.8 at% pure, although ≥99.95 at% metals can be prepared at great effort. The hydrogen and oxygen contents of the ≥99.8 at% pure metals are usually of the order of 200 to 400 ppm atomic, whereas the carbon content is <100 ppm atomic and the nitrogen is <10 ppm atomic. The highest metallic impurities are about 10 ppm atomic, but most are <1 ppm atomic.

Commercial-grade rare earth metals are about 98 at% pure but occasionally can be as low as 95 at% pure (Ref 1). The major impurities are usually oxygen (1 to 2 at%), followed by hydrogen (0.5 to 1 at%), and the container material used to melt the rare earth metals (molybdenum, tantalum, or carbon) (0.5 at%). These impurity levels can have pronounced effects on some of the physical properties (Ref 1), and thus the data, information, and discussions that follow concerning the physical and chemical properties of the rare earths are based on research-grade materials. The last section of this article on applications is concerned with commercial-grade material. In some commercial applications, such as permanent magnets, impurities are helpful because they prevent domain wall motion, thus improving the magnetic strength of the magnet material. In other cases, the amount of rare earth added to an alloy is less than 1 wt%, and the impurities in the rare earth metal are diluted to an insignificant concentration having no effect.

Preparation and Purification

Rare earth elements are found in nature intimately mixed in varying proportions depending on the ore. Separation into pure-component rare earths is done on a large scale by liquid-liquid extraction and by ion exchange on a smaller scale. For more information on the separation techniques, the reader is referred to the review by Powell (Ref 2). The preparation of the pure metal from the separated oxide and its subsequent purification is discussed in this section.

The procedures established at the Ames Laboratory (Ref 3) use the rule "Make pure reactants, keep them pure." Twelve of the rare earth metals are made by the calcium reduction of the fluoride in tantalum crucibles under an argon atmosphere. To obtain the high-purity reactants, the pure oxide is reacted with a dynamic anhydrous hydrogen fluoride

(HF)-argon atmosphere in a platinum-lined Inconel tube furnace at 650 °C (1200 °F). To achieve higher purity, this fluoride is melted in a platinum crucible under a dynamic HF-argon atmosphere. Calcium is purified by distillation under a partial pressure of helium. The distilled calcium and melted fluoride are handled in a purified helium atmosphere to keep the calcium pure. Stoichiometric quantities of calcium and the rare earth fluoride, RF_3, are weighed, mixed, and packed into a tantalum crucible in a helium-filled glove box. The filled crucible is heated in an induction furnace under an argon atmosphere to above the melting points of all of the reactants and products to achieve reaction and separation of the liquid metal and slag. After the reduction step, the slag is removed and residual volatile impurities (Ca, CaF_2, RF_3) are removed by vacuum melting.

In establishing procedures to vacuum melt and/or distill the calcium-reduced metals, the variation in their melting points (Fig. 1) and vapor pressures (or boiling points as shown in Fig. 2) provides a natural grouping. Metals with low melting points and high boiling points (La, Ce, Pr, and Nd) prepared by the calcium reduction of the fluorides are vacuum melted at ~1800 °C (3300 °F) then cooled slowly and held molten just above their melting point to permit tantalum dissolved at high temperatures to precipitate out of solution and settle to the bottom of the crucible. The metals with high melting points and high boiling points (Gd, Tb, Y, and Lu) dissolve too much tantalum at their melting points (0.09 to 1.4 at%), and they are distilled from the reduction crucible into a condenser (an inverted tantalum crucible), leaving the tantalum in the distilland. Impurities such as oxygen and carbon are found in the distillate in these metals with high boiling points. The four remaining metals (Dy, Ho, Er, and Sc), which are also prepared by calcium reduction of their fluorides, have high melting points and relatively low boiling points and can be vaporized below their melting points (sublimed). In the sublimation process they are purified with respect to oxygen, nitrogen, and carbon, as well as tantalum.

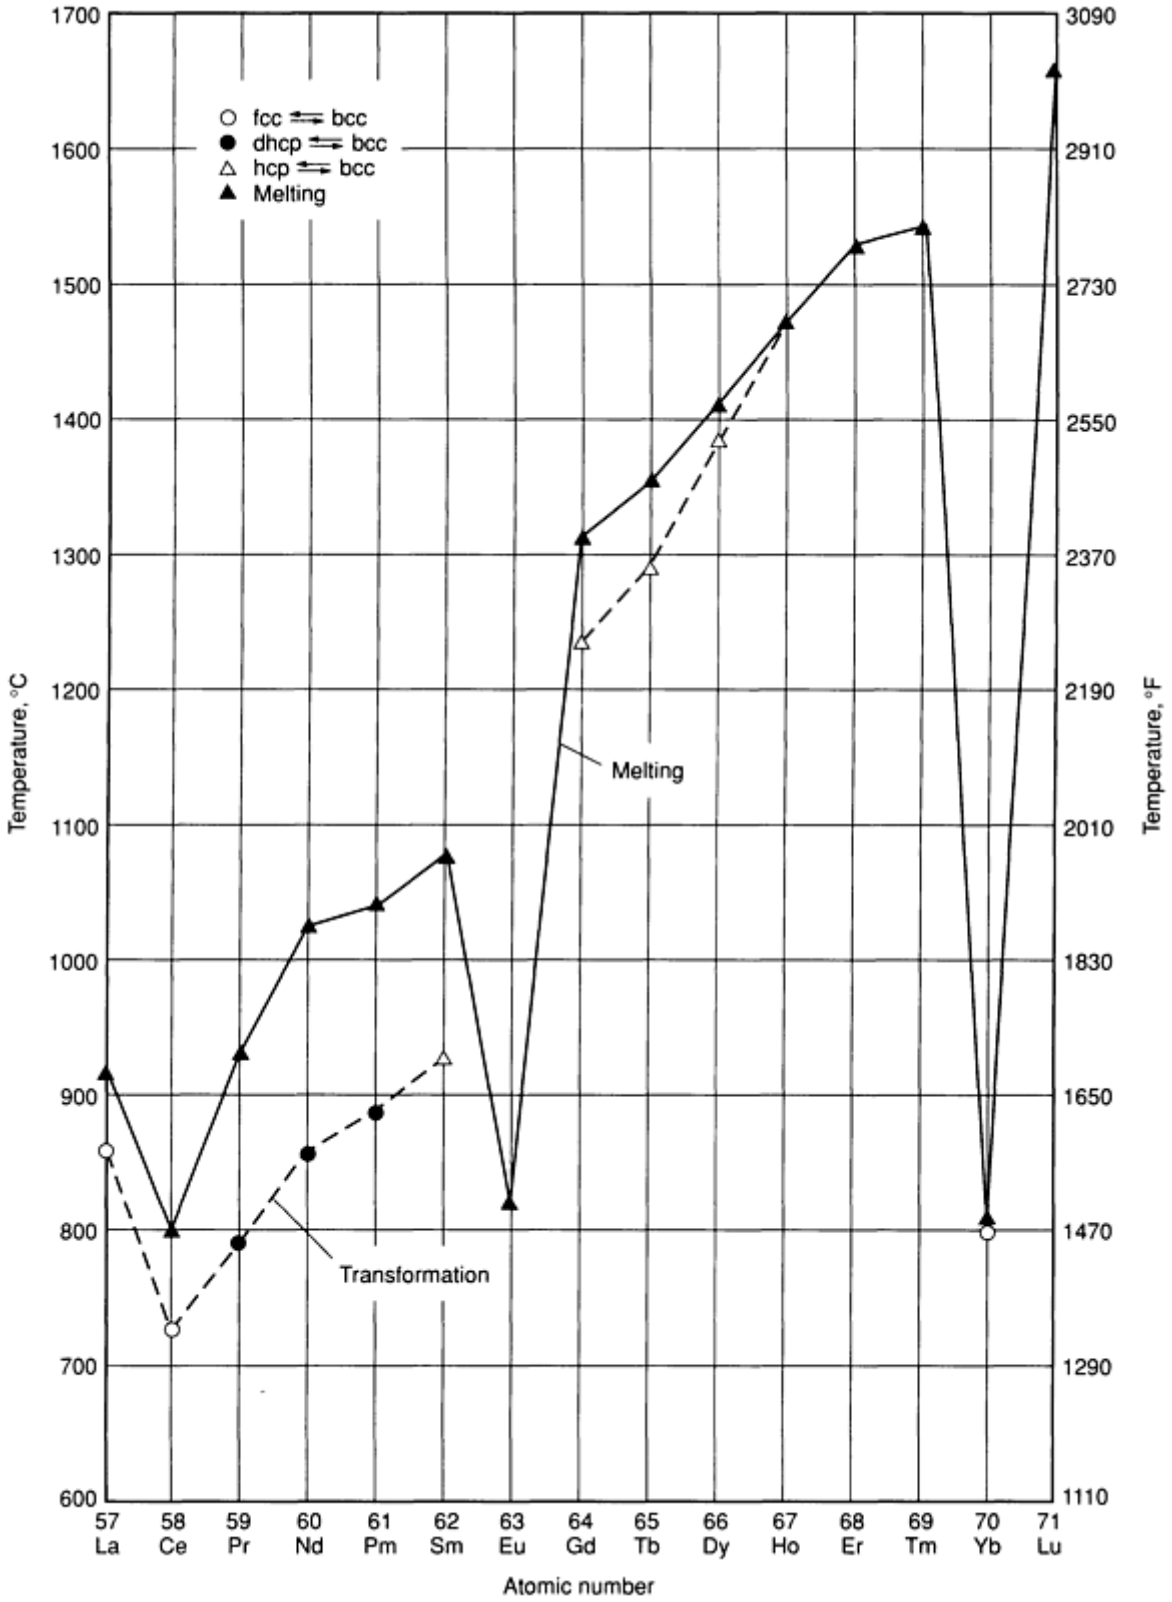

Fig. 1 The melting and close-packed (fcc, dhcp, hcp) to bcc transformation temperatures versus the lanthanide atomic number

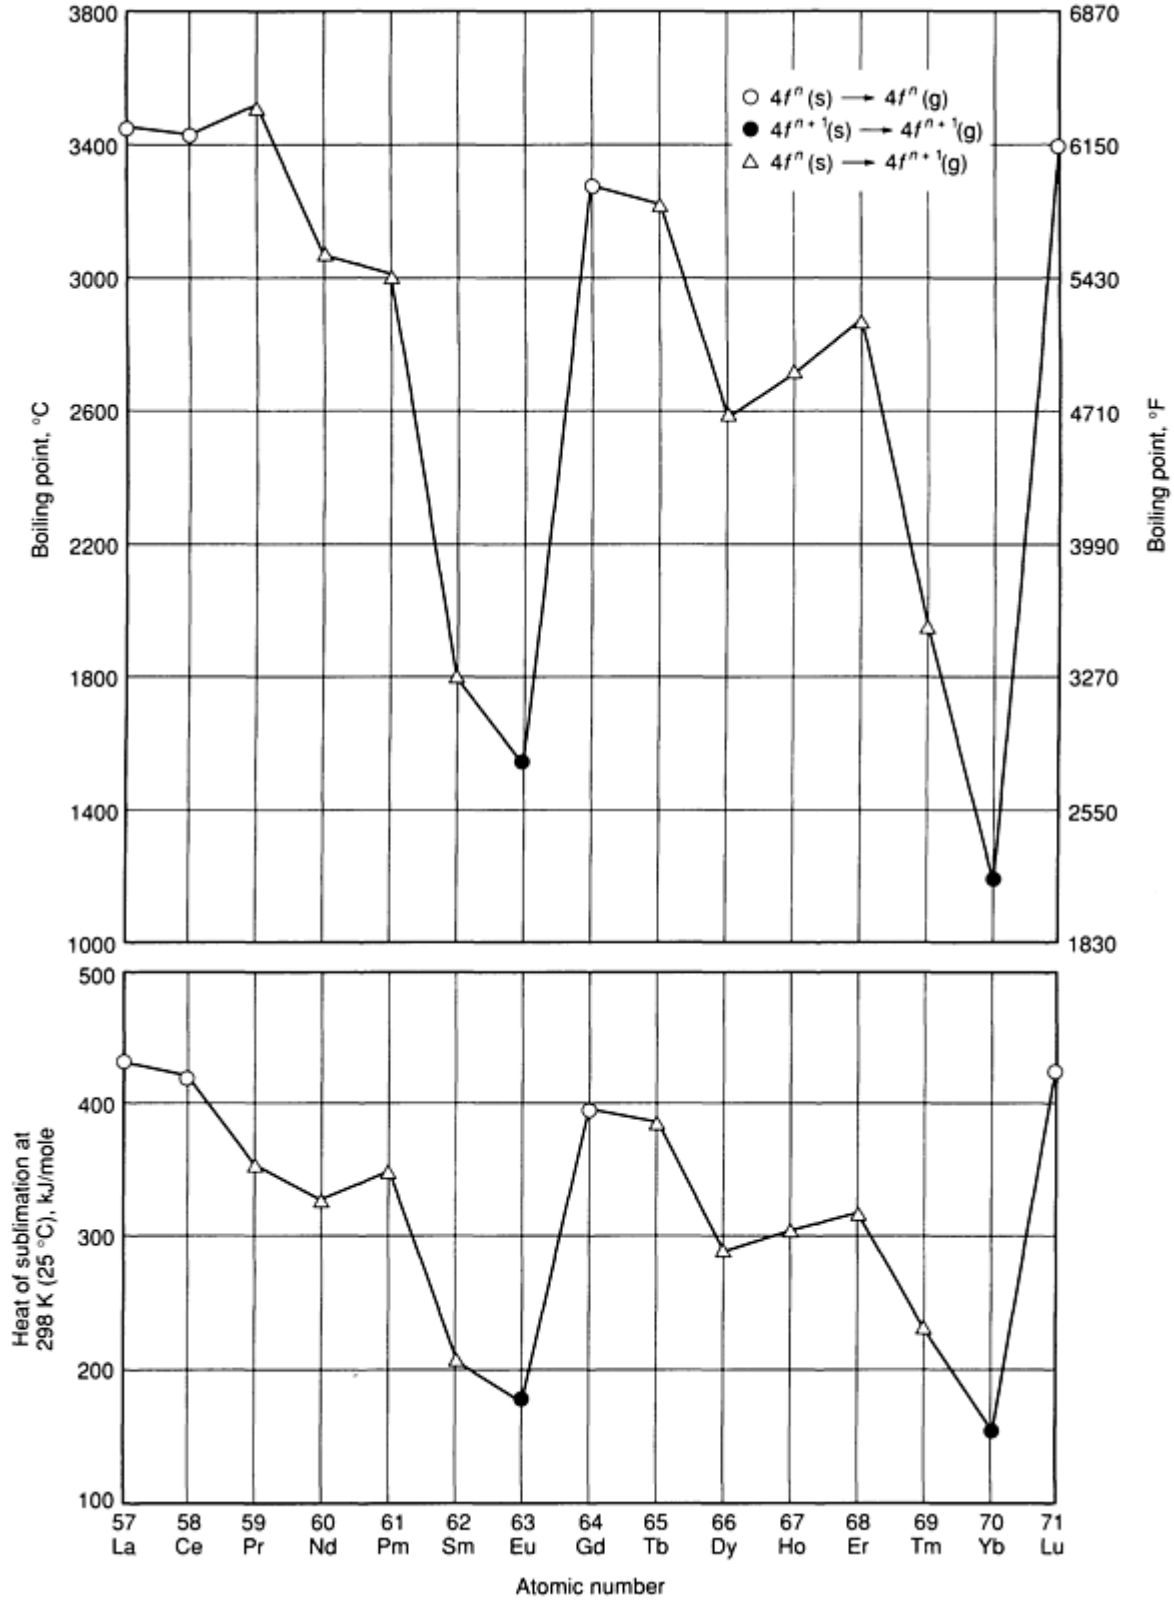

Fig. 2 The boiling points and heats of sublimation versus the lanthanide atomic number. s, solid; g, gas

Four of the rare earth metals (Sm, Eu, Tm, and Yb) have low boiling points (Fig. 2) and are prepared directly from their oxide by reaction with lanthanum, cerium, or mischmetal chips. The equilibrium established between the reductant and oxide is driven to completion by the vaporization of the volatile metal. The as-reduced/distilled metals (Sm, Eu, Tm, or

Yb) are readily purified by vacuum sublimation. Multiple sublimations can be used to further purify these four metals as well as Dy, Ho, Er, and Sc.

Solid-state electrolysis has been used to obtain small quantities of ultrahigh-purity rare earth metals. In this method, a high direct current is passed through a rod of the metal in ultrahigh vacuum (10^{-10} Pa, or 10^{-12} torr). The current heats the metal and transports the impurities to the anode or cathode. Zone refining was combined with solid-state electrolysis to obtain the highest purity thus far achieved in gadolinium and neodymium (Ref 4). The lowest-melting metals (La and Ce) and the low-boiling-point metals (Sm, Eu, Tm, and Yb) are not readily purified by solid-state electrolysis. Float zone melting of lanthanum and cerium under ultrahigh vacuum and multiple sublimations of Sm, Eu, Tm, and Yb under ultrahigh vacuum yields the purest metals.

Physical Properties

Because impurities have pronounced effects on the properties of rare earth elements, the following discussions and information on properties are based on research-grade materials. Additional information on the properties of the rare earth elements is given in the article "Properties of Pure Metals" in this Volume.

The Electronic Configurations. The number of 4*f* electrons in a given lanthanide element depends on the state of matter and also on its chemical environment. This is illustrated in Table 1, where the electronic configurations of the rare earth (R) elements are given for the free gaseous atom (the ground state), the metallic form, and the R^{2+}, R^{3+}, and R^{4+} ionic species. The free-atom configurations are of indirect interest to the material scientist or engineer, but they are important in:

- Certain thermochemical cycle calculations, in particular those that involve the heat of sublimation, that is, R (metal) $\rightarrow$ R (gas) at 298 K
- Physical processes that involve vaporization (see the section "Boiling Points and Sublimation Energies" in this article)

Considering the number of 4*f* electrons in the R^{3+} state as normal, then the lanthanide series as a whole has $4f^n$ electrons, where $n = 0$ for La, $n = 1$ for Ce, . . . to $n = 14$ for Lu. However, in the gaseous state the most common configuration is $4f^{n+1}6s^2$, whereas only La, Ce, Gd, and Lu have the normal $4f^n$ configuration ($4f^n5d^16s^2$). The normal configuration for the metallic state is $4f^n$ $(5d6s)^3$ (that is, trivalent) with only europium (Eu) and ytterbium (Yb) having the divalent $4f^{n+1}$ $(5d6s)^2$ configuration.

Table 1 The electronic structures of the rare earth elements in various states of matter

Element	Neutral atom configuration		4*f* configuration of known oxidation states M^{2+}	M^{3+}	M^{4+}	Metallic state number of electrons Valence	4*f*
Sc		$3d4s^2$	···	0	···	3	0
Y		$4d5s^2$	···	0	···	3	0
La		$5d6s^2$	···	0	···	3	0
Ce	$4f$	$5d6s^2$	···	1	0	3	1
Pr	$4f^3$	$6s^2$	···	2	1	3	2
Nd	$4f^4$	$6s^2$	···	3	···	3	3
Pm	$4f^5$	$6s^2$	···	4	···	3	4
Sm	$4f^6$	$6s^2$	6	5	···	3	5
Eu	$4f^7$	$6s^2$	7	6	···	2	7
Gd	$4f^7$	$5d6s^2$	···	7	···	3	7
Tb	$4f^9$	$6s^2$	···	8	7	3	8
Dy	$4f^{10}$	$6s^2$	···	9	···	3	9
Ho	$4f^{11}$	$6s^2$	···	10	···	3	10
Er	$4f^{12}$	$6s^2$	···	11	···	3	11
Tm	$4f^{13}$	$6s^2$	···	12	···	3	12
Yb	$4f^{14}$	$6s^2$	14	13	···	2	14
Lu	$4f^{14}$	$5d6s^2$	···	14	···	3	14

As seen in Table 1, the R^{3+} valence state is common to all of these elements, although a few of the lanthanides exhibit other valence states, such as R^{4+} for Ce, Pr, and Tb, and R^{2+} for Sm, Eu, and Yb. The Ce^{4+}, Eu^{2+}, and Yb^{2+} states are quite common in nature and are used by industry to separate these three elements from the remaining rare earths by relatively cheap chemical methods. Some important uses also depend upon these nontrivalent states.

The overall chemical and metallurgical properties of the rare earth elements are due to their outer electrons 5*d*6*s* (3*d*4*s* for Sc, and 4*d*5*s* for Y). There is some variation in the chemical properties of the lanthanides due to the lanthanide contraction (discussed below) and hybridization of the 4*f* electrons with the valence electrons. For many uses it is not cost effective to separate the lanthanides in order to use the element that gives the best properties, and so they are used as mixed rare earths.

For properties that depend upon the number of 4*f* electrons (that is, magnetic and optical properties), separated, and sometimes quite pure, individual rare earth elements are generally required.

Structure, Metallic Radius, Atomic Volume, and Density. The rare earth metals crystallize in all of the common metallic structures and several unique ones. The room-temperature structures as one proceeds along the lanthanide series are:

- A double *c* hexagonal close-packed (dhcp) structure for lanthanum
- A face-centered cubic (fcc) structure for cerium
- A dhcp structure for praseodymium neodymium, and promethium
- A unique nine-layer hexagonal structure for samarium (Sm-type structure)
- A body-centered cubic (bcc) structure for europium
- A hexagonal close-packed (hcp) structure for gadolinium through thulium (that is, Gd, Tb, Dy, Ho, Er, and Tm)
- An fcc structure for ytterbium
- An hcp structure for lutetium

Both scandium and yttrium have hcp structures at room temperature (Ref 3, 5). At high temperatures, many of the metals (La through Sm, Gd, Tb, Dy, Sc, and Y) transform to a bcc phase before melting. The remaining four hcp metals (Ho, Er, Tm, and Lu) are monotropic as is bcc europium. At intermediate temperatures, lanthanum crystallizes in the fcc structure, and samarium crystallizes in the hcp structure. Below room temperature cerium transforms to a dhcp, and upon further cooling an fcc structure that is about 15 vol% smaller than the room-temperature fcc phase. This large-volume contraction is due to an apparent valence increase of $\sim\frac{2}{3}$ of an electron per atom. Both terbium (Tb) and dysprosium (Dy) undergo an hcp to an orthorhombic distortion due to magnetoelastic effects when these metals order magnetically. Ytterbium (Yb) upon cooling just below room temperature becomes hcp.

The metallic radii for a coordination number of twelve (CN = 12) are shown in Fig. 3, where it is seen that the radii of the trivalent lanthanide metals fall on a smooth curve from lanthanum (La) to lutetium (Lu) with a cusp at gadolinium. The tendency of cerium (Ce) toward tetravalency is obvious, in that its metallic radius lies below that established by the normal trivalent metals. The divalent character of europium (Eu) and of ytterbium (Yb) is also obvious with their large metallic radii. This divalent character is evident in other physical properties and plays an important role in their preparation, purification, alloying behavior, and compound formation. The radius of yttrium (Y) is essentially identical to that of gadolinium (Gd), whereas that of scandium (Sc) is 0.16406 nm, which is significantly smaller than that of 0.17349 nm for lutetium (the smallest lanthanide metal).

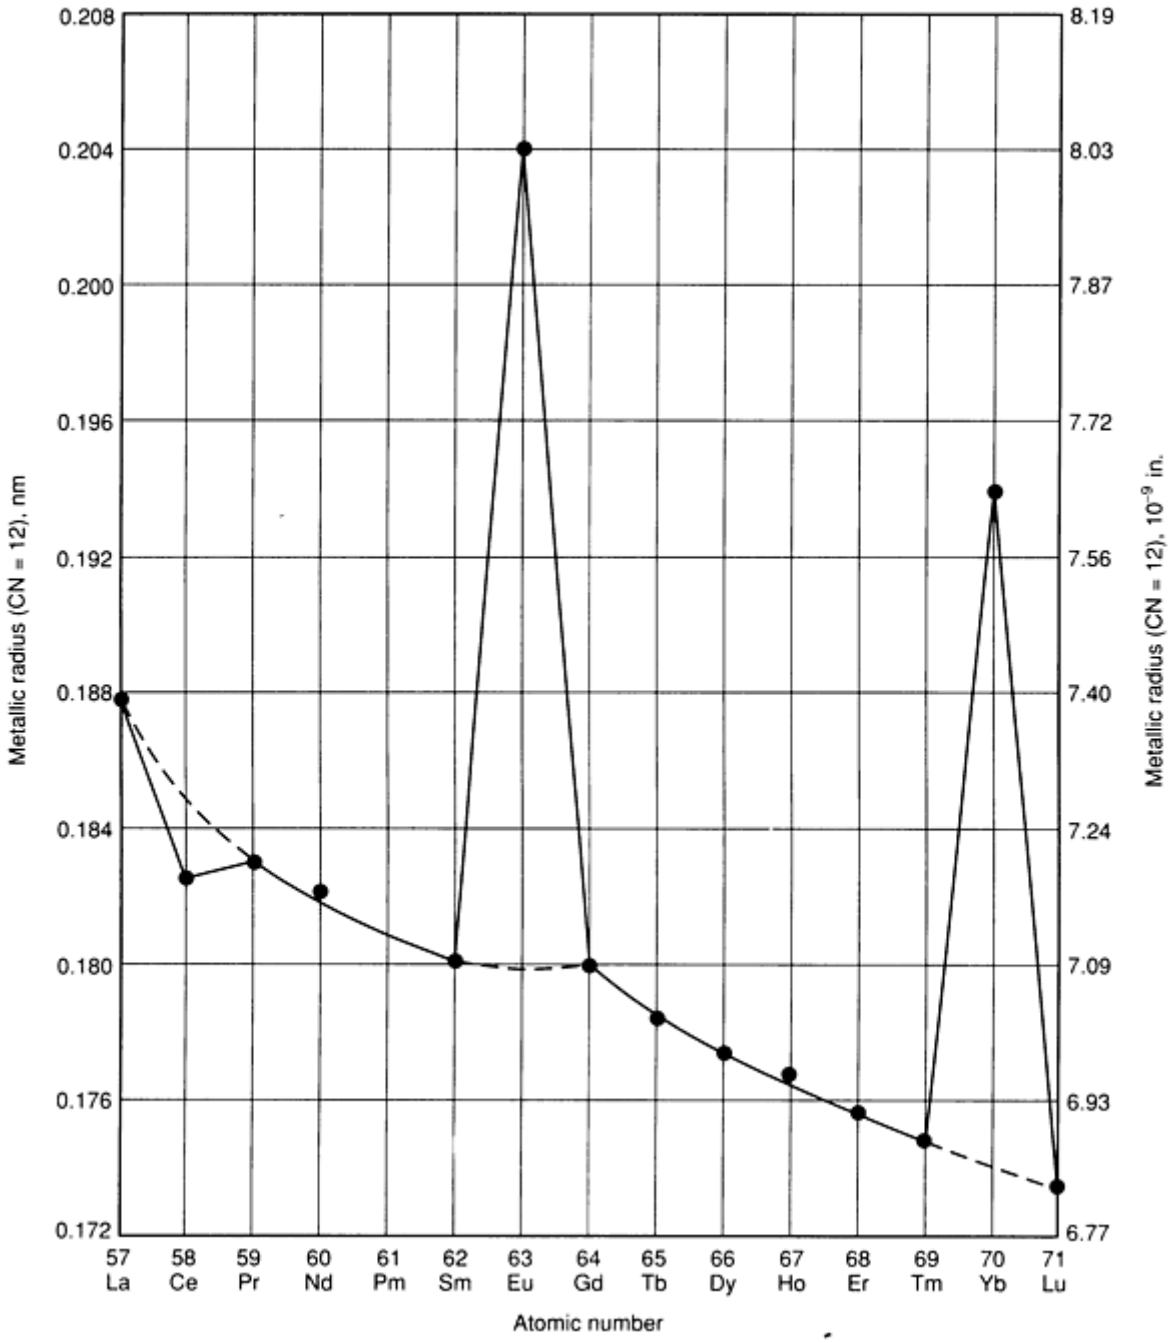

Fig. 3 The metallic radius for a coordination number (CN) of twelve versus the lanthanide atomic number

The atomic volumes of the lanthanides, as expected from the geometrical relationship between the radius and volume, vary in an identical manner to the function of atomic number as the radius (Fig. 3). The density shows a reciprocal behavior, with lanthanum (La) the least dense of the trivalent lanthanides and lutetium (Lu) the most dense. Furthermore, the densities of europium (Eu) and ytterbium (Yb) are significantly less than those of their immediate respective

neighbors. Because of their small masses scandium (Sc) and yttrium (Y) are significantly less dense than any of the lanthanides.

Melting and Transformation Temperatures. The melting points for the lanthanide metals are shown in Fig. 1. It is noted that the melting points rise rapidly from 918 °C (1684 °F) for lanthanum (La) up to 1663 °C (3025 °F) for lutetium (Lu). The divalent character of europium (Eu) and ytterbium (Yb) is evident in their low melting points, which are comparable to those of the alkaline earth metals. The melting points of scandium (Sc) and yttrium (Y) are relatively high, 1541 °C (2805 °F) and 1522 °C (2772 °F), respectively, close to those for erbium (Er), 1529 °C (2784 °F), and thulium (Tm), 1545 °C (2813 °F).

The close-packed to bcc-phase transformations are also shown in Fig. 1 and they tend to follow the melting-point trend. But as seen, the transformation temperature from gadolinium to holmium (Gd, Tb, Dy, Ho) increases more rapidly as a function of atomic number than the melting point, and, thus, the bcc phase becomes metastable with respect to liquid formation at holmium and for the remaining three trivalent lanthanide metals. Scandium and yttrium also have an hcp-to-bcc transformation at 1337 °C (2439 °F) and 1478 °C (2692 °F), respectively.

Boiling Points and Sublimation Energies. The boiling points of the lanthanide metals vary as a function of atomic number in a sawtoothlike manner (Fig. 2), which contrasts to the smooth variation observed for the radii (Fig. 3) and melting points (Fig. 1) of the lanthanide metals (other than the divalent europium and ytterbium metals). The boiling points vary from extremely high temperatures in several lanthanide metals (La, Ce, Pr, Gd, Tb, and Lu) and also yttrium (which is not shown in Fig. 2), to quite low temperatures for other lanthanides (Sm, Eu, Tm, and Yb). The remaining five lanthanides (Nd, Pm, Dy, Ho, and Er) and scandium (Sc) have intermediate boiling-point temperatures between these extremes. The large difference in boiling points (vapor pressures) and melting temperatures means that there is considerable variation in the methods used to prepare and purify the rare earths, as discussed in the section "Preparation and Purification" in this article.

The large variation in the boiling points of the lanthanide metals occurs because the electronic configurations of both the solid and the gas phases are involved in the process. This is best seen in the heats of sublimation, which are related to the boiling points via Trouton's rule and plotted at the bottom of Fig. 2. The heat of sublimation is the energy required to remove one gram atom from the solid at 25 °C (77 °F). In Fig. 2 the open circles represent the metals that are trivalent in the solid state ($4f^n$) and vaporize to a trivalent gaseous atom ($4f^n$) (see Table 1). This vaporization process requires ~420 kJ/mole. The solid circles in Fig. 2 denote the two divalent metals ($4f^{n+1}$) that vaporize to a divalent gaseous atom ($4f^{n+1}$). But in this case these elements (europium and ytterbium) only require ~164 kJ/mole to complete the process. The elements indicated by open triangles are trivalent in the solid ($4f^n$), vaporize to a divalent gaseous atom ($4f^{n+1}$), and have intermediate sublimation energies. Thus, the electronic configurations play an important role in the vaporization process, and in turn on the preparation, purification, and physical and chemical metallurgy of the lanthanide metals.

Magnetic properties. The second most extensively studied property of rare earth metals--second only to crystal structure determinations--is their magnetic behavior. The reason for this is the measurement of the magnetic properties yields information about the *f* electrons of the lanthanide element in the substance being examined. These studies have led to many interesting and exciting scientific discoveries and to one of the major uses of two rare earths in the metallic form, namely the use of neodymium in Nd-Fe-B permanent magnets and samarium in Sm-Co permanent magnets.

The 4*f* electrons are energetically and radially buried in an atom, do not enter into the bonding, and are only slightly influenced by the external environment around the lanthanide atom. Unpaired 4*f* electrons have a magnetic moment that gives rise to larger magnetic susceptibilities, two to four orders of magnitude larger than those of normal metals. Because the 4*f* electrons are radially buried, they do not directly overlap (as do the 3*d* electrons of manganese, iron, cobalt, and nickel, which accounts for the magnetic behaviors of the 3*d* transition metals). The 4*f* electrons on one lanthanide atom communicate with those on another lanthanide via the valence (primarily the *s*) electrons. As the free valence electron moves through the solid it is polarized by the first 4*f* electron (its spin is aligned parallel with the 4*f* spin), and as it passes by the second atom the 4*f* electron of the second atom is in turn polarized by the valence electron. This indirect exchange, called the RKKY interaction, is weaker than the direct overlap found in the 3*d* metals, but it is sufficiently strong for the 4*f* electrons to align magnetically at about room temperature (for Gd) or below (for the other lanthanides). Many unusual magnetic structures have been found, not only in the metals, but also in their compounds (Ref 6). In the metals, the 4*f* electrons of the first members of the lanthanide series (called the light lanthanides) align antiparallel to each other (antiferromagnets). Their ordering temperatures, called the Néel temperatures (T_N), are shown in Fig. 4. In these metals, two ordering temperatures are found (even in cerium, which are only 1 K apart). The higher ordering temperature is due to magnetic alignment of 4*f* spins on the hexagonal sites in the dhcp or Sm-type structures, whereas the lower one is due to ordering on the cubic sites. In the case of the last half of the lanthanide series (called the heavy lanthanides) they order

antiferromagnetically at high temperatures, and then upon further cooling they order ferromagnetically or ferrimagnetically (see Fig. 4), with the exception of gadolinium (Gd), which is a ferromagnet at all temperatures (Ref 7).

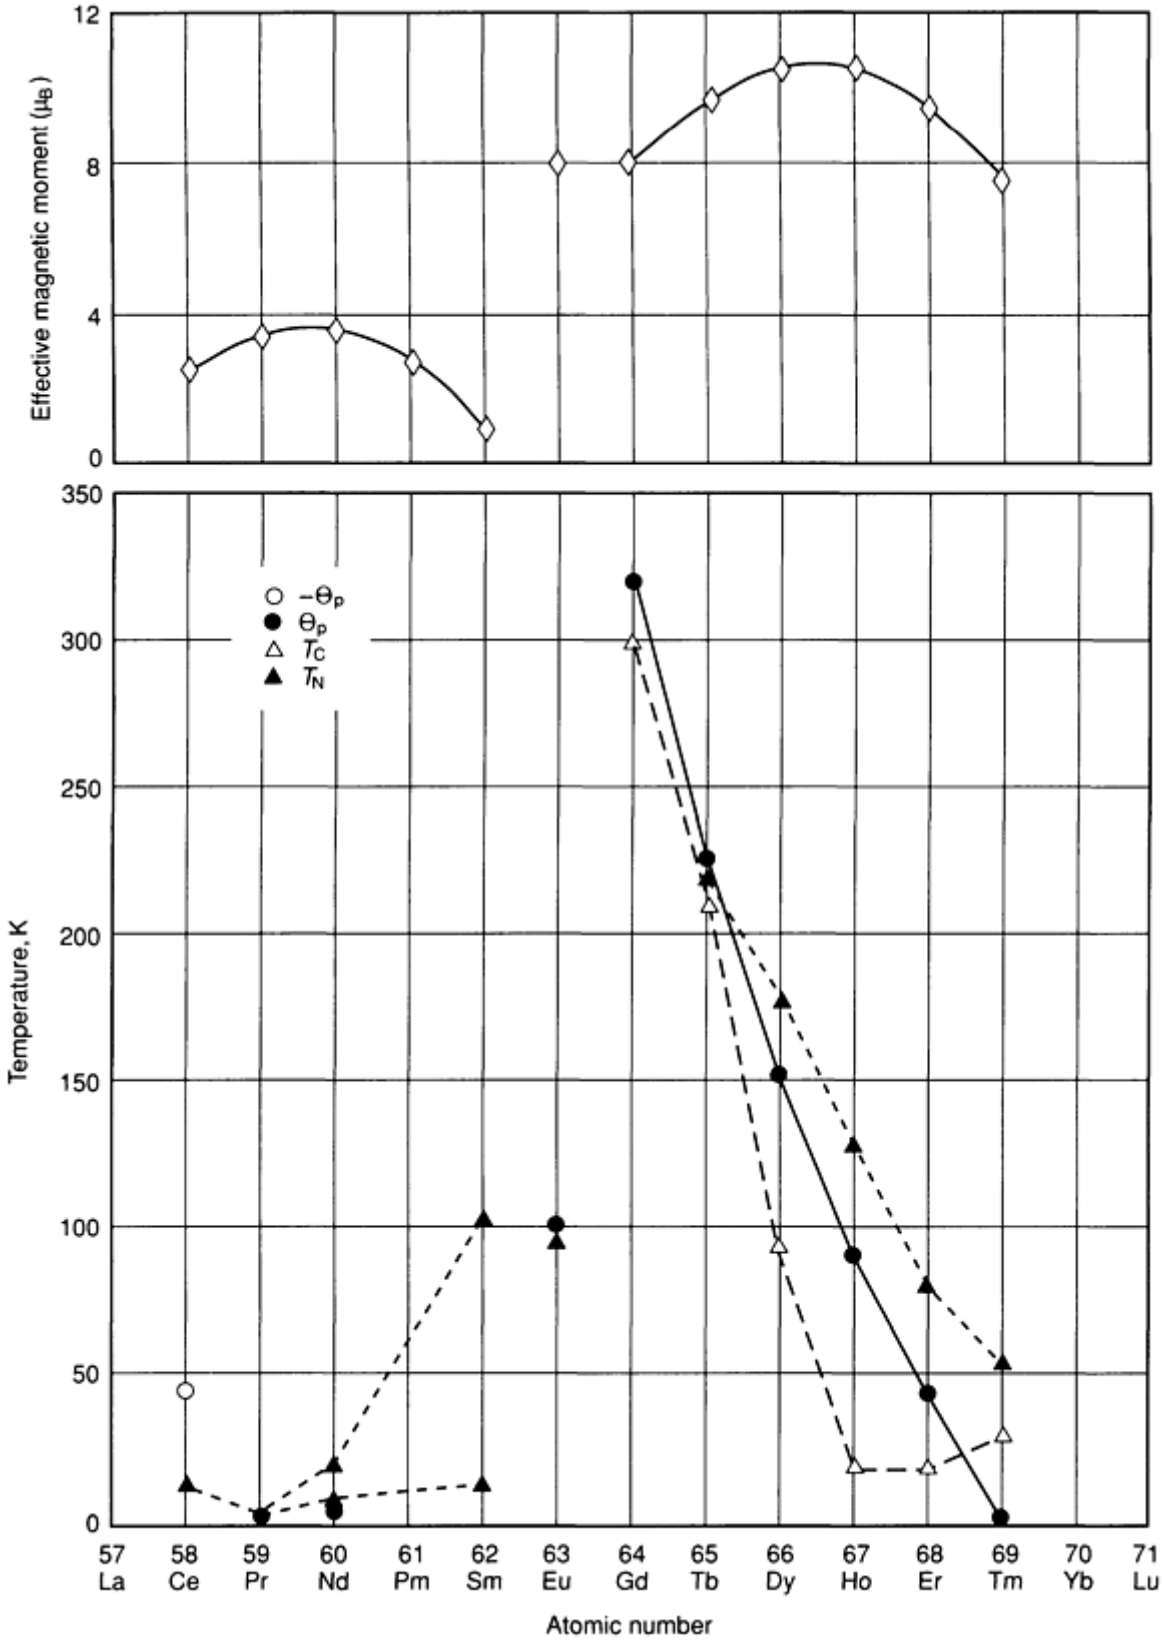

Fig. 4 The various magnetic temperatures (lower portion) and effective magnetic moments (upper portion) of the lanthanide metals. The paramagnetic ordering temperatures, θ_p, which can be negative (Ce) or positive (the other lanthanides) is obtained at high temperatures above the magnetic ordering temperatures, T_N or T_C. The

symbol T_C represents the Curie or ferromagnetic ordering temperature, and T_N represents the Néel or antiferromagnetic ordering temperature. The lines are not connected to europium (Eu) because it is divalent and the other magnetic lanthanides are trivalent.

The magnetic ordering temperatures are a maximum at gadolinium (Gd), which has seven unpaired 4*f* electrons (the maximum possible) and then fall off to each side as the number of unpaired 4*f* electrons is reduced by one with each succeeding lanthanide. The magnetic moment, however, depends not only on the number of unpaired 4*f* electrons but also on their orbital motion. This gives rise to the peak observed in the magnetic moment of the light lanthanides (at Pr-Nd) and a peak in the heavy lanthanides (at Dy-Ho) as shown in the top part of Fig. 4.

The combination of the light lanthanides with the iron group metals, in the appropriate intermetallic compounds, results in the highest-strength permanent magnets known today, the Sm-Co and Nd-Fe-B families. These magnetic materials are discussed in the section "Magnetic Materials" of this article and in the article "Permanent Magnet Materials" in this Volume.

Elastic and Mechanical Properties. As reported by Scott (Ref 8) in his review of elastic and mechanical properties of rare earth metals, the values reported in literature vary considerably because of the wide range of impurity levels in the metals; variations by a factor of 10 are not uncommon, especially for the mechanical properties. The values given here are thought to be the most reliable and the closest to the intrinsic property of the given metal.

In general, the elastic properties increase with increasing purity. The chosen values for the lanthanide metals are plotted in Fig. 5 as a function of the atomic number. The anomalies are clearly evident at cerium (Ce) (premonition of the $\gamma \rightarrow \alpha$ transformation) and divalent europium (Eu) and ytterbium (Yb). Furthermore, there is an increase in the elastic moduli as a function of increasing atomic number until a maximum is reached at thulium (Tm). As expected the single-crystal c_{ij} values exhibit the same trend as observed in Fig. 5 for the bulk elastic constants. The elastic constants are similar in magnitude to those of aluminum, zinc, cadmium, and lead.

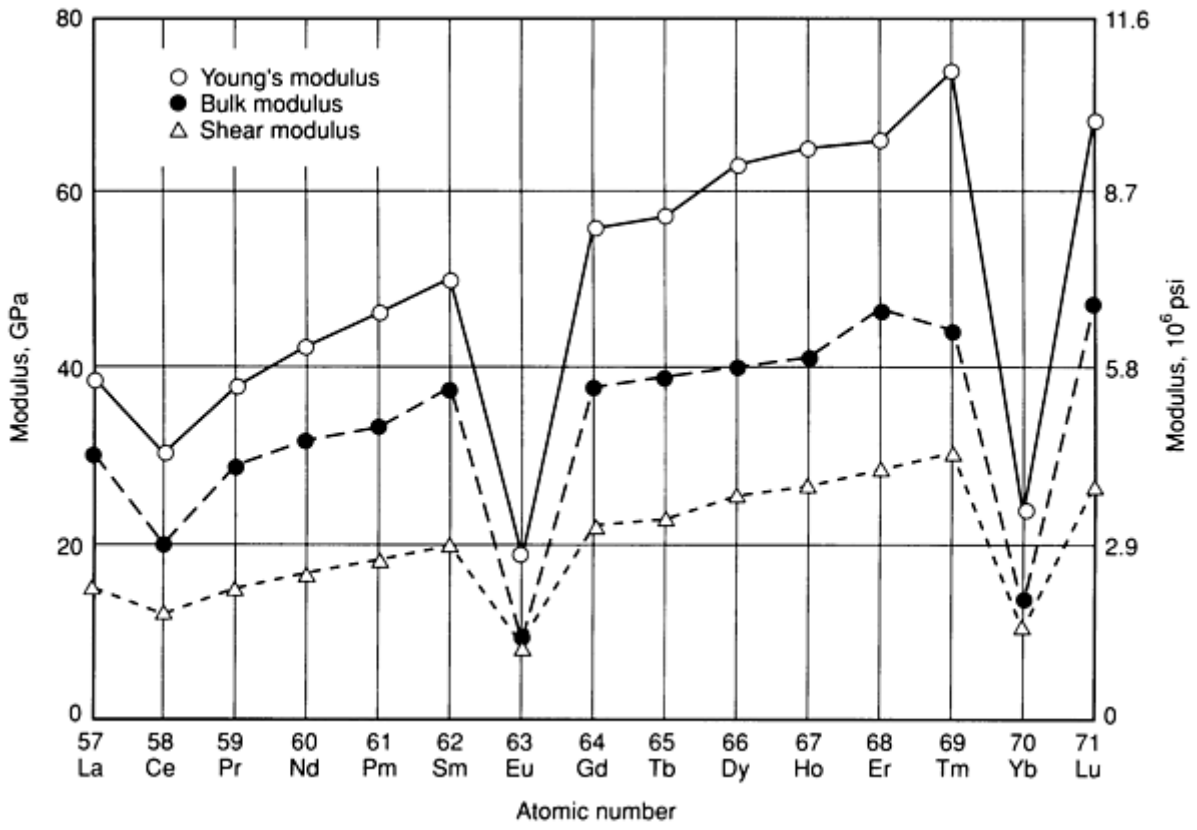

Fig. 5 The bulk elastic constants of the lanthanide metals versus the atomic number

The hardness and strength values for the lanthanides follow the same periodic trend as observed for the elastic moduli shown in Fig. 5, but the experimental scatter of the data is larger. Cerium, europium, and ytterbium have anomalous low values for the same reason as discussed above for the elastic constants. The increase of the mechanical properties from the light lanthanides to the heavy lanthanides also seems to occur, and is similar to that of aluminum at the low range of the reported lanthanide values, and falls between those of aluminum and titanium for the upper range of values. Most of the rare earths do not neck down before fracture, and therefore, the ultimate tensile strength and fracture strength are nearly the same.

Chemical Properties

Chemical Reactivity. The rare earths are extremely reactive metals, especially with respect to the normal atmospheric gases (Ref 5). The light trivalent lanthanides will oxidize upon exposure to air at room temperature and therefore should be stored in vacuum or under helium or argon in sealed containers (Ref 3). The heavy lanthanides, and scandium (Sc) and yttrium (Y) do not oxidize at room temperature; they form a protective oxide coating just as aluminum, which prevents further oxidation. The rate of oxidation depends on several variables and is higher when:

- The impurity level (of most common impurities) is high
- The relative humidity is high (Ref 5)
- The temperature is high (Ref 5)
- The atomic number of the lanthanide is low (Ref 5)

The presence of impurities such as carbon, iron, calcium, and many of the *p*-group elements such as zinc, gallium, germanium, and their congeners greatly increases the rate of oxidation. For the *p*-group elements the rate of oxidation increases as one goes down the periodic table in a given group. The presence of iron is quite important in the major application of cerium lighter flints.

This chemical reactivity is due to the large negative free energy of formation of the oxides--among the most negative of all the elements in the periodic table (see Fig. 6). This chemical reactivity is responsible for some uses of the rare earth metals, such as getters in vacuum tubes, lighter flints, incendiary devices, and getters in metals and alloys.

Fig. 6 The standard free energies of formation of the rare earth and some selected nonrare earth oxides. Because the values of the light lanthanide metal (R) sesquioxides lie close to one another (also the heavy rare earth metal [R'] sesquioxides), the free energies are drawn in a broad band for the two groups, except where departures become evident. Broken lines are used for clarity.

Divalent europium (Eu) oxidizes much more readily than any of the trivalent rare earth metals, and special precautions are necessary when handling this metal (Ref 3, 5). Divalent ytterbium (Yb), however, is relatively inert and can be handled in air without any difficulties.

The rare earth metals (R) react slowly with N_2 and high temperatures are required to observe any appreciable reaction. Furthermore, the formation of RN on the surface greatly reduces any further nitridation (Ref 5). The free energies of formation of the nitrides are shown in Fig. 7. These data show that the rare earth nitrides are among the most stable nitrides, exceeded only by TiN and ZrN in stability.

Fig. 7 The standard free energies of formation of the rare earth and some selected nonrare earth nitrides as a function of temperature

The metals will easily hydride at elevated temperatures (400 to 600 °C, or 750 to 1100 °F). Unless special care is taken, when the metal is hydrided up to and beyond RH_2 in hydrogen content, the solid material fragments (Ref 5).

The rare earth metals will react exothermically with sulfur, selenium, and phosphorus. If heated to the appropriate temperature the reaction will take off and could seriously damage the crucible, furnace, vacuum enclosures, and so forth. However, at low temperatures some of the rare earths will hardly react (for example, the heavy lanthanides with sulfur). The free energies of formation of some of the rare earth sulfides and oxysulfides are shown in Fig. 8.

Fig. 8 The standard free energies of formation of the rare earth and some selected nonrare earth sulfides and oxysulfides as a function of temperature. The broad bands marked La_2O_2S-Gd_2O_2S and Tb_2O_2S-Tm_2O_2S contain the free energy versus temperature curves for R_2O_2S with R = La, Pr, Nd, Sm, and Gd, and R' = Tb, Dy, Ho, Er, and Tm, respectively.

Metallography and Surface Passivation. The recommended metallographic polishing method is to electropolish the metal in 6% perchloric acid dissolved in absolute methanol at dry-ice temperatures, which leaves the metal with a shiny silvery color and a passivated surface (Ref 3, 5). This electropolishing procedure is also used to clean the metal surface after mechanical fabrication and/or heat-treating operations. However, when cleaning or polishing cerium or ytterbium, the low-temperature phases β-Ce or α-Yb form at the dry-ice temperature. The room-temperature forms may be maintained by chemically polishing or cleaning with Roman's solution, a complex solution of organic and mineral acids.

Alloy Formation

The rare earth metals are fairly large, electropositive elements (Fig. 9). Because of their large sizes they are not readily dissolved in the solid state of most of the common metals, and because they are considerably more electropositive than most metals, the rare earths tend to form compounds with them (Ref 5).

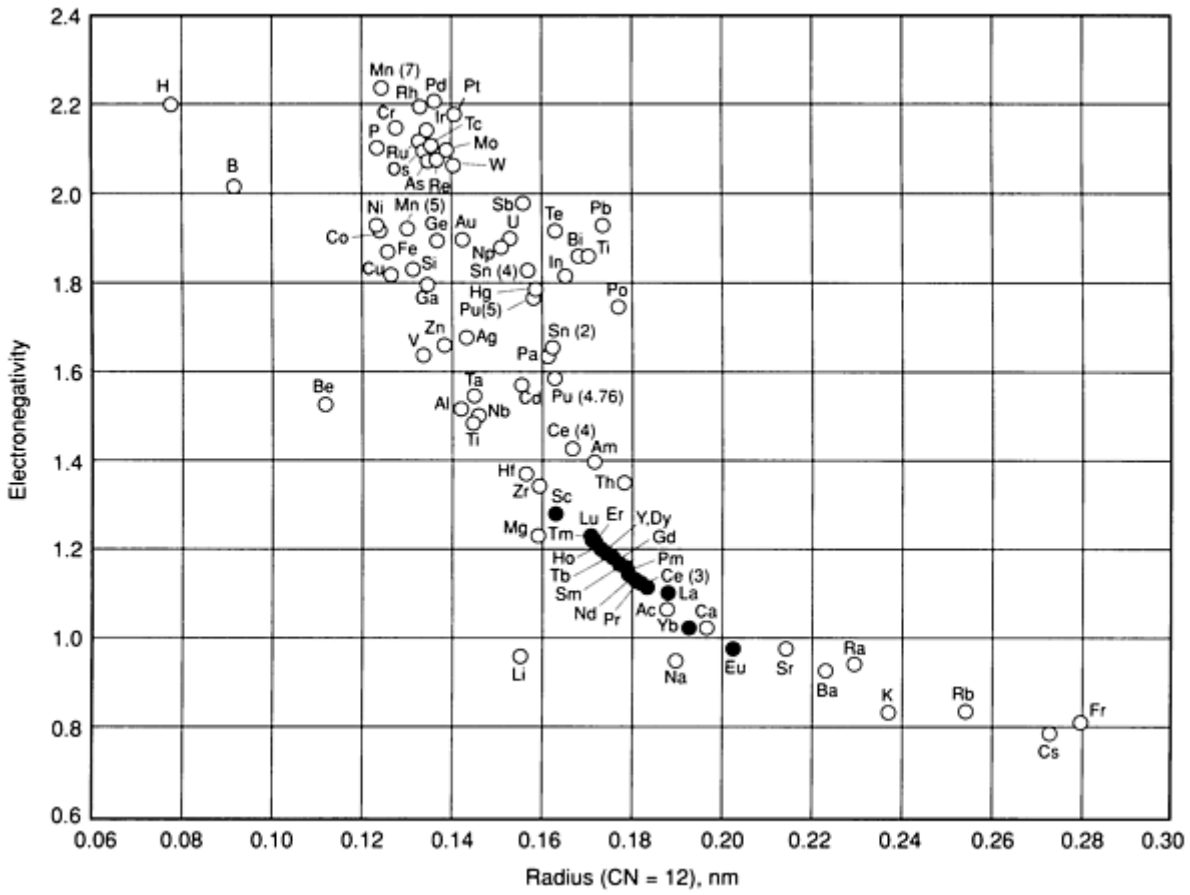

Fig. 9 A plot of the electronegativity (in Pauling's units) versus the metallic radius for a coordination number (CN) of 12 of the elements. The rare earth elements are indicated by the solid points.

Solid Solution Alloys. The rare earth metals form extensive solid solutions with each other and with zirconium and thorium. The divalent metals (magnesium, zinc, cadmium, and mercury) form extensive solid solutions in the high-temperature bcc forms of the rare earth metals, but the rare earths are essentially insoluble in these divalent metals. The bcc phases of the rare earth metals can be retained metastably at room temperature by rapid quenching of alloys containing magnesium and cadmium. The rare earths form extensive solid solutions in silver and gold, but these two metals do not dissolve to any extent in the rare earths (Ref 5).

Compound Formation. The rare earth metals form compounds with the elements to the right of the group VIA elements in the periodic table, except the rare gases, but not with the elements to the left of the group VIIA elements, except hydrogen, beryllium, and magnesium. The light lanthanides generally form fewer compounds than the heavy lanthanides and yttrium. It has been estimated that more than 3000 binary compounds are formed by the rare earth metals with the other elements in the periodic table. The melting points of the intermetallic compounds from the VIIA through the IIB groups are comparable to those of the component metals and rarely exceed the melting point of the highest-melting pure metal, and if so by less than 100 °C (210 °F). From the IIIB through VIB groups the melting points for at least one of the compounds are much higher (several hundreds to more than one thousand °C) than that of the highest-melting component element (generally the rare earth element). Boron and carbon are exceptions because of their elemental high melting points, but most of the rare earth borides and carbides are high-melting compounds. The crystal chemistry of the more than 3000 rare earth binary compounds has been extensively studied; but because of space limitations, the reader is referred to Gschneidner and Daane (Ref 5) and references cited therein for further information.

Liquid Immiscibility. The rare earth metals form immiscible liquids with the alkali, alkaline earth, the group VA metals, and uranium. For chromium and molybdenum, only the light lanthanides, form immiscible liquids, whereas the heavy lanthanides scandium (Sc) and yttrium (Y) form simple eutectics. In the case of manganese, only lanthanum and cerium form immiscible liquids and no intermetallic phases; the remaining rare earths form one or more intermetallic compounds with manganese and presumably no immiscible liquids. Divalent europium (Eu) and ytterbium (Yb) form immiscible liquids with the trivalent rare earth metals (R). The width of the immiscibility gap appears to be larger in the Eu-R systems than in the corresponding Yb-R system. Furthermore, the immiscibility-gap width becomes increasingly larger with increasing atomic number of R for a series of R-Yb alloys, which is consistent with the sizes of the elements (Fig. 3).

Applications

This section describes various applications of commercial-grade rare earth elements and commercial alloys, which include rare earth elements as additives. A number of commercial alloys with rare earth constituents are given in Tables 2 and 3. Table 2 lists alloys where rare earth elements (usually Y, La, or Ce) are added as metal alloying components. Table 3 lists materials in which rare earths (primarily Y) are added as finely dispersed oxides.

Table 2 Commercial alloys containing rare earth metals

Designation	Alloy type	Rare earth	Composition, wt%	Remarks
AiResist 13	Co superalloy	Y	0.1	High-temperature parts

MA 6000	Ni superalloy	Y_2O_3	1.1	Creep resistance

Alloy Additives. The application of rare earths as alloy additives in metallurgy depends on one or more of the following properties:

- A high chemical affinity for carbon, nitrogen, oxygen, sulfur, and other tramp elements
- Metallic size
- Low vapor pressure
- Alloy formation properties

In many of these applications the rare earths are added as the naturally occurring mixture of elements as reduced from monazite or bastnasite ore. This material is called mischmetal and has the approximate rare earth distribution of 50% Ce, 30% La, 15% Nd, and 5% Pr.

Ductile Iron (Ref 9). Rare earths, which are added as mischmetal, cerium, lanthanum, or yttrium, are used to control the microstructure and chemical form of the excess carbon in cast irons. With no additive the carbon forms graphite flakes and results in gray iron--a cast iron that is easily machinable, and has high thermal conductivity, but low tensile strength. The rare earths (R) modify the carbon morphology in cast irons by removing free oxygen and sulfur from the melt

through formation of stable compounds such as oxysulfides (R_2O_2S), which act as nuclei for the growth of spheroidal graphite. This ductile or nodular iron has improved tensile strength, is more ductile, but has a lower thermal conductivity than gray iron. In addition, the rare earths tie up undesirable trace elements, such as lead and antimony, as intermetallic compounds.

Steels (Ref 10). In the late 1960s it was found that rare earth additions, as mischmetal or as a mixed rare earth silicide, would reduce the sulfur content to extremely low levels and control the morphology of the sulfide inclusion. This sulfide shape control greatly improved transverse shelf energy of the high-strength low-alloy (HSLA) steels, which made the forming of the steel into intricate parts and shapes much more efficient and economical. This application lasted into the early 1980s in the United States, Europe, and Japan, but now has been replaced almost exclusively by calcium. The People's Republic of China, however, still uses the rare earths in its steels. Several of the commercial alloys are listed in Table 2.

Superalloys. The rare earth elements are sometimes added to superalloys, which are a broad class of heat-resistant alloys based on iron, cobalt, or nickel. These alloys are essential for use in the gas turbine engines that power present-day jets, electrical generators, and so on. They are also used in environments where good corrosion resistance is required. Less than 1 wt% of rare earths, which are used as individual metals, dramatically improves the performance of these alloys. For example, lanthanum raises the operating temperature of nickel-base Hastelloy X from about 950 °C (1750 °F) to about 1100 °C (2000 °F). An extensive list of commercial superalloys that contain rare earths is shown in Table 2.

Magnesium Alloys (Ref 11). The alloy behavior of magnesium is notable for the variety of elements with which it forms solid solutions, including the rare earths. Alloys developed early used mischmetal (MM) to reduce microporosity in wrought alloys such as Mg-1.25Zn-0.17MM (Ref 11). This alloy was difficult to cast, but other alloys containing various amounts of zinc, zirconium, and mischmetal were developed with good castability. Rare earth additions are especially effective in improving the creep resistance of magnesium-base alloys. The rare earths also refine the grain size and improve the strength, ductility, toughness, weldability, machinability, and corrosion resistance. Recently developed alloys have contained separate rare earths. Didymium (an Nd-Pr mixture) is the most effective, followed by cerium-free mischmetal, mischmetal, cerium, and lanthanum, in order of decreasing effectiveness. An Mg-Al-Zn-Nd alloy has good corrosion resistance in an aqueous saline solution. Also an Mg-Y-Nd-Zr alloy was shown to have good corrosion resistance, good castability, and stability to 300 °C (570 °F). Some of the commercial alloys are listed in Table 2.

Recently, just as with aluminum (see below), it has been discovered that a melt-spun amorphous magnesium alloy containing 10 at% Ce and 10 at% Ni has a tensile fracture strength more than twice as large as conventional, optimum age-hardened alloys. It also has good ductility.

Aluminum Alloys. The addition of mischmetal to aluminum-base alloys used for high-tension transmission lines improves tensile strength, heat resistance, vibration resistance, corrosion resistance, and extrudability. Two aluminum-base alloys used in the automobile industry contain 22Si-1MM and 2.5Cu-1.5Ni-0.8Mg-1.2Fe-1.2Si-O.15MM (all wt%). These alloys are used for making cast parts with good high-temperature properties and fatigue strength. They are also used in the aircraft, small engine, and other fields.

A new development involving the use of rare earths in aluminum is the low-density glassy alloys containing about 90 at% Al, 5 to 9 at% transition metals, and about 5 at% rare earths (Ref 12). The transition metals studied include iron, cobalt, nickel, and rhodium, and the rare earths studied include cerium, neodymium, and yttrium. The melt-spun produced materials have extremely high tensile strengths, about twice that of the best crystalline commercial alloy. The alloys begin to crystallize between 250 to 300 °C (480 to 570 °F). They are also quite ductile and because of their low density are of interest to the aerospace industry.

An alloy of aluminum containing 8 wt% Fe and 4 wt% Ce is made by rapid solidification of the melt and processed by powder metallurgy techniques. Quick quenching of the alloy allows large amounts of insoluble metallic elements to be finely dispersed within the aluminum matrix and produces a dispersion-strengthened alloy. The alloy has creep resistance, elevated-temperature tensile strength, thermal stability, and corrosion resistance.

Another related area of application is the use of 1 to 3 wt% mischmetal in aluminum-carbon composites to improve the wetting of the carbon and thus the incorporation of the graphite dispersoid into the metal matrix. The ultimate tensile strength is improved by about 20%, and much more carbon can be incorporated (Ref 13).

Titanium Alloys. The rare earths in titanium alloys are usually present as dispersoids but are also present in solution. The dispersoids are normally oxides but can be sulfides, oxycarbides, or oxysulfides. The dispersoids produced by rapid solidification are ultrafine and serve as barriers to the movement of dislocations, and thus affect the behavior of the alloys in a number of ways. The finer and more stable the dispersoid at high temperatures, the better the properties of the alloys. The smallest and most closely spaced dispersoids are obtained with erbium and yttrium. The dispersoids also maintain their small size upon annealing to about 1000 °C (1830 °F). Alloys with most of the other rare earths and mischmetal have been investigated with various degrees of success. Among the alloys that have found practical applications are those with erbium (Er) or yttrium (Y), added as metals or oxides. Some of these are Ti-6Al-2Sn-4Zr-2Er, Ti-6Al-2Sn-4Zr-2Mo-0.1Si-2Er, Ti-8Al-4Y, Ti-3Er, and Ti-(0.74-1.84)Y (all wt%).

Copper. Mischmetal or yttrium additions to oxygen-free high-conductivity (OFHC) copper improve the oxidation resistance, with little or no adverse effect on the electrical conductivity. At 0.1 wt% Y the oxidation resistance is nearly doubled at 600 °C (1100 °F). Mischmetal (0.1 wt%) greatly improves the hot workability and deep drawing characteristics of bronzes containing less than 1 wt% lead. The mischmetal (MM) forms $MMPb_3$ and prevents the liquefaction of the lead at grain boundaries. In leaded bearing bronzes containing 11 to 50 wt% lead, MM additions guarantee a high uniformity in the lead distribution, promote favorable dendritic solidification, produce a better appearance, and improve the mechanical properties. Mischmetal at 0.2 wt% added to a leaded bearing bronze reduced the coefficient of friction by a factor of four.

Zinc. The main use of rare earths in zinc is in the form of Galfan, a Zn-5Al-0.05MM (in wt%) alloy used in galvanizing baths (Ref 14). The alloy was developed by the International Lead Zinc Research Organization. Galfan was found to be superior in corrosion resistance and formability and equal in weldability and paintability when compared to the normal galvanizing alloys.

Oxide-Dispersion-Strengthened (ODS) Alloys. Yttrium oxide (Y_2O_3) is widely used as a dispersed oxide in superalloys (Ref 15, 16). The oxide is introduced into the alloy by mechanical alloying, which is a high-energy ball milling process that permits solid-state processing and gives the biggest improvement in properties. The milled powders are hot extruded or hot isostatically pressed, which produces a fine dispersion of yttrium oxide in a segregation-free matrix. These compacted alloys have a capacity for secondary recrystallization that results in oriented coarse grains with improved high-temperature creep resistance, strength, and oxidation resistance (Ref 17). Application of these high-strength, high-temperature alloys has been primarily in gas turbine blades, vanes, and combustors. However, any application that requires high-temperature strength creep resistance and corrosion resistance can use oxide-dispersion-strength superalloys. Table 3 lists a number of commercial ODS alloys.

Lighter Flints. A 50 to 75 wt% mischmetal-iron alloy containing a few other alloying additives is used as a lighter flint. This alloy, due to the pyrophoric nature of cerium, ignites or sparks when sharply struck. A large free energy of formation of the rare earth oxides (see Fig. 6) is the main basis for this application. Lighter flints were first sold in 1908, making this one of the oldest uses of the rare earths. They are still used today, although the volume is smaller than it was 20 years ago. Furthermore, lighter flints are the only metallurgical market in which the rare earths (considering the group as one component) are the major constituent.

Magnetic Materials. This section briefly reviews the use of rare earth elements in magnetic materials. Additional information on magnetic materials containing earth elements is given in the article "Permanent Magnet Materials" in this Volume.

Samarium-Cobalt Permanent Magnets. Although the magnetic properties of the rare earth materials had been studied extensively in the 1950s and early 1960s, it was not until 1966 that Strnat and Hoffer noted that YCo_5 had an extremely large magnetocrystalline anisotropy and an unheard of theoretical energy product, which suggested that it would make an excellent permanent magnet (Ref 5). Within a few years, first $SmCo_5$ and then Sm_2Co_{17} were found to be the best permanent magnets ever produced. Most of the strength of the magnet comes from the cobalt atoms, but the role of the samarium (or other rare earths such as Pr, Ce, and Y) is crucial for the permanent magnet properties. The magnetic moments of the 3*d* electrons of cobalt and the 4*f* electrons of samarium couple parallel to each other (which further increases the magnetic strength), but because the 4*f* moments in the hexagonal crystalline environment are difficult to rotate in an applied magnetic field, the cobalt moments are locked in, giving rise to the superior permanent magnet properties. About 15 years later these magnets were, for the most part, superseded by the even more powerful Nd-Fe-B permanent magnets (see below). However, the high magnetic-ordering (Curie) temperatures of the Sm-Co alloys (700 to 900 °C, or 1300 to 1650 °F) gives them a distinct advantage over the Nd-Fe-B alloy (Curie temperature of ~300 °C, or 570 °F) for high-temperature (>100 °C) applications.

Nd-Fe-B Permanent Magnets (Ref 5). More recently, a new family of rare earth permanent magnets was discovered in 1981, and their superior permanent magnet properties were realized by 1983. The major component in these magnets is the tetragonal $Nd_2Fe_{14}B$. In this case the major contribution to the magnetic strength comes from the iron, plus some from the neodymium. The role of the neodymium atom (as it is for the samarium atom in the Sm-Co alloys) is to lock in the magnetic moments of the iron and to prevent them from rotating in an applied magnetic field. The Nd-Fe-B alloys have a higher magnetic energy product than the Sm-Co alloys, but the major advantage of the former is that neodymium and iron are cheaper than the samarium and cobalt, respectively. The main disadvantage of the $Nd_2Fe_{14}B$ compound (as noted above in the previous subsection) is its low Curie temperature. However, the Curie point can be improved by the substitution of cobalt for iron and dysprosium for neodymium. Dysprosium additions also substantially increase the intrinsic coercivity and reduce the reversible temperature coefficient and remanence. Currently this application is the largest market for an individual rare earth *metal* (neodymium), and it is currently growing at a rate better than 25% per year.

Terfenol (Ref 5). The ternary intermetallic compound $[(Tb_{0.3}Dy_{0.7})Fe_2]$, which is known as Terfenol, exhibits giant magnetostrictions in an applied field, ~100 times larger than in nickel. That is, when a magnetic field is applied to a magnetostrictive material, it will expand or contract. Conversely, when stress is applied to the material, a magnetic pulse is generated. Its magnetostrictive properties were discovered in 1971 and commercial production began about 15 years later. Some of the uses of terfenol include sonar devices, micropositioners, and liquid-control valves.

Magnetic Refrigerants. The intermetallic compound $PrNi_5$, which has the hexagonal $CaCu_5$ structure, is used to obtain extremely low temperatures in conjunction with the nuclear magnetic cooling of copper. The $PrNi_5$ is used as the first stage and copper as the second stage in a two-stage adiabatic demagnetization unit. The entire unit is cooled down in the presence of two magnetic fields (one around the $PrNi_5$ stage and the second around the copper) by a dilution refrigerator to ~25 mK. When the ~6 T field is slowly removed from the $PrNi_5$ stage, the entire unit is cooled down to ~5 mK. When the field is reduced around the copper in the second stage, a temperature of ~30 μK can then be reached. In 1983 Japanese scientists set a new record of 27 μK for *the lowest working temperature at which useful experiments could be performed on materials other than the refrigerant itself* (Ref 5).

Other lanthanides, especially gadolinium compounds, have been used as magnetic refrigerants for cooling gases or systems to various temperatures as low as 4 K. In this case the magnetic refrigerant rotates through a magnetic field and in so doing warms and cools itself. As the refrigerant enters the magnetic field, it warms up and thus allows heat to be removed and vented by exchange gas (just as heat is removed during the compression cycle of an air conditioner or refrigerator). When the refrigerant leaves the magnetic field, it cools down to cool the system or gas (just as cooling occurs during the expansion of the coolant in a refrigerator). The gadolinium refrigerant is rotated at a speed of ~5 rpm. The main advantages of the magnetic refrigerator are that it is quite compact and has a large refrigeration power per unit volume. It also is quite reliable, has a long lifetime, and is vibration free. Magnetic refrigerators are claimed to be more efficient than most cryogenic cooling systems, especially below the temperature of liquid nitrogen (77 K) (Ref 18).

Magnetooptical Materials (Ref 19). A fairly recent commercial development is the use of amorphous rare earth-transition metal alloys for information storage as magnetooptic discs.** In this application amorphous $Tb_{25}(Fe_{0.9}Co_{0.1})_{75}$ thin films (500 to 2000 Å thick) are RF or DC sputtered on a substrate and coated by a transparent ceramic film. A laser light is used to write, read, or erase the information on the amorphous alloy by making use of the Kerr rotation. Storage densities of $\sim 10^8/cm^2$ have been achieved, which is 15 to 50 times larger than the densities found in a conventional magnetic hard disk.** Gadolinium is sometimes used instead of terbium, and neodymium additions are used to increase the Kerr rotation. The initial application of these magnetooptic storage devices is for personal computers and work stations.

Hydrogen Storage Alloys. A large number of compounds formed between iron, cobalt, and nickel with the rare earth metals have the ability to absorb large quantities of hydrogen. For example, $LaNi_5$ will form $LaNi_5H_6$ under a few atmospheres of H_2 pressure. This compound has a larger number of hydrogen atoms per cubic volume than liquid H_2. Furthermore, the hysteresis of the absorption/desorption cycle is small, and a large heat is associated with this reaction. Some of the applications using these properties include hydrogen storage, heat pumps, heat engines, isotope separation, hydrogen gas separation and purification, energy storage, and catalysis (Ref 20). A rechargeable battery based on the rare earth-nickel-hydride cell could develop into the most important technological application of these materials (Ref 21).

Miscellaneous Applications. Rare earth elements have a variety of specialized applications in instruments and materials. Some miscellaneous applications are described below.

Electron Emitter-LaB_6 (Ref 5). The superior thermionic properties of LaB_6 have been known for nearly 40 years. LaB_6 is composed of B_6 clusters and lanthanum atoms in a CsCl-like arrangement. This compound has a melting point >2500 °C (4500 °F) and a low vapor pressure that when combined with its low work function and excellent thermionic emission current make LaB_6 a better electron emitter than tungsten. The thermionic emission can be improved by using <111> oriented single crystals. LaB_6 is used in electron guns of electron microscopes where high intensities are highly desirable, if not essential.

High-Pressure Gage. At high pressure ytterbium becomes a semiconductor at ~2 GPa (290 ksi) and room temperature, and as a result the electrical resistance increases by an order of magnitude from its ambient pressure value. A further increase of pressure results in the room-temperature fcc polymorph transforming to the high-(temperature) pressure bcc form at ~4 GPa (580 ksi), with a resultant sharp drop of the resistivity to a value comparable to the 1 atmosphere value (Ref 5). Scientists and engineers make use of this large resistivity increase and drop as a high-pressure gage. The ytterbium is usually used in the form of a thin wire.

Getters. The reactivity of the rare earth metals with O_2, N_2, CO_2, H_2O, and so forth, and the large, negative free energies of formation for the oxides, nitrides, and hydrides (among the most negative in the periodic table, see Fig. 6 and 7) account for their past use as getters in vacuum tubes such as television and cathode-ray tubes. The rare earth metals, usually a mischmetal alloy, react with the residual gases in the tube, thus increasing the lifetime of the filament. Rare earth metals are not used in this way anymore.

Corrosion Protection of Metals. In the past few years scientists, especially in Australia, have found that the rare earths can act as inhibitors in aqueous corrosion and as coatings for corrosion protection. The rare earths, as ions in solution, are nearly as effective as chromates in inhibiting corrosion of aluminum alloys, mild steel, and zinc in aqueous solutions. Cerium hydroxide peroxide coatings, ~100 nm thick, have been applied on aluminum alloys, zinc, cadmium, magnesium, and steel to provide corrosion protection that is as good as the common coatings used (that is, zinc, cadmium, and chromates). The main impetus for using the rare earths in corrosion protection is to replace many of the environmentally unacceptable materials currently being used by nontoxic materials and still afford good corrosion protection. The rare earths are nontoxic and seem to provide the necessary protection.

Germanium and Germanium Compounds

J.H. Adams, Eagle-Picher Industries, Inc.

Introduction

GERMANIUM (Ge) is a semiconducting metalloid element found in Group IV A and period 4 of the periodic table. Although it looks like a metal, it is fragile like glass. Its electrical resistivity is about midway between that of metallic conductors and that of good electrical insulators. Although it was first isolated by Winkler in 1886, no commercial application was found for it until the early 1940s, when it was found to have interesting electrical properties. Its first significant use was in solid-state electronics, and with it the transistor was invented. Indeed, the entire modern field of semiconductors owes its development to the early successful use of germanium. Germanium is still used in the field of electronics, but its use in the field of infrared optics surpassed its electronic applications in the1970s. Germanium has also found widespread use in the fields of gamma ray spectroscopy, catalysis, and fiber optics. The physical, thermal, and electronic properties of germanium metal are given in Table 1. Table 2 lists the optical properties of germanium.

Sources

The crust of the earth is estimated to contain 1.5 to 7 g of germanium per ton. Germanium usually occurs widely dispersed in minerals such as sphalerite; it rarely occurs in concentrated form. Almost all germanium production has been from zinc smelters. Copper smelters are the second largest source. There are only a few actual minerals of germanium, some with germanium concentrations up to about 8%. Most of these have occurred in Africa, with the highest

concentration near Tsumeb, Southwest Africa (now Namibia). Reference 1 reviews 19 germanium minerals found near Tsumeb. Several papers on the geochemistry of germanium are collected in Ref 2.

Germanium also occurs in significant concentrations in many coals around the world. The concentration of germanium within many coal veins varies from top to bottom, with the highest concentration occurring in the upper and lower few centimeters. It is assumed that this distribution within the vein indicates the deposition of germanium from solution after the vein was formed. When coal is burned in power-generating or coking plants, the germanium tends to concentrate in the fly ash or flue dust produced. Any recovery of germanium from coal would most likely be from such ash or dust. Significant germanium recovery from coal in Britain was reported in the1950s (Ref 3), and smaller amounts have been reported from other countries since then.

Chemical Properties

This section focuses on the chemical properties of various germanium compounds. The physical, thermal, electronic,and optical properties of germanium metal are summarized in Tables 1 and 2.

Germanium Metal. Germanium is quite stable in air up to 400 °C (750 °F) where slow oxidation begins. Oxidation becomes noticeably more rapid above 600 °C (1100 °F). The metal resists concentrated hydrochloric acid, concentrated hydrofluoric acid, and concentrated sodium hydroxide solutions, even at their boiling points. It is not attacked by cold sulfuric acid but does react slowly with hot sulfuric acid. Nitric acid attacks germanium more readily at all temperatures than does sulfuric acid. Germanium reacts readily with mixtures of nitric and hydrofluoric acids and with molten alkalies; it reacts more slowly with aqua regia. The principal reaction route for the mixed acids is the oxidation of the germanium with one constituent followed by the dissolution of the oxide by the other constituent. The reaction with fused alkalies is a direct oxidation with the release of hydrogen. Germanium also reacts readily with the halogens to form the respective tetrahalides.

In compounds, germanium can have a valence of either 2 or 4. Although the divalent compounds tend to be less stable than the tetravalent ones, most can be stored at room temperature for years with no change in composition. At higher temperatures, most of the divalent compounds decompose. Reference 4 reviews the syntheses and properties of many germanium compounds (including divalent ones) and provides a good discussion of the properties of germanium bonds. An excellent earlier review of inorganic germanium compounds is given in Ref 5.

Germanium Halides. Germanium tetrachloride ($GeCl_4$) is made by the reaction of hydrochloric acid on germanium concentrates containing oxides and/or germanates. It can also be made by the reaction of chlorine on heated metallic germanium. The properties of $GeCl_4$ are shown in Table 3.

Table 3 Properties of germanium tetrachloride

Property	Value
Molecular weight	214.40
Color	Colorless
Density at 25 °C (77 °F), g/cm^3 (lb/in.^{3})	1.874 (0.0677)

Melting point, °C (°F)	-49.5 (-57.1)
Boiling point, °C (°F)	83.1 (181.58)
Refractive index at 25 °C (77 °F), 0.5893 μm	1.464
Heat capacity (constant pressure) of vapor at 25 °C (77 °F), J/kg · K (Btu/lb · °F)	499 (0.1073)
Heat of vaporization at boiling point, J/g (Btu/lb)	137 (58.94)
Heat of formation at 25 °C (77 °F), J/g (Btu/lb)	-3318 (-1427)
Vapor pressure, Pa (psi)	
At 225 K (-55 °F)	10^2 (0.0145)
At 253 K (-5 °F)	10^3 (0.145)
At 294 K (69 °F)	10^4 (1.45)
At 356 K (181 °F)	10^5 (14.5)
At 462 K (372 °F)	10^6 (145)
At 550 K (530 °F) (T_c)	3.850×10^6 (558)

Germanium tetrachloride is soluble in solvents such as acetone, absolute ethanol, benzene, carbon disulfide, carbon tetrachloride, chloroform, and diethyl ether. It is only slightly soluble in concentrated hydrochloric acid, with the solubility dropping with acid normality and reaching a minimum at about 5 *N*. At HCl concentrations below about 5 *N*, the tetrachloride begins to hydrolyze to GeO_2 (see the section "Germanium Oxides" below). Germanium tetrachloride is insoluble in concentrated sulfuric acid and does not react with it. The solubility of free chlorine in $GeCl_4$ can reach as high as 4 wt%, especially at low temperatures.

Germanium tetrabromide ($GeBr_4$) and tetraiodide (GeI_4) can be easily prepared by the reaction of the respective halogen with germanium metal and by the reaction of GeO_2 with HBr and HI solutions, respectively. The preparation of germanium tetrafluoride (GeF_4) is not so straightforward, and pure GeF_4 is usually made by decomposing barium hexafluorogermanate at about 700 °C (1300 °F).

Germanium Oxides. Germanium dioxide (GeO_2) is usually made by the hydrolysis of $GeCl_4$ with water. It is also made by the ignition of germanium disulfide. Solid GeO_2 exists in soluble, insoluble, and vitreous forms. The properties of these three forms are given in Table 4. The soluble form is the usual product of hydrolyzing $GeCl_4$. The insoluble form can be prepared by heating soluble oxide at 300 to 900 °C (570 to 1650 °F), especially in the presence of about 0.5 wt% alkali halides. The glassy, or vitreous, form is prepared by melting either of the other forms and then cooling the melt.

Table 4 Properties of solid forms of germanium dioxide

Property	Soluble	Insoluble	Vitreous
Structure	Hexagonal	Tetragonal	Amorphous
Density at 25 °C (77 °F), g/cm^3	4.228	6.239	3.637
Melting point, °C (°F)	1116 (2040)	1086 (1987)	. . .
Solubility in water at 25 °C (77 °F), g/L	4.53	Insoluble	5.18
Solubility in water at 100 °C (212 °F), g/L	13	Insoluble	. . .
Solubility in HCl, HF, and NaOH solutions	Soluble	Insoluble	Soluble

Germanium monoxide (GeO) can best be prepared in pure form by heating a mixture of germanium and GeO_2 in the absence of oxygen. At temperatures above 710 °C (1310 °F), GeO sublimes from the mixture and condenses as a glassy deposit in the cooler part of the reaction vessel. Germanium monoxide is stable at room temperature.

Germanates are usually prepared by the fusion of GeO_2 with alkali oxides or carbonates in platinum crucibles. Sodium heptagermanate ($Na_3HGe_7O_{16}$) is precipitated by the neutralization of a sodium hydroxide solution of GeO_2 with hydrochloric acid to a pH above 7.

Germanides can be formed by melting other metals with germanium in the proper stoichiometric concentrations and then freezing the melt. They can also be prepared by vacuum sintering the two metals together; sintering is usually followed by long annealing. Other procedures include the thermal dissociation of one germanide into another and the electrolysis of fused mixed salts. The preparation and properties of about 200 germanides have been tabulated and reviewed (Ref 6). One of the germanides that has been prepared most often is magnesium germanide (Mg_2Ge).

Germanes, or germanium hydrides, are commonly prepared by the reaction of a germanide, such as Mg_2Ge, with hydrochloric acid. They can also be produced by the reduction of $GeCl_4$ with lithium aluminum hydride and by the reduction of GeO_2 by sodium borohydride in water solution. The preparation and properties of the germanes are reviewed in Ref 7 and 8.

Miscellaneous Inorganic Compounds. Germanium nitride (GE_3N_4) is about as inert as tetragonal GeO_2. It is prepared most easily from germanium powder and ammonia at 700 to 850 °C (1300 to 1560 °F). The nitride does not react with most mineral acids, aqua regia, or caustic solutions, even when hot. Germanium disulfide (GeS_2) is an unusual and useful compound because it is insoluble in strong acids such as 6 *N* HCl and 12 *N* H_2SO_4. This insolubility permits the recovery of germanium from acid solutions by gassing with H_2S. The disulfide can also be made by the reaction of GeO_2 with sulfur.

Organogermanium Compounds. The field of organogermanium chemistry has drawn widespread interest for many years. Organogermanium compounds are generally characterized as having low chemical reactivity and relatively high thermal stability. The synthesis of many begins with a Grignard reaction. Many excellent reviews of the organogermanium literature have been published (Ref 4, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19). During the 1980s, several organogermanium compounds were produced in commercial quantities. These included spirogermanium (which is 2-aza-8-germanspiro decane-2-propamine-8,8-diethyl-N,N-dimethyl dihydrochloride) and carboxyethyl germanium sesquioxide. These compounds have been studied extensively for their anticancer and blood pressure effects.

Manufacturing and Processing

Ore Processing. None of the minerals mentioned earlier in the section "Sources" is mined solely for its germanium content. Almost all of the germanium recovered worldwide is a by-product of other metals, primarily zinc, copper, and lead. The enriched copper-lead concentrates from Tsumeb, Namibia, have been treated in a vertical retort from which germanium sulfide is sublimed and separated (Ref 3). The copper-zinc ores of Katanga, Zaire, have been treated by roasting with H_2SO_4, followed by leaching and selective precipitation of the germanium with MgO (Ref 3). In the United States, zinc concentrates have been roasted and then sintered for germanium recovery. In this process, the sinter fume is chemically leached, and the germanium is selectively precipitated from the leach solution by fractional neutralization; it is then sent to the germanium refinery (Ref 20). Because of the low solubility of germanium sulfide and tannate in acid solutions, germanium has been recovered by precipitating it from acid solutions with H_2S or tannic acid. Sulfide precipitates are usually oxidized with sodium chlorate or permanganate, followed by, or concurrent with, dissolution in concentrated HCl and distillation of the resulting $GeCl_4$. Tannic acid precipitates are usually upgraded by igniting the precipitate to the oxide and dissolving the oxide in concentrated HCl, with subsequent distillation of the $GeCl_4$. Germanium can also be recovered from the still residue in the distillation of zinc metal (Ref 21).

From June 1986 to September 1987, germanium was recovered from the Apex Mine near St. George, UT. This was an unusual operation in that germanium was the major product from the mine, with gallium a valuable by-product. Copper was also recovered because the Apex Mine was an old abandoned copper mine. The process involved dissolution of the screened ore in sulfuric acid, followed by cementation of the copper, solvent extraction of the gallium, and precipitation of the germanium with H_2S. The GeS_2 precipitate was oxidized with sodium chlorate and dissolved in HCl. The $GeCl_4$ formed was distilled and then hydrolyzed to a crude GeO_2. Unfortunately, the operation was not a financial success, and the producer was forced into bankruptcy. The assets of the producer were purchased in 1989 by the Hecla Mining Company, which made major changes in the processing circuit, including the addition of a solvent extraction system for germanium recovery. Start-up of the revised operation was scheduled for March 1990.

In electrolytic zinc plants, which have become increasingly important for environmental reasons, germanium is precipitated, usually along with iron, during the purification of the $ZnSO_4$ electrolyte prior to electrolysis. Germanium is one of several impurities that have an adverse effect on zinc electrolysis. If the germanium concentration is high enough in the separated solids, economic recovery of germanium is possible. During recent years, several solvent extraction and

ion exchange processes have been developed (Ref 22, 23, 24, 25, 26, 27, 28) that provide better germanium separations, primarily from $ZnSO_4$ electrolytes.

Purification. Regardless of the source of the germanium, all germanium concentrates are purified by similar techniques. The ease with which concentrated germanium oxides and germanates react with concentrated hydrochloric acid, and the convenient boiling point of the resulting $GeCl_4$ (83.1 °C, or 181.6 °F), make chlorination a standard refining step. An oxidizing agent is often added to the primary distillation or to the subsequent fractionation, or both, to suppress the volatility of arsenic (Ref 29). Other purification steps are used to separate certain other objectionable impurities, if present. The fractionation is usually done in glass or quartz because most subsequent uses of $GeCl_4$ require impurity levels of no more than about 1 mg/kg (1 ppm).

The purified $GeCl_4$ is hydrolyzed with deionized water to produce GeO_2, which is removed by filtration and dried. The dried GeO_2 is reduced with hydrogen at about 760 °C (1400 °F) to germanium metal powder, which is subsequently melted and cast into so-called first-reduction, or as-reduced, bars. These bars are then subjected to zone refining to produce intrinsic or electronic-grade germanium metal. Zone refining is ideally suited for the refining of germanium; in fact, the original development of this procedure was prompted by the need for ultrapure germanium (Ref 30). Zone refining results in polycrystalline germanium, usually containing less than 100 ng total impurities per gram of germanium and less than 0.5 ng of electrically active impurities per gram of germanium. For extremely high-purity applications, such as for uncompensated gamma ray detector crystals, germanium has been refined to impurity concentrations of less than 0.0003 ng/g (0.0003 ppb). However, zone refining is not equally efficient in removing all impurities. Boron and silicon are not removed easily with this method and must be removed from germanium before the zone-refining step.

For use as a semiconductor, refined germanium is grown into single crystals from the melt. The electronic properties are controlled by the addition of selected impurities (dopants) to the melt before crystal growth begins. The grown crystal is sliced and fabricated into devices, and the germanium scrap generated is recycled through the refinery into intrinsic germanium.

For use in infrared optics, zone-refined germanium is recast or grown into forms suitable for lens and window manufacture. After the germanium is annealed, it is cut and ground into lens or window blanks, which are then polished, coated, and assembled into an infrared system.

Environmentally, the production of germanium is quite harmless. Among the products produced, the chemicals consumed, and the by-products made, only arsenic would normally be considered a problem. The bulk of the arsenic is separated from the germanium at the smelter, and the small amounts entering the germanium-refining plant are easily controlled. The acids, bases, and chlorine used in processing and in gas scrubbing can be neutralized and held in permanent containment ponds or disposed of in hazardous-waste landfills. No hazardous substances are known to be discharged into surface waters or municipal treatment facilities from germanium-refining plants.

Economic Aspects

World reserves of germanium have been estimated at 4000 Mg (4400 tons), but it is impossible to discuss reserves without considering price. In many applications the cost of germanium is a very small part of the overall cost, and increasing the germanium price substantially would have little impact on its use in such applications. However,substantial increases in its price would expand germanium reserves significantly.

Because germanium is almost always recovered as a by-product, its price and availability over the long range are subject to supply and demand considerations for its host products, usually zinc and copper, as well as for itself. This is not the case over the short term (6 to 24 months) because producers often recover germanium from stockpiles of smelter residues that can last for years. Therefore, short-term pricing is largely controlled only by demand. Figure 1 plots the price levels of intrinsic germanium in the United States over the past 35 years; prices are adjusted for inflation. The November 1978 adjusted price of $469/kg was an all-time low. During 1985 a two-tiered pricing structure was implemented: The higher price is for 10 kg lots, and the lower price applies to 100 kg lots. The prices in December 1989 were $1060 (adjusted price $841) for 10 kg lots and $750 ($595) for 100 kg lots.

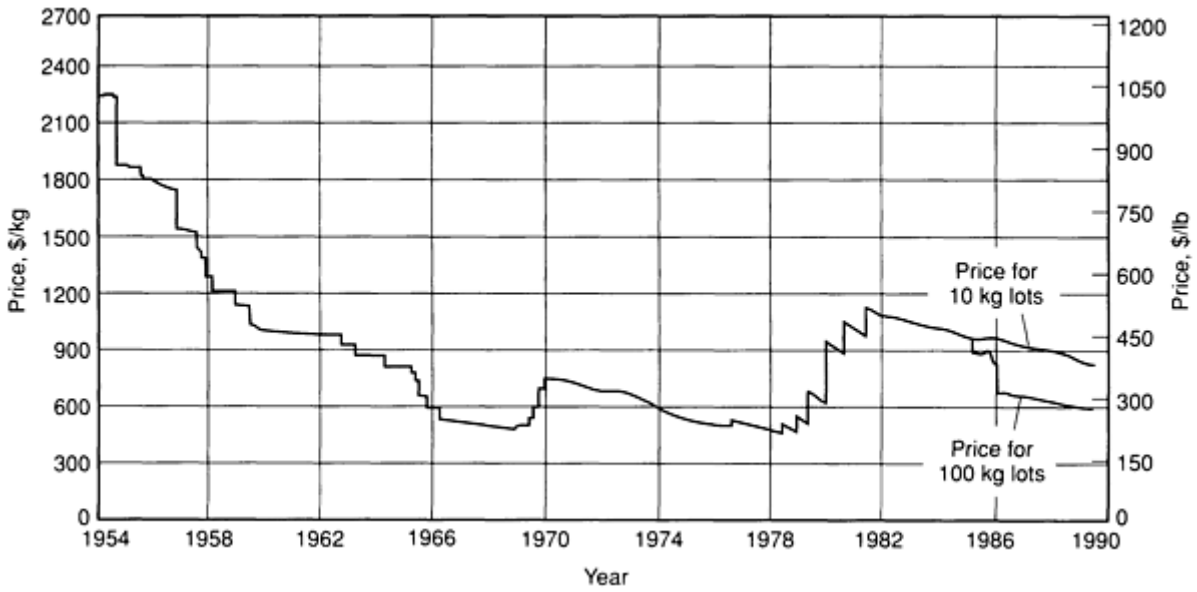

Fig. 1 Historical price of intrinsic germanium in the United States in constant 1983 dollars

Information concerning world production rates of germanium is difficult to obtain. This is due in part to the fact that there are very few producers. It is known that world production exceeded 100 Mg/yr (110 tons/yr) during the period of peak demand for semiconductors. Production has varied between 30 and 80 Mg/yr (33 and 88 tons/yr) during the 1970s and between 80 and 110Mg/yr (88 and 120 tons/yr) in the 1980s.

An annual review of germanium is published by the U.S. Bureau of Mines (Ref 31) with a broader survey published every 5 years (Ref 32). The *Engineering and Mining Journal* also published an annual germanium review through 1986 (Ref 33). The economics of germanium, with special emphasis on world trade, have been reviewed by Roskill Information Services (Ref 34, 35, 36, 37, 38, 39, 40).

Specifications

Most electronic-grade GeO_2 is 99.9999% minimum purity (6N) as measured spectrographically and has 0.1 to 0.2% maximum volatile content, a bulk density of 1.5 to 2.0 g/cm^3 as specified by the customer, a metal billet resistivity of at least 5 ohm-cm average on the last third of the billet to freeze, and an N-type billet conductivity. The GeO_2 intended for chemical use, such as for use as a catalyst, is at least 5N pure spectrographically, at least 98% finer than 325 mesh, and at least 99.9% soluble in water and/or ethylene glycol.

Most intrinsic germanium metal sold is N-type with a resistivity of at least 40 ohm-cm at 25 °C (77 °F) or 50 ohm-cm at 20 °C (68 °F). Germanium metal prepared for use in infrared optics is usually specified to be N-type with a resistivity of 5 to 40 ohm-cm, to be stress-free and fine annealed, and to have certain minimum transmission (ormaximum absorption) characteristics in the 3 to 5 or 8 to 12 μm wavelength ranges. Either polycrystalline or single-crystal material will be specified.

Germanium single crystals intended for electronic applications will usually be specified according to conductivity type, dopant, resistivity, orientation, and maximum dislocation density. They will be specified to be lineage-free unless the specified resistivity is below about 0.5 ohm-cm. Minority carrier lifetime and majority carrier mobility are occasionally specified.

The $GeCl_4$ refined for use in making optical fibers is usually specified to contain less than 1 to 5 ppb of each of seven impurities; chromium, manganese, iron, cobalt, nickel, copper, and zinc. Limits are sometimes specified for a few other elements. Also of concern are hydrogen-bearing impurities; therefore, maximum limits of 10 to 20 ppm are usually placed on HCl, OH, CH_2, and CH_3 contents.

Analytical and Test Methods

The analysis of ores for germanium is usually done with an emission spectrograph but can be done in the field with the phenylfluorone method (Ref 41). Analysis of germanium refinery samples is usually done after fusion of the sample with KOH or NaOH in nickel crucibles. Following distillation of the $GeCl_4$ from HCl solution of the fusion, the germanium can be determined in one of three ways:

- Gravimetrically, usually by precipitation of GeS_2 from acid solution and by ignition to GeO_2
- Titrimetrically, usually by reduction with sodium hypophosphite and titration with KIO_3 solution
- Spectrally, with an atomic absorption spectrophotometer

The last procedure is not considered as accurate as the first two. Excellent reviews of the analytical chemistry of germanium are given in Ref 42 and 43.

Analysis of refined germanium products is done in a wide variety of ways, including several methods that have become ASTM standards (Ref 44). Electronic grade GeO_2 is analyzed using an emission spectrograph to determine its spectrographic purity. Its volatile content is measured in accord with ASTM F 5 and its bulk density with F 6. Other ASTM standards cover the preparation of a metal billet from a sample of the oxide (F 27), and the determination of the conductivity type (F 42) and resistivity (F 43) of the billet.

The type and resistivity of all grades of germanium metal are also measured in accord with F 42 and F 43. The transmission characteristics of optical grade germanium are determined with an infrared spectrophotometer, and the measurement of the interstitial oxygen content of the metal is covered in F 120 and F 122. Germanium single crystals can be further evaluated in accord with ASTM F 26, F 28, F 76, F 334, F 389,and F 398.

The overall spectrographic purity of $GeCl_4$ can be determined by using an emission spectrograph to examine a sample of GeO_2 that has been produced from the $GeCl_4$ by hydrolysis with deionized water. The trace metal impurities of concern to fiber optic producers are determined by flameless atomic absorption, and the hydrogen-bearing impurity concentrations are measured by infrared absorption of the $GeCl_4$.

Toxicology

Germanium compounds generally have a low order of toxicity (Ref 45). Only germanium hydride is considered toxic, with a maximum time-weighted average 8-h safe exposure limit of only 0.2 ppm (Ref 46). The lethal dose median for GeO_2 is 750 mg/kg, and that of germanium is 586 mg/kg (Ref 47). The toxicity of specific germanium compounds usually must be considered more from the standpoint of the other part of the compound than from the germanium content. The biological activity of germanium is reviewed in Ref 8, 11, and 13.

Uses

The main use for germanium remained in the field of semiconductor electronics into the 1970s. Its earliest use in 1941 was as a solid-state diode that performed as a detector in radar systems. This device was adapted to radio circuits as a radio frequency detector, and the germanium transistor was invented in 1947. This invention revolutionized the electronics industry and caused a sharp increase in the demand for germanium. The use of germanium in these conventional semiconductor roles reached a peak in the early 1960s, with world consumption averaging over 100 Mg/yr (110 tons/yr). Except for a brief upsurge in this demand during 1969, there has been a general decline in this application of germanium since the early 1960s.

The use of germanium as a semiconductor substrate deserves special mention. In this application, single-crystal wafers of germanium are used as substrates for the epitaxial deposition of gallium arsenide (GaAs) or gallium arsenide phosphide (GaAsP) for use as light-emitting diodes or solar cells. These substrates take the place of more expensive gallium arsenide wafers. Many metric tons of germanium were consumed in the mid-1970s for the production of GaAsP-Ge light-emitting diodes for calculators and watches (Ref 48). The large-scale production of GaAs-Ge solar cells did not begin until 1989, and production is expected to increase in the 1990s. Although the use of germanium as a substrate for GaAs solar cells

provides stronger, lighter, and cheaper cells while maintaining the high conversion efficiency of gallium arsenide, one study (Ref 49) suggests that the widespread use of germanium for this application would require several times the present world output of germanium. However, there are large, untapped sources of germanium, and it is not inconceivable that, with sufficient incentive, such demands could be met in time.

The largest use of germanium is in the field of infrared optics. In this application, the transparency of germanium to infrared wavelengths longer than 2 μm and its high refractive index are utilized rather than its electrical properties. Other advantageous properties of germanium for this use are its low dispersion; easy machinability; reasonable strength; low price compared to other infrared materials; good resistance to atmospheric oxidation, to moisture, and to chemical attack; and availability in large sizes. It has been estimated that the world demand for germanium for infrared devices would increase to 55 to 70 Mg/yr (60 to 77 tons/yr) during the 1980s (Ref 50). It is now estimated that 55 to 65 Mg/yr (60 to 72) tons/yr) was indeed consumed in this application from 1987 to 1989.

Infrared devices are principally used for military applications. Infrared systems with germanium usually operate in the 8 to 12 μm range and usually contain several germanium lenses, a germanium window, and a color-correcting lens made from a Ge-Sb-Se glass, a Ge-As-Se glass, or ZnSe. Some of the viewers also utilize a germanium infrared detector.

The U.S. government was so impressed with the importance of germanium for infrared applications that a decision was made in April 1987 to add intrinsic germanium metal to its strategic stockpile. From May 1987 through September 1989, stockpile orders were placed for 69 Mg (76 tons) of germanium. Deliveries were scheduled from July 1987 through January 1991. Some additional germanium is expected to be ordered for the stockpile.

Nonmilitary infrared applications for germanium include CO_2 lasers, intrusion alarms, and police and border patrol surveillance devices. Germanium is used as a thin film coating for infrared materials to decrease reflection losses and/or to provide heavy filtering action below 2 μm. Germanium metal is also used in specially prepared germanium single crystals for gamma ray detectors. Both the older lithium-drifted detectors and the purer, more expensive intrinsic detectors, which do not have to be stored in liquid nitrogen, do an excellent job of spectral analysis of gamma radiation and are important analytical tools.

The primary application of germanium dioxide is in the preparation of germanium metal. However, there are several other uses that provide significant markets for the oxide. The largest of these is its use in place of antimony oxide (Sb_2O_3) as a catalyst in the reaction of ethylene glycol with terephthalic acid in the production of polyester fibers and polyethylene terephthalate (PET) resins. Although more expensive than Sb_2O_3, GeO_2 produces a polyester fiber that does not yellow with age, which is especially attractive to makers of white shirts and other white fabrics. The PET resins are used almost entirely in making beverage bottles such as 2- and 3-liter soft drink bottles. Germanium dioxide produces a stronger, clearer bottle than those made with Sb_2O_3, but the change to GeO_2 is also being driven by the concern over the long-term effects of trace contamination of the bottle contents with antimony. The use of GeO_2 in this application is more widespread in the Far East than in other parts of the world.

Another significant use of GeO_2 is the production of bismuth germanium oxide crystals ($Bi_4Ge_3O_{12}$). These scintillation crystals are used primarily in positron emission tomography scanners, which are expected to find increased use as suitable radioisotopes become less expensive. Germanium dioxide is also used in significant quantities in the production of spirogermanium and carboxyethyl germanium sesquioxide (Ref 45), both of which have medical applications. In addition, GeO_2 is included in a few special glass formulations, primarily to increase the refractive index of the glass.

The only significant application of $GeCl_4$, besides its use in the production of GeO_2, is in optical fibers (Ref 51). In this application, $GeCl_4$ is converted to GeO_2, which is deposited, along with SiO_2 and sometimes B_2O_3 and/or P_2O_5, on the inside of a pure quartz tube and subsequently collapsed to form a solid rod or preform. The preform is then drawn into fine fibers that can be used as optical waveguides, primarily in the 0.8 to 1.6 μm wavelength region. Such fibers have proved very useful, especially in long-distance telephone lines. Phone signals have been transmitted over 100 km (65 miles) on such fibers without amplification. Germanium dioxide provides the higher refractive index fibercore, which prevents signal loss; also, it produces an extremely clear glass that provides very low signal absorption at the selected wavelengths at which infrared emitters are available.

Other uses of germanium include the use of magnesium germanate as a phosphor, the addition of lead germanate to barium titanate capacitors, the use of germanium-gold alloys in dental fillings and precision castings, and the use of germanium single crystals as x-ray monochromators for high-energy physics applications.

Gallium and Gallium Compounds

Deborah A. Kramer, Division of Mineral Commodities, U.S. Bureau of Mines

Introduction

GALLIUM-BASE COMPONENTS can be found in a variety of products ranging from compact disk players to advanced military electronic warfare systems. Compared with components made of silicon, a material gallium arsenide (GaAs) has replaced in some of these applications, components made a GaAs can emit light, have greater resistance to radiation, and operate at faster speeds and higher temperatures. However, GaAs components are more costly and more difficult to fabricate than those of silicon, so they are used only in applications where the advantage of their properties significantly outweighs their cost disadvantage.

Gallium occurs in very low concentrations in the crust of the Earth and virtually all primary gallium is recovered as a by-product, principally from the processing of bauxite to alumina. Most gallium applications require very high purity levels, and the metal must be refined before use until it contains no more than 1 ppm total impurities. Most gallium metal recovery and refining facilities are in Europe.

Complex processing techniques are used to produce single crystals of gallium and GaAs (Fig. 1); complex techniques also are required for the fabrication of gallium and GaAs optoelectronic devices and integrated circuits (ICs). Japan and the United States lead the world in GaAs crystal and device fabrication. Considerable investments are being made to increase processing efficiency, develop new devices, and increase the applications of current GaAs-base components.

Uses

Gallium has limited commercial applications in its metallic form. Its principal use is in the manufacture of semiconducting compounds, mainly GaAs and gallium phosphide (GaP). Over 90% of the gallium consumed in the United States is used for optoelectronic devices and ICs. Optoelectronic devices--light-emitting diodes (LEDs), laser diodes, photodiodes, and solar (photovoltaic) cells--take advantage of the ability of GaAs to convert electrical energy into optical energy and vice versa. The principal market for optoelectronic devices is in nonmilitary applications, including communications systems and consumer electronic goods. Gallium-arsenide-base integrated circuits are used primarily in defense applications, although developments in recent years have increased their use in the commercial sector. Gallium-arsenide-base integrated circuits are important, particularly in defense applications, because they can send information about five times faster, withstand more radiation, and operate at higher temperatures than comparable silicon-base integrated circuits.

Optoelectronic Devices

An LED is a semiconductor that emits light when an electric current is passed through it. Light-emitting diodes have been in commercial use for many years. The first commercial applications for LED (technology were in displays for hand-held calculators and digital watches. Today, LEDs are used in visual displays in automobiles, calculators, appliances, consumer electronic equipment, and a wide variety of industrial equipment. Light-emitting diodes are also used as a light source in short-distance fiber-optic communications systems.

Light-emitting diodes consist of layers of an epitaxially grown material on a substrate. These epitaxial layers are normally gallium aluminum arsenide (GaAlAs), gallium arsenide phosphide (GaAsP), or indium gallium arsenide phosphide (InGaAsP); the substrate material is either GaAs or GaP. The materials used to fabricate LEDs determine the color of light that is emitted. With GaP substrates, the wavelength of light can cover the spectrum from 555 nm (pure green) to about 700 nm (red). With GaAs substrates, light emitted from the LED is limited to wavelengths at the red and infrared end of the spectrum.

Laser diodes operate on the same principle as LEDs, but they convert electrical energy to a coherent light output. Laser diodes, also called semiconductor lasers or injection laser diodes, principally consist of an epitaxial layer of GaAs, GaAlAs, or InGaAsP on a GaAs substrate. The two most commonly used laser diodes are GaAlAs and InGaAsP diodes.

Gallium aluminum arsenide laser diodes operate at about 780 to 900 nm and are used in a wide variety of consumer products and in communications systems. Consumer product applications for GaAlAs diodes include uses in compact disk players, nonimpact laser printers, and optical video disk players. Communications applications include short-range fiber-optic communications systems, satellite communications, radar transmission, and local cable television transmission systems. In 1988, GaAlAs laser diodes operating in the visible end of the spectrum (670 to 680 nm) where introduced to compete with helium-neon gas lasers in several applications. The principal application for GaAlAs visible laser diodes is in bar code scanners, although they can also be used in laser printers, pointers, and a variety of specialized applications (Ref 1).

Indium gallium arsenide phosphide laser diodes operate at longer wavelengths (1300 to 500 nm). They are primarily used for transmitting high-frequency long-distance signals in fiber-optic communication systems and in cable television supertrunks.

Photodiodes, or detectors, are used to detect a light impulse generated by a source, such as an LED or laser diode, and convert it to an electrical impulse. Photodiodes are fabricated from the same materials as LEDs and are used primarily as light detectors in fiber-optics systems. There are two types of gallium-base photodiodes: Photodiodes of GaAlAs

epitaxially grown on a GaAs substrate are used to detect light at short wavelengths, and photodiodes of InGaAsP on a indium phosphide (InP) substrate are used to detect light at longer wavelengths.

Because of its ability to convert light to electrical energy, GaAs is an excellent material for solar cells. Although solar cells are not in widespread use, they have been used to power communications satellites. The advantage GaAs has in this application is its electrical conversion efficiency ;GaAs solar cells have been demonstrated to convert 22% of the available sunlight to electricity, compared with about 16% for silicon solar cells. Because of their higher energy efficiency, GaAs solar cells can be smaller than those constructed of silicon and still provide the same power to the satellite. Consequently, a satellite can carry a greater pay-load when GaAs is used as the solar cell material. Gallium arsenide is also more resistant to radiation than silicon; consequently, GaAs solar cells have a longer life in space environments (Ref 2).

One defense application of optoelectronic GaAs is in night vision equipment. The GaAs component converts infrared radiation to visible light, enabling soldiers to see at night. Four layers of GaAlAs are epitaxially deposited on a GaAs substrate. The substrate and two of the layers are removed, yielding a thin GaAlAs film. Fabrication of these devices is closely controlled to prevent defects in the crystal structure. Even small imperfections in the night vision device cannot be tolerated.

Substitute materials are available for GaAs-base devices in many of the optoelectronic applications. Liquid crystal displays (LCDs), organic compounds that change their light reflection and refraction properties when a current is applied, are the most common substitute for LEDs. For example, LEDs have virtually been replaced by LCDs in one of their original applications--digital watches.

The principal competition for gallium-base laser diodes is from InP devices; because InP devices emit light at a longer wavelength than GaAs devices, they are suitable for fiber-optic communications applications. However, InP technology is at an earlier stage of development than GaAs technology; thus, InP devices are more costly. Germanium-or silicon-base devices are the primary substitutes for gallium-base photodiodes. Competing materials for solar cells are silicon, copper indium diselenide, and cadmium telluride. Although these materials are not as efficient in thin-film solar cells as GaAs, they are generally less costly.

Integrated Circuits

Although ICs currently represent as smaller share of the GaAs market than optoelectronic devices, they are considered to have potential for greater growth. Two types of ICs are produced commercially: analog and digital. Analog ICs are designed to process signals generated by radar and military electronic warfare systems, as well as those generated by satellite communications systems. Digital ICs essentially function as memory and logic elements of computers.

Analog or microwave ICs are used principally in defense applications. Although silicon technology is preferred for signals at frequencies of 3 GHz or less, such as those in television, radios, and computers, silicon operates too slowly at higher frequencies. For these higher frequencies, up to 30 GHz, GaAs microwave ICs are used. One type of GaAs IC, the monolithic microwave integrated circuit (MMIC), combines several discrete components on one chip and can perform functions that used to require bulky circuits consisting of vacuum tubes and waveguides.

One application of GaAs MMICs is in phased-array radar systems. With the development of the GaAs MMIC, the size of radar components can be decreased significantly, with improved signal-to-noise ratios. In phased-array radar, the antenna elements are fixed in a matrix in a single plane rather than in a rotating dish, and they are steered electronically to allow objects in the sky to be individually identified. Because GaAs MMICs are small, the size of the antennas can be reduced significantly, perhaps enough to eventually enable phased-array radar systems to fit on an airplane. Current phased-array radar systems are too large for this application.

Another defense application of GaAs MMICs is in expendable decoys designed to provide fighter aircraft with protection against radar-directed antiaircraft missiles. These decoys contain a small radar transmitter and receiver that, when ejected from an aircraft, begin transmitting the same frequency of radar energy as that reflected from the aircraft, although at a higher strength. Thus a radar-directed missile would home in on the decoy rather than the aircraft. Because of the small size of GaAs MMIC components in the radar, these decoys are only about 150 mm (6 in.) long and 25 mm (1 in.) in diameter.

Gallium arsenide MMICs are also a component of solid-state phased-array jammers. These jammers can be mounted on aircraft to receive and jam radar signals. With GaAs MMIC technology, the need for jamming pods is eliminated, providing space to carry additional weapons.

Gallium arsenide technology is in its infancy, and many defense applications for MMICs are still being developed. These military applications include space-based radar, missile seekers, "smart" munitions, and other electronic warfare devices, as well as navigation and communications equipment. Gallium arsenide MMIC technology may spread to the commercial sector; potential applications include direct-broadcast satellite receivers and business communications equipment such as cellular telephones.

Digital ICs. The first digital GaAs-base ICs were introduced into the U.S. market as off-the-shelf products in 1984. Consequently, their use in computer systems has thus far been limited. Most GaAs components have been used in high-speed supercomputers that are still being developed. Because of the high cost of GaAs as compared with that of silicon, GaAs digital ICs are not expected to replaced silicon ICs in high-volume commercial applications such as personal computers. The use of GaAs digital ICs will instead be confined to operations in which large quantities of data must be interpreted in a very short time, such as in weather-forecasting and surveillance satellites. Gallium arsenide digital ICs also may be used in space-borne signal-processing applications, such as those required for implementation of the U.S. Strategic Defense Initiative.

Although digital GaAs components are not expected to replace silicon in most high-volume applications, two ICs introduced in 1988 were designed to be exact, yet higher-speed, replacements for silicon components. One device is a static random-access memory IC that can be used in supercomputers and as cache storage in less-powerful systems. The other is a programmable logic device for use in personal computers, workstations, network servers, and other applications (Ref 3).

Other Applications

Gallium is used in applications other than those in which its semiconductor properties are important. Gallium oxide is used in making single-crystal garnets for special applications. As used in the electronics industry, the term garnet refers to compounds of mixed M_2O_3 metal oxides. Gallium gadolinium garnet (GGG) is used as the substrate for a bubble memory device. The single crystals are produced by conventional means, and an epitaxial layer is added that contains rare earth oxides. These rare earth oxides provide magnetic domains, or bubbles, that can be oriented to store information and moved by an electric field for information readout.

Memory devices can be made with silicon materials, bubbles, or magnetic tape or disks. These three technologies compete on the bases of cost and size. Silicon devices are low in cost and small, but they require power to retain information; otherwise the data are volatile and subject to loss. Although bubbles are costlier and disks are bulkier than comparable silicon devices, they are nonvolatile, which makes them attractive for certain applications. Although not commonly used in most computer applications, GGG bubble memories are suited to dirty environments and environments that are subjected to wide fluctuations in temperature. Commercial applications for GGG bubble memories include petrochemical data collection and plant machine control.

Gallium, scandium, and gadolinium oxides are used in another mixed-oxide single-crystal garnet. Gallium scandium gadolinium garnet (GSGG) has demonstrated efficiency as a laser host with potential inertial fusion energy applications.

Small quantities of metallic gallium are used for low-melting-points alloys, for dental alloys, and as components in some magnesium, cadmium, and titanium alloys. Gallium is also used in high-temperature thermometers and as a substitute for mercury in switches; it is suitable for these applications because it has the longest liquid range of any element. Gallium has additional uses in glasses and mirror coatings.

Properties and Grades

Gallium arsenide has several properties that give it advantages over silicon in many applications. These advantages are particularly prominent in optoelectronic applications. When stimulated by an electric current, GaAs gives off either visible or infrared light; silicon only gives off energy in the form of infrared radiation or heat. This makes GaAs a useful material for fabricating LEDs and laser diodes, applications for which silicon cannot be used. Both GaAs and silicon can convert light to electrical energy, which makes them useful for photodiodes and solar cells, but GaAs can convert more of the available light to electrical energy, making it more energy efficient.

In IC applications, the properties of GaAs make it especially suitable for defense applications. Gallium arsenide is about ten times more resistant to radiation than silicon. This resistance is essential in satellite operations in space, where components are exposed to damaging radiation from the sun. Gallium arsenide circuits also can operate at higher temperatures than can those of silicon: The maximum temperature is approximately 350 °C (660 °F) for GaAs and 275 °C (525 °F) for silicon. Therefore, the use of GaAs circuits reduces the need for bulky cooling equipment. Also, electrons move up to five or six times faster through GaAs than through silicon, making operation of GaAs-base circuits much faster than that of silicon circuits. High-speed circuit technology is growing in importance because defense applications are becoming increasingly sophisticated and require split-second decision-making capabilities. Typical physical properties of GaAs are provided in Table 1.

Table 1 Selected physical properties of GaAs

Property	**Amount**
Molecular weight	144.6
Melting point, K	1511
Density, g/cm^3	
At 300 K (solid)	5.3165 ± 0.0015
At 1511 K (solid)	5.2
At 1511 K (liquid)	5.7

All of these properties make GaAs attractive, but GaAs has several drawbacks that limit its use only to those applications where its properties are crucial. The first of these drawbacks is its high cost. Another drawback is that GaAs fabrication is a much more intricate process than silicon fabrication. It is much more difficult to grow a single-crystal ingot from two elements than it is from one, especially when the arsenic tends to diffuse out of the melt a temperatures lower than those required for GaAs crystal growth. Consequently, GaAs wafers have more imperfections in the crystal structure than silicon wafers, and these imperfections may be adversely affect the electronic properties of a device constructed on the wafer. Gallium arsenide also has lower production yields than silicon. From ingot to usable wafers, GaAs has an effective yield of about 15%. Gallium arsenide wafers are brittle and subject to breakage during device fabrication, decreasing the effective yield still further.

Purity requirements for the raw materials to produce GaAs are stringent. For optoelectronic devices, the gallium and arsenic must be at least 99.9999% pure; for ICs, a purity of 99.99999% is required. These two purity levels are referred to by several names: 99.9999% pure gallium is often called 6 nines (6N) or optoelectronic grade, and 99.99999% pure gallium is called 7 nines (7N), semiinsulating, or IC grade. For 7N gallium, the total of the impurities must be less than 100 ppb. In addition to the difficulty of consistency producing material with such high purity, it is difficult to analyze for the small quantity of impurities. Certain impurities can cause more problems during GaAs production than others. The impurities of most concern are calcium, carbon, copper, iron, magnesium, manganese, nickel, selenium, silicon, sulfur, tellurium, and tin. Generally these elements should be present in concentrations of less than 1 ppb in both the gallium and

arsenic. Lead, mercury, and zinc should be present in concentrations of less than 5 ppb. Although aluminum, chlorine, and sodium are often present, each of their concentrations should be less than 10 ppb.

Resources

Although gallium is as abundant in the crust of the Earth as lead, it is widely disseminated and is rarely found in concentrations greater than 0.1%. Consequently, gallium is nearly always recovered as a by-product during processing of ores or other materials to recover other metals. The principal materials in which gallium is found are bauxite, coal, phosphate ores, and sphalerite (zinc ore). Of these, gallium is currently commercially recovered during the processing of bauxite to alumina and the processing of sphalerite to zinc.

Bauxite generally is considered the best source of by-product gallium because gallium occurs in virtually all bauxites and is somewhat concentrated during the extraction of alumina from bauxite via the Bayer process. The gallium content of bauxite varies depending on the individual deposit, averaging about 50 ppm for the world. Bauxites containing high quantities of gallium, 70 to 80 ppm, are found in India, Suriname, and the United States. Figure 2 shows an estimate of the world gallium reserves available from bauxite, based on bauxite reserves, and the average gallium content of the bauxite in each country (Ref 5).

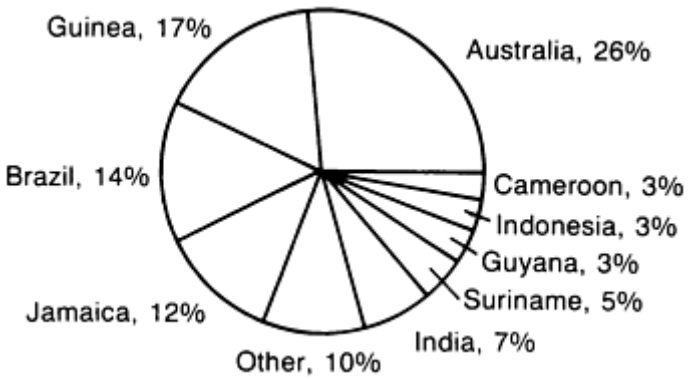

Fig. 2 World gallium reserves in bauxite. Total is 400,000 metric tonnes, based on a 40% recovery.

Although world gallium reserves of over 1 million metric tonnes (or megagrams, Mg) are available from bauxite, much of this bauxite will not be mined for many decades, and only about 40% of the available gallium is recoverable with current technology. According to U.S. Bureau of Mines projections, Australia, Jamaica, the Soviet Union, and the United States have the most potential for gallium recovery from bauxite.

Because gallium is not recovered at many of the alumina plants throughout the world, and because most of the gallium originally contained in the bauxite does not dissolve during the alumina extraction process, large quantities of gallium are discarded in the red mud residue. Although not currently considered a gallium resource material, the red mud residue represents a large potential gallium resource. Much of the residue is contained in tailings ponds near the alumina refineries and would be an easily accessible resource.

Zinc ores also represent a significant source of gallium, although not all zinc ores contain gallium. Sphalerite, a zinc sulfide mineral, generally contains detectable quantities of gallium, but little quantitative information is available to present an accurate assessment of the gallium potential of these ores. Based on the assumption that the average gallium content of sphalerite is 50 ppm, domestic sphalerite reserves of 21×10^6 Mg contain 1050 Mg of gallium. Total world reserves of 147×10^6 Mg of sphalerite may contain as much as 7350 Mg of gallium. The countries with the largest sphalerite reserves are Canada, the United States, and Australia. As with bauxite, much of this ore will not be mined for many decades and represents a long-term source of gallium.

Coal fly ash and phosphate flue dusts also contain gallium, but because of the availability of gallium from bauxite and sphalerite, it is unlikely that these materials would be used as principal sources of gallium. However, technology for the recovery of gallium from these materials has been developed.

Recovery Technology

Gallium Recovery From Bauxite. Throughout the world, alumina is recovered from bauxite by the Bayer process. In this process, alumina is extracted from bauxite through digestion with a hot caustic solution. After the slurry is cooled and solid residue is separated from the aluminum-containing liquor, the solution is seeded with alumina trihydrate crystals to precipitate the dissolved aluminum as alumina trihydrate. Alumina trihydrate is separated from the solution and calcined to produce alumina, and the caustic solution is recycled to the bauxite digestion step.

Because gallium is chemically similar to aluminum, it tends to remain with aluminum during processing. When the aluminum is extracted during digestion, gallium is also extracted. Gallium is not removed from the solution during subsequent processing steps, and because the solution is recycled, gallium builds up to an equilibrium concentration of 100 to 125 ppm. When gallium recovery is desired, a bleed steam is separated from the caustic solution before it is recycled to the digestion step. Crude gallium metal, 97.0 to 99.9% pure (3N), is recovered from the bleed solution by two principal processes: the Beja process and the de la Bretèque process. Simplified flow-sheets for these processes are shown in Fig. 3 and 4.

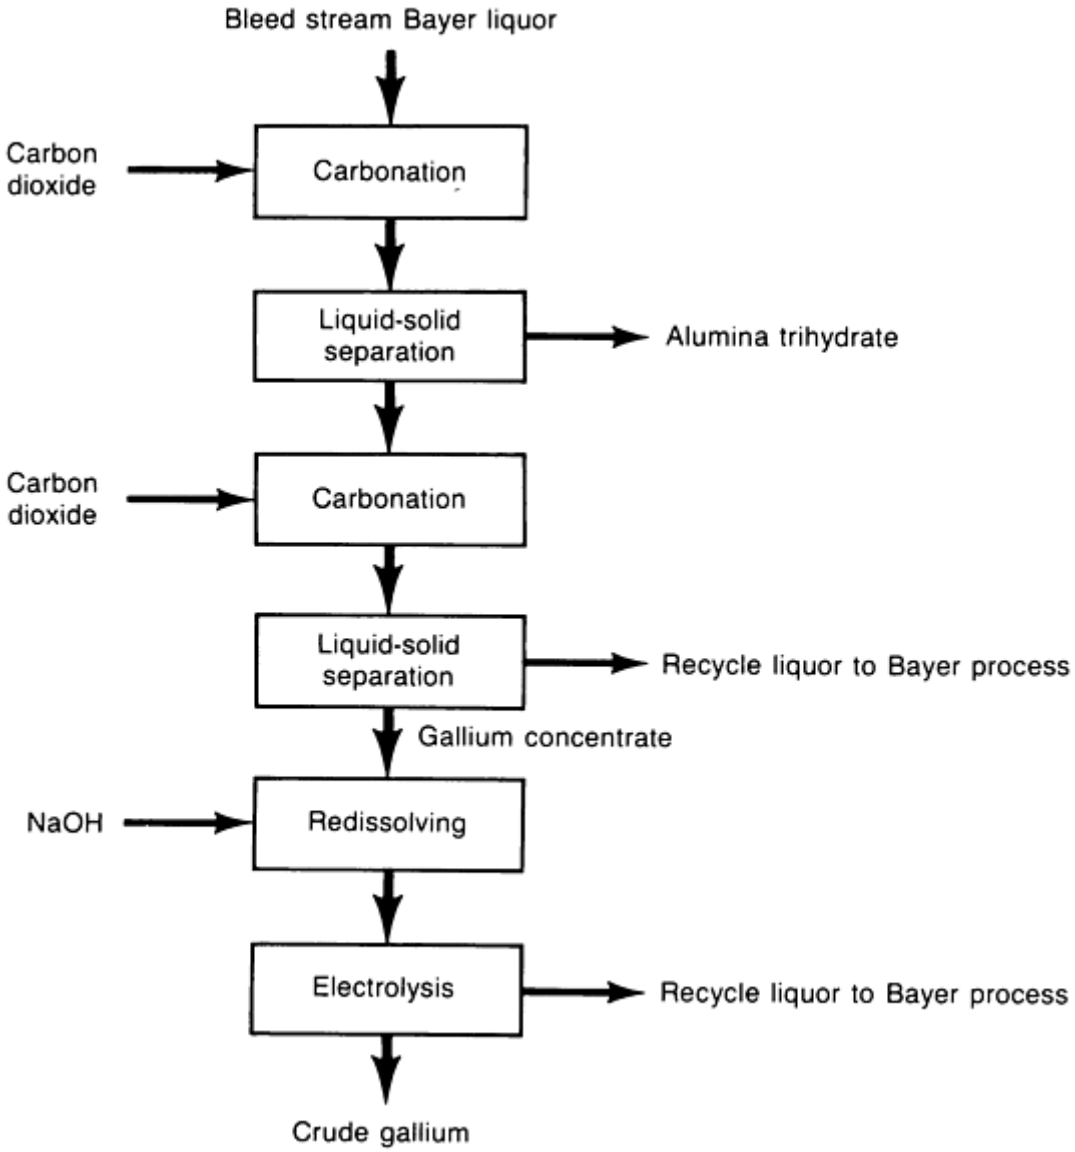

Fig. 3 Beja process for recovering crude gallium from Bayer liquors

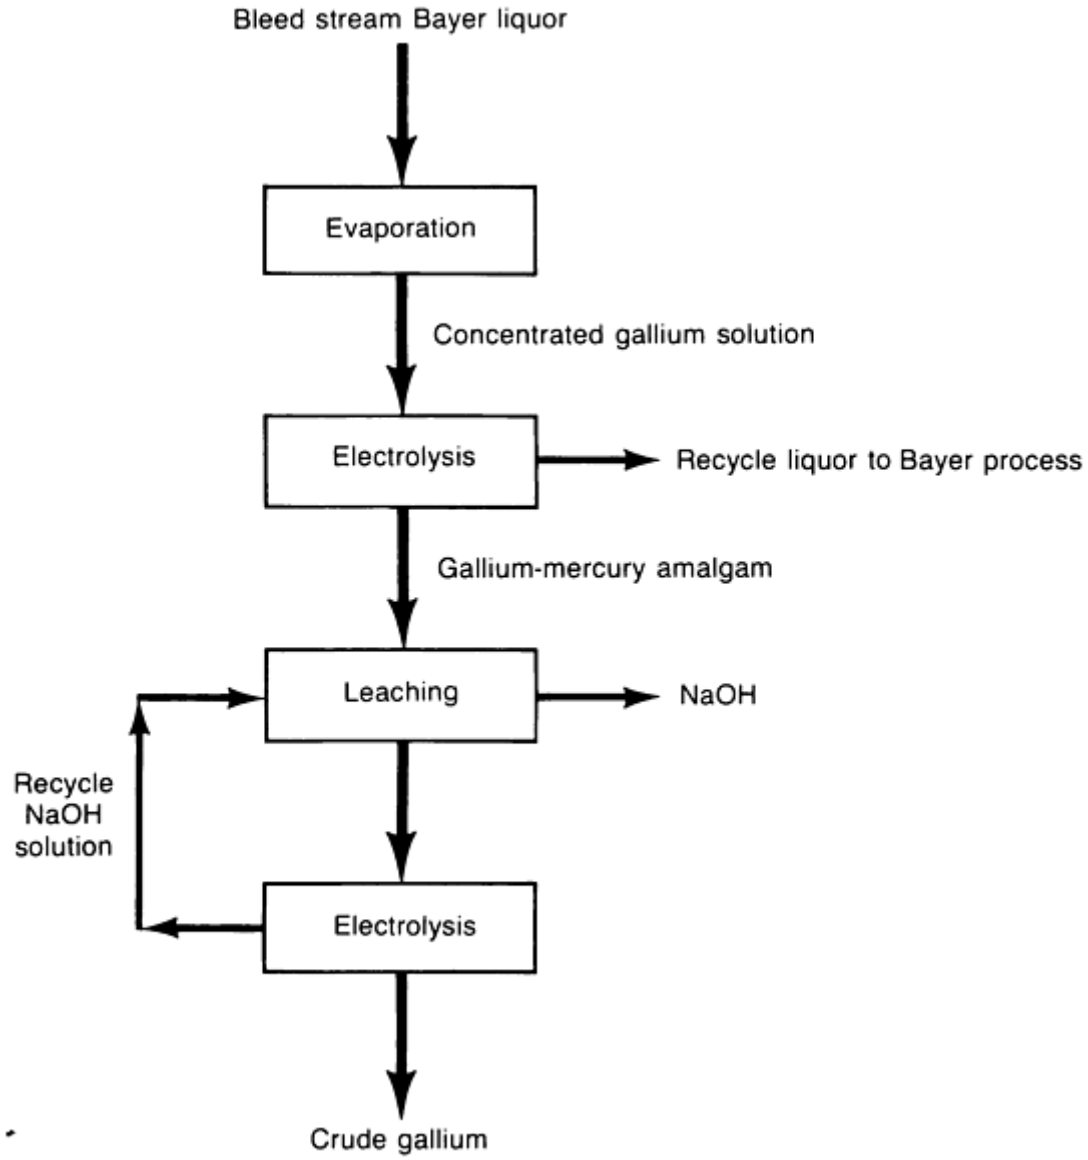

Fig. 4 The de la Bretèque process for recovering crude gallium from Bayer liquors

In the Beja process, carbon dioxide is injected into the bleed solution to precipitate aluminum not recovered in the Bayer process as alumina trihydrate. The trihydrate is separated from the solution, and the gallium-containing solution is carbonated again. In the second carbonation, a gallium precipitate containing between 0.3 and 1% Ga is recovered. Both of the carbonation steps are carefully controlled so that about 90% of the aluminum is removed during the first carbonation and 90% of the gallium is precipitated during the second carbonation. After the gallium precipitate is separated from the solution, which is recycled to the Bayer process, the precipitate is dissolved in a caustic solution to increase the gallium-to-aluminum ratio. This solution is electrolyzed to recover crude gallium as a liquid. The spent solution is recycled to the Bayer process (Ref 6).

In the de la Bretèque process, the bleed stream from the Bayer process is concentrated by evaporation to increase the gallium concentration. The concentrated solution is directly electrolyzed using a highly agitated mercury cathode. The agitation allows the gallium to form an amalgam with the mercury. When the gallium concentration reaches about 1% in the amalgam, it is drawn off and leached with a caustic solution. This yields a concentrated gallium solution from which crude gallium can be recovered by electrolysis (Ref 7).

Because mercury losses are significant owing to the high level of cathode agitation in the de la Bretèque process, a modification to the process was developed by Vereinigte Aluminum Werke AG (VAW) of the Federal Republic of Germany. Instead of a gallium-mercury amalgam prepared by electrolysis, this process uses a sodium-mercury amalgam

prepared by electrolyzing the caustic solution with a mercury cathode. Gallium is then extracted by a cementation process as the gallium in solution replaces the sodium in the amalgam. Subsequent gallium recovery follows the same steps as in the de la Bretèque process.

Although the de la Bretèque process and the VAW modification are the most commonly used processes, several companies have developed proprietary recovery techniques that they claim are less costly than conventional processes. Rhône-Poulenc S.A. uses a liquid-liquid extraction technique at its plants in France and Australia to recover gallium from Bayer liquors. The Sumitomo Chemical Company of Japan uses an unidentified absorbent to extract gallium directly from Bayer liquors.

Gallium Recovery From Zinc Ore. Dowa Mining Company, the only company that currently recovers gallium from zinc ore, uses an electrolytic method for recovering zinc. In this method, a roasted zinc concentrate is leached with sulfuric acid to produce a zinc sulfate solution, which is neutralized to remove impurities. Impurities that precipitate from the zinc sulfate solution include gallium, aluminum, and iron. Leaching this residue with a caustic solution extracts the gallium, along with the aluminum and iron impurities. After the remaining residue is separated from the gallium-containing solution, the solution is neutralized to precipitate the metal hydroxides. The hydroxide solids are leached with hydrochloric acid to dissolve gallium and aluminum, and the gallium is separated from the aluminum in solution by solvent extraction with ether. Distillation of the ether solution yields a gallium-rich residue that still contains some iron, which is removed by treating the residue with a strong caustic solution that extracts the gallium and leaves the iron as a solid. Iron residue is filtered from the gallium-containing solution, and crude gallium is recovered by electrolysis. A simplified flowsheet for this process is shown in Fig. 5.

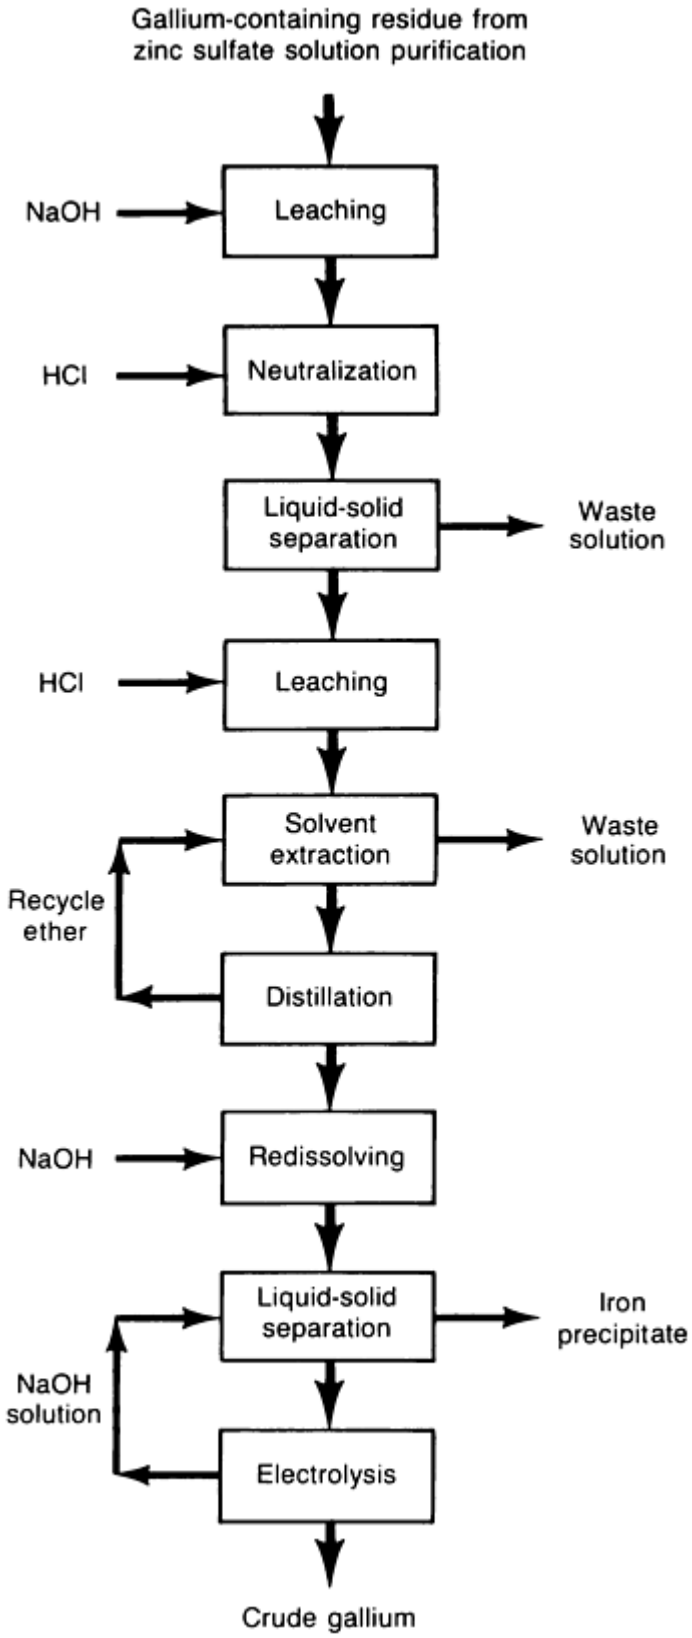

Fig. 5 Gallium recovery from zinc ore

Gallium Recovery From Other Sources. Other sources of gallium that have been investigated include phosphate flue dust, coal fly ash, aluminum smelter flue dusts, and iron oxide minerals found in Utah. The only sources that have been commercially treated to recover gallium are the minerals in Utah and aluminum smelter flue dusts. In 1986, St. George Mining Corporation, a subsidiary of Musto Exploration Ltd., began recovery of gallium from an abandoned

copper mine near St. George, UT. Although much of the copper had been mined, the remaining iron oxide minerals contained an average of 0.042% Ga. St. George Mining ceased operation in 1987 and filed for bankruptcy. Hecla Mining Company purchased the property in 1989 and restarted operations in 1990, after completing process development.

In the Hecla process (Fig. 6), copper, germanium, and gallium are separated from the ore by a sulfuric acid leach. After neutralization of the leach liquor with ammonia, separation of the three metals is accomplished by selective solvent extraction. Cathode copper, 4N gallium metal, and a sodium metagermanate concentrate are recovered with this process.

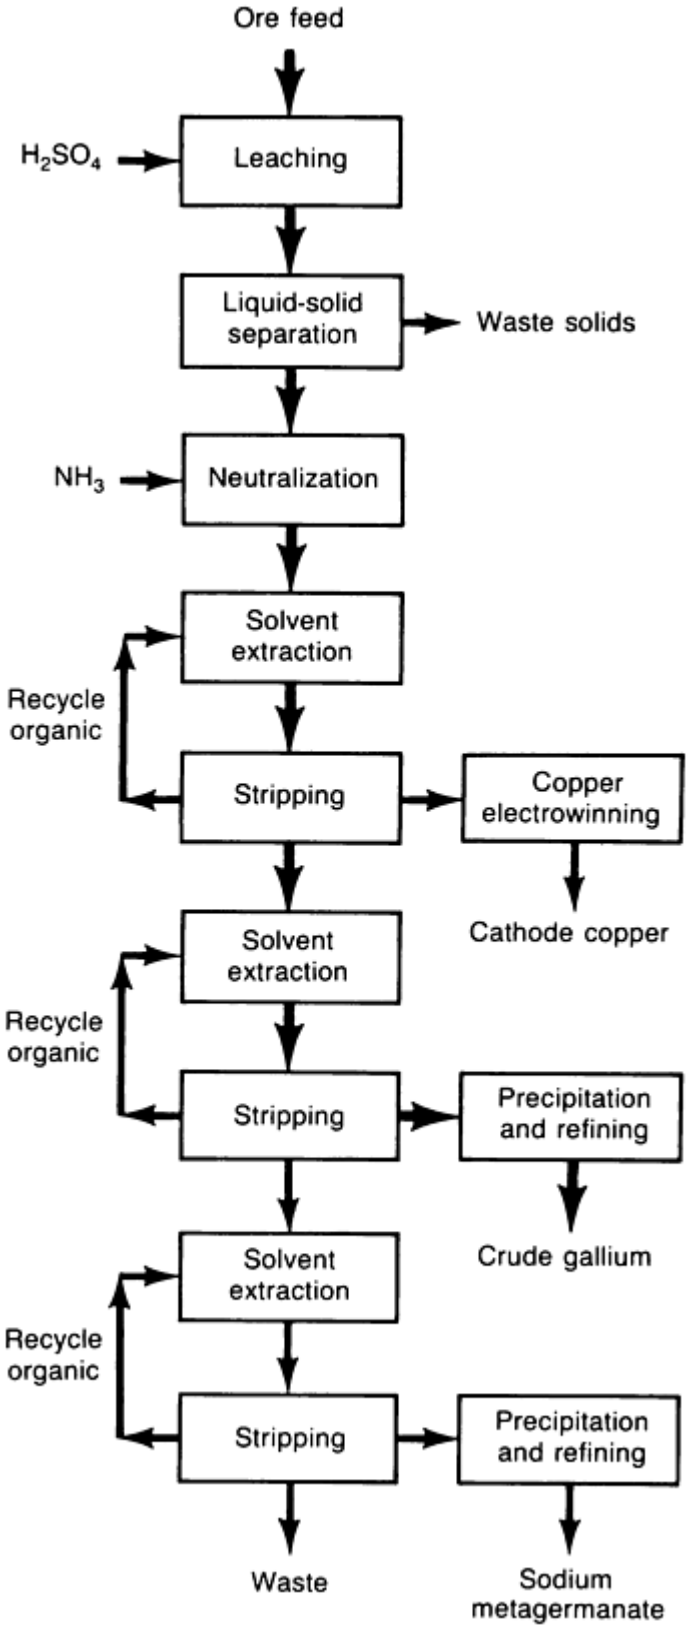

Fig. 6 Gallium recovery from the Hecla Mining Company mine near St. George, UT

In July 1987, Elkem A/S of Norway began producing crude gallium by using aluminum smelter flue dust as a source material. Dusts generated at two smelters in Mosjoen and Tyssedal are blended to yield material with average concentrations of:

Element	Concentration, %
Carbon	33
Fluorine	17
Oxygen	17
Aluminum	13
Sodium	9
Iron	6
Sulfur	3
Calcium	1.5
Gallium	0.5

Leaching the flue dust with hydrochloric acid extracts the gallium. Solids are filtered from the liquid phase and mixed with portland cement before disposal. The liquid phase undergoes a series of solvent extraction stages to separate gallium from dissolved impurities. After cleaning and stripping, crude gallium is recovered by electrolysis of the water phase. A simplified flowsheet for this process is shown in Fig. 7.

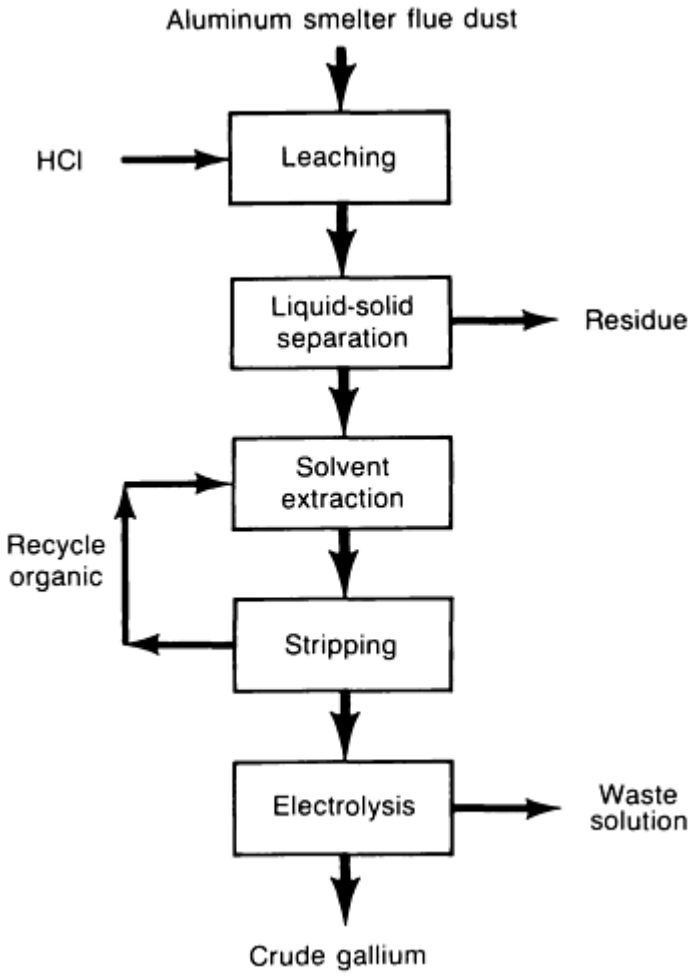

Fig. 7 Elkem A/S process for recovering gallium from aluminum smelter flue dust

Gallium Purification. Most applications for gallium require metal with a purity of either 6N or 7N. Crude gallium is purified in essentially two steps. The first step produces 99.99% pure (4N) gallium, and the second produces metal with a purity of 6N to 7N.

Many of the impurities in crude gallium occur in the surface oxide or as finely dispersed phases in the metal. Liquid gallium filtration and heating under vacuum remove these types of impurities. Metallic impurities can be reduced to less than 0.01%, producing 4N gallium, by sequential washing with hydrochloric acid. Another method that can be used is electrolytic refining, which involves anodic dissolution of gallium in an alkaline solution and then deposition at a liquid gallium cathode.

The principal method used to produce 6N and 7N metal is gradual crystallization of molten gallium. In this process, impurities remain in the liquid phase and do not contaminate the gallium crystal. Crystallization is repeated until gallium of the desired purity is obtained. Another method of producing high-purity gallium is to convert the gallium to a halide compound, such as gallium trichloride, which is then zone refined. High-purity gallium is recovered by electrolysis of the halide compound.

Fabrication of GaAs Crystals

Gallium arsenide single crystals are more difficult to fabricate (grow) than those of silicon. With silicon, only one material needs to be controlled, whereas with GaAs, a one-to-one ratio of gallium atoms to arsenic atoms must be maintained. At the same time, arsenic volatilizes at the temperatures needed to grow crystals. To prevent a loss of arsenic, which would result in the formation of an undesirable gallium-rich crystal, GaAs ingots are grown in an enclosed environment.

Crystal Growth Methods. Two basic methods are used to fabricate GaAs single-crystal ingots. One is the boat-growth horizontal Bridgeman (HB) technique, which is also known as the gradient freeze technique; the other is the liquid-encapsulated Czochralski (LEC) technique. Ingots produced by the HB method are D-shaped and have a typical cross-sectional area of about 13 cm^2 (2 $in.^2$). Single-crystal ingots grown by the LEC method are round and are generally 75 mm (3 in.) in diameter, with a cross-sectional area of about 45 cm^2 (7 $in.^2$). Some 100 mm (4 in.) diam GaAs ingots have been produced by the LEC method, but they are not yet the industry standard.

In HB growth, gallium and arsenic in the proper ratio are placed in one end of a silicon dioxide (quartz) or pyrolytic boron nitride boat. A seed GaAs crystal is contained at the other end of the boat. The boat is placed in a sealed quartz tube, which is evacuated to a very low pressure. The tube is placed in a multiple-zone furnace, where the gallium and arsenic react to form GaAs. The compound is heated to 1240 °C (2265 °F), the melting point of GaAs. The GaAs melt is slowly cooled from the seed end, resulting in single-crystal growth.

In the LEC method of crystal growth, carefully weighed pieces of gallium and arsenic are melted in a pressurized vessel (crystal puller). The GaAs melt is contained in a crucible constructed of either high-purity quartz or pyrolytic boron nitride. The melt is covered with a layer of boric oxide, which retards arsenic loss from the melt by sublimation. A seed crystal is lowered through the boric oxide into the melt and slowly withdrawn as both the seed and crucible are rotating.

HB Versus LEC Ingots. Each of the two methods produces GaAs ingots with particular advantages and disadvantages. Crystals formed by the boat-growth HB method are particularly suitable for optoelectronic applications because their structure is highly perfect with respect to dislocations. Optoelectronic devices also requires crystals with a high doping concentration, which boat-grown crystals readily provide because the silicon dissolved from the quartz boat contributes to crystal doping. However, the high doping concentration becomes a problem if semiinsulating GaAs crystals for ICs are being produced. The silicon impurities are called shallow donors, or *N*-type dopants. To compensate for these impurities, either a controlled quantity of gallium oxide can be added to the melt, or chromium (a deep acceptor, or *P*-type dopant) can be added. Also, crystal growth can be accomplished in a boron nitride container, which eliminates any contact with silicon-containing material during growth.

The shape of the HB-grown ingot makes it inconvenient for subsequent wafer processing because automated wafer-processing systems are designed to handle round wafers. Ingots grown by LEC generally contain more crystal structure defects, that is, they have dislocation densities, than HB-grown ingots. This affects the electronic properties of the device constructed on the GaAs. Dislocation densities in HB wafers normally run between 500 and 20,000/cm^2 (3000 and 130,000/$in.^2$); those in LEC wafers can be as large as 100,000/cm^2 (645,000/$in.^2$). Because chips are batch processed wafer by wafer, the larger the wafer, the more chips per wafer and the lower the cost per chip. A 75 mm (3 in.) diam LEC-grown wafer can yield more of the same-size chips than can a 50 × 40 mm (2 × 1.5 in.) HB wafer. Consequently, the capital costs for an HB system are significantly less than those for an LEC system.

Wafer Processing and Doping. After the ingots are grown, the ends are cut off, and the ingots are shaped by grinding the edges. Ingots are then sliced into wafers (Fig. 8). Wafers go through several stages of surface preparation, polishing, and testing before they are ready for device manufacture or epitaxial growth. Wafer preparation steps are done in a clean room and with minimal contact to avoid introducing surface contaminants. In LEC growth, the effective yield from starting material finished wafers is currently less than 15%.

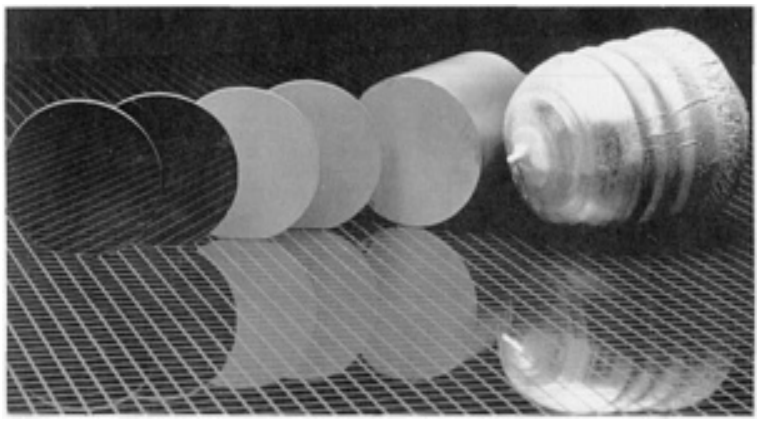

Fig. 8 LEC-grown GaAs ingot and wafers. Courtesy of Morgan Semiconductor Division of Ethyl Corporation

Pure GaAs is semiinsulating, which means that it is not a conductor of electricity. In order for GaAs to conduct electricity, a small number of atoms of another element must be incorporated into the GaAS crystal structure; the incorporation of these atoms is called doping. The atoms act as electron donors or electron acceptors. Electron donor atoms have one more electron than the atoms that they are replacing, and this extra electron is free to move within the crystal as an electrical charge carrier. Electron acceptors have one less electron than the atoms they are replacing and behave as positively charged particles to serve as electrical charge carries (Ref 8).

Before devices can be manufactured from GaAs wafers, the wafers must be doped with another metal or metals. Normally, that is accomplished either by ion implantation or by some type of epitaxial growth. Because GaAs is a semiinsulating substrate, no special isolation areas are required to separate each device fabricated on the chip. The lack of these isolation areas results in more-compact higher-density circuits, and adds to the speed advantage of GaAs.

In ion implantation, ions of another material are implanted into specific areas of the semiinsulating GaAs to make those areas electronically active. Areas of the chip that are to remain semiinsulating are covered with a photoresist mask before ion implantation. The process of ion implantation may be repeated several times with different metals on different areas of the chip, depending on the type and complexity of the device being manufactured. After ion implantation, the GaAs must be annealed at about 850 °C (1560 °F) to activate the implanted dopants and remove crystal damage incurred during implantation. When annealing, as in crystal growth, several techniques, including encapsulation of the chip, are used to prevent arsenic losses at the elevated temperature. After doping, optoelectronic device of IC manufacture can be completed through deposition of layers of metals and insulators by various techniques.

A similar technique, called ion cluster beam, is not used as frequently as ion implantation. In this technique, ions are grouped together and implanted into the wafer at lower speeds than those used in ion implantation. This process is reported to result in less damage to the crystal structure.

The deposition of an epitaxial layer is another means of creating electronically active regions on the GaAs substrate. There are four principal methods for growing epitaxial layers: liquid-phase epitaxy (LPE), vapor-phase epitaxy (VPE), metal-organic chemical vapor deposition (MOCVD), and molecular beam epitaxy (MBE). Liquid-phase epitaxy is generally not considered suitable for complex semiconductor production because it cannot be as precisely controlled as the other three techniques. In LPE, the substrate wafer is contained in a graphite boat within a quartz furnace tube, where it is contacted with solutions containing the metals to be deposited. Cooling the solution causes the metals to precipitate on the substrate. LPE produces relatively thick epitaxial layers, and the boundaries between layers are gradual rather than sharply defined.

Two methods of VPE are used to grow epitaxial layers on a GaAs substrate: the hydride method and the chloride method. In VPE, GaAs substrates are mounted in a reactor. To make GaAsP epitaxial layers, two gaseous streams are introduced into the reactor. In the hydride process, one gas stream combines arsine (AsH_3) and phosphine (PH_3) with a hydrogen carrier gas; the other gas stream is a hydrochloric acid gas that has been passed over a gallium reservoir to form gallium trichloride, and that also is mixed with a hydrogen carrier gas, Dopants are added to the gas streams if necessary. Gallium trichloride reacts with the AsH_3 and PH_3 gases to deposit a GaAsP layer on the substrate. In the chloride process, arsenic

trichloride and phosphorus trichloride gases are substituted for AsH_3 and PH_3. Vapor-phase epitaxy technology can coat multiple wafers at the same time, and the layer thickness, molecular composition, and dopant concentration can be more closely controlled than with LPE.

In MOCVD, wafers are placed in a quartz reactor, which is maintained at atmospheric or slightly reduced pressure and at a temperature between 650 and 750 °C (1200 and 1380 °F). Metals to be deposited are in the forms of gases that chemically combine on the heated substrate. For example, to prepare a GaAlAs layer, gallium and aluminum are present in the form of organic gases, generally trimethyl or triethyl gallium and aluminum [$(CH_3)_3Ga$ or $(C_2H_5)_3Ga$ and $(CH_3)_3Al$ or $(C_2H_5)_3Al$] in a hydrogen carrier gas. Arsenic is in the form of AsH_3 in the hydrogen carrier gas. Dopants may also be added. The flow rates of these gases are carefully controlled. As the gases mix in the reactor and contact the hot wafers, they react to form GaAlAs and methane or ethane, and the GaAlAs deposits on the substrate wafers.

With MBE, the GaAs substrate is mounted on a heating block in a reactor maintained under a vacuum, along with effusion cells containing the elements to be deposited. For a GaAlAs layer, the effusion cells would contain gallium, aluminum, arsenic, and dopants. The elements are heated to temperatures that cause them to evaporate. By precise opening and closing of mechanical shutters in front of the effusion cells, the concentration of each element as it deposits can be carefully controlled.

With both MOCVD and MBE, the process can be repeated to build many thin layers of materials with differing compositions. After the epitaxial layers are deposited, device manufacture can be completed through deposition of metallic and insulating layers.

As with crystal growth methods, both MOCVD and MBE have advantages and disadvantages. Metal-organic chemical vapor deposition can coat multiple wafers at a time, whereas MBE systems can coat only one. Molecular beam epitaxy requires a vacuum, whereas MOCVD can be performed at atmospheric pressure. The cost of MOCVD equipment is approximately one-third the cost of MBE equipment. Molecular beam epitaxy provides the most precise control over the composition and thickness of the epitaxial layers, and it also provides the greatest reproducibility. In addition, MOCVD uses AsH_3 gas and therefore must be performed in a room equipped with safety equipment to prevent the toxic gas from escaping.

Secondary Recovery

Sources of Scrap. Because of the low yield in processing gallium to optoelectronic devices or ICs, substantial quantities of new scrap are generated during the various processing stages. These wastes have varying gallium and impurity contents, depending upon the processing step from which they result. Gallium-arsenide-based scrap, rather than metallic gallium, represents the bulk of the scrap that is recycled.

During the processing of gallium metal into a GaAs device, waste is generated during the GaAs ingot formation. If the ingot formed does not exhibit single-crystal structure or if it contains excessive quantities of impurities, it is considered to be scrap. also, some GaAs remains in the reactor after the ingot is produced and can be recycled.

During the wafer preparation and polishing stage, significant quantities of wastes are generated. Before wafers are sliced from the ingot, both ends of the ingot are cut off and discarded because impurities are concentrated at the tail end of the ingot and crystal imperfections occur at the seed end. These ends represent up to 25% of the weight of the ingot. As the crystal is sliced into wafers, two types of wastes are generated: saw kerf, which is essentially GaAs sawdust, and broken wafers. When the wafers are polished with an abrasive lapping compound, a low-grade waste is generated.

During the epitaxial growth process, various wastes are produced, depending on the growth method used. In LPE, metallic gallium contaminated with arsenic and dopant metals results, and in VPE, exhaust gases containing GaAs are produced. Because GaAs is a brittle material, wafers can break during the fabrication of electrical circuitry on their surfaces. These broken wafers can also be recycled.

The gallium content of these waste materials ranges from less than 1 to 99.99%. Wastes from LPE normally have the highest gallium content, 98 to 99.99%. Ingot ends and wafers broken during processing generally contain 39 to 48% Ga, VPE exhaust gases contain 6 to 15% Ga, saw kerf contains up to 30% Ga (wet basis), and lapping compound wastes contain less than 1% Ga. These wastes are contaminated with small quantities of many impurities, the most common being aluminum oxide, copper, chromium, germanium, indium, silicon, silicon carbide, tin, and zinc. Wafers broken during the fabrication of electrical circuitry also contain gold and silver impurities. In addition to metallic impurities, the scrap may be contaminated with materials introduced during processing, such as water, silicone oils, waxes, plastics, and glass.

In the processing of GaAs scrap, the material is crushed, if necessary, and then dissolved in a hot acidic solution. This acid solution is neutralized with caustic solution to precipitate the gallium as gallium hydroxide, which is filtered from the solution and washed. The gallium hydroxide filter cake is redissolved in a caustic solution and electrolyzed to recover 3N to 4N gallium metal. This metal can be refined to 6N or 7N gallium by conventional purification techniques if desired.

Some GaAs manufacturers recycle their own scrap, or scrap may be sold to metal traders, to a company that specializes in recycling GaAs, or to the GaAs manufacturer's gallium supplier, who can recover the gallium and return it to the customer. In general the prices commanded by GaAs scrap parallel the price fluctuations of 4N gallium metal. Also, prices are dependent on the type and gallium content of the scrap; saw kerf sells for a lower price than ingot scrap, which in turn sells for a lower price than metallic (LPE) scrap.

Although GaAs scrap is an important component in the flow of gallium materials throughout the world, it cannot be considered an additional long-term source of world gallium supply. Gallium arsenide scrap that is recycled is new scrap, which means that it has not reached the consumer as an end product and is present only in the closed-loop operations among the companies that recover gallium from GaAs scrap and the wafer and device manufacturers. Because this closed loop occasionally crosses international boundaries, it is difficult to distinguish between gallium recovered from scrap and virgin gallium when evaluating the gallium supply of an individual county.

World Supply and Demand

Little information is published detailing gallium production and trade data. The United States and Japan are the only countries for which detailed data are available. In many cases, no distinctions are made in published figures among virgin, recycled, and purified gallium. As an example, the United States ships some GaAs scrap to the Federal Republic of Germany for gallium recovery, and the recovered gallium is returned to the United States. This gallium may be counted twice as a part of the domestic supply. Or, one country recovers virgin gallium and ships it to a second country for refining to 7N gallium. Each country may count this as production, thus doubling the quantity of gallium that appears to be available. Consequently, the figures determined for gallium supply and demand are subject to significant interpretation.

Gallium Production. Tables 2 and 3 show estimates of both primary and secondary gallium production. These figures were derived from U.S. production data, published by the U.S. Bureau of Mines; U.S. import data, supplied by the U.S. Commerce Department; and production and import data for Japan, published in *Roskill's Letter From Japan.* Because most of the world's gallium demand is centered in Japan and the United States, these sources are believed to provide data on about 85% of the gallium produced in the world.

(a) New scrap only

High-Purity Arsenic Production. Arsenic is recovered as arsenic trioxide in about 20 countries for the smelting or roasting of nonferrous metal ores or concentrates. Arsenic metal, which accounts for only about 3% of the world demand for arsenic, is produced by the reduction of arsenic trioxide. Commercial-grade arsenic metal, 99% pure arsenic, is produced in only a few countries, and this grade accounts for the majority of arsenic metal production. High-purity arsenic, 4N purity or greater, is used in the semiconductor industry.

Gallium Arsenide Ingot, Wafer, and Device Manufacturers. Table 4 lists companies involved in various phases of GaAs wafer and device manufacture. As is evident from the number of companies listed for these countries, most of the advanced GaAs manufacturing occurs in the United States and Japan. Some companies are fully integrated from GaAs ingot manufacture through device manufacture, whereas others make either wafers or devices.

Research and Development

Considerable research is being done concerning all phases of gallium extraction, GaAs material properties, and GaAs-based device manufacturing. Because GaAs IC manufacture is still in the developmental stage, much of the research activity centers on designing nd manufacturing devices.

The U.S. Department of Defense sponsors a great deal of gallium research through Defense Advanced Research Projects Agency (DARPA) and the National Aeronautics and Space Administration (NASA), as well as through the laboratories of the service branches. Over the past few years, the focus of DARPA in funding projects has been to increase the efficiency of processing GaAs devices. Although a variety of microwave and digital ICs have been fabricated from GaAs, many of these are prototype devices. Projects funded through DARPA have been principally designed to increase the limited production of the prototype devices to full-scale manufacturing. Improving the manufacturing process may allow more complex ICs to be developed with increased radiation resistance and faster speed. The principal focus of NASA-funded research, on the other hand has been the investigation of optoelectronic devices, particularly solar cells. The main thrust of this research is to increase the energy efficiency and reduce the cost of GaAs-base solar cells.

In 1986, the Department of Defense began a $135 million program to develop MMICs for military electronic applications. The program is called MIMIC, for microwave/millimeter wave monolithic integrated circuit. MIMIC would provide funds for companies that are already involved in GaAs research to accelerate their activities.

Most of the companies that are involved in the commercial GaAs market, both in optoelectronic devices and ICs, are involved in the development of devices that optimize the properties of GaAs. Among the new devices being developed are the high-electron-mobility transistor (HEMT), the heterojunction bipolar transistor (HBT), the ballistic transistor, and the quantum-well laser. HEMT consists of an undoped GaAs substrate with a thin epitaxial layer of silicon-doped GaAlAs on top. When an electric current is passed through the HEMT, electrons from the impurity atoms in the GaAlAs layer fall into the GaAs layer, where they move very fast. The HBT operates in essentially the same manner, but the GaAlAs layer is more highly doped. Both HEMTs and HBTs could increase the signal processing speed in MMICs and digital ICs.

A ballistic transistor is basically a sandwich structure with two GaAlAs layers on both sides of an ultrathin GaAs layer. As in an HEMT device, electrons from the GaAlAs layer fall into GaAs layer and pick up speed. However, because the GaAs layer is so thin, electrons pass through the GaAs layer and into the second GaAlAs layer without slowing down. This enhanced electron movement could increase the speed of digital ICs and would allow MMICs to operate at high frequencies.

The quantum-well laser is fabricated in the same way and with the same material as the ballistic transistor, but instead of passing through the GaAs layer, electrons are trapped in this layer. By confining the charge carriers to this very small area, the chance is increased that they will recombine to emit light. Consequently, this structure increases the amount of light generated for a specific electrical signal (Ref 9). Development of these new devices has been made possible with the advent of MOCVD and MBE, which are capable of depositing ultrathin layers on a substrate.

With increased emphasis on developing new devices, demands have been placed on the GaAs substrate manufacturers to supply better-quality and more-uniform substrates. Consequently, GaAs wafer manufacturers have been refining their crystal growth techniques to produce material with fewer defects, to improve the yield from gallium and arsenic metals to GaAs wafers, and to increase the scale of production. At the same time, wafer manufacturers are trying to produce large-diameter wafers that ultimately could increase the yield form wafer to device.

Companies involved in epitaxial growth are also working to improve properties such as the uniformity in the thickness and composition of the epitaxial layers. Recently, metal-organic molecular beam epitaxy (MOMBE), also referred to as chemical beam epitaxy, has been developed to combine advantages of MOCVD and MBE. These advantages include superior epitaxial layer thickness and uniformity, defect-free surfaces, the ability to grow layers on more than one wafer at a time, and the ability to introduce and control phosphorus atoms for optoelectronic device fabrication. The MOMBE technology was introduced in early 1987.

Work is also being done on combining GaAs with other materials to take advantage of the best qualities in each material. Prototypes of GaAs epitaxial layers growth on silicon substrates have been produced, and sample quantities have been shipped to customers for testing. By using GaAs layers on a silicon wafer, the superior structural properties of silicon can be combined with the electrical and optical properties of GaAs. Larger, more durable wafers can be produced with light-emitting properties and increased radiation resistance.

Two methods can be used for producing the combination GaAs-silicon wafers. Gallium arsenide can be deposited by MOCVD or MBE over the entire silicon wafer, a method called blanket epitaxy, or islands of GaAs can be epitaxially deposited on the silicon wafer, a method called selective epitaxy. Wafers produced by blanket epitaxy could replace bulk GaAs wafers for GaAs MMICs and digital ICs. Wafers produced by selective epitaxy can combine silicon ICs with GaAs optoelectronic devices, GaAs MMICs or GaAs digital ICs. Blanket epitaxial wafers would require less gallium than that consumed in the fabrication of bulk GaAs wafers, and selective epitaxial wafers would allow GaAs to be used in areas in which its use is not currently feasible.

In solar cells, where GaAs has not supplanted silicon to any great degree, epitaxially deposited GaAs layers on germanium substrates may represent hybrid substitute material for silicon. Gallium arsenide is fragile and can only be deposited in thick layers on a GaAs substrate. This puts GaAsat a disadvantage in comparison with silicon, which is sturdy and can be epitaxially grown in thinner layers. Germanium substrates are stronger and less costly than GaAs substrates, and GaAs epitaxial layers can be grown thinner using MOCVD. Consequently, the increased energy efficiency and radiation resistance of GaAs solar cells can be exploited while reducing the total weight of GaAs-based solar cells. While providing the same amount of power as silicon solar cells, GaAs-on-germanium solar cells can be made smaller, thereby allowing a satellite to carry a larger payload.

By continuing to push the limits of GaAs technology, researchers have also developed the optical equivalent of the transistor, a GaAs-base IC that controls light in the same manner a transistor controls electrical current. Thousands of alternating layers of GaAs and GaAlAs, each 40 atoms thick, are used in the construction of the IC. When a voltage is applied, the material becomes transparent, allowing a laser beam to shine through. A second, less-powerful laser beam concentrates the electrical voltage in certain layers, which become opaque. Thus the second laser beam controls the transmission of the first laser beam. The outgoing light beam from one device can then be used as an input for a second device. Development of these devices could be a step toward developing an optical computing device that would use light rather than electrical power to transmit information.

Basic research is being performed on the extraction of gallium from nontraditional source materials. The U.S. Bureau of Mines has investigated the extraction of gallium from phosphorus flue dust and low-grade domestic resources (Ref 10, 11). Work is also being done by private firms on the recovery of gallium from coal fly ash and phosphorus flue dust.

Strategic Factors

Despite the fact that gallium is currently being used in some sophisticated military and satellite systems, and is planned to be incorporated into additional systems, it has not been designated as a material to be added to the U.S. National Defense Stockpile. In 1986, government and private agencies assessed the need to stockpile gallium, but it was determined that in the event of a national emergency, gallium supplies would be adequate. If consumption increases dramatically, it is likely that this assessment would be reevaluated.

Because the United States produces only small quantities of gallium metal, imports must supply the bulk of the U.S. demand. This important dependence is likely to continue. A gallium extraction plant is scheduled to open in Utah in 1990, but this plant will not have the capability to produce 6N and 7N metal. Consequently, most of the high-purity metal will continue to be imported from Europe; small quantities may be purified in the United States.

With Rapid technological progress, especially in GaAs IC development, the status of world supply and demand is changing dramatically. The status of GaAs has advanced in the past decade or so from that of a laboratory curiosity to that of a material with distinct applications and almost no effective substitutes at present. The development of fiberoptic telecommunications systems, the advent sophisticated electronic military warfare, the widespread use of consumer electronics, and the need to process vast quantities of data in the shortest time possible have provided the impetus for

implementing a large number of GaAs research and development programs. By continuing to push the limits of GaAS technology, its applications have expanded. At the same time, continuing research into developing other alternate materials, such as InP, superconductors, and organic polymer semiconductors, may yield materials with properties superior to those of GaAs. Development of these potential substitutes could radically alter the future of GaAs technology.

Indium and Bismuth

Laurence G. Stevens and C.E.T. White, Indium Corporation of America

Introduction

INDIUM and BISMUTH, although distinct in several properties and areas of application, have relatively low melting temperatures and some common areas of application. One common application area, for example, is in low-melting-temperature solders (that is, solders with a melting point or range below the tin-lead eutectic temperature of 183 °C, or 360 °F). These solders fall into the general group of either indium-base solders or bismuth-base solders.

Another common and significant use of bismuth and indium is in fusible alloys. Most fusible alloys contain large percentages of bismuth and occasionally some indium. However, the largest application of bismuth is in chemical products such as cosmetics, pharmaceuticals, and industrial or laboratory chemicals. Indium is primarily used in solders and fusible alloys, although it has found increasing application in other technologies such as semiconductors and solar cells.

Indium

Indium was discovered in 1863 by F. Reich and H.T. Richter at the Freiburg School of Mines in Germany while they were checking local zinc ores for thallium by spectrograph. The new element was named indium from the characteristics indigo blue lines of its spectrum. Subsequent work on flue dusts from the zinc works in Goslar, Germany yielded the pure metal, which was first exhibited in 1867. Indium, however, remained a laboratory curiosity until the 1920s.

Occurrence. Indium does not occur naturally in concentrated deposits. It is widely distributed in nature in the form of minerals, although generally in very low concentrations. The crust of the earth has been estimated to contain 0.1 ppm of indium, which means that the element has about the same relative abundance as silver.

The geochemical properties of indium are such that it tends to occur in nature with base metals of groups II-B and IV-A of the periodic table. Historically, indium has been recovered almost exclusively as a byproduct of zinc produced from sphaleritic and marmatitic zinc ores. It has, however, been reported in other base metal ores, particularly those of copper, lead, and tin. The association of indium with zinc ores tends to be in the high-temperature sulfide deposits typically found in the western United States. The lower-temperature strataband deposits of the Mississippi Valley area are, in general, barren of indium. Indium has been found in ores from many countries besides the United States and Germany, including Australia, Bolivia, Canada, Finland, Italy, Japan, Peru, Sweden, and the Soviet Union. Most ores contain less than 0.001% In, and many contain less than 0.0001% In. Like many of the rarer metals, indium becomes concentrated in by-products during the recovery of the major metals. Because indium is most frequently associated with zinc, commercial production comes from zinc residues, slag, flue dusts, and metallic intermediates in zinc smelting and associated lead smelting.

Recovery. A variety of methods are employed in the recovery of indium, depending on the source material and its indium content. Among the more common methods are leaching the indium-containing by-product in sulfuric or hydrochloric acid, purifying the leach solution with indium strips, and sponging the crude indium on zinc or aluminum sheets. Solvent extraction with diphosphoric (2-ethylhexyl) acid or tributyl phosphate is effective in removing indium from dilute solutions. Another recovery procedure involves precipitating indium phosphate selectively from slightly acidic solutions, converting the phosphate to the oxide by leaching in a strong caustic soda solution, and then reducing the oxide to metal. Indium that is distilled with zinc in zinc retort smelting processes concentrates in the zinc-lead bottom metal during the first-stage evaporation and reflux purification of zinc, and can be separated as a high-grade slag. Indium is recovered from the slag by leaching and sponging on zinc or aluminum. The decline in production of zinc by zinc retort smelting processes has reduced the importance of this procedure in the recovery of indium. Other techniques have been developed for more-complex feed materials.

Sponge indium generally is from 99.0 to 99.5% pure and requires upgrading for most uses, particularly for those in the semiconductor industry. Refining techniques involve soluble-anode electrolysis. Suitable addition agents are required to

obtain a satisfactory deposit. For the highest-purity grades used for compound semiconductors, refining is supplemented by other methods. Purities of 99.97, 99.99, 99.999, and 99.9999% are obtained.

Production. The first reported production of indium was in 1867, when H.T. Richter, one of its discoverers, exhibited 500 g (1.1 lb) that had been extracted from the flue dust of the Goslar, Germany zinc works. Only laboratory quantities were produced during the next 50 years, and it was not until 1926 that any appreciable amount of indium metal was produced. In that year, Dr. William S. Murray, who later founded the Indium Corporation of America, produced 7 $\frac{3}{4}$ kg (250 troy oz) of metal from a complex sulfide ore at Kingman, AZ. Production from this general area totalled about 1 metric ton (32,000 troy oz) in the period from 1926 to 1934. The Anaconda Company began production of indium from its Montana properties in 1934, with a peak production rate of 2.5 metric tons (82,000 troy oz) in 1944.

Additional uses developed in the period after the Second World War, and total production had climbed to 5.0 metric tons (160,000 troy oz) per year by 1950 with the advent of production from the American Smelting and Refining Company (ASARCO). In 1945, the then Cerro De Pasco Corporation began producing indium in Peru and reached a production level of 1.2 metric tons (40,000 troy oz) per year by 1948. Canadian production commenced in 1942 in research quantities and reached substantial levels in 1955 when Cominco Limited completed a new plant with a capacity in excess of 15.5 metric tons (500,000 troy oz) per year. Subsequently, production of indium was commenced on a commercial scale in West Germany (Preussag AG), Belgium (Métallurgie Hoboken-Overpelt S.A.-N.V.), France and Italy (Ste Miniere et Métallurgique de Penarroya), Japan (Nippon Mining Company, Dowa Mining Company, Mitsui Mining & Smelting Company, and Sumitomo Metal Mining Company), East Germany (V.E.B. Bunt Metal), the Netherlands (Billiton B.V.), the United Kingdom (Capper Pass & Sons Ltd.), and the Soviet Union (various government combines). Production from the People's Republic of China has recently appeared on the market. New and/or increased production in Canada by Cominco Ltd. and the Falconbridge Ltd./Indium Corporation has been announced and will commence in the early 1990s.

Few production figures are reported by producers, and total world reported production includes estimated outputs for various countries. In 1973, estimated worldwide indium production reached a peak up to that point of 60.4 metric tons (1,941,000 troy oz). Subsequent production levels have fluctuated from a low of 40 metric tons (1,300,000 troy oz) in 1982 to the 1989 estimate (Ref 1) of close to 100 metric tons (3,200,000 troy oz).

Pricing History. The price of indium was first quoted in the "Metal and Mineral Markets" section of the Engineering and Mining Journal in September 1930; the price was set at $15 per gram. The price gradually decreased as demand developed and additional supplies became available. The quoted price was $72 per kg ($2.25/troy oz) in 1945. Prices for the basic commercial grade (99.97% pure metal) held in the range of $48 to $72 per kg ($1.50 to $2.25/troy oz) until 1972. After 1972, prices began an upward trend and peaked at close to $320 per kg ($10.00/troy oz). Recently, however, prices have fallen because of increasing supplies. The most recent quotations set the price at $230 to $250 per kg ($7.15 to $7.80/troy oz). The higher-purity grades command premiums depending on the final purity desired.

Properties. Indium (atomic number 49) is in subgroup III-A of the periodic table and is a silvery-white metal with a brilliant metallic luster. Indium is softer than lead (it can be scratched with the fingernail, for example) and is highly malleable and ductile. The highly plastic nature of indium permits almost indefinite deformation under compression. Its elongation is abnormally low because indium does not work harden. Indium retains its plasticity and ductility even under cryogenic conditions.

Among the other interesting properties of indium is the wide spread between its melting point (156.6 °C, or 313.9 °F) and its boiling point (2080 °C, or 3775 °F) and its ability to wet glass, quartz, and many ceramics. As an additive, indium tends to harden and strengthen tin- and lead-based solders; its most marked effect is on lead-base solders. Another feature of indium is the improved thermal fatigue resistance obtained in the binary lead-indium system and the ternary lead-silver-indium system as compared to that of the lead-tin and lead-tin-silver systems.

The chemical properties of indium are largely determined by its position in group III-A of the periodic table. The properties of elements in this subgroup are determined by the behavior of the incomplete outer electronic shell, which consists of 2 S electrons and 1 P electron; thus, principal valences of 1 and 3 may be anticipated. The increasing stability of the S electrons in the higher atomic numbers of this subgroup point to characteristic valences of 1 for the higher atomic numbers and 3 for the lower numbers. Indium, which is in an intermediate position in the subgroup, displays both valences, but its most common valence is 3.

Typical mechanical, thermal, and electrical properties of pure indium are given in the article "Properties of Pure Metals" in this Volume. In the electromotive series, indium falls between thallium and cadmium with a standard potential of 0.34 V. It is readily attacked by hot mineral acids but not by water or alkalies.

Initial Areas of Application. The first commercial use of indium was in the production of dental alloys. This was initiated in 1933, when the Williams Gold Company of Buffalo, NY, in conjunction with Dr. William S.Murray, developed a series of gold-base dental alloys containing indium. Indium acts as an oxygen scavenger, resulting in alloys with improved tensile strength, ductility, and resistance to discoloration. Indium is still used in dental alloys.

Dr. Murray originally was interested in using indium as an addition to silver-plated flatware. During the period from 1926 to 1934, he and his associates developed a series of indium plating baths. In 1934, the Indium Corporation of America was incorporated to carry on the work. The original indium plating baths were of the alkaline cyanide type, but most plating at the present time is done from a sulfamate type bath that has fewer environmental restrictions. Other baths are occasionally used, including fluoroborate and sulfate baths.

The flatware application did not prove successful, but other applications of indium plating, in particular the plating of bearings, became important. Indium was applied in the form of an electroplate on the lead layer of steel-backed silver-lead bearings; the plate was then diffused into the lead layer. The indium addition gave the bearing improved strength and hardness, increased corrosion resistance, and improved antiseizure properties. This type of bearing found extensive use in aircraft piston engines during World War II, but its use has declined since the advent of jet engines. Nevertheless, indium still finds use in high-performance engine components such as the crankshaft bearing shown in Fig. 1.

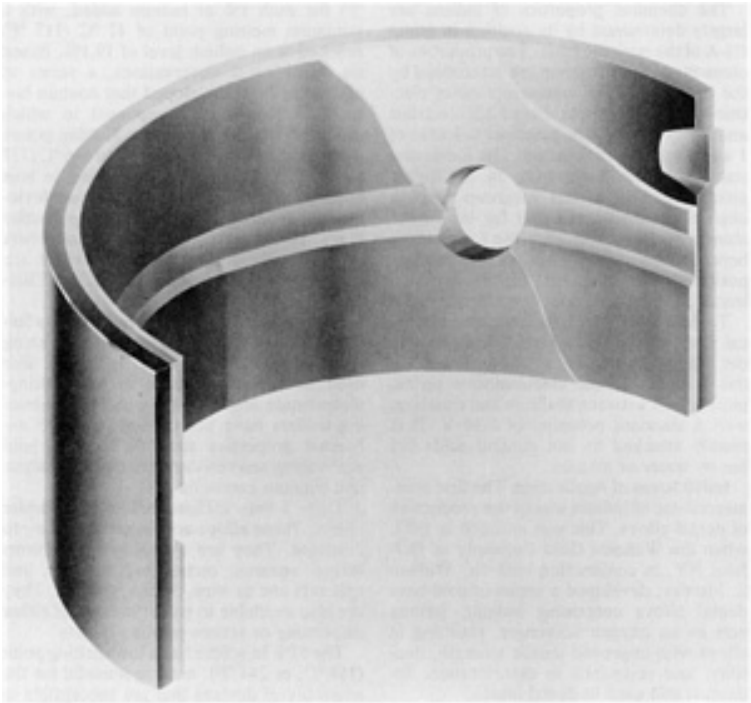

Fig. 1 Indium-plated crankshaft bearing for a high-performance reciprocating engine. The indium is applied as an electroplate on a lead-bronze shell. Courtesy of Vandervel America, Inc.

It was noted as early as 1935 that the addition of indium to low-melting alloys such as Wood's and Lipowitz's metals caused the melting point to drop 1.45 °C (2.6 °F) for each 1% of indium added, with a minimum melting point of 47 °C (117 °F) reached at an indium level of 19.1%. Based on these initial observations, a series of alloys has been developed that contain bismuth as the major component to which indium additions are made. Melting points of these alloys extend from 47 to 146 °C (117 to 295 °F). These alloys are used in lens blocking and in temperature overload devices such as safety links, fuses, and sprinkler plugs. These are now classified as members of the family of fusible alloys, which are described in more detail in the section "Bismuth" in this article.

Low-Melting-Temperature Indium-Base Solders. Besides being used as a strengthening agent in lead-base solders, indium is also used as a base material in low-melting-temperature solders. Many indium-containing solders have been developed with enhanced properties such as reduced gold scavenging and resistance to thermal fatigue and alkaline corrosion.

Table 1 lists various indium-base solder alloys. These alloys are, in general, easy to fabricate. They are available as preforms (discs, squares, rectangles, washers, and spheres) and as wire, ribbon, and foil. They are also available in solder creams of either dispensing or screen-printing quality.

Table 1 Indium-base and indium-alloyed solders

(a) For alloys specified in ASTM B 774, impurity limits are 0.001% Ag and 0.01% Bi max (when nominals are not specified), 0.08% Cu max, 0.1% Sb max, 0.08% Zn max.

(b) Melting point

The 52% In solder has a low melting point (118 °C, or 244 °F), making it useful for the assembly of devices that are susceptible to temperature damage if conventional solders are used. It will also wet glass, quartz, and many ceramics, which makes it valuable for glass-to-metal seals. The series of solders containing 19 to 80% In (Table 1) have melting points ranging from 147 to 280 °C (117 to 535 °F). In comparison with conventional tin-lead solders, these indium-lead solders have improved thermal fatigue characteristics, and they greatly reduce the scavenging of gold surfaced. The temperature range is wide enough to permit two-or even three-step soldering. The 5% In solder is a high-temperature silver-bearing solder with good thermal fatigue properties. It is used extensively in the assembly of diodes and rectifiers.

The application techniques for indium-base alloys are similar to those used for the conventional tin-lead solders. In the case of preforms, oven heating is used for short runs, and conveyor-type furnaces are used for large runs. In special cases, the use of induction heating, heat guns, or reducing atmospheres is recommended. Vapor-phase soldering with indium-base alloys continues to gain in importance, particularly for the joining of back-plane connector pins to printed boards. Wave soldering has been performed satisfactorily with these alloys, but indium-base solders tend to dross slightly more than do tin-lead alloys.

Indium-base solders are generally considered to be specialty solders. They possess special properties that make them valuable for specific applications such as those described below.

Glass-to-Metal Seals. Pure indium, the 52In-48Sn alloy, and the 97In-3Ag alloy will wet glass, quartz, and many ceramics. Therefore, they find use in glass-to-metal seals; also, because of their low vapor pressure, they are useful as seals in vacuum systems. They retain their plasticity down to liquid-helium temperatures and thus can be used for sealing cryogenic systems.

Resistance to Thermal Fatigue. The indium-lead and indium-lead-silver alloys listed in Table 1 have a much greater resistance to thermal fatigue than do the conventional lead-tin solders. This advantage, coupled with the marked reduction in the scavenging and leaching of gold surfaces associated with these alloys, has led to their use in electronic assemblies.

Silver-Palladium Compatibility. Conventional tin-lead solders cannot be used to solder in silver-palladium metallizations when high service temperatures are required because of the formation of the palladium-tin (PdSn) intermetallic. When tin-lead solders are used, a significant reduction in adhesion strength can occur at a temperature of 150 °C (300 °F) in a few hundred hours, leading to ultimate failure of the solder bond. Lead-silver-indium solders are compatible with silver-palladium conductors at service temperatures up to 200 °C (400 °F).

Large Temperature Differentials. The lead-indium composition is a solid-solution system (noneutectic) with an available temperature range from the melting point of indium (156.6 °C, or 313.9 °F) to the melting point of lead (327 °C, or 621 °F). This wide range permits a choice of alloys with temperature differentials large enough for step soldering.

Corrosion Resistance. Indium-base solders have good resistance to alkaline corrosion. However, corrosion resistance in the presence of traces of halide ions is not satisfactory, necessitating the use of hermetic seals or conformal coatings.

Other Applications. Besides solder and fusible alloys, indium is used in a variety of other applications. Nuclear reactor control rods containing 80% Ag, 15% In, and 5% Cd were developed in the 1950s and have been used in the majority of pressurized water reactors built since that time. Other important applications are described below.

Sodium Lamps. A major application of indium in Europe has been in the manufacture of low-pressure sodium lamps, which are mainly used for outdoor lighting. The indium is applied as an oxide coating on the inside of the glass cylinder that forms the outer envelope of the lamp. The coating reflects the infrared waves emitted by the lamp while letting the visible light pass through, thus permitting the lamp to operate at a higher temperature. This yields an improved lumens-per-watt efficiency in comparison with that of conventional incandescent lamps. The lamp emits an orange light and has not found favor in the United States, where the blue-white light of the mercury vapor lamp is preferred.

Conductive films of indium oxide and indium-tin-oxide on glass find many applications. These include conductive patterns for liquid crystal displays (LCDs) and windshield defoggers and deicers as well as transparent electrodes for flat-panel displays. The high transparency of these coatings to visible light makes them well suited for these applications. Because these coatings reflect infrared radiation while passing visible light, they have the potential to be used for residential and commercial building glass.

Seals and Gaskets. The softness and plasticity of indium make it an excellent material not only for solder applications but also for gaskets and seals. Indium has the ability to work into the oxide skin of other metals and thus can improve the electrical and thermal conductivity of junctions of these metals while acting as a metallic seal against corrosion.

Semiconductors. With the invention of the germanium transistor in 1946, a major new market for indium developed in the production of alloy junction transistors. In these transistors, indium is used in the P-N junction, which is formed by alloying discs or spheres of indium into a wafer of N-doped germanium. This use of indium peaked around 1969 and 1970, but it has declined since then because germanium has been replaced by silicon in most semiconductor applications. Germanium semiconductors are now produced only for replacement purposes.

Intermetallic semiconductors formed with indium and group V elements such as antimony, arsenic, and phosphorus have received considerable attention in recent years. Indium antimonide has been used for infrared detectors but has been limited to military applications because it does not developed optimum parameters until cooled to liquid-nitrogen temperatures (77 K). Indium phosphide has more potential for commercial applications, such as a quaternary laser diode containing indium-gallium-arsenic-phosphorus. Gunn effect diodes, IMPATT (impact avalanche transit time) diodes, and millimeter wave oscillator circuits are under development.

Solar Cells. Indium phosphide and indium-copper-diselenide/cadmium sulfide are under active investigation as materials for solar cells. Among photovoltaic materials, copper-indium-diselenide is one of the best at absorbing light.

Bismuth

Unlike indium, bismuth has been known by mankind for many centuries. It was probably not recognized as a specific metal by the early Orientals, Greeks, and Romans, but Europeans, in particular, were becoming aware of its properties by the Middle Ages. In the 15th century, Basil Valentine referred to it as wismut. This was Latinized to bisemutum by the early metallurgist Georgus Agricola in the 16th century. By the middle of the 18th century, work by several metallurgists in Europe had resulted in the widespread recognition of bismuth as a specific metal.

Occurrence. The concentration of bismuth in the crust of the earth has been estimated to be 0.2 ppm, the same order of magnitude as that of silver. Some natural bismuth is found in veins associated with silver, lead, zinc, and tin in areas of Bolivia, Canada, and Germany. Specific bismuth ores include bismite (Bi_2O_3), bismuthinite (Bi_2S_3), and bismutite ($Bi_2O_3 \cdot CO_2 \cdot H_2O$). However, the majority of the bismuth produced is recovered as a by-product during the smelting and refining of lead, copper, tin, silver, and gold ores; lead and copper ores supply the vast majority of the metal. Mine production has been reported from Australia, Bolivia, Canada, the People's Republic of China, the Federal Republic of Germany, Japan, Korea, Mexico, Peru, Romania, the United States, the Soviet Union, and Yugoslavia. Production reported in Belgium, Italy, and the United Kingdom is from imported ores and by-products (Ref 2).

Recovery. Bismuth is recovered primarily during the smelting of copper and lead ores. In copper smelting, a portion of the bismuth is volatilized in the copper converter and caught along with such elements as lead, arsenic, and antimony as a dust in a bag-house or Cottrell system. This dust is transferred to a lead-smelting operation. A major part of the bismuth remains with the metallic copper. During electrolytic refining of the copper, the bismuth accumulates in the anode slime along with such other impurities as lead, selenium, tellurium, and the precious metals. The procedure for handling the anode slimes is such that the bismuth is collected in the lead.

Bismuth is found in most lead ores and accompanies the lead through the smelting and refining operations. In the furnace kettle process for refining lead bullion, the bismuth is not removed unless it exceeds 0.05%, the specified limit for bismuth in commercial lead. The two most important methods for removing bismuth from lead are the Betterton-Kroll process and the Betts process. The Betterton-Kroll process is based on the formation of high-melting compounds such as Ca_2Bi_2 and Mg_3Bi_2 thatseparate from the molten lead bullion bath and can be skimmed off as dross. In the actual process, magnesium and calcium-lead are stirred into the molten bullion, the charge is cooled, and the bismuth dross is skimmed off. The bismuth dross is then melted in small kettles, and the entrapped lead is removed by liquation. The dross is subsequently treated with lead chloride or chlorine to remove the calcium and magnesium; further chlorination is used to remove the lead. A final treatment with caustic soda produces 99.95% Bi.

In the Betts process, lead bullion is electrolyzed in a solution of lead fluosilicate and free fluosilicic acid with pure-lead cathodes. The impurities, including bismuth, are collected in the anode slimes, which are filtered, dried, and smelted. The resulting metal is cupelled, driving the bismuth into the slag and litharge. The slag is reduced to metal containing 20 to 25% Bi, which is then refined to a purity of 99.95% with the same procedure used in the Betterton-Kroll process. Final refining involves repeated treatments with caustic soda and niter followed by a finishing treatment with caustic to yield bismuth that is 99.995% pure.

Bismuth occurring as an oxide or carbonate can be recovered by leaching with hydrochloric acid followed by precipitation and separation of the oxychloride. Removal of copper from the filtrate is accomplished with scrap iron. Repeated precipitations are made, and the purified oxychloride is smelted with lime and charcoal to yield the pure metal.

World production of bismuth per year has varied from 3190 metric tons (3515 tons) in 1984 to 4326 metric tons (4770 tons) in 1985. Mine output ran from 2770 to 4410 metric tons (3053 to 4860 tons) during this period. Actual production capacity is 6940 metric tons (7650 tons). A summary of bismuth production by country is given in Table 2.

(a) In addition to the countries listed, Brazil, Bulgaria, the German Democratic Republic, Greece, Mozambique, and Namibia are believed to have produced bismuth, but available information is inadequate for formulation of reliable estimates of output levels.

(b) Data were originally compiled in units of 10^3lb; to convert to metric tons, multiply by 0.4536.

(c) Preliminary data.

(d) Estimated data.

(e) It is believed that bismuth-rich residues were stockpiled at the mine head during the period 1983-1985 and released into the world market in subsequent years.

(f) Figures listed under mine output are reported in Canadian sources as production of refined metal and bullion plus recoverable bismuth content of exported concentrate.

(g) Mine output figures have been estimated based on reported metal output figures.

(h) Reported figure.

(i) Withheld to avoid disclosing company proprietary data; excluded from total.

Pricing History. Bismuth prices have generally held in the $4.40 to $5.50 per kg ($2.00 to $2.50/lb) range since the 1950s; occasional excursions above this level have been brought about by special conditions. The price trend firmed in 1984 and peaked at $14.44 per kg ($6.55/lb) in January 1985. Subsequent prices have varied between $6.60 and $13.20 per kg ($3.00 and $6.00/lb). The quoted price in December 1989 was $9.25 to $10.12 per kg ($4.20 to $4.60/lb).

Properties. Bismuth (atomic number 83) is found in subgroup V-A of the periodic table. It is a brittle crystalline metal with a high metallic lustre and a pinkish tinge. It is one of the two metals (gallium is the other) that expand upon freezing; for bismuth, this expansion is 3.32%. Bismuth has the lowest thermal conductivity of any metal with the exception of mercury. It is the most diamagnetic of all metals, with a mass susceptibility of -1.35×10^6. When influenced by a magnetic field, bismuth displays the greatest increase in resistivity of all the metals. Its thermal conductivity, however, decreases in a magnetic field. Unlike most metals, bismuth has an electrical resistance that is greater in the solid state than in the liquid state by a ratio of approximately 2.

Bismuth, like other members of its subgroup, forms two sets of compounds in which it is trivalent or pentavalent; the trivalent compounds are the more common. Bismuth is soluble in mineral acids but not in water or alkalis. It has the tendency to form oxysalts, particularly with the chloride and nitrate. Mechanical and thermal properties of bismuth are given in the article "Properties of Pure Metals" in this Volume.

Uses. A summary of bismuth consumption in the United States by category is given in Table 3. The chemicals category in Table 3 includes bismuth compounds used as catalysts in the manufacture of plastics and in the synthesis of methanol. The largest use of bismuth in this category is in the manufacture of acrylonitrile using bismuth phosphomolybdate. Bismuth oxychloride is included in cosmetics to give pearlescence to such products as lipstick, eye shadow, and nail polish. Bismuth appears in pharmaceutical products primarily as oxysalts in various indigestion remedies.

(a) Original data were compiled in units of 10^3 lb; to convert to metric tons, multiply by 0.4536.

(b) Includes industrial and laboratory chemicals, cosmetics, and pharmaceuticals.

(c) Includes experimental uses.

Bismuth is used as an additive in steel and aluminum to improve machinability; In wrought iron it reduces the formation of graphite on freezing. Another application of bismuth is in thermoelectric devices containing intermetallic compounds of bismuth with selenium and/or tellurium; these devices make use of the Peltier effect for refrigeration. Some recently developed high-temperature superconductors also contain bismuth compounds, in particular those in the bismuth-strontium-calcium-copper-oxygen system.

Fusible alloys include a group of binary, ternary, quaternary, and quinary alloys containing bismuth, lead, tin, cadmium, and indium. The term fusible alloy refers to any of the more than 100 white-metal alloys that melt at relatively low temperatures, that is, below the melting point of tin-lead eutectic solder (183 °C, or 360 °F). The melting points of these alloys range as low as 47 °C (116 °F). Fusible alloys are used for lens blocking and tube bending, for anchoring chucks and fixtures, and for mounting thin sections such as gas turbine blades for machining. The eutectic fusible alloys,

which can be tailored to give a specific melting point, find application in temperature control devices and in fire protection devices such as sprinkler heads. Applications of selected fusible alloys are listed in Table 4.

Table 4 Suitability of selected fusible alloys for various applications

Alloy compositions and melting temperatures are given in Tables 5 and 6.

Application	Suitable alloys
Matrix metal for	
Large bearings	X
Punch and die assemblies	Y
Small bearings	Y
Anchoring for	
Rods and tubular members	Y
Bushings in drill jigs, plates, and fixtures	C, Y, Z
Inserts and parts in ceramics, plastics, metal powders, and wood	G, Z
Locator members in aircraft and automotive assembly drilling, inspection, and welding fixtures	C, H, Z
Hold-down bolts in floors	G, Z
Magnets in chucks, instruments, and work-holding devices	H, Z
Needles in lace and textile machinery	G, H, T
Patterns in foundry match plates	G, H, T
Precision parts for testing and inspection	A, B, C, G, Z
Reamers for axial and concentric alignment in turret tool holders	C, H
Shafts in permanent-magnet rotors	H, Y
Chucking for	
Lens buffing and grinding	A, C

Gem cutting	G, Z
Metal spinning of reentrant and bottleneck shapes	C, G
Fusible cores for	
Electroforming	G, H, Z
Founding	C, G
Holding and forming fiberglass and plastic laminates	C, G
Compound wax patterns	B, C
Punch and die applications	
Light sheet metal embossing dies	C, G, H, Y, Z
Form blocks for bending, forming, and joggling and extruded shapes, sheet metal, and tubing	H, Y
Soft-metal dies for lost-wax patterns	H, Z
Pilots for die casting and plastic trim dies	H
Repairing broken dies	Y
Stretch press form blocks	G, H
Stripper plates in stamping dies	Y
Guerin process dies	C, G, H, Y
Mold applications	
Duplicating plaster or plastic patterns	G, H, Z
Casting plastics, phenolics, elastomers, epoxies, and polyesters	G, H, Z
Forming sheet and tubular polyethylene plastics by vacuum or air pressure	H, Z
Plastic teeth (dental)	H

Prosthetic development work	A, H, Z
Encapsulating avionic, electrical, and electronic components	H, Z
Pattern applications	
Dental models (special compositions)	A
Duplicate patterns for foundry match plates, ceramics, plastics, and pottery	C, H, Z
Lining and sealing core boxes	H
Model airplane, railroad, and ship parts	G, H, T
Spray-metallizing, altering, and repairing patterns and core boxes	T, Z
Tracer models for pantograph engraving and duplicating	H, Z
Miscellaneous applications	
Filler for tube and mold bending	C, G
Low-melting solders	. . .
Heat-transfer mediums in constant-temperature baths	. . .
Seals for bright-annealing and nitriding furnaces	. . .
Seals for adjustment screws on torque wrenches and instruments	. . .
Hold-down clamp pads	. . .
Ammunition composites	. . .
Fire detection apparatus and alarm systems	. . .
Safety plugs for tanks and cylinders for compressed gas	. . .
Fusible elements in automatic sprinkler heads and fire door release links	. . .
Automatic shutoffs for gas and electric water-heating systems	. . .

Selenium rectifiers such as the counterelectrode	. . .
Lead and bismuth additions to aluminum and other metals and alloys to obtain free-cutting materials	. . .

Many of the fusible alloys used in industrial applications are based on eutectic compositions (see Table 5). Under ambient temperature, such an alloy has sufficient strength to hold parts together; at a specific elevated temperature, however, the fusible alloy link will melt, thus disconnecting the parts. In fire sprinklers, the links melt when dangerous temperatures are reached, releasing water from piping systems and extinguishing the fire. Boiler plugs and furnace controls react similarly because an increase in temperature beyond the safety limits of the furnace or boiler operation will melt the plug. When the fusible alloy link melts, pressure or heat in the boiler can be dissipated, or feeding of the fuel supply can be ceased, thereby reducing operation to a safe level.

Table 5 Compositions and melting temperatures of selected eutectic fusible alloys

(c) Also contains 4.0% In

A fusible alloy with a long melting range is useful in staking rods and tubing in assemblies because the alloy is distributed around part surfaces while still molten and provides a firm anchorage after it solidifies.

Properties of Fusible Alloys. Table 7 lists various physical properties of selected fusible alloys. Fusible alloys are ageable, and thus their mechanical properties often depend on the period of time that has elapsed since casting, as well as on the casting conditions and the solidification rate. Test conditions also affect mechanical property values. For example, many fusible alloys can appear brittle when subjected to sudden shock but exhibit high ductility under slow rates of strain.

Table 7 Physical properties of selected fusible alloys

Alloy	Density		Tensile strength		Hardness, HB	Maximum 30-s load		Safe sustained load		Electrical conductivity, % compared with copper

In certain alloys, normal thermal contraction due to cooling after solidification can be partly, completely, or more than compensated for by expansion due to aging. For example, bismuth alloys containing 33 to 66% Pb exhibit net expansion after solidification and during subsequent aging. Some fusible alloys show no contraction (shrinkage) and expand rapidly

while still warm; others show slight shrinkage during the first few minutes after solidification and then begin to expand; in still others, expansion does not commence until some time after the fusible alloy casting has cooled to room temperature. Cumulative growth and shrinkage data for selected fusible alloys are given in Table 8.

Table 8 Cumulative growth and shrinkage data for selected fusible alloys

Alloy compositions are given in Tables 5 and 6.

(a) Data are in mm/mm (in./in.) compared to cold mold dimensions of a 13 × 13 × 250 mm ($\frac{1}{2}$ × $\frac{1}{2}$ × 10 in.) test bar with a weight of about 0.45 kg (1 lb).

Each of the three characteristics--net expansion, net contraction, and little or no volume change--can provide specific advantages, depending on the application. For example, a wood pattern used for making molds must be of somewhat greater dimensions than those desired in the casting to compensate for shrinkage of the casting on solidification and during cooling to room temperature. Where metal patterns are cast from a master wood pattern, two such allowances will have to be made unless the alloy used for the metal patterns possesses zero shrinkage. Fusible alloys with eutectic compositions are often used for casting metal patterns from wood masters because they undergo definite growth that is sufficient to allow for cleaning of production castings without reducing dimensions below required values. The growth

characteristics of fusible alloys are often used to advantage when a metal part is to be firmly anchored in a lathe chuck. After the part is machined, the fusible alloy is melted away.

In general, the load-bearing capacity of fusible alloys is good, although some deformation will occur under prolonged stress. In addition, hardness and other mechanical properties of many fusible alloys change gradually with time, probably because of the same microstructural changes caused by aging that affect growth or shrinkage.

Bismuth-Base Solders. Alloys rich in bismuth generally are not considered to be good solders. When using the traditional halide-activated fluxes at the low soldering temperatures required with these alloys, the flux often does not reach its activation temperature. Consequently, fluxing activity is inefficient, and wetting can be poor. In these instances, fluxes with other activation mechanisms should be used to improve soldering quality (for example, fluxes with organic acids and/or chelation agents).

Although alloys rich in bismuth can be difficult to use as solders, bismuth-base solder alloys (Table 9) do find use in such applications as:

- Soldering heat-treated surfaces when a higher soldering temperature would result in a softening of the part
- Soldering joints where the adjacent material is heat sensitive and deterioration would occur at a higher soldering temperature
- Step soldering operations where a low temperature is necessary to protect a nearby solder joint
- Construction of temperature-overload devices such as safety links, fuses, and plugs where positive-pressure contact is too variable or inconsistent for assembly operation
- Soldering low-temperature alloys such as pewter
- Machine-soldering operations for through-hole soldering of very thick multilayer printed circuit boards
- Assembly operations, such as surface mounting, where the integrated circuit packages would be vulnerable to thermal damage at the temperatures required for conventional tin-lead soldering
- Assembly operations using injection-molded circuit boards where the glass transition temperature is too low for the use of tin-lead alloys

In addition, several bismuth-base alloys (particularly the 42Sn-58Bi eutectic alloy) are being used for wave techniques, during which surface-mounted devices are directly exposed to molten solder. This direct exposure has provided an incentive to lower solder temperatures to the range of 150 to 170 °C (300 to 340 °F) by using bismuth-base solders. Conventional tin-lead solders require temperatures between 240 and 250 °C (460 and 480 °F). In some respects such as fatigue strength and dissolution of copper, bismuth-base joints from wave soldering are superior to those made by conventional tin-lead soldering; however, their ductility is substantially lower.

Table 9 Bismuth-base solder alloys

Composition, wt%					Melting temperatures			
					Solidus		Liquidus

12.6	47.47	39.93	. . .	. . .	146	294	176	349

Table 9 lists various bismuth-base solders. These alloys tend to be more difficult to fabricate than indium-base solders, and thus the range of available preforms is not as large. They can be supplied as wire, rod, sheet, and ingots. Solder creams of the 42Sn-58Bi eutectic alloy, the 43Sn-43Pb-14Bi composition, and the 57.42Bi-41.58Sn-100Pb alloy are available. Most of the other listed alloys could also possibly be used for solder creams; however, in some cases they would have to be compounded just prior to use because of the aggressive fluxes required.

The 58% Bi and 14% Bi solder alloys are commonly used for low-melting-temperature soldering. Joint strength is comparable to that produced with tin-lead solders, although the ductility is somewhat lower. Leaching of copper and beryllium-copper is substantially reduced when these alloys are used. The 46% Bi alloy has a melting point at the boiling point of water and characteristics similar to those of the 58% Bi and 14% Bi alloys.

Magnetically Soft Materials

Douglas W. Dietrich, Carpenter Technology Corporation

Introduction

MAGNETIC MATERIALS are broadly classified into two groups with either hard or soft magnetic characteristics. Hard magnetic materials are characterized by retaining a large amount of residual magnetism after exposure to a strong magnetic field. These materials typically have coercive force, H_c, values of several hundred to several thousand oersteds (Oe) and are considered to be permanent magnets. The coercive force is a measure of the magnetizing force required to reduce the magnetic induction to zero after the material has been magnetized. In contrast, soft magnetic materials become magnetized by relatively low-strength magnetic fields, and when the applied field is removed, they return to a state of relatively low residual magnetism. Soft magnetic materials typically exhibit coercive force values of approximately 400 A $\cdot$ m^{-1} (5 Oe) to as low as 0.16 A $\cdot$ m^{-1} (0.002 Oe). Soft magnetic behavior is essential in any application involving changing electromagnetic induction such as solenoids, relays, motors, generators, transformers, magnetic shielding, and so on.

Important characteristics of magnetically soft materials also include:

- High permeability
- High saturation induction
- Low hysteresis-energy loss
- Low eddy-current loss in alternating flux applications
- In specialized cases, constant permeability at low field strengths and/or a minimum or definite change in permeability with temperature

Cost, availability, strength, corrosion resistance, and ease of processing are several other factors that influence the final selection of a soft magnetic material.

Magnetically soft materials manufactured in large quantities include high-purity iron, low-carbon irons, silicon steels, iron-nickel alloys, iron-cobalt alloys, ferritic iron-chrome alloys, and ferrites. Soft magnetic amorphous materials are being produced commercially; however, their characteristics are covered in the article "Metallic Glasses" in this Volume.

Ferromagnetic Properties

In crystalline materials, the basis for ferromagnetism lies in the alignment of magnetic moments from noncompensated electron spins in the 3*d* shell of the transition series elements such as iron, nickel, and cobalt. In ferromagnetic materials that are below their Curie temperature, the magnetic moments of adjacent atoms are coupled parallel to each other. For a small volume of material, all of the individual magnetic moments are aligned in one direction. This small volume is magnetized to saturation and is known as a magnetic domain. An adjacent volume of material, also magnetized to saturation, may have the summation of its magnetic moments point in another direction. Where two such volumes meet (with differing alignments), a domain boundary wall must exist. The total magnetization of a sample of material is the net vector summation of all the individual component domain magnetization vectors. In the demagnetized state, the net summation of all domains approaches zero. The net magnetization of a material can be changed by domain wall movement and/or by rotation of the individual domain magnetization vectors. The energies required to cause domain rotation and wall motion are associated with the materials' crystalline structure, grain size, residual stress, impurities, and so on.

In crystalline ferromagnetic materials, magnetization occurs spontaneously in preferred easy directions. The easy directions are those in which the crystalline anisotropy is a minimum. In iron the easy direction is the cube edge <100>. In nickel, the easy magnetization direction is the <111> cube diagonal (Fig. 1). The crystalline anisotropy constant (K_1) is a measure of the energy required to turn the spontaneous magnetization vector from the preferred direction into the direction of the applied magnetizing field. If K_1 approaches zero, it is relatively easy to turn the magnetization in any direction, and the permeability is likely to be high.

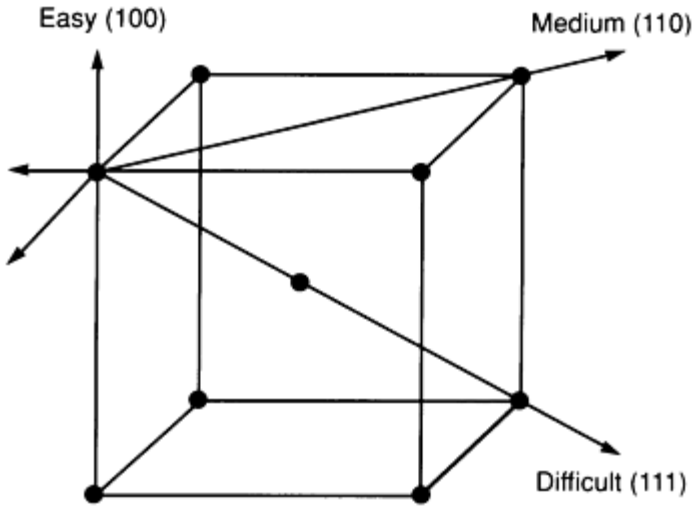

Fig. 1 Crystallographic orientation of iron showing ease of magnetization in the three principal directions

As an external magnetic field is applied to a ferromagnetic material, the magnetic domains that happen to coincide with the applied field grow at the expense of less favorable domains. Upon further increase of the external field the domains rotate into a parallel direction to this field. Particularly during domain rotation, the crystalline lattice spacing may be altered so that the material expands or contracts slightly. This change in dimensions when magnetized is known as magnetostriction. Positive magnetostriction is an elongation of the material in the direction of the applied field. The change is extremely small; for example, pure nickel has a saturation magnetostriction coefficient (λ_1) of approximately -38×10^{-6} $\Delta l/l$. In very high permeability alloys, λ_1 approaches zero. Conversely, applying external stress to ferromagnetic material causes the magnetic hysteresis loop to change.

The ferromagnetic and electrical properties of materials can be divided into two general categories: those that are structure sensitive and those that are structure insensitive. Structure insensitive refers to those properties not markedly affected by small changes in gross composition, small amounts of certain impurities, heat treatment, or plastic deformation. Several generally accepted structure-insensitive properties are the saturation induction (B_s), resistivity (ρ), and Curie temperature (T_c). These properties are largely dependent upon the composition of the alloy selected and are not changed substantially in the process of manufacturing a component from the alloy.

Structure-sensitive properties are those drastically affected by impurities: residual strain, grain size, and so on. Permeability (μ), coercive force (H_c), hysteresis losses (W_h), residual induction (B_r), and magnetic stability are all considered to be structure sensitive. A means of controlling structure-sensitive properties is through manufacturing processing of the alloy and/or by the proper use of a final annealing heat treatment.

Effect of Impurities on Magnetic Properties

Elements such as carbon, oxygen, nitrogen, and sulfur are commonly found as impurities in all alloys (see the article "Preparation and Characterization of Pure Metals" in this Volume). Even in very low concentrations these elements tend to locate at interstitial sites in the crystalline lattice; thus, the lattice can be severely strained. Very minor concentrations may interfere with the easy movement of magnetic domains and impair soft magnetic properties. Figure 2 shows the approximate relationship between carbon content and the hysteresis loss of iron. Hysteresis losses are similarly related to sulfur and oxygen content. Furthermore, if carbon and/or nitrogen remains in the alloy uncombined, or if these elements exceed their respective solubility limits near room temperature, they may migrate in time and precipitate in a form of fine particles that can pin the magnetic domain walls. This causes a hardening of the magnetic properties known as aging.

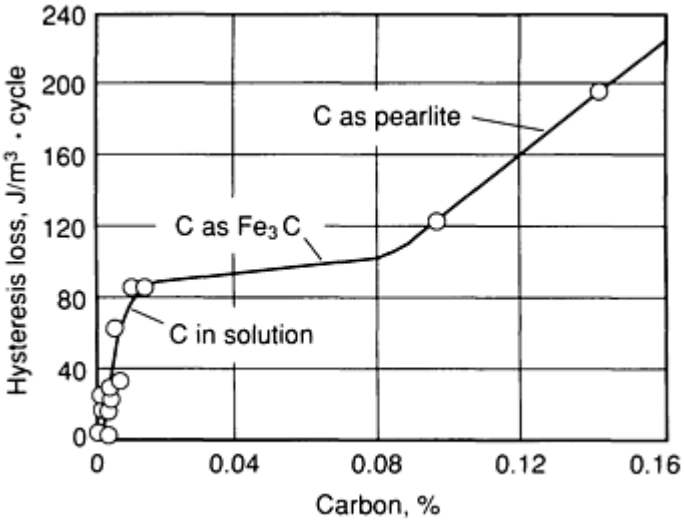

Fig. 2 Relationship between carbon content and hysteresis loss for unalloyed iron. Induction *B* = 1 T (10 kG).

Steel producers utilize raw materials and melting methods that provide impurity levels for those alloys guaranteed to provide a certain level of magnetic performance. In certain cases, particularly with fully processed silicon steels, the producer then utilizes a decarburization heat treatment to further reduce the carbon content of the as-supplied strip product. This process is not economically or physically possible for all soft magnetic alloys and for heavier strip or bar product forms. Thus, it is often desirable and necessary that the consumer anneal the parts in a strongly reducing, nonoxidizing atmosphere as part of the component manufacturing process. Annealing of the final part further reduces impurities, particularly carbon and sulfur, below the levels that can be achieved by melting control alone. In iron alloys and silicon steels, the content of the finished part should be less than 0.003% C to optimize soft magnetic properties and minimize aging.

Effect of Alloying Additions on Magnetic Properties

The major constituents of most soft magnetic alloys are one or more of the common ferromagnetic elements: iron, nickel, or cobalt. Most useful combinations of these elements and the typical additional alloying additions made to soft magnetic alloys are fully substitutional. They contribute to the control of crystalline lattice structure to promote high permeability, low coercive force, and low hysteresis loss.

Certain alloying additions may also increase electrical resistivity that helps to reduce eddy-current losses in alternating current (ac) devices. For example, pure iron can exhibit good soft magnetic properties and has a high saturation induction. It is used extensively in direct current (dc) applications and small fractional horsepower motors; however, its low electrical resistivity results in high eddy-current losses in ac applications. Figure 3 shows the changes in resistivity that result from additions of various elements to iron.

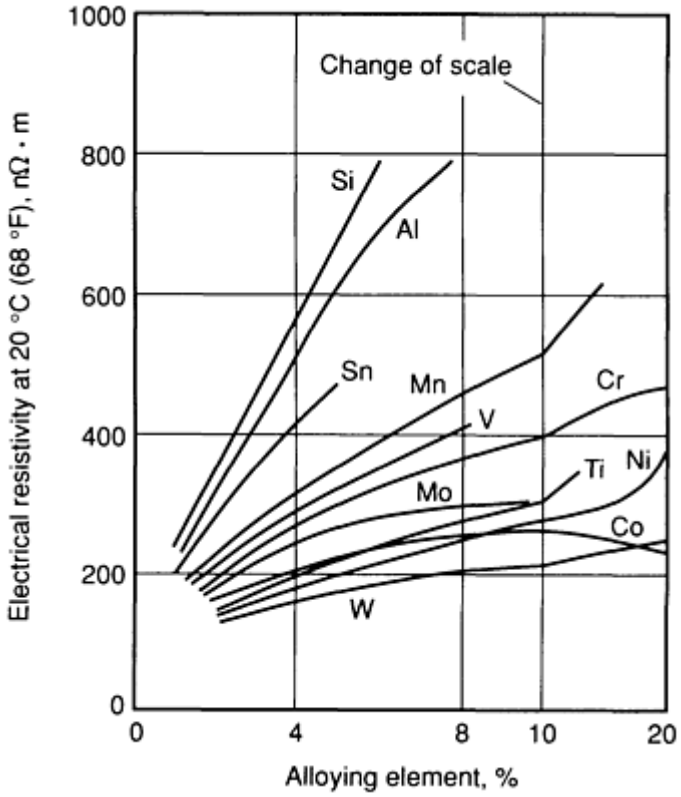

Fig. 3 Effect of alloying elements on electrical resistivity of iron

Silicon. As a result, iron alloys containing 1 to 4% silicon are commonly used in ac applications. Well-annealed pure iron is very soft, typically ranging from 20 to 40 HRB. The addition of silicon also strengthens the annealed alloy. Iron containing ~2.5% Si exhibits an annealed hardness of ~90 HRB.

Silicon additions greater than approximately 2.5% to pure iron can eliminate the transformation from α to γ phase found in pure iron. Consequently, higher silicon-content alloys can be annealed to promote grain growth at high temperatures without passing through a phase transformation. The lack of a phase transformation also facilitates the development of preferentially oriented (cube on edge) grain structure in silicon steels. The oriented silicon steels typically contain 3.15% Si.

Cobalt. Most alloying additions made to iron lower its saturation induction (B_s) as shown in Fig. 4. However, the addition of cobalt results in increased saturation induction up to approximately 2.46 T (24.6 kG) at approximately 35% Co.

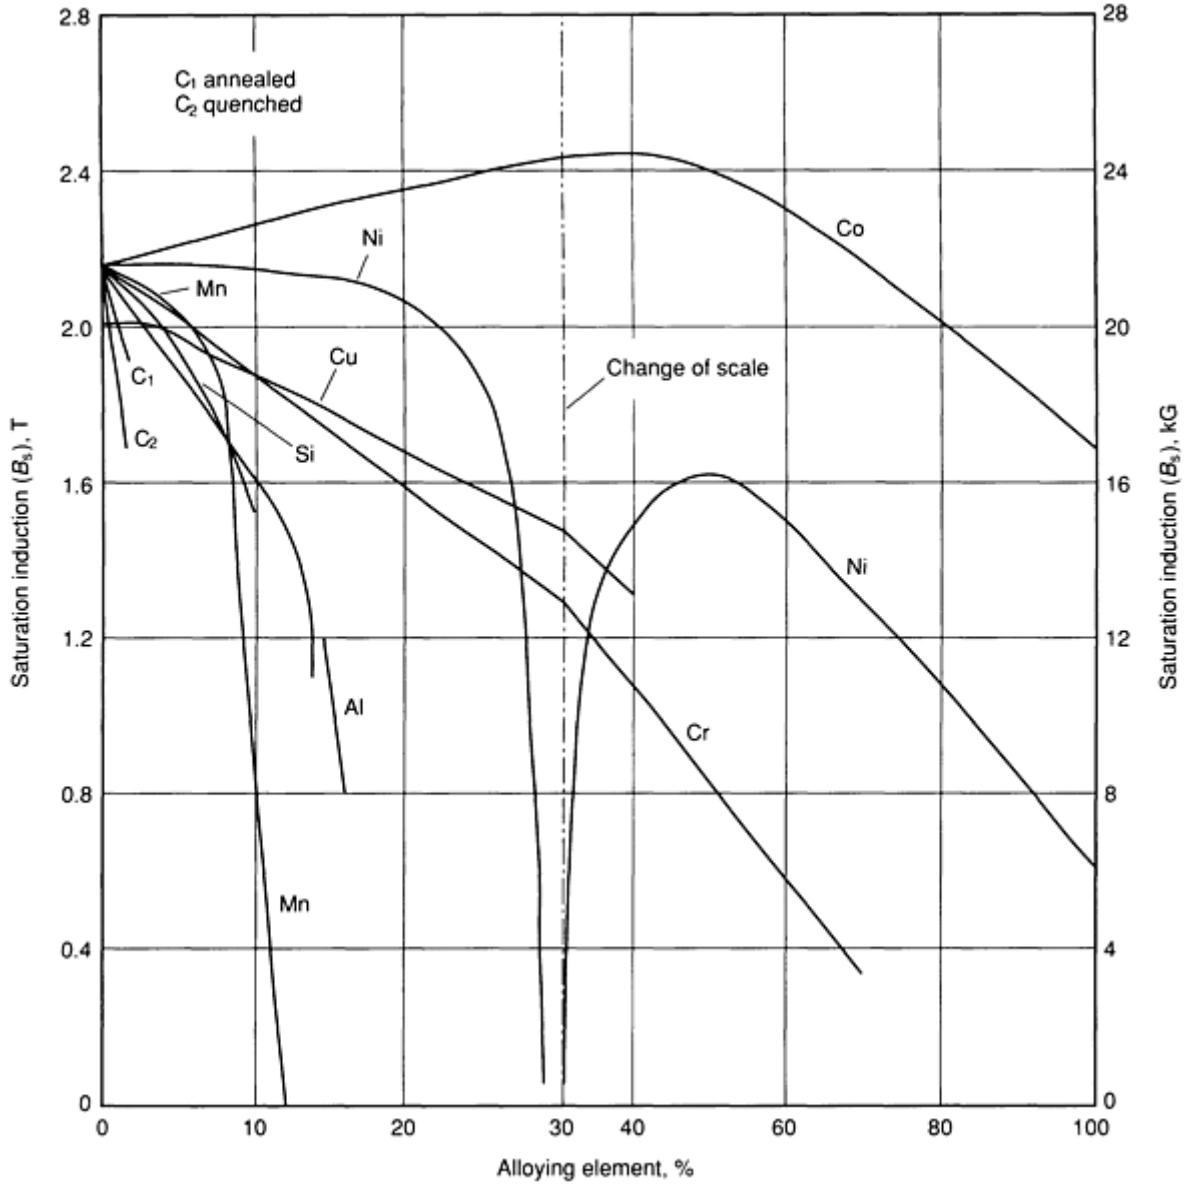

Fig. 4 Effect of alloying elements on room-temperature saturation induction of iron

Vanadium. The addition of vanadium to 50Co-50Fe alloys can improve processing by allowing quenching to obtain ductility for cold rolling of strip products.

Phosphorus may be added to pure irons and silicon irons to enhance stampability and machinability and to aid the sintering of powdered irons.

Chromium is added to iron to produce ferritic stainless steels with suitable soft magnetic characteristics for certain applications.

Additional Elements. Additions of molybdenum, copper, and/or chrome can be made to ~80Ni-Fe alloys to optimize crystallographic parameters to achieve very high permeability. The significance of each of these alloying additions is reviewed in greater detail in the section on classification of alloys in this article.

Effect of Heat Treatment

In certain special cases, particularly fully processed lamination iron and silicon steels, the as-supplied coil product can possibly be stamped and the laminations placed into service without a reheat treatment. Fully processed lamination

materials represent a large volume of the soft magnetic alloy market but they are not typical of most magnetic alloys. Nearly all of the other materials discussed in this article should be annealed as a finished (or nearly finished) component to develop their optimum soft magnetic properties. Even fully processed grades of silicon steel may require a low-temperature stress-relief heat treatment for removal of fabrication stresses.

Most alloys supplied for the stamping of laminations are provided in a cold-rolled unannealed condition. This condition provides best stamping characteristics, acceptable flatness, and minimum burr. Even when thin or heavy sheet and strip products are produced in a mill-annealed condition for forming, bending, or deep drawing (see the article "Carbon and Low-Alloy Steel Sheet and Strip" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Vol 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*), the mill anneal is intended to provide mechanical properties suitable for the fabrication operations. These products usually exhibit a fine grain structure to prevent cracking and orange peel during forming. The mill anneal is not intended to provide the soft magnetic properties in the as-shipped product. Similarly, bar products are generally produced to provide optimum machinability, and wire products are made for formability by bending or perhaps cold heading. Parts made from bar or wire product forms also require annealing to obtain optimum soft magnetic properties.

Three major objectives of annealing are to:

- Eliminate stresses
- Promote/control grain growth
- Further reduce impurities, particularly carbon, nitrogen, and sulfur

Annealing may also control a particular phase transformation or provide a critical degree of ordering in some high-permeability alloys.

Minimizing Residual Stress. The structure-sensitive properties of soft magnetic materials are very strongly influenced by residual stress, both remaining from the manufacturing of the material as well as from the stresses introduced by fabrication of the part. In oriented silicon steels, a compressive stress of as little as 3.45 to 6.9 MPa (0.5 to 1.0 ksi) can increase core loss by 50 to 100%. Very high permeability nickel-iron tape cores can be damaged just by squeezing them by hand. Thus, great care must be taken to remove residual stresses by annealing and to minimize new stresses introduced during assembly. Machined parts should be annealed as near to finished dimensions as possible. If finishing operations are required for close tolerances after annealing, they should be limited to light machining or grinding passes.

Maximizing Grain Size. For most applications of nonoriented magnetic materials, grain size should be as large as possible. A fine grain structure has a large grain-boundary surface area per unit volume. Grain boundaries represent a physical discontinuity of the crystalline structure that impedes the movement of magnetic domains. A coarse grain structure provides less grain-boundary surface area per unit volume and generally results in softer dc magnetic properties (Fig. 5a). In ac applications, as the frequency is increased, there may be an optimum grain-size range that provides best magnetic performance. Figure 5(b) presents data for oriented silicon steel for which an optimum grain-size range exists.

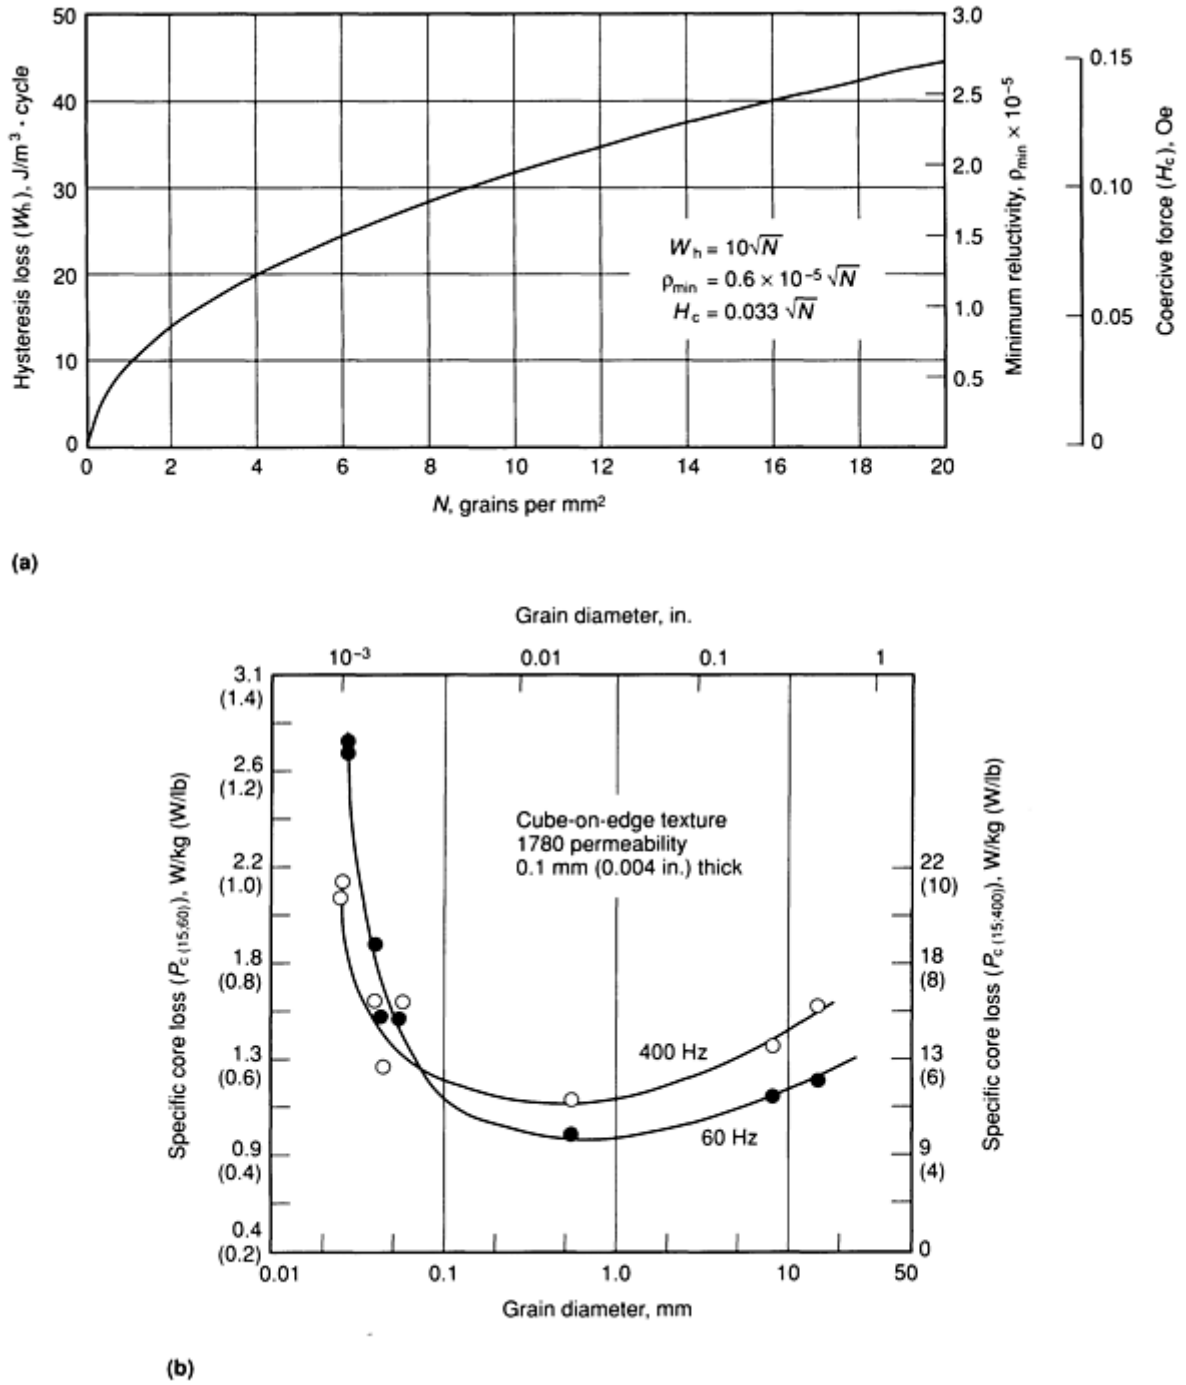

Fig. 5 Effect of grain size on magnetic properties of pure iron and silicon iron. (a) Relationship between grain size and hysteresis loss for high-purity iron at *B* = 1 T (10 kG). (b) Variation of core loss with grain size for samples of 3.15 Si-Fe having similar cube-on-edge textures and chemical purity. $P_{c(15;60)}$ is the measured magnetic core loss at 15 kG and 60 Hz; $P_{c(15;400)}$ is the measured magnetic core loss at 15 kG and 400 Hz.

Reducing Impurity Levels. The exposure of stamped laminations or machined components to annealing temperatures suitable for the alloy will result in stress relief and the desirable grain growth. These two objectives of annealing can be achieved in a vacuum furnace or inert (protective) atmosphere furnace. Adequate soft magnetic properties for the particular application may result. However, for optimum properties, most soft magnetic alloys should also undergo decarburization during the annealing treatment. Suitable annealing atmospheres for the reduction of carbon include forming gas (5 to 10% H_2 and 90 to 95% N_2), dissociated ammonia, or pure hydrogen. Stronger reducing effects are achieved with greater hydrogen content. A moist atmosphere (10 °C, or 50 °F dew point) may also promote rapid decarburization in low-carbon irons and some silicon irons, but the atmosphere must remain nonoxidizing to the iron and silicon present in the alloy. Thus, moist annealing is usually used only on irons and low-silicon-content steels and at

temperatures of ~845 °C (1550 °F) or lower. If the section size of the part is large, decarburization may be ineffective. However, smaller parts and strip or foil products may benefit greatly by decarburization.

The thermal cycles and furnace atmospheres used to heat treat soft magnetic alloys vary greatly depending upon the alloy system, processing history, and properties desired. Each of the subsequent sections provides general information about the heat treatment of various alloys. However, it is strongly recommended that the producers of the alloys be contacted for specific information regarding annealing of their products.

Alloy Classifications and Magnetic Testing Methods

The comparison of magnetic test data among different materials, or even different forms of the same alloy, can be vary misleading if the data are not developed by similar methods. Factors such as annealing temperature, annealing atmosphere, cooling rate, specimen configuration, and test frequency all have a profound effect on the magnetic test data. Various standards organizations have developed both material and testing method standards for magnetic materials. Throughout this article, reference will be made to American Society for Testing and Materials (ASTM) test methods and materials standards. Test method standards describe appropriate test equipment, electrical circuits, and specimen configurations to provide meaningful reproducible test results. Material standards have been prepared for many of the more commonly used soft magnetic alloys. They generally provide typical magnetic data and magnetic test capability limits using appropriate test methods. The material standards often provide grade designation, physical and mechanical properties, chemical analyses, and appropriate heat-treating information. ASTM A 340-87 provides symbols and definitions of terms related to magnetics.

High-Purity Iron

For many years, extremely high-purity iron has been produced for researching its magnetic characteristics. Those impurities that have the strongest detrimental effect on its magnetic properties are carbon, sulfur, and nitrogen. These elements can all be reduced to levels well below their room-temperature solubility in iron by annealing at 1300 to 1500 °C (2370 to 2730 °F) in hydrogen for several hours. It is necessary to cool slowly from the high temperature through the γ to α transformation to produce excellent soft magnetic properties. Heat treatment of iron in this temperature range is not a normal commercial practice but has been used for research into the capabilities of extremely pure iron. Bozorth reported a maximum dc permeability of greater than 10^6 for purified iron in the mid-1930s.

The saturation induction of iron based upon a density of 7.878 g/cm^3 (0.2846 lb/in.^{3}) is reported as 2.158 T (21.58 kG). The electrical resistivity is 9.8 μΩ· cm (59 Ω· circ mil/ft) at 20 °C (68 °F), and the temperature coefficient of resistivity is 0.0065/°C (0.0036/°F).

Commercially Pure Irons--Vacuum Induction Melted. Commercial high-purity irons are available from specialty steel manufacturers with a purity of approximately 99.8% Fe. This product is produced by vacuum induction melting (VIM), sometimes followed by vacuum consumable electrode remelting. It is manufactured in billet, bar, wire, or strip forms suitable for fabrication by forging, forming, or machining. Because of its high saturation induction and low electrical resistivity (10.7 μΩ· cm), high-purity irons have been used primarily in dc applications as flux carriers, electromagnetic lenses, and pole pieces or pole caps. The high-purity irons have been used in high-vacuum systems with low outgassing demands. Following fabrication of the parts, they must be annealed to develop the desired soft magnetic properties. Maximum dc permeabilities of approximately 1.7×10^4 and coercivity of approximately 20 A · m^{-1} (0.25 Oe) can be attained in bar product forms. Annealing is typically performed in a strongly reducing atmosphere, such as hydrogen, at temperatures between 815 to 980 °C (1500 to 1800 °F), for 4 h, followed by furnace cooling. The magnetic-property capabilities of this product are guaranteed by the producer at levels dependent upon the product form, method of testing and annealing process employed.

Commercially Pure Irons--Air-Furnace Melted. Commercial soft magnetic irons with a purity of approximately 99.1 to 99.8% iron are also available in billet, bar, wire, or strip forms. Historically, Armco Electromagnetic Iron generally fits into this category. Iron of this purity level can be produced by the electric-arc melting process. These irons have a saturation induction of about 2.15 T (21.5 kG), a specific gravity of 7.86, and an electrical resistivity of approximately 13 μΩ· cm at 20 °C (68 °F). The as-supplied carbon content of low-carbon magnetic iron is below 0.025%, typically 0.010% or less. The machinability of low-carbon iron bars is somewhat difficult due to the physical softness of the product. A variation of this product contains approximately 0.15% P, which strengthens the ferritic structure and enhances its machinability. The phosphorus content is not detrimental to the soft magnetic capability of the iron. These

grades of low-carbon magnetic iron are covered by ASTM specification A 848-87 and are sold to guaranteed magnetic-property capability limits.

After fabrication, the parts must be annealed to develop the desired magnetic characteristics. A typical annealing cycle consists of heating to approximately 815 to 845 °C (1500 to 1550 °F) in a reducing atmosphere (forming gas $90N_2$-$10H_2$, dissociated NH_3, or pure hydrogen) for 1 to 4 h at temperature, followed by furnace cooling. Bar products will typically exhibit a dc maximum permeability of 5×10^3 and a coercivity below 80 $A \cdot m^{-1}$ (1.0 Oe). These grades of low-carbon irons are produced to minimize magnetic aging following proper annealing. A typical guarantee would be 5% maximum increase in coercive force after aging at 100 °C (212 °F) for 200 h. Producers should be contacted for specific information concerning their products. Typical dc magnetic properties for annealed bar and heavy strip product forms of low-carbon magnetic iron and silicon irons are given in Table 1 and Table 2.

Table 1 Typical dc magnetic properties of low-carbon irons and silicon-iron bar products and heavy strip (>1.0 mm, or >0.040 in.) after annealing compared

Metal or alloy	Product form	ASTM test method[a]	Maximum permeability, $\mu_m \times 10^3$	From 1.5 T (15 kG)		Saturation induction, B_i		Resistivity μΩ· cm
				B_r, T (kG)	H_c, A · m^{-1} (Oe)	T	kG	
Low-carbon irons:								
Vacuum-melted high-purity iron	Bar	A 341	8	0.11-0.58 (1.1-5.8)	32 (0.40)	2.15	21.5	10
	Bar	A 596	17	1.00 (10)	20 (0.25)	2.15	21.5	10
	Strip	A 596	17	1.00 (10)	20 (0.25)	2.15	21.5	10
Air-melted magnetic iron[b]	Bar	A 341	7	0.25-1.20 (2.5-12)	60 (0.75)	2.15	21.5	13
	Bar	A 596	8	1.42 (14.2)	68 (0.85)	2.15	21.5	13
	Strip	A 596	11	1.38 (13.8)	48 (0.60)	2.15	21.5	13
Iron-carbon steel:								
1010 steel	. . .	. . .	3.8	0.90 (9)	80-160 (1.0-2.0)	2.15	21.5	13
Silicon irons[c]:								
1 Si-Fe	Strip	A 341	7.7	0.80-1.10 (8-11)	44 (0.55)	2.10	21.0	25
	Strip	A 596	14.8	1.31 (13.1)	32 (0.40)	2.10	21.0	25

1 Si-Fe (FM)[(d)]	Bar	A 341	9	0.20-1.10 (2-11)	40 (0.50)	2.10	21.0	25
2.5 Si-Fe	Strip	A 596	18	1.30 (13.0)	28 (0.35)	2.05	20.5	40
2.5 Si-Fe (FM)[(d)]	Bar	A 341	10	0.25-1.20 (2.5-12.0)	32 (0.40)	2.05	20.5	40
	Bar	A 596	14	1.37 (13.7)	24 (0.30)	2.05	20.5	40
4 Si-Fe	Bar	A 596	18.5	1.08 (10.8)	24 (0.30)	1.95	19.5	58

(a) ASTM A 341, straight length test samples using permeameter; ASTM A 596, ring test samples, machined or stamped.

(b) ASTM Material Standard A 848-87.

(c) All silicon irons shown are included in ASTM Material Standard A 867-86.

(d) FM, free machining

Table 2 Nominal compositions, typical annealing cycles, and typical mechanical properties of low-carbon iron and silicon-iron bar products and heavy strip (>1.0 mm, or 0.040 in.)

Metal or alloy	Nominal composition					Annealing cycle used to develop Table 1 data[b]				Annealed mechanical properties					
										Ultimate tensile strength		Yield strength		Elongation, %,	Hardness, HRB
	C	Si	Al[a]	P	Fe	Temperature	Time, h	Atmosphere	Cooling[c]	MPa	ksi	MPa	ksi		
Low-carbon irons:															
Vacuum-melted high-purity iron	<0.01	0.02	. . .	. . .	~99.9	955 °C (1750 °F)	4	Wet H_2	Furn	235	34	124	18	55	<20

1 Si-Fe (FM)[d]	0.02	1.1	0.5	0.15	bal	845 °C (1550 °F)	4	Wet H_2	Furn	434	63	262	38	40	70
2.5 Si-Fe	0.02	2.5	0.5	. . .	bal	1065 °C (1950 °F)	4	Dry H_2	Furn	517	75	414	60	35	85

2.5 Si-Fe (FM)[(d)]	0.02	2.4	0.5	0.15	bal	1065 °C (1950 °F)	4	Dry H_2	Furn	551	80	448	65	35	88
4 Si-Fe	0.02	4.0	0.5	. . .	bal	1065 °C (1950 °F)	4	Dry H_2	Furn	655	95	517	75	30	95

(a) Up to 0.5% Al optional--usually substituted for some of the silicon content.

(b) Annealing cycles given only as an example--other cycles may be more desirable depending upon equipment available and specific application.

(c) Furn, furnace cooled nominally 55 °C/h (100 °F/h) to 110 °C/h (200 °F/h).

(d) FM, free machining

Low-Carbon Steels

For applications that require less than superior magnetic properties, low-carbon steels such as 1008, 1010, 12L14, and so on, are sometimes used (see the article "Classification and Designation of Carbon and Low-Alloy Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,*Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). Such steels are not sold to magnetic quality specifications and may show considerable variation in quality, depending upon melting methods and the physical condition of the as-supplied product. Parts made from these steels will generally show improved soft magnetic characteristics if annealed as normally recommended for higher-quality, soft magnetic low-carbon iron. The degree of improvement is not guaranteed, however, and the parts may be subject to considerable magnetic aging over time. Due to their low cost, availability, and machinability, they have been used as pole pieces in electromagnets, magnetic clutches, and other noncritically designed flux carriers.

Compressed Powdered Iron. For applications in which complicated magnetic parts would otherwise require considerable machining, it may be helpful to press iron powder in a mold and sinter the part in vacuum or in a reducing atmosphere. Figure 6 shows anticipated effects of sintering temperature and sintering time on magnetic permeability of powdered iron, expressed as a percentage of the permeability of annealed, low-carbon, soft magnetic irons, for a constant magnetizing force.

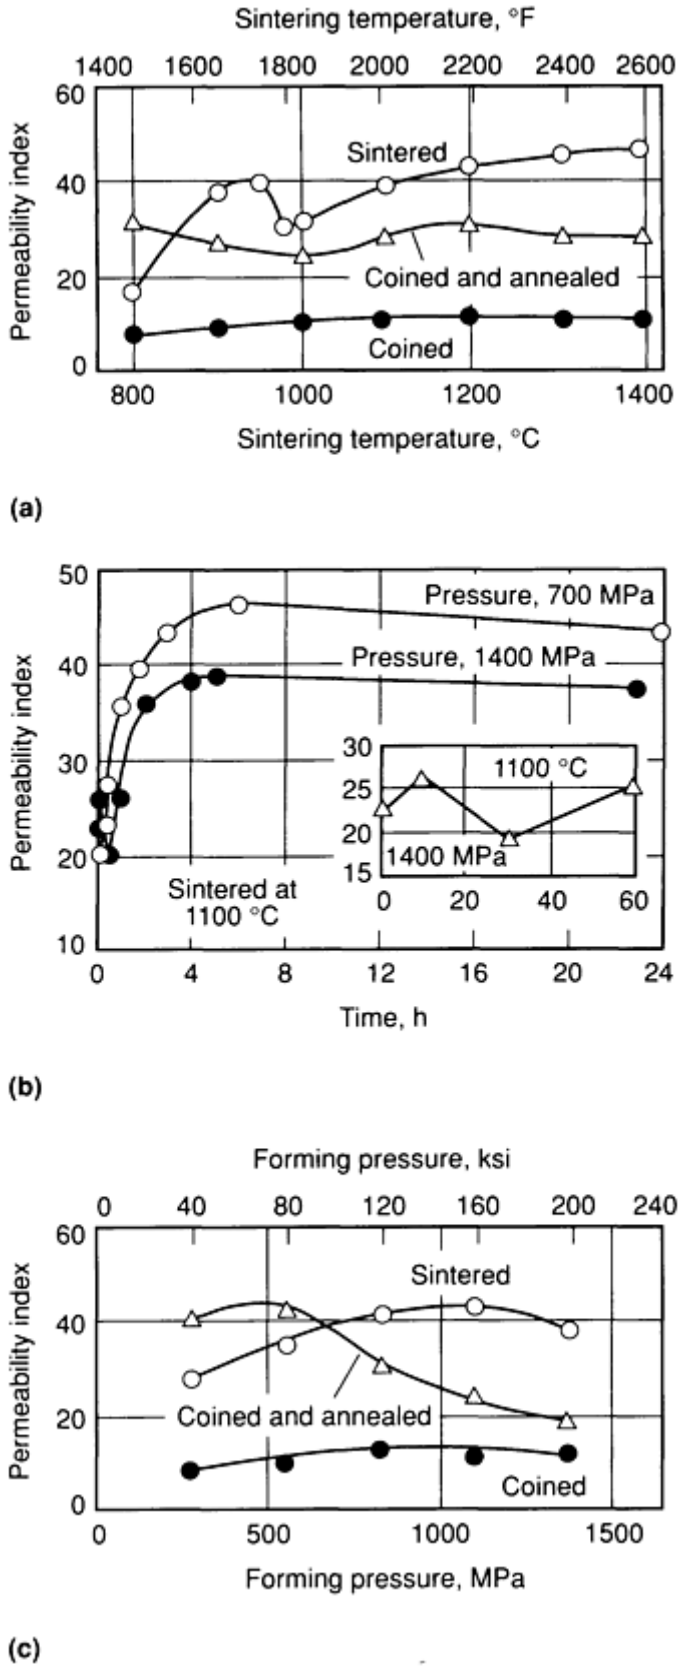

Fig. 6 Variations in the permeability index of P/M iron as a function of (a) sintering temperature, (b) duration of sintering, and (c) forming pressure. The magnetic permeability (for a constant magnetizing force) is shown as a percentage of the permeability of annealed, hot-rolled, low-carbon steel in (a) and (c).

Depending upon the powder metallurgy (P/M) techniques, starting powder quality, and final part configuration, the density of finished P/M iron parts can range from 6.2 g/cm^3 (0.224 lb/in.^{3}) to virtually full density of 7.8 g/cm^3 (0.282 lb/in.^{3}). It has been shown that the magnetic properties, as well as electrical resistivity, are a function of the density of the component. Higher saturation induction, residual induction, and maximum permeability result from increased density, whereas coercive force and resistivity are lowered.

There are presently two ASTM standards prepared that specifically cover magnetic properties of soft magnetic iron P/M parts (ASTM A 811-83) and iron powders containing 0.45 to 0.80% P intended for use in P/M-produced soft magnetic components (ASTM A 839-87).

The use of P/M techniques to make magnetically soft components may eliminate all machining operations and save a substantial amount of the total cost, compared to conventional manufacturing. If stress-inducing secondary machining operations are required to finish the sintered P/M part, then final stress-relief annealing may be required to restore its magnetic characteristics.

Low-Carbon Lamination Steel. Low-carbon sheet and strip products are available in a variety of thicknesses, commonly called motor lamination steel. These steels have low carbon content, typically less than 0.06%, and may have phosphorus and manganese added to increase resistivity and improve punchability. Motor lamination steel is usually intended for applications wherein the laminations will be annealed by the purchaser to develop the desired magnetic properties. The magnetic-property capability is not guaranteed by the producer except for special classes of this product. ASTM standard A 726-85 covers this category of product.
