Similar low-carbon iron, but melted to tighter analysis requirements, is produced as fully processed cold-rolled lamination steel as described in ASTM A 840-85. Fully processed product refers to lamination steel manufactured by hot rolling, pickling, cold rolling to finish thickness, and continuous annealing to achieve core loss values below the maximum guaranteed limits. It is intended for applications where the lamination can be used in the as-stamped condition, without the need for further heat treatment. Although low-carbon steels exhibit power losses higher than those of silicon steels, they have better permeability at high flux density. This combination of magnetic properties, coupled with low price, makes low-carbon steels especially suitable for applications such as fractional-horsepower motors, which are used intermittently.

Silicon Steels (Flat-Rolled Products)

The beneficial effects of silicon additions to iron include:

- Increase of electrical resistivity
- Suppression of the γ loop enabling desirable grain growth
- Development of preferred orientation grain structure

The addition of silicon also reduces magnetocrystalline anisotropy energy, and at ~6.5% Si content reduces the magnetostriction constants to nearly zero. High-permeability and low hysteresis losses can therefore be attained at the 6.5Si-Fe composition. On the negative side, the addition of silicon to iron lowers magnetic saturation, lowers Curie temperature, and seriously decreases mechanical ductility. At silicon levels above ~4%, the alloy becomes brittle and difficult to process by cold-rolling methods; thus, few commercial steels contain more than ~3.5% Si.

The commercial grades of silicon steel in common use are made mostly in electric or basic oxygen furnaces. Continuous casting and/or vacuum degassing (V-D) may be employed. Flat-rolled silicon-iron sheet and strip has low sulfur content, typically below 0.025%, with better grades below 0.01%. Manganese may be present up to approximately 0.70%. Residual elements such as chromium, molybdenum, nickel, copper, and phosphorus may also be present. The major alloying addition is silicon plus up to 0.6% Al (optional). These alloys are not generally sold on the basis of their composition, but rather are sold based upon controlled magnetic properties, particularly ac core losses.

Table 3 gives examples of properties specified by ASTM and American Iron and Steel Institute (AISI) for standard grades of electrical steel. The AISI designations were adopted in 1946 to eliminate the wide variety in nomenclature formerly used. When originally adopted, the AISI designation number approximated ten times the maximum core loss, in watts per pound, exhibited by 29 gage (0.36 mm, or 0.014 in.) samples when tested at a flux density of 1.5 T (15 kG) and a

magnetic circuit frequency of 60 Hz. Note that fully processed M-36 tested as 0.36 mm (0.014 in.) strip now has a maximum allowable core loss of 4.2 W/kg (1.9 W/lb), not an approximate level of 7.9 W/kg (3.6 W/lb).

Table 3 Magnetic and thermal properties of selected conventional and high permeability flat-rolled electrical steels

AISI Type (approximate equivalent)	Nominal (Si + Al) content, %	Thickness		ASTM designation	Maximum core loss at 60 Hz and B = 1.5 T (15 kG)		Typical relative peak permeability, μ_p		Typical 60 Hz rms excitation to produce 1.5T (15 kG) A · cm^{-1}	Saturation induction, b_s		Thermal conductivity	
		mm	in.		W/kg	W/lb	at 60 Hz and 1.5 T (15 kG)	at H_p of 0.8 kA · m^{-1} (10 Oe)		T	kG	W/m · K	Btu/ft · h · °F

(d) B = 1.7 T (17 kG)

The AISI designations are still in common use, but the newer ASTM designations provide more specific information regarding the grade identified. A typical ASTM designation is 47S200. The first two digits of the ASTM designation indicate the thickness in mm (× 100). Following these digits is a letter (C, D, F, S, G, H, or P) that indicates the material type and the respective magnetic test conditions. The last three digits provide an indication of the maximum allowable core loss in units of either (watts/kg) × 100, or (watts/lb) × 100. If the core-loss value is expressed in watts/kg, the grade designation takes the suffix M, indicating an ASTM metric standard. Several ASTM flat-rolled products specifications are

written in English and metric versions, such as A 677-84 and its companion metric specification A 677M-83. A general summary of the ASTM code letter designation is shown in Table 4. Refer to ASTM standard A 664-87 for a complete explanation of the identification practice and the conditions that apply to the test parameters.

Table 4 ASTM letter code designations for electrical steel and lamination steel grades (ASTM standard A 664-87)

Letter code	Grade	Condition	Core loss test parameters with cyclic frequency, *f*, at 60 Hz			
			Induction, *B*		Test specimen	Specimen condition
			T	kG		
C	Low-carbon lamination steel	Fully processed	1.5	15	50/50 grain Epstein	As sheared
D	Low-carbon lamination steel	Semiprocessed	1.5	15	50/50 grain Epstein	Quality development annealed[(a)]
F	Nonoriented electrical steel	Fully processed	1.5	15	50/50 grain Epstein	As sheared
S	Nonoriented electrical steel	Semiprocessed	1.5	15	50/50 grain Epstein	Quality development annealed[(a)]
G	Grain-oriented electrical steel	Fully processed	1.5	15	Parallel grain Epstein	Stress-relief annealed[(b)]
H	Grain-oriented electrical steel	Fully processed	1.7	17	Parallel grain Epstein	Stress-relief annealed[(b)]
P	Grain-oriented electrical steel, high permeability	Fully processed	1.7	17	Parallel grain Epstein	Stress-relief annealed[(b)]

(a) Quality development anneal--either 790 °C (1450 °F) or 845 °C (1550 °F) soak 1 h. Temperature depends on particular grade.

(b) Stress relief anneal--usually in the range from 790 °C (1450 °F) to 845 °C (1550 °F) for 1 h

The typical relative peak permeability at 60 Hz and 1.5 T (15 kG) and typical 60 Hz rms excitation to produce 1.5 T (15 kG) induction are shown, because these are useful design parameters for the application of these materials. Best permeability at high induction is obtained in steels with lower silicon contents. Low core loss is obtained with higher silicon contents, larger grains, lower impurity levels, and thinner gages. Nonoriented silicon irons are preferred for motor laminations.

Nonoriented Silicon Steels. Nonoriented (isotropic) flat-rolled products are available in semiprocessed and fully processed conditions and contain 0.5 to 3.5% Si. The vast majority of finished nonoriented silicon steel is sold in either

full-width coils (860 to 1220 mm, or 34 to 48 in. widths) or slit-width coils, but some are sold as sheared sheets. Fully processed electrical steel frequently is coated with organic or inorganic materials after mill annealing to reduce eddy currents in lamination stacks.

Semiprocessed Grades. The carbon contents of semiprocessed grades are relatively low, usually below 0.030%. However, semiprocessed product is not sufficiently decarburized for general use as supplied; therefore, decarburization and annealing to develop potential magnetic quality and to avoid magnetic aging must be done by the user. Anneals of this type are typically performed at temperatures between 790 and 845 °C (1450 and 1550 °F) for approximately 1 h with a suitable decarburization atmosphere. The atmosphere must contain sufficient moisture to promote decarburization without excessive oxidation of the metal. An atmosphere of 20% H_2, 80% N_2, and a dew point of 15 °C (55 °F) often meets these requirements. However, it is necessary to contact the manufacturer for specific recommendations and procedures for safe and proper annealing of these alloys.

Semiprocessed electrical steels are usually supplied without a surface insulation coating or with only a thin, tightly adhering oxide to provide insulation resistance.

Fully processed grades are process annealed by the manufacturer in moist hydrogen at about 825 °C (1520 °F) to reduce carbon. The final annealing operation is carried out by the manufacturer at a higher temperature (up to 1100 °C, or 2010 °F for continuous strip) to promote grain growth and development of magnetic properties. The desirable magnetic characteristics are thus produced during the manufacturing so additional heat treatment by the purchaser is generally not required. All coils are sampled and tested in accordance with ASTM specifications A 343, A 347, and 804 method of test, and graded as to quality. These products are primarily intended for commercial power frequency (50 to 60 Hz) applications and are sold to maximum core loss limits at a particular induction, typically 1.5 T (15 kG).

Oriented Silicon Steels. Grain size is important in silicon steel with regard to core losses and low flux-density permeability. However, for high-flux density permeability, crystallographic orientation is a major controlling factor. Like iron, silicon steels are more easily magnetized in the direction of the cube edge, {100}, as shown in Fig. 7.

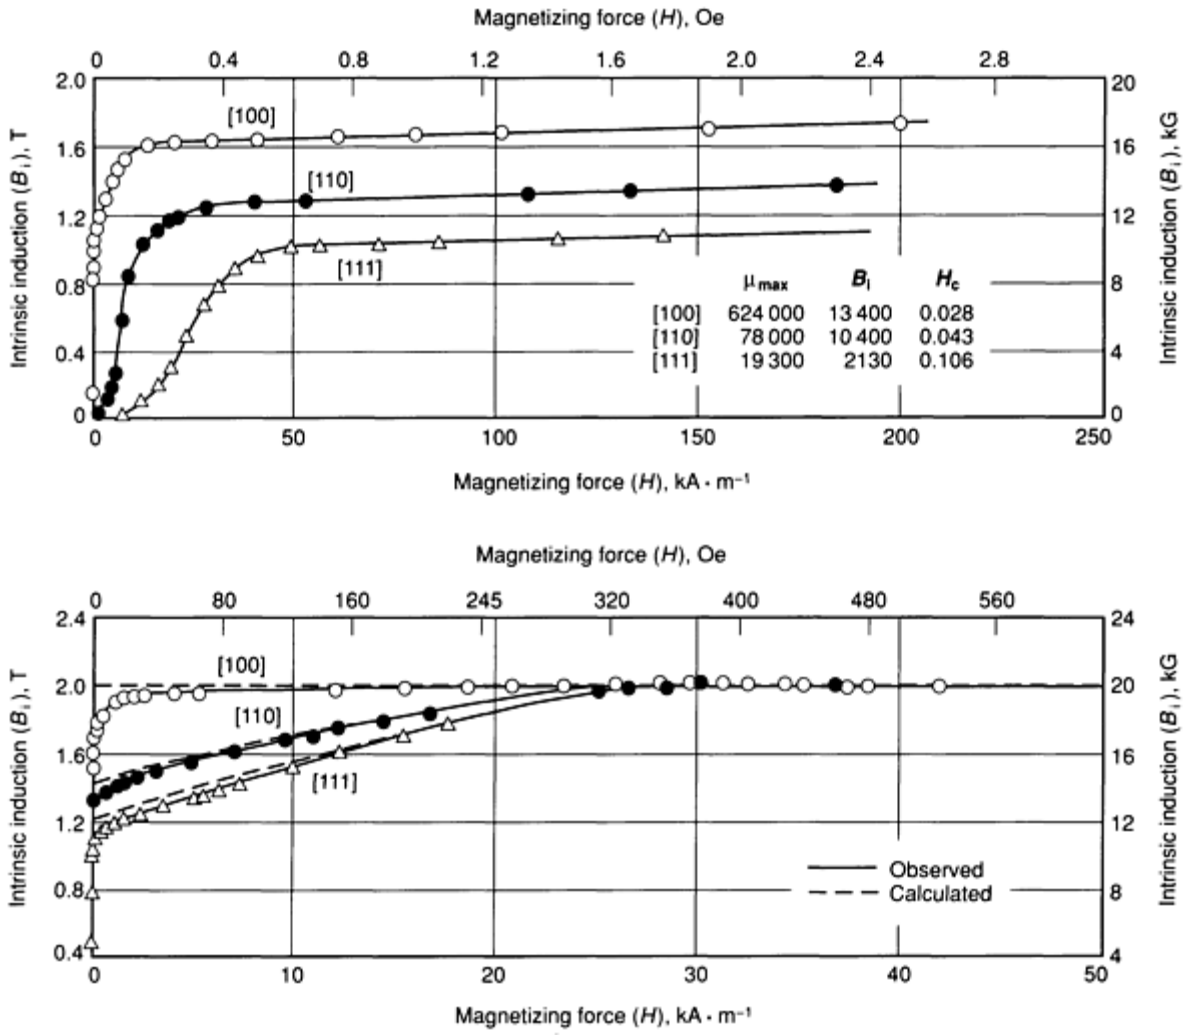

Fig. 7 Observed and calculated *B-H* curves for [100], [110], and [111] directions in single crystals of 3 to 3.5% Si steel

As mentioned previously, when the silicon content in pure iron exceeds approximately $2\frac{1}{2}\%$, the allotropic transformation of iron from α to γ is suppressed. The absence of this transformation allows the higher silicon-iron alloy to be fully ferritic up to the melting point. This behavior permits the manufacturer of these strip products to apply special cold-rolling and heat-treating techniques to promote secondary recrystallization in the final anneal. The processing results in a well-developed crystallographic texture with the cube edge parallel to the rolling direction {110}{001}, often referred to as the Goss or cube-on-edge orientation. Conventional-oriented (anisotropic) grades contain about 3.15% Si.

Around 1970, improved {110}<001> crystallographic texture was developed by modification of composition and processing. The improved high-permeability material usually contains about 2.9 to 3.2% Si. Conventional grain-oriented 3.15% Si steel has grains about 3 mm (0.12 in.) in diameter. The high-permeability silicon steel tends to have grains about 8 mm (0.31 in.) or larger in diameter. Ideally, grain diameter should be less than 3 mm (0.12 in.) to minimize excess eddy-current effects from domain-wall motion. Special coatings provide electrical insulation and induced tensile stresses in the steel substrate. In this case, the induced stresses lower core loss and minimize noise in transformers.

Oriented Silicon Steel Versus Nonoriented Silicon Steel. Figure 8 compares the variation in flux density and core loss, with respect to direction of rolling, for oriented and nonoriented silicon steels. These curves indicate the advantage of using oriented steels in a manner such that the critical flux path of the application is parallel to the sheet or strip cold-rolling direction. Corresponding *B-H* curves and half hysteresis loops are given in Fig. 9.

Aging. High-grade, fully processed, silicon electrical steel does not age as received from the mill because its carbon content has been reduced to about 0.003% or less. With higher carbon contents, however, core loss can increase with time because of carbide precipitation. Also, silicon steel may age appreciably if not correctly heat treated in a manner that completely stabilizes its physical structure. Table 5 lists typical applications of electrical steel sheet and strip.

Table 5 Silicon contents, mass densities, and applications of electrical steel sheet and strip

ASTM specification	AISI type	Nominal (Si + Al) content, %	Assumed density, g/cm^3	Characteristics and applications
Lamination steel				
A 726 or A 840	. . .	0	7.85	High magnetic saturation; magnetic properties may not be guaranteed; intermittent-duty small motors
Nonoriented electrical steels

Silicon-Iron Bar and Heavy Strip

Silicon irons containing between approximately 1 and 4% Si (and optionally up to approximately 0.5% Al) have been used extensively for the manufacture of ac and dc relay cores, printer hammers, flux-path components, pole pieces, and rapidly activated solenoids such as automotive fuel injectors, and so on. For high-volume screw-machine applications, free-machining grades containing approximately 0.15% P are produced. At this level, phosphorus has no significant effect on the magnetic characteristics. These grades have been commonly known as relay steels or silicon core irons.

These products are typically supplied in a condition suitable for forging, machining, stamping, or forming. After fabrication, the parts should be annealed to remove stress, to increase grain size, and to reduce their carbon content. ASTM standard A 867-86 describes the characteristics of silicon-iron bar products and provides dc magnetic-property capability, which can be guaranteed by the alloy manufacturers. Tables 1 and 2 present dc magnetic properties for silicon-iron bar and heavy strip products.

Silicon irons containing approximately 1% Si exhibit the phase transformation discussed for low-carbon irons. As a result, it is common practice to anneal these alloys at 815 to 870 °C (1500 to 1600 °F), which is below the Ac_1

transformation temperature. Alloys containing ~2.5% Si can be annealed at higher temperatures and show continued improvement in permeability with increasing annealing temperature. Figure 10 shows the dc normal induction curves for 2.5Si-Fe annealed at four temperatures from 730 to 1065 °C (1350 to 1950 °F). The maximum permeabilities ranged from a low of approximately 1.7×10^3 to a high of approximately 1.4×10^4 in the example, thus illustrating the importance of proper annealing. The manufacturer of these alloys should be contacted for specific annealing information.

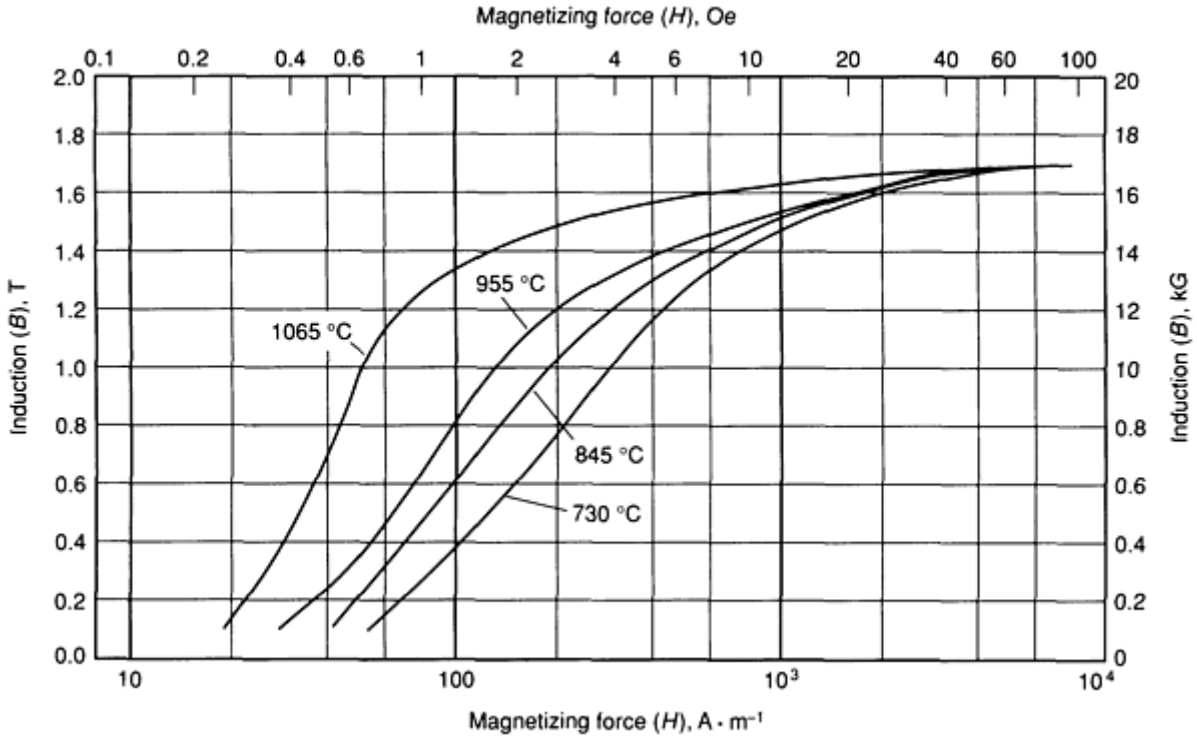

Fig. 10 Direct-current normal induction curves for 2.5% Si-Fe heavy strip, that was annealed at various temperatures. Ring test specimens are from 1.52 mm (0.060 in.) thick strip, annealed in pure dry hydrogen, 2 h at heat, then furnace cooled. Tested per ASTM standard A 596

Iron-Aluminum Alloys

Although aluminum and silicon have similar effects on electrical resistivity and some magnetic properties of iron, aluminum is seldom substituted for silicon because of the resulting difficulties in fabrication. Aluminum is used most commonly as small (<0.5%) additions to the better grades of nonoriented silicon steel to increase electrical resistivity and thereby reduce eddy currents without impairing cold workability. Alloys of 12% Al or 16% Al and iron have high resistivity and can provide high permeability. At low flux densities, the magnetic properties of these alloys can be made to approach those of some of the low nickel-content nickel-iron alloys (see the section "Nickel-Iron Alloys" in this article). High-aluminum alloys are very difficult to process and have not been readily available in large quantities.

Nickel-Iron Alloys

The effect of nickel content in nickel-iron alloys on saturation induction (B_s) and on initial permeability (μ_0) after annealing are illustrated in Fig. 11 and Fig. 12. Below ~28% Ni, the crystalline structure is bcc low-carbon martensite if cooled rapidly and ferrite and austenite if cooled slowly, and these alloys are not considered useful for soft magnetic applications. Above ~28% Ni, the structure is fcc austenite. The Curie temperature in this system is approximately room temperature at ~28% Ni and increases rapidly up to ~610 °C (1130 °F) at 68% Ni. Thus, these austenitic alloys are ferromagnetic. The magnetic properties are controlled by saturation magnetization and the magnetic anisotropy energies, particularly magnetocrystalline (K_1) and magnetostrictive (λ_1) anisotropies.

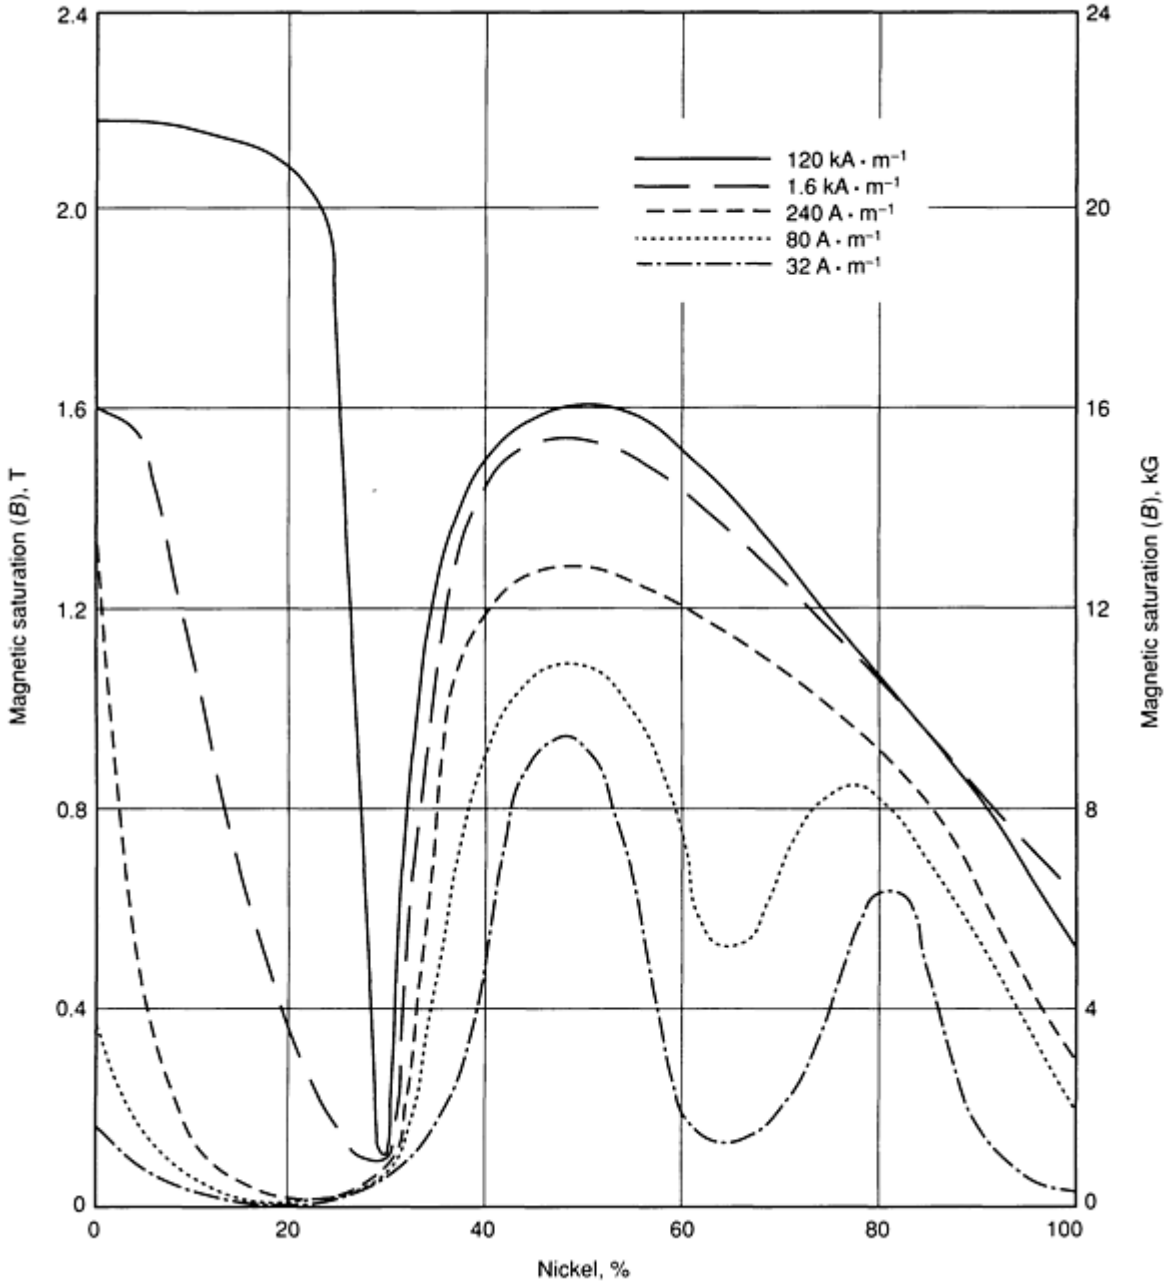

Fig. 11 Magnetic saturation of binary nickel-iron alloys at various field strengths. All samples were annealed at 1000 °C (1830 °F) and cooled in the furnace.

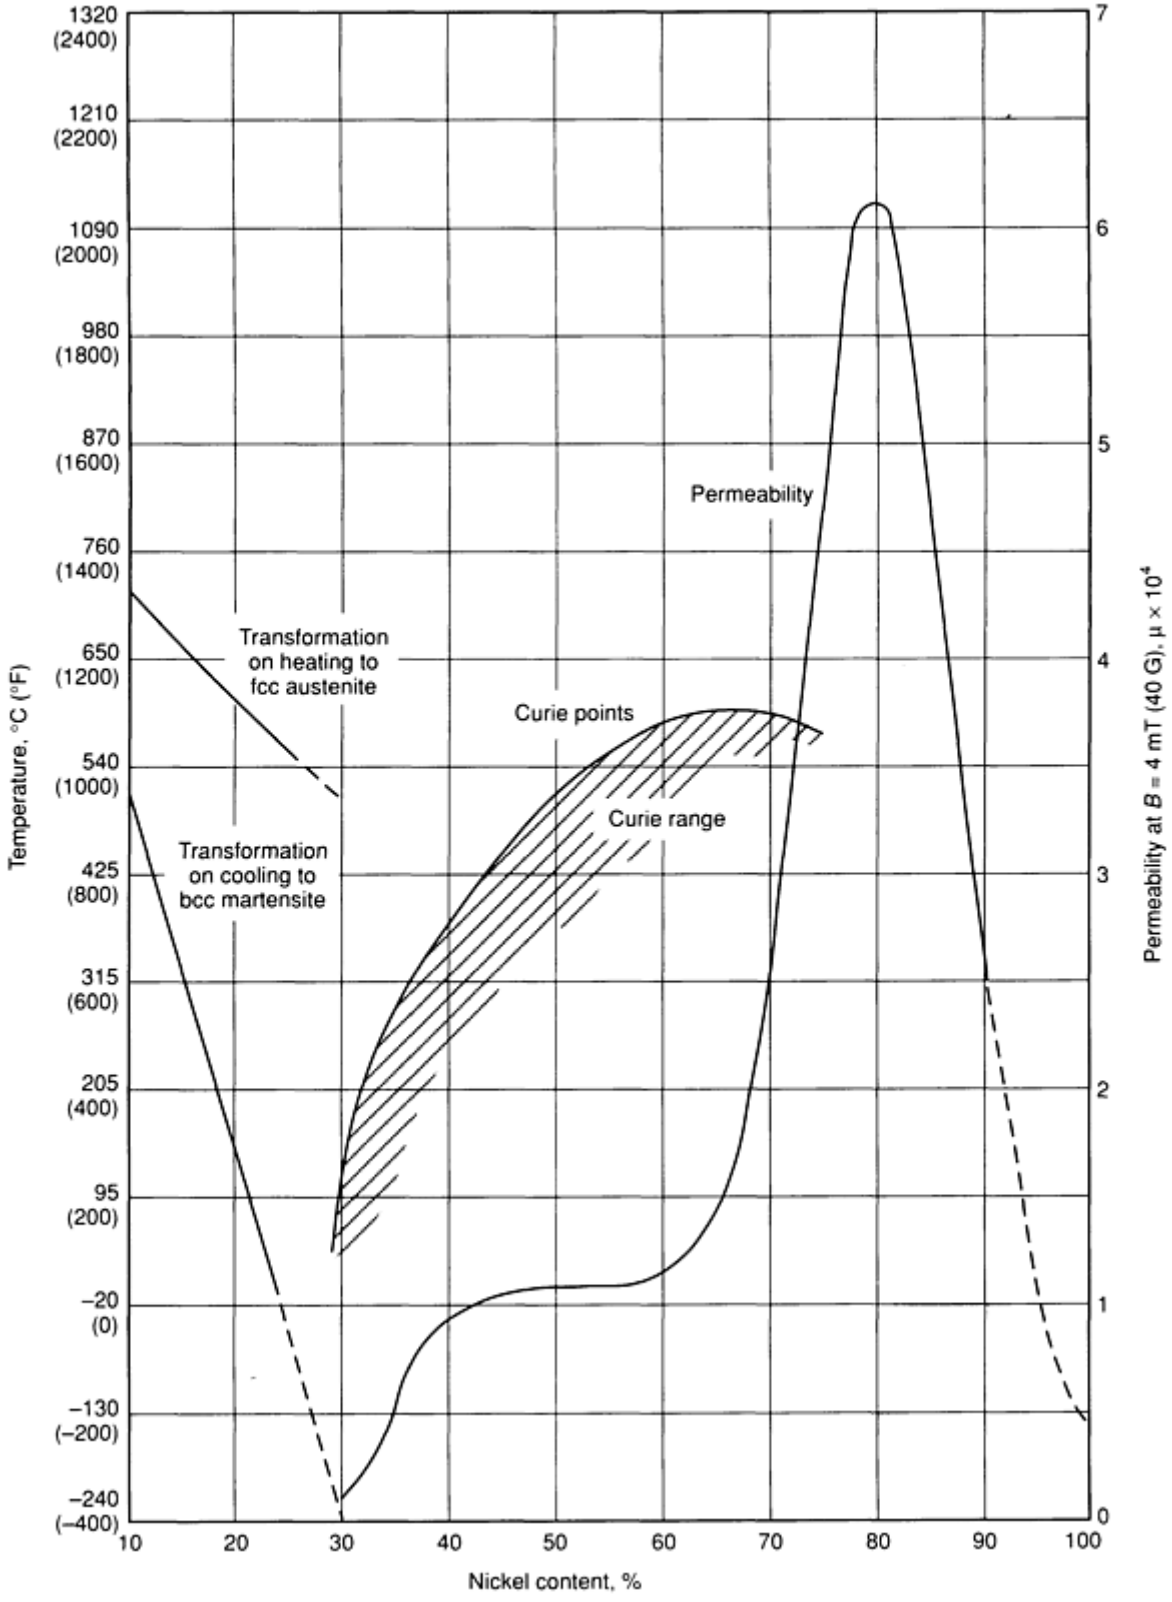

Fig. 12 Effect of nickel content on initial permeability, Curie temperature, and transformation in nickel-iron alloys

Two broad classes of commercial alloys have been developed in the nickel-iron system. The high-nickel alloys (about 79% Ni) have high initial and maximum permeabilities and very low hysteresis losses, but they also have a saturation induction of only ~0.8 T (8 kG). The low-nickel alloys (about 45 to 50% Ni) are lower in initial and maximum permeability than the 79% Ni alloys, but are still much higher than silicon irons. The low-nickel alloys have a saturation

induction of about 1.5 T (15 kG). Values of initial permeability (at B of 4 mT, or 40 G) above 1.2×10^4 are typically obtained in low-nickel alloys, and values above 6.5×10^4 are obtained for 79Ni-4Mo-Fe alloys at 60 Hz using 0.36 mm (0.014 in.) thick laminations. Maximum dc permeabilities of 1.4×10^5 for low-nickel alloys and 3.75×10^5 for high-nickel alloys are routinely attained.

Figure 13 contains data from early laboratory studies to illustrate the effect of both composition and heat treatment on initial permeability. To obtain very high magnetic permeability, both the magnetocrystalline anisotropy (K_1) and the magnetostrictive anisotropy (λ_1) must be minimized. The magnetostrictive anisotropy is highly dependent upon the alloy composition. Generally, there is little that the purchaser can do to the alloy that will change this characteristic. However, in the high-nickel alloys, the magnetocrystalline anisotropy can be altered by the appropriate annealing cycle cooling rate. In these alloys, short-range atomic ordering occurs as the alloy is cooled from ~760 °C (1400 °F) to ~400 °C (750 °F). The degree of ordering has a profound effect on K_1, and, therefore, each composition will have an optimum cooling rate that minimizes the net anisotropy energies and can result in very high permeability.

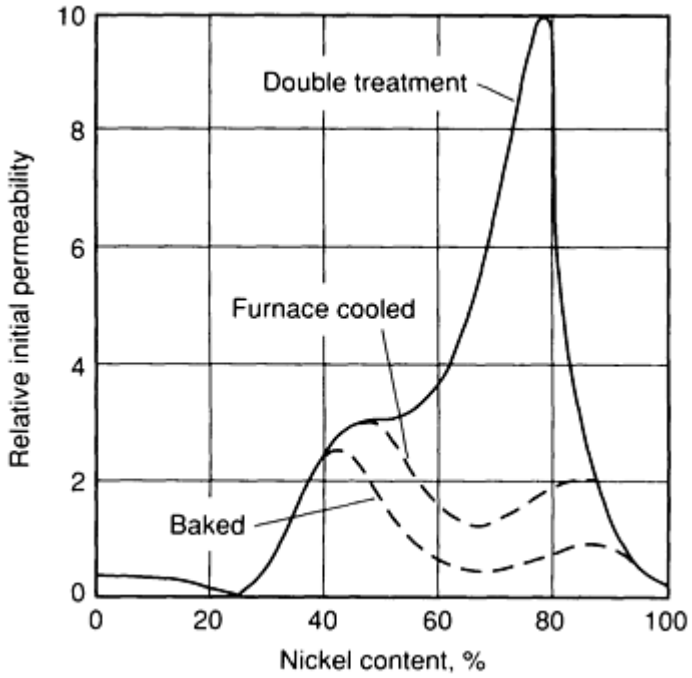

Fig. 13 Relative initial permeability at 2 mT (20 G) for Ni-Fe alloys given various heat treatments. Treatments were as follows: furnace cooled--1 h at 900 to 950 °C (1650 to 1740 °F), cooled at 100 °C/h (180 °F/h); baked--furnace cooled plus 20 h at 450 °C (840 °F); double treatment--furnace cooled plus 1 h at 600 °C (1110 °F) and cooled at 1500 °C/min (2700 °F/min).

High-Nickel Alloys. Figure 13 illustrates that in ~78.5Ni-Fe the initial permeability was low after either furnace cooling or baking at 450 °C (840 °F). However, if the same alloy was rapidly cooled from 600 °C (1110 °F), the initial permeability was increased dramatically. High-purity 78.5 Ni-Fe can exhibit an initial dc permeability of 5×10^4 and a maximum permeability of 3×10^5. These properties are obtained on ring laminations annealed in dry hydrogen at 1175 °C (2150 °F), rapid furnace cooled to room temperature, then reheated to 600 °C (1110 °F), and oil quenched. This alloy has limited commercial use because the complex heat treatment is not easily performed on parts. Also, its electrical resistivity is only 16 $\mu\Omega \cdot$ cm, which allows large eddy-current losses in ac applications.

Alloying additions of 4 to 5% Mo, or of copper and chromium to ~79Ni-Fe, alter the kinetics of ordering and the magnetostrictive anisotropy energy. Alloying also increases the electrical resistivity; however, saturation induction is reduced to the 0.8 T (8 kG) level. Specially steel manufacturers produce a variety of carefully design very high-permeability alloys that permit the use of practical commercial annealing procedures. Popular alloys include the Moly-Permalloys (typically 80Ni-4 to 5Mo-bal Fe) and MuMetals (typically 77Ni-5Cu-2Cr-bal Fe).

High-permeability alloys must also be of high commercial purity. Air- and vacuum-melting practices are both used to produce low-nickel alloys, but nearly all of the high-nickel alloys are produced by VIM. Figure 14 shows a historical perspective of the change in initial permeability of 80Ni-4Mo-Fe alloys when VIM became widely used around 1960. Interstitial impurities such as carbon, sulfur, oxygen, and nitrogen must be minimized by special melting procedures and by careful final annealing of laminations and other core configurations. Sulfur contents higher than several ppm and carbon in excess of 20 ppm are detrimental to final-annealed magnetic properties in high-nickel alloys.

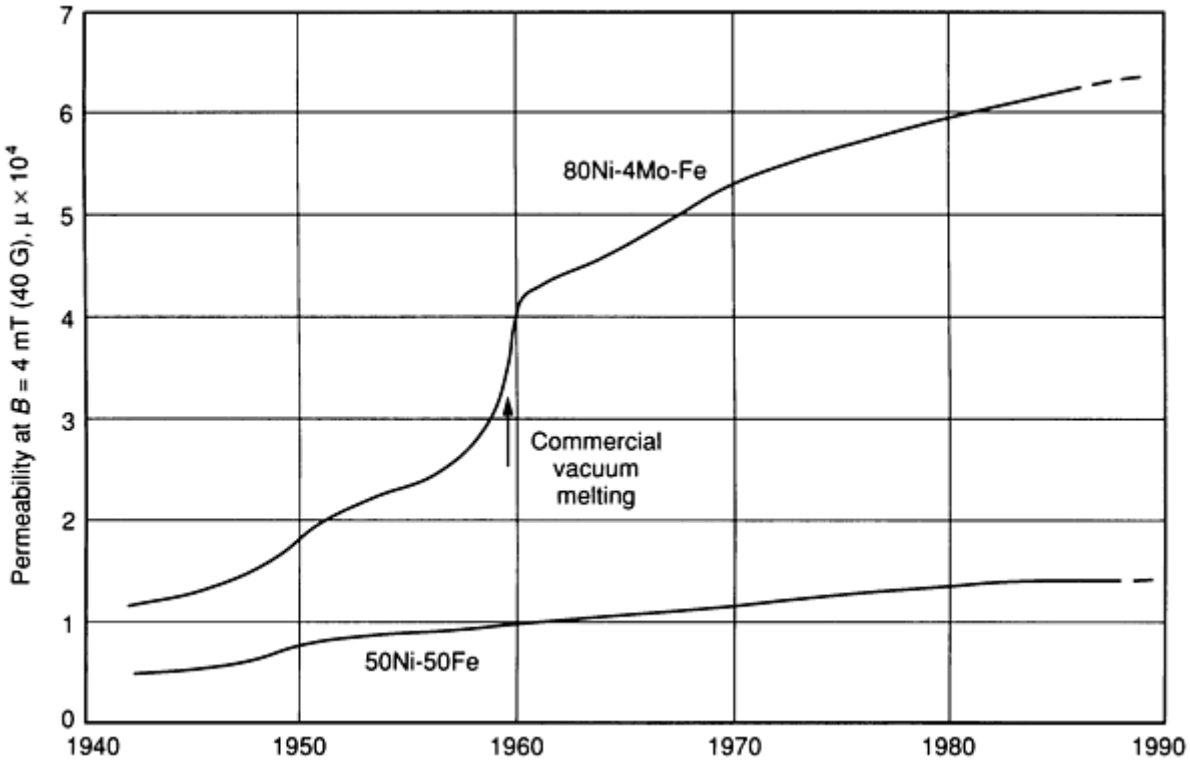

Fig. 14 Progress in initial permeability values of commercial-grade nickel-iron alloys since early 1940s. Frequency, *f*, is 60 Hz. Thickness of annealed laminations was 0.36 mm (0.014 in.).

Laminations or parts made from these high-nickel alloys are usually commercially annealed in pure dry hydrogen (dew point less than -50 °C, or -58 °F, at ~1000 to 1205 °C, or 1830 to 2200 °F, for several hours to eliminate stresses, to increase grain size, and to provide for alloy purification). They are cooled at any practical rate down to the critical ordering temperature range. The rate of cooling through the ordering range is typically 55 °C/h (100 °F/h) to 350 °C/h (630 °F/h), depending upon the alloy being heat treated. Although the cooling rate below the ordering range is not critical, stresses due to rapid quenching must be avoided.

Vacuum furnaces may be used to anneal some high-nickel soft magnetic alloys if the application does not demand the optimum magnetic properties. However, dry hydrogen is strongly recommended for annealing nickel-iron alloys. Parts must always be thoroughly degreased to remove oils (particularly sulfur-bearing oils) prior to annealing.

Low-Nickel Alloys. In alloys containing approximately 45 to 50% Ni, the effect of cooling rate on initial permeability is not great, as evidenced in Fig. 13. The typical annealing cycle to develop high permeability for these low-nickel alloys is similar to the high-nickel cycle, except that any cooling rate between ~55 °C/h (100 °F/h) and ~140 °C/h (252 °F/h) is usually suggested. A dry hydrogen atmosphere is also recommended for annealing low-nickel alloys.

Magnetic Properties of Nickel-Iron Alloys. The nickel-iron alloys are generally manufactured as strip or sheet product; however, billet, bar, and wire can be produced as needed. Strip products are usually supplied in a cold-rolled condition for stamping laminations or as thin foil for winding of tape toroidal cores. Strip and sheet products may also be supplied in a low-temperature, mill-annealed, fine-grain condition suitable for forming and deep drawing. ASTM standard A 753 describes the as-supplied condition and the magnetic property capabilities of many of the higher-volume-usage

nickel-iron alloys. Tables 6, 7, and 8 provide typical dc and ac magnetic characteristics and some mechanical properties of nickel-iron alloys.

Table 6 Typical dc magnetic properties of annealed high-permeability nickel-iron alloys. Data for 0.30 to 1.52 mm (0.012 to 0.060 in.) thickness strip; ring laminations annealed in dry hydrogen at 1175 °C (2150 °F) (unless otherwise noted), 2 to 4 h at temperature. ASTM A 596

(a) All nickel-iron soft magnetic alloys should be annealed in a dry (-50 °C, or -58 °F) hydrogen atmosphere, typically for 2 to 4 h; cool as recommended by producer. Vacuum annealing generally provides lower properties, which may be acceptable depending upon specific application.

(b) RT, room temperature

Nickel-iron alloys can be processed and heat treated to develop a wide range of properties for a variety of applications. The scope of these application is too extensive to report in detail in this article, thus only a brief listing of several applications can be presented (Table 9). The high-nickel alloys have been used extensively for magnetic shielding, high-quality, low-noise audio frequency transformers, ground fault interrupter cores, antishoplifting devices, tape recorder head laminations, magnetometer bobbin cores, and so on. Domestic producers of the specialty alloys listed in Table 9 are shown in Table 10.

Table 9 Application of nickel-iron and iron-cobalt magnetically soft alloys

Application	Specialty alloy[(a)]	Special property
Instrument transformer	79Ni-4Mo-Fe, 77Ni-5Cu-2Cr-Fe, 49Ni-Fe	High permeability, low noise and losses
Audio transformer	79Ni-4Mo-Fe, 49Ni-Fe, 45Ni-Fe, 45Ni-3Mo-Fe	High permeability, low noise and losses, transformer grade
Hearing aid transformers	79Ni-4Mo-Fe	High initial permeability, low losses
Radar pulse transformers	2V-49Co-49Fe, oriented 49Ni-Fe, 79Ni-4Mo-Fe, 45Ni-3Mo-Fe	Processed for square hysteresis loop, tape toroidal cores
Magnetic amplifiers	Oriented 49Ni-Fe, 79Ni-4Mo-Fe	Processed for square hysteresis loop, tape toroidal cores
Transducers	2V-49Co-49Fe, 45-50Ni-Fe	High saturation magnetostriction
Shielding	79Ni-4Mo-Fe, 77Ni-5Cu-2Cr-Fe, 49Ni-Fe	High permeability at low induction levels
Ground fault (GFI) interruptor core	79Ni-4Mo-Fe	High permeability, temperature stability
Sensitive dc relays	45 to 49Ni-Fe, 78Ni-Fe	High permeability, low losses, low coercive force
Electromagnet pole tips	2V-49Co-49Fe, 27Co-0.6Cr-Fe	High saturation induction
Tape recorder head laminations	79Ni-5Mo-Fe	High permeability, low losses (0.05 to 0.03 mm (0.002 to 0.001 in.)
Telephone diaphragm armature	2V-49Co-49Fe	High incremental permeability
Temperature compensator	29 to 36Ni-Fe	Low Curie temperature

High-output power generators	2V-49Co-49Fe, 27Co-0.6Cr-Fe	High saturation
Dry reed magnetic switches	51Ni-Fe	Controlled expansion glass/metal sealing
Chart recorder (instrument) motors, synchronous motors	49Ni-Fe	Moderate saturation, low losses, nonoriented grade
Loading coils	81-2 brittle Moly-Permalloy	Constant permeability with changing temperature

Various articles present extremely high permeability figures for Supermalloy, which was originally developed as a high-purity vacuum-induction-melted 79Ni-5Mo-Fe alloy at a time when most nickel-iron alloys were still being air melted. Furthermore, Supermalloy data generally refers to thin foil (0.1 mm, or 0.004 in., and less) tape toroidal cores, annealed in pure dry hydrogen at ~1290 °C (2350 °F), held for several hours, and very carefully cooled at the optimum rate. In some cases, the cooling may be performed under the influence of a magnetic field. It should, therefore, be apparent that Supermalloy properties represent a specialized case of handling a high-quality 79Ni-5Mo-Fe alloy. Supermalloy properties cannot be obtained in product forms such as bars or heavy strip, even if the same basic alloy was used to manufacture the heavier products.

Most applications of the 50Ni-Fe alloys are based on the requirements of moderately high saturation and permeabilities greater than those available on silicon irons. Heavy strip of 50Ni-Fe has been used for the manufacture of sensitive relays and safety shutoff valves for gas-fired devices. Lamination thicknesses 0.50 to 0.1 mm (0.020 to 0.004 in.) can be produced as a semioriented product that provides its best magnetic properties, after annealing, in the direction of cold rolling. Referred to as the transformer grade, it has been used primarily in audio frequency transformers. Lamination thicknesses can also be manufactured in a nonoriented condition used for rotating components such as resolvers, servosynchros, and rotor laminations. This condition is generally known as motor or rotor grade.

In 50% Ni alloys, the magnetocrystalline anisotropy is not zero. By proper melt control, manufacturing practice, and careful annealing, a strong cube texture can be developed, particularly in tape toroidal cores. These cores will exhibit a square hysteresis loop. The ratio of remanence to saturation induction (B_r/B_s) will typically exceed 0.98. These products have been known as Deltamax (Allegheny Ludlum Corporation), Hipernik V (Westinghouse Electric Corporation). HyRa 49 (Carpenter Technology Corporation), and Orthonol (Spang & Company, Specialty Metals Division).

The relatively low Curie temperature of nickel-iron alloys in the range from 28% Ni to ~52% Ni provides an anomalous thermal-expansion behavior. Thus, these alloys are used as low or controlled expansion alloys and glass-to-metal sealing alloys. Compositions, particularly around 51Ni-Fe, have been used in wire form to manufacture dry reed switches. This application requires thermal-expansion and glass-sealing characteristics matching those of the glass envelope, as well as soft magnetic behavior.

Constant Permeability With Changing Temperature. In all magnetic materials, magnetic properties change with temperature. The change in flux density with temperature for iron tested at four different values of magnetizing force is plotted in Fig. 15. Operation of a device at a flux density of 1.5 T (15 kG) would be only slightly affected by variations in operating temperatures near ambient. There is a similar minimized temperature effect for all materials, except that the flux density for optimum operations depends on the materials, given the proper flux density and temperature range. Large changes occur for all ferromagnetic alloys at temperatures approaching the Curie temperature of the alloy. Approximate Curie temperatures for several soft magnetic alloys are listed below:

Nominal alloy composition	Curie temperature, T_c	
	°C	°F
29-32Ni-Fe	20 to 150	68 to 300
36 Ni-Fe	275	530
77Ni-5Cu-2Cr-Fe	405	760
79Ni-4Mo-Fe	455	850
50Ni-Fe	500	930
3Si-Fe	730	1350
0.5Si-Fe	755	1390

Pure iron	770	1420
27Co-0.6Cr-Fe	925	1700
2V-49Co-49Fe	970	1775

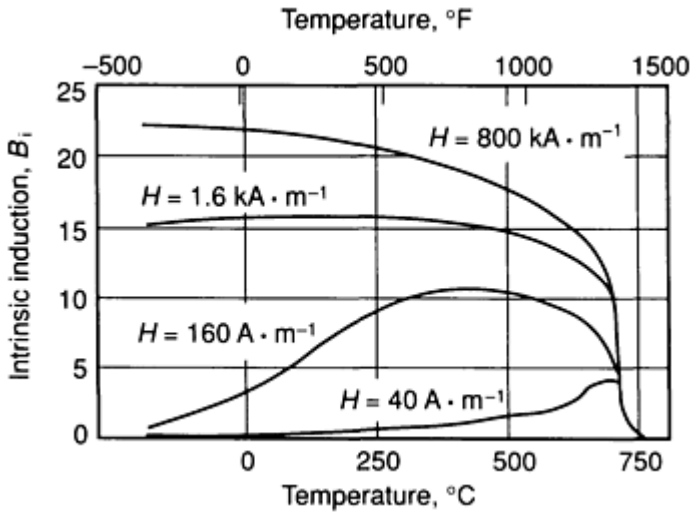

Fig. 15 Variation of induction with temperature for iron, at four different values of magnetizing force

It is not always possible to operate a material at the best flux density for temperature stability. One way of obtaining better temperature stability is to use magnetic materials in insulated powder form, such as pressed Permalloy powder cores, which have good temperature stability due to the presence of many built-air gaps. Another method involves use of nickel-iron alloys, such as Isoperm or Compernik (Westinghouse Electric Corporation), that have been drastically cold rolled and then underannealed to produce a partly strained alloy less sensitive to temperature changes.

However, each of these methods sacrifices the higher permeability of the basic alloys that could be used in the magnetic circuit. The air gap effect of the powdered cores shears the hysteresis loop, and the residual stress remaining in alloys such as Conpernik and Isoperm has the same effect. (It is not known if Conpernik or Isoperm are in commercial production.)

Alloys for Magnetic Temperature Compensation. Many measuring instruments and other devices depend upon maintaining constant flux, produced by a permanent magnet, across an air gap. Unfortunately, as a permanent magnet is warmed, it loses strength and the air gap flux density changes. To compensate for such changes, a certain amount of the magnetic flux can be shunted around the air gap of the instrument by using an alloy with high negative magnetic temperature coefficient in the temperature range of interest. The amount of shunted flux, therefore, decreases with increasing ambient temperature, forcing more flux through the gap than would normally occur. Nearly complete compensation for temperature changes can be made by correct design of parts. Watt-hour meters and automobile speedometers are examples in which a temperature compensator shunt has been used to compensate for the change in pole strength of the permanent magnet (and the change in electrical resistivity of the aluminum drag disk) over their designed working-temperature range.

Nickel-iron alloys containing between ~28% and 36% Ni are frequently used commercially for this purpose because the Curie temperature for these alloys range from about room temperature up to ~275 °C (530 °F). Table 11 and Fig. 16 show how some typical nickel-iron alloys vary in permeability with temperature at H of 3.7 kA · m^{-1} (46 Oe). Temperature-compensation alloys are produced commercially by several producers, among them Carpenter Technology Corporation. The alloys are generally manufactured as annealed strip products.

Table 11 Permeability of nickel-iron magnetic alloys used for temperature compensation

	45 °C (-50 °F)	-20 °C (0 °F)	10 °C (50 °F)	25 °C (77 °F)	40 °C (100 °F)	65 °C (150 °F)	95 °C (200 °F)	120 °C (250 °F)
29.0% Ni	92	70	25	3	2	. . .	. . .	. . .
29.5% Ni	120	102	74	46	27	4	. . .	. . .
31.0% Ni	156	140	120	110	98	73	45	15
32.5% Ni	212	202	191	180	170	145	120	85

(a) Remainder is iron in all alloys.

(b) Temperature-permeability properties can be varied by manufacturing procedure and thermal treatment at finished size. Above values are average and representative of temperature-permeability properties available in a commercial product.

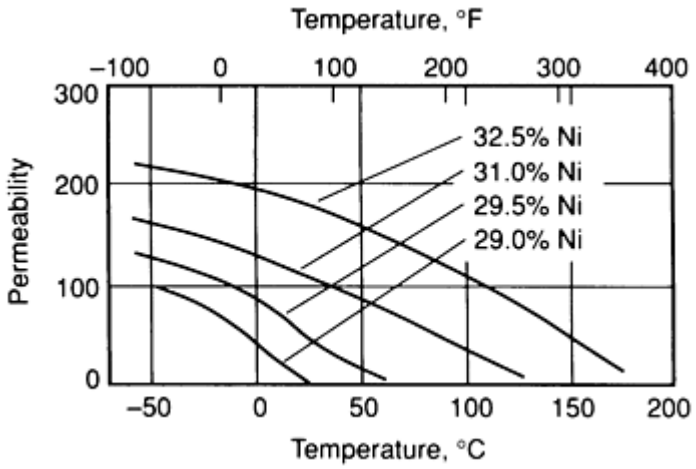

Fig. 16 Effect of nickel content on the permeability-temperature characteristics of annealed nickel-iron temperature-compensator alloys at H of 3.7 kA · m^{-1} (46 Oe)

Iron-Cobalt Alloys

Pure iron has a saturation induction of 2.158T (21.58 kG). Higher saturation values can be achieved only in alloys of iron and cobalt. The highest known value is approximately 2.46 T (24.6 kG), which occurs at a cobalt content of ~35%.

In Fig. 17, the dc magnetic induction response at several magnetizing forces from 0.25 to 1400 kA · m^{-1} (0.003 to 17 kOe) for binary iron-cobalt composition is shown. The composition corresponding to ~50Co-50Fe is of particular interest due to its peaked response at low magnetizing force (that is, high permeability). The room-temperature crystallographic structure of iron-cobalt alloys containing up to approximately 70% Co is ferritic (α-Fe), except that the 50Co-50Fe compositional range orders very rapidly to α', a brittle cesium-chloride type structure, upon cooling below ~725 °C (1340 °F). The binary 50:50 alloy was originally known as Permindur (Western Electric Company), but was never widely manufactured due to its extreme brittleness. In the 1930s, Bell Laboratories Inc. developed a modified alloy by adding ~

2% V, which slowed the embrittling reaction sufficiently so that hot-rolled strip (thickness less than 3.04 mm, or 0.120 in.) could be rapidly cooled, retaining the ductile structure. The vanadium addition also provides increased resistivity (to 43 μΩ· cm), but does lower saturation induction slightly. Vanadium additions greater than ~2% shift the Fe-Co-V phase boundary limits, producing semihard and hard magnetic materials such as Remendur 27, P6, and Vicalloy--which are covered in the article "Permanent Magnet Materials" in this Volume. The fully heat-treated coercive force values for these alloys are ~2.2, 4.4, and 24 kA · m^{-1} (27, 55, and 300 Oe), respectively.

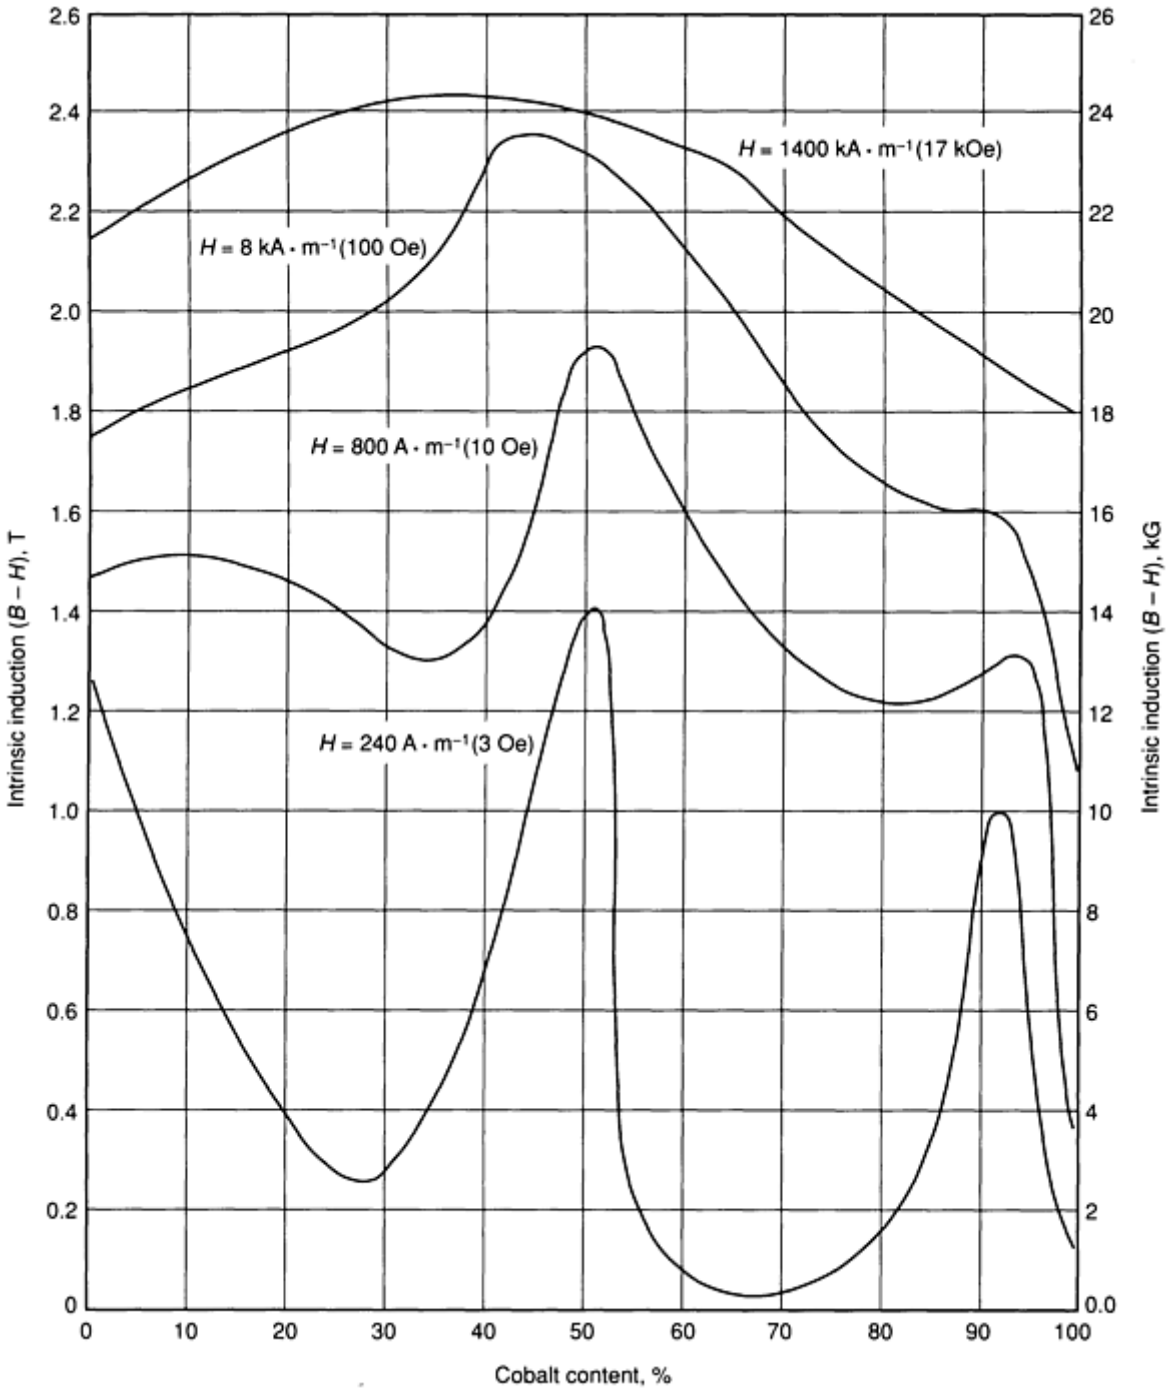

Fig. 17 Intrinsic induction of iron-cobalt alloys at various magnetizing levels

Alloy 2V-49Co-49Fe. The soft magnetic alloy consisting of essentially 2V-49Co-49Fe has been known as Vanadium Permendur (Allegheny Ludlum Corporation), 2V-Permendur, Supermendur, and is currently domestically produced as Hiperco 50, Hiperco 50A (Carpenter Technology Corporation), or Permendur V (Spang & Company, Specialty Metals Division). With specialized mill processing, this alloy can be cold rolled to nearly any gage (0.025 mm, or 0.001 in.,

thickness, or less). In typical lamination thicknesses (0.64 to 0.15 mm, or 0.025 to 0.006 in.), the cold-rolled unannealed strip can be stamped (30 to 39 HRC) into various rotor/stator/transformer lamination configurations. Thinner strip is generally wound into tape toroidal cores. This alloy is also available in round bars and can be processed in certain wire sizes. Bar products cannot be provided in a disordered condition because it is physically impossible to cool the bars at a sufficiently rapid rate. Machining, handling, and the application of bar-product forms must be performed carefully due to limited ductility.

Alloy 27Co-0.6Cr-Fe. Another iron-cobalt alloy composition, containing 27Co-0.6Cr-bal Fe, is commercially available, designated as Hiperco 27 (Carpenter Technology Corporation). It is primarily produced as a lamination strip product and as a bar product. The 27% Co content provides saturation levels similar to the 2V-49Co-49Fe composition, and does not require the same degree of specialized manufacturing. The addition of 0.6% Cr increases electrical resistivity to 19 μΩ· cm. Its lower cobalt content makes the alloy less expensive, but it is not as magnetically soft as the 2V-49Co-49Fe alloy. In dc field applications (pole pieces, flux return members, and so on), energy losses due to low resistivity and relatively low permeability (hysteresis losses) may not be of concern. Therefore, the 27Co-Fe alloy may be preferred due to its high saturation and lower price. In ac applications, particularly as frequency is increased, the 2V-49Co-49Fe alloy is generally selected.

Magnetic Properties of Iron-Cobalt Alloys. The iron-cobalt alloys exhibit a high positive magnetostrictive coefficient, which has made them useful in transducers (sonar) and in extremely accurate positioning devices. The magnetostrictive coefficients at saturation are approximately 36×10^{-6} and 60×10^{-6} $\Delta l/l$ for the 27Co-Fe and the 2V-49Co-49Fe alloys, respectively.

All iron-cobalt alloys must be heat treated as finished laminations or as machined components. The heat treatments vary depending upon the intended application. The 2V-49Co-49Fe alloys and the 27Co-0.6Cr-Fe alloys have both been used extensively as laminations in generator and motor applications for aircraft, submarines, tanks, and so on, where the high flux density of these alloys permits the design of equipment with less weight and bulk. For high-speed rotating components, relatively low annealing temperatures such as 760 to 790 °C (1400 to 1450 °F) may be employed to maintain strength, but at some sacrifice in soft magnetic characteristics. For applications where strength is not important, higher annealing temperatures are used. Both alloys undergo a sluggish transformation back to the α phase when heated above their respective temperature. For 2V-49Co-49Fe of high purity, this temperature is approximately 900 °C (1650 °F). The Ac_1 temperature for 27Co-Fe is approximately 955 °C (1750 °F). These alloys should not be annealed above their respective Ac_1temperature unless extremely slow cooling (less than 11 °C/h, or 20 °F/h) is employed to allow complete transformation from the γ phase to the α phase. A typical annealing cycle for the 2V-49Co-49Fe alloy to develop good soft magnetic properties is: dry hydrogen atmosphere 845 to 870 °C (1550 to 1600 °F), 4 h at soak, and cool nominally at 110 °C/h (200 °F/h). If annealed below the Ac_1 temperature, the cooling rate is not critical.

Iron-cobalt alloys tend to form a thin, tight, blue oxide film during annealing. This can be prevented in extremely low dewpoint furnaces or hard vacuum furnaces but may not always be preventable in larger commercial annealing facilities. The thin blue oxide layer is generally not harmful to magnetic properties. In fact, oxide is sometimes deliberately developed on laminations by holding in a most atmosphere at ~540 °C (1000 °F) to provide interlamination resistance to reduce eddy-current losses.

In specialized applications, usually tape toroids, high-purity 2V-49Co-49Fe cores may be final annealed under the influence of an applied magnetic field. Magnetic-field annealing can be beneficial to providing a particularly square magnetic hysteresis loop with low core loss. Supermendur (Western Electric Company) is a high-purity variation of the 2V-49Co-49Fe alloy, which is specially processed and domain oriented by heat treatment in a magnetic field. Data presented for Supermendur generally applies only to-thin-strip (0.1 mm, or 0.004 in., and less) processed and often magnetic-field annealed. Properties reported for Supernmendur include a maximum permeability of 7×10^4 occurring at 2.0 T (20 kG), coercive force of 16 $A \cdot m^{-1}$ (0.20 Oe), and B_r of 2.14 T (2.14 kG) from B_s of 2.4 T (24 kG). Core-loss values of ~18 W/kg (8 W/lb) at 400 Hz and 2.0 T (20 kG) have been reported for 0.1 mm (0.004 in.) thick strip. It is not possible to reproduce the high permeability values or loop-squareness data reported for Supermendur in bar, heavy strip, or even lamination stock product forms. When comparing the properties of various soft magnetic alloys, it is always necessary to know all the details of the product form, test method, and annealing practices employed.

Some typical magnetic and mechanical properties of several iron-cobalt alloys are shown in Tables 12 and 13. Several applications of Co-Fe alloys are listed in Table 9. Both the 27Co-Fe and 2V-49Co-49Fe alloys are included in ASTM standard A 801-86. Figure 18 provides a comparison of the typical dc normal induction properties of iron-cobalt alloys as well as nickel-iron, low-carbon iron, and ferritic (430F) stainless products. It is strongly suggested that the material

producers be contacted for more detailed information regarding variations of these alloys manufactured for specific purposes, and for the proper selection and processing methods.

Ferrites

Ferrites for high-frequency applications are ceramics with characteristics spinel-magnetic structures ($M{\cdot}Fe_2O_4$, where M is a metal) and usually comprise solid solutions of iron oxide and one or more oxides of other metals such as manganese, zinc, magnesium, copper, nickel, and cobalt. They are unique among magnetic materials in their outstanding magnetic properties at high frequencies, which result from very high resistivities ranging from about $10^8\ \Omega\cdot$ cm to as high as $10^{14}\ \Omega\cdot$ cm. Hence, at frequencies where eddy-current losses for metals become excessive, ferrites make ideal soft magnetic materials. Because ferrites have inherently high corrosion resistance, parts made of these materials normally do not require protective finishing.

Disadvantages of ferrites include low magnetic saturation, low Curie temperature, and relatively poor mechanical properties compared with those of metals. Ferrites are produced from powdered raw materials by mixing, calcining, bill milling, pressing to shape, and firing to the desired magnetic properties. The final product is hard, brittle, and unmachinable, and thus close dimensional tolerances must be obtained by grinding.

Types of Ferrite. Many different ferrites are available for magnetic use. They can be classified into three general types:

- Square-loop ferrites for computer memories
- Linear ferrites for transformers and for inductors in filters
- Microwave ferrites for microwave devices

In recent years, due to increasing use of semiconductors for computer memories, square-loop ferrites have decreased in importance.

Microstructure and composition have much stronger influences on the magnetic properties of ferrites than on those of metals. Hence, properties of finished ferrite parts can vary drastically with purity and structure of raw materials, with the nature of binders used, and with the ceramic-processing technique employed. In general, lithium ferrites, Mn-Mg-Zn ferrites, and Mn-Mg-Di ferrites are used for computer memories. (Di is the symbol for didymium, a mixture of the rate earth elements praseodymium and neodymium.) Lithium ferrite is higher in Curie temperature and saturation magnetization, but lower in switching speed, than Mn-Mg-Zn and Mn-Mg-Di ferrites. Linear ferrites comprise Mn-Zn and Ni-Zn ferrites. Mn-Zn ferrite is higher in saturation magnetization, but lower in resistivity, than Ni-Zn ferrite. Mn-Zn ferrite is preferred for frequencies up to about 1 MHz. For microwave applications, Ni-Zn, Mg-Mn-Al, and Mg-Mn-Cu ferrites are used, as well as garnets of the type $M_{3+x}Fe_{5-x}O_{12}$ (where M = Y + Al, or M = Y + Gd + Al).

Stainless Steels

The magnetic behavior of stainless steels varies considerably, ranging from paramagnetic (nonmagnetic) in fully austenitic grades, to hard or permanent magnetic behavior in the hardened martensitic grades, to soft magnetic properties in ferritic stainless steels.

Austenitic Stainless Steels. All austenitic stainless steels are paramagnetic (nonmagnetic) in the annealed, fully austenitic condition. The dc magnetic permeabilities range from ~1.003 to ~1.005 when measured at magnetizing forces of 16 kA · m^{-1} (200 Oe). The permeability increases with cold work due to deformation-induced martensite, a ferromagnetic structure. For certain grades such as types 302 and 304, the increase in magnetic permeability can be appreciable, resulting in these grades being weakly ferromagnetic in the heavily cold-worked condition. This phenomenon is illustrated graphically in Fig. 19 for nine austenitic stainless steels.

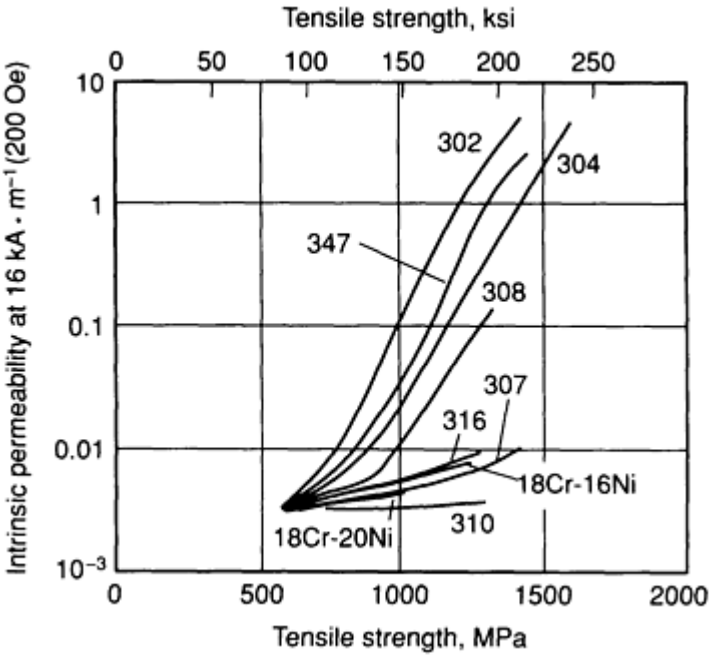

Fig. 19 Correlation of increased tensile strength from cold working and the permeability of cold-worked austenitic stainless steels. Annealed hot-rolled strips 2.4 to 3.2 mm (0.095 to 0.125 in.) thick before cold reduction. For normal permeability values, add unity to the numbers given on vertical scale.

The differing performance among grades is a reflection of their composition. In particular, nickel increases austenite stability, thereby decreasing the work-hardening rate and the rate of increase of magnetic permeability. Consequently, the higher-nickel grades exhibit lower magnetic permeabilities than the lower-nickel grades when cold worked in equivalent amounts.

The magnetic permeabilities achievable in austenitic stainless steels are very low when compared to conventional magnetic materials. Consequently, it is their nonmagnetic behavior that is of more concern. Certain applications, such as housings and components for magnetic detection equipment used for security, measuring, and control purposes, require that the steel be nonmagnetic, since the presence of even weakly ferromagnet parts can adversely affect performance. If the magnetic permeability of an austenitic stainless steel is of particular concern, it can be measured by relatively simple means, as described in ASTM standard A 342-Method No. 6. The equipment described is commercially available at relatively low cost.

Ferritic stainless steels are ferromagnetic and have been used as soft magnetic components in products such as solenoid housings, cores, and pole pieces. Although their magnetic properties are not generally as good as conventional soft magnetic alloys, they have been successfully used for magnetic components that must withstand corrosive environments. As such, they offer a cost-effective alternative to plated iron and silicon-iron components. In addition, the relatively high electrical resistivity of ferritic stainless steels has resulted in superior ac performance.

Special restricted analyses of AISI type 430F are produced for use in solenoid valve components. The ASTM A 838-85 specification provides typical properties for these alloys. Alloy type 1 is 430F containing approximately 0.4% Si and exhibiting an electrical resistivity of 60 μΩ· cm. When fully mill annealed, it has a hardness of approximately 78 HRB. Its maximum dc permeability is approximately 2×10^3, with a coercivity of approximately 160 $A \cdot m^{-1}$ (2 Oe). Alloy type 2 is a higher-silicon version of 430F, with an electrical resistivity of 76 μΩ· cm and a fully annealed hardness of 82 HRB. Despite its higher hardness, alloy type 2 typically exhibits a dc permeability of 2.6×10^3 and a coercivity of 130 $A \cdot m^{-1}$ (1.6 Oe). Both alloys are available in round centerless ground (C.G.) bar form fully processed, so that in many applications they are suitable for high-volume screw machining of parts, passivation, and placement into service without annealing. Hex bars and other special-shape products may only be available in a cold-drawn condition suitable for machining, but they may require annealing of the parts to develop soft magnetic properties.

Magnetic properties of selected ferritic stainless steels are listed in Table 14.

Table 14 Magnetic properties of selected ferritic and martensitic stainless steels. Data determined on round bars 9.53 to 15.88 mm (0.375 to 0.625 in.) in diameter per ASTM A 341 using Fahy permeameter.

Grade	ASTM A 838	Condition[(a)]	Rockwell hardness	Maximum permeability, μm	Coercive force, H_c		Resistivity, μΩ· cm

Martensitic and Precipitation-Hardenable Stainless Steels. All martensitic and most precipitation-hardenable stainless steels are ferromagnetic. Due to the stresses induced by hardening, these grades exhibit permanent magnetic properties in the hardened condition. For a given grade, the coercive force tends to increase with increasing hardness, rendering these alloys more difficult to demagnetize. If the hardenable martensitic stainless steels are used in the annealed condition, they suffer from:

- Poorer magnetic properties due to the presence of a significant volume of chrome-carbides, which contribute to pinning domain-wall movement.
- Reduced corrosion resistance due to matrix depletion of chromium

The ferritic nonhardenable 430 or 430F grades are preferred for soft magnetic applications for these reasons. Magnetic properties of selected martensitic stainless steels are shown in Table 14.

Additional information is available in the article "Wrought Stainless Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Corrosion Resistance of Magnetically Soft Materials

In specific applications, corrosion resistance may limit the choices of magnetically soft materials. Pure irons and silicon irons corrode readily in mild atmospheres. Consequently, these materials may require protection by painting, plating, potting, or molding.

Iron Alloys and Silicon Steels. If parts machined from iron or silicon-iron alloys are to be plated, they are annealed to develop soft magnetic properties first. Annealing should generally be performed in a dry atmosphere to prevent the formation of iron/silicon oxides that may impair plating adherence. If oxides are formed during annealing, they must usually be removed by a mechanical means. Acid-bath cleaning of these materials usually results in a rough-pitted surface and undersize dimensions.

Nickel-Iron Alloys. Alloys of ~50Ni-Fe have only mild resistance to corrosion and will rust in industrial environments. For example, annealed 50Ni-Fe alloys have shown approximately 15 to 25% of their surface area rusted after 200-h exposure to neutral salt spray at 35 °C (95 °F). High-nickel soft magnetic alloys possess fair corrosion resistance, but they will tarnish with time in industrial atmospheres. Plating, painting, or an epoxy coating can generally be used on these materials if required.

Ferritic Stainless Steels. Where the base material must be corrosion resistant, the ferritic stainless steels may be used. Allowance must be made, however, for lower permeability, high coercive force, and lower saturation than available

in most other soft magnetic grades. The nonhardening types such as 430 or 430F solenoid varieties provide the best soft magnetic properties of the stainless grades.

Selection of Alloys for Power Generation Applications

The tonnage of magnetically soft materials such as nickel-iron or cobalt-iron alloy used for specialized applications is small compared to the volume of materials used for fractional horsepower motors, heavy rotating equipment, and power frequency transformers. Materials used in these industries range from commercial low-carbon steel sheet and strip to high-silicon and grain-oriented silicon steels.

Tables 15 and 16 can be used as guides to compositions, grades, and gages previously used for several applications; these tables also take into account factors such as cost, availability, punchability, temperature, and corrosion resistance. Several different alloys may be suitable for a given set of conditions.

Table 15 Soft magnetic materials used for motors and generators. Where more than one grade of silicon sheet is shown, they are listed in the order of increasing cost and efficiency as a result of electrical properties

(a) For core laminations for welding transformers, M-27 and M-22 are recommended in 0.46 mm (0.0185 in.) sheet.

There is a gradual increase in price per pound of silicon irons as the alloy core losses improve (that is, decreasing M number). In considering the relationship between electrical properties and gage, it may appear practical to downgrade to a less expensive, lower-efficiency alloy, but to use a thinner gage. For example, a stack of 0.36 mm (0.014 in.) M-43

laminations (29 gage) and the same size stack of 0.47 mm (0.0185 in.) M-36 laminations (26 gage) may be similar in electrical properties, even though. M-36 alloy is more efficient and slightly more expensive. However, selection on this basis does not consider all aspects of the cost.

Most important of these is the cost of making laminations from the strip or sheet. A punch press running at constant speed will produce the same number of laminations regardless of material thickness. Hence, it would require 31% more machine time to produce a stack of a given size from 29 gage (0.36 mm, or 0.014 in.) than from 26 gage (0.47 mm, or 0.0185 in.) sheet. Annealing, stacking, and handling costs also increase as the gage becomes thinner. Therefore, where electrical efficiency is critical and thin-gage material is used, the major cost is in making the stack with thinner laminations. It is false economy to down-grade the material and sacrifice electrical properties for only slight savings in material cost.

Motors and Generators

Table 15 lists information on alloys used for motors and generators.

Starting Motors. For small starting motors that operate infrequently and for short periods of time, there is little emphasis on electrical efficiency. For this reason, the least expensive core material has generally been used, regardless of gage. The most common gage for such applications is 24 gage (0.63 mm, or 0.025 in.). For heavier starting motors (up to 75 kW, or 100 hp), 29 gage (0.36 mm, or 0.014 in.) M-36 is more efficient. For the largest starting motors, efficiency is of greater importance, and upgrading of material is justified.

Intermittent Service Devices. Table 15 also lists materials and thicknesses used for ac and dc motors and generators for intermittent service. For small motors used in highly competitive, light-duty consumer items, electrical efficiency had been of secondary consideration. To some extent, higher-quality silicon irons are now being selected for these applications today.

For gyros and selsyns, which are specialized applications demanding more efficiency, higher-grade materials in thinner gages are recommended. Large industrial motors, even in intermittent operation, require more efficiency than small motors, and it is for this reason that both intermediate gages and intermediate materials are recommended for large motors.

Continuous Service Devices. Compositions and gages of sheets for motors and generators for continuous operation are also presented in Table 15. Upgrading of material for the more rigorous service is recommended but the same principles of selection should be followed. In high-speed rotating machinery, yield strength of the magnetic rotor material may be the decisive factor in alloy selection.

Airborne power generation requires compact, high-output equipment that places further demands on the material. Generally, the high-cobalt alloy, 2V-49Ni-49Fe in 0.15 to 0.38 mm (0.006 to 0.015 in.) lamination thickness, has been selected primarily due to its high saturation induction and low hysteresis losses. The 27Co-0.6Cr-Fe alloy has also been used for this application.

Transformers

Table 16 lists examples of magnetically soft silicon irons for nonrotating equipment, the highest-volume use of which are power transformers. In 50 to 60 Hz power transformers, an important consideration is weight. The volume of a transformer is closely proportional to that of the core, and the weight of core and coil are usually about equal. For minimum weight, material with the highest possible operating flux density must be used. Over-voltage requirements must be considered. Regular oriented grades M-6 to M-4 exhibit flux densities of about 1.8 to 1.84 T (18.4 kG) in a field of 800 $A \cdot m^{-1}$ (10 Oe). This limits design flux density to about 1.7 T (17 kG). Somewhat higher flux density is attainable with the high-permeability grades designated P by ASTM nomenclature in Table 3.

Although core weight is important, values of energy losses for transformers are receiving more attention as cost of generating electrical power escalate. This factor is placing emphasis on the importance of reducing core loss by lower operating inductions or through the use of higher-quality grades of core material, and lower hysteresis losses.

Noise produced in transformers results ultimately from magnetostriction of the core material, which varies with operating flux density, silicon content, operating strain, and type of surface insulation. Flux density is important in magnetostriction

and joint noise. For typical designs of power transformers using grain-oriented material, a 10% reduction in flux density will reduce noise about 3 decibels (dB).

Design and Fabrication of Magnetic Cores

The purpose of the core metal in a motor, generator, or transformer is to offer the best path for the magnetic lines of flux, and its success in this respect is measured by its permeability. Cores are usually composed of a large number of thin metal laminations that are fabricated by punching from thin sheets of metal, and after being enameled are assembled to form a core. The enamel forms an insulation between laminations that reduces the eddy currents induced in the metal of the core by transformer action. Normal oxidation scale is frequently sufficient insulation for this.

Interlaminar insulation is necessary for high electrical efficiency in the magnetic core, wether the application is static or rotating. For small cores used in fractional-horsepower motors, an oxide surface on the laminations may insulate the core adequately. Insulations of AISI types C-1, C-2, C-3 C-4, and C-5 are used for more rigorous requirements.

Organic-Type Insulation. Types C-1 and C-3 are organic and cannot be successfully applied to laminations before annealing. They are unsuitable for electrical equipment operated at high temperatures or for power transformers with certain types of coolants. However, they improve the punchability of the sheet steel.

Inorganic-type Insulation. Inorganic types C-4 and C-5 are used when insulation requirements are severe and when annealing temperatures up to 790 °C (1450 °F) must be withstood. Typical values of interlaminar resistance for these two types are between 3 and 100 Ω· cm/lamination under a pressure of 2070 kPa (300 psi). These coatings also can be made to impart residual tensile stresses in the steel substrate, which can improve magnetic properties.

Core insulation must be sufficiently thin and uniform so as to have no more than 2.0% effect on the lamination factor (solidity of the core). To calculate the required insulation for most operations at power frequency, the square of the resistivity, in ohm-centimeters per lamination, should at least equal the square of the width of the magnetic path, in inches. This usually ensures a negligible interlaminar loss that is less than 1.0% of the core loss.

Core Selection Based on Ease of Fabrication. Laminations usually are fabricated by punching the required shape from flat or coiled sheet or from coiled strip. Selection of grade and gage is based primarily on electrical requirements. Differences in punchability may be considered in final selection. Studies of electrical sheet indicate that punchability decreases as silicon content increases, but test results are not conclusive. High-silicon alloys are inherently more abrasive, but they are also more brittle and can be punched with less roll and drag at the edges than can the more ductile low-silicon grades.

Optimum punchability also depends on factors other than steel composition or method of manufacture. If it is difficult to punch a fully processed sheet, it may be advisable to use a semiprocessed grade with magnetic properties not fully developed by the supplier. In this situation, the laminations must be annealed to produce the desired properties.

The advantage of the better punchability of semiprocessed electrical sheet is offset somewhat by the need for better control of annealing conditions during fabrication and by adhesion of laminations during annealing. It is impractical to grade steel for electrical properties after laminations have been fabricated. Therefore, the supplier must grade the product by annealing samples cut from the sheet before it is shipped. The lower cost of the semiprocessed material may influence the designer's decision.

Permanent Magnet Materials

Revised by J.W. Fiepke, Crucible Magnetics, a Division of Crucible Materials Corporation

Introduction

PERMANENT MAGNET is the term used to describe solid materials that have sufficiently high resistance to demagnetizing fields and sufficiently high magnetic flux output to provide useful and stable magnetic fields. Permanent magnets are normally used in a single magnetic state. This implies insensitivity to temperature effects, mechanical shock, and demagnetizing fields. This article does not consider magnetic memory or recording materials in which the magnetic state is altered during use. It does include, however, hysteresis alloys used in motors.

Permanent magnet materials include a variety of alloys, intermetallics, and ceramics. Commonly included are certain steels, Alnico, Cunife, iron-cobalt alloys containing vanadium or molybdenum, platinum-cobalt, hard ferrites, and rare-earth alloys. Each type of magnet material possesses unique magnetic and mechanical properties, corrosion resistance, temperature sensitivity, fabrication limitations, and cost. These factors provide designers with a wide range of options in designing magnetic parts.

Permanent magnet materials are based on the cooperation of atomic and molecular moments within a magnet body to produce a high magnetic induction. This induced magnetization is retained because of a strong resistance to demagnetization. These materials are classified ferromagnetic or ferromagnetic and do not include diamagnetic or paramagnetic materials. The natural ferromagnetic elements are iron, nickel, and cobalt. Other elements, such manganese or chromium, can be made ferromagnetic by alloying to induce proper atomic spacing. Ferromagnetic metals combine with other metals or with oxides to form ferromagnetic substances; ceramic magnets are of this type. Although scientific literature lists many magnetic substances, relatively few have gained commercial acceptance because of the commercial requirement for low cost and high efficiency.

Permanent magnet materials are marketed under a variety of trade names designations throughout the world. The United States designations will be used here; other designations are listed in Table 1.

Table 1 Principal magnet designations and their suppliers

Designation	Magnet type	Country	Company
Alnico	Alnico	U.S.	Arnold, CMSC Corp., Crucible, Hitachi Permanent Magnet Co., Thomas & Skinner
		England	Magnetic Materials Group, Mullard, S G Magnets, Swift Levicks
		France	Giffey-Pretre, Ugimag
		Germany	Baermann, Krupp, Magnetfabrik-Bonn, Thyssen
		India	Elpro

Permanent magnet materials are developed for their chief magnetic characteristics: high induction, high resistance to demagnetization, and maximum energy content. Magnetic induction is limited by composition; the highest saturations induction is found in binary iron-cobalt alloys. Resistance to demagnetization is conditioned less by composition than by shape or crystal anisotropies and the mechanisms that subdivide materials into microscopic regions. Precipitations, strains and other material imperfections, and fine particle technology are all used to obtain a characteristic resistance to demagnetization.

Maximum energy content is most important because permanent magnets are used primarily to produce a magnetic flux field (which is a form of potential energy). Maximum energy content and certain other characteristics of materials used for magnets, are best described by its hysteresis loop. Hysteresis is measured by successively applying magnetizing and demagnetizing fields to a sample and observing the related magnetic induction.

Fundamentals of Magnetism

For understanding a permanent magnet, Faraday's concept of representing a magnetic flux field by lines of force is very useful. The lines of force radiate outward from a north pole and return at a south pole. The lines of force can be revealed by a powder pattern made by sprinkling iron powder on a paper placed above a bar magnet. The number of lines per unit area is thee magnetic induction and is designated *B*. Induction in the magnet consists of lines of force due to the magnetic field and lines of magnetization due to the ferromagnetism of the magnet:

$$B = H + B_i \qquad \textbf{(Eq 1)}$$

where H is the magnetic field strength and B_i is the intrinsic induction.*

Magnetic Hysteresis. A hysteresis loop is a common method of characterizing a permanent magnet. The intrinsic induction is measured as the magnetizing field is changed (see Fig. 1). Starting with a virgin state of the material at the origin 0, induction increases along curve I to the point marked +S as the field is increased from zero to maximum. The point +S is the point at which induction no longer increases with higher magnetizing field, and is known as the saturation induction. When the magnetizing field is reduced to zero in permanent magnets, most of the induction is retained. In Fig. 1, when the field is reduced through zero and reversed to -S, the induction decreases from +S to B_r to -S. At zero field, there is a remanent magnetization in the sample, defined as B_r; the value of B_r approaches the saturation induction in well prepared permanent magnet materials. This point on the hysteresis loop is called residual induction.

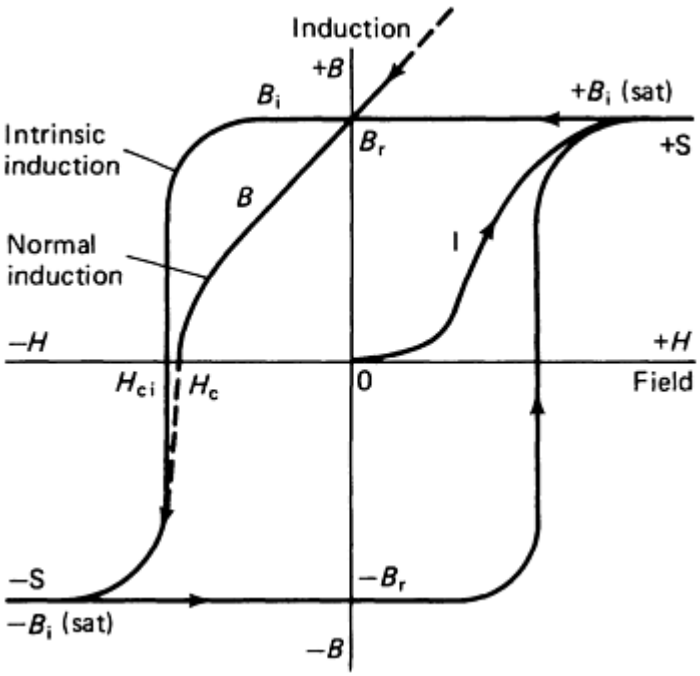

Fig. 1 Major hysteresis loop for a permanent magnet material. B_i (sat) is the saturation induction

If the field is increased again in the positive direction, the induction passes through $-B_r$ to +S as shown, and not through the origin. Thus, there is a hysteresis effect, and this plot is called the hysteresis loop. The two halves of the loop are generally symmetrical and from a major loop, which represents the maximum energy content, orthe amount of magnetic energy that can be stored in the material. Innumerable minor loops can be measured within the major loop, measurements being made to show the effects of lesser fields on magnets under operating conditions.

Demagnetization. The particular value of the demagnetizing field needed to reduce B_i (or J) to zero is called the intrinsic coercive force H_{ci}. Figure 1 includes the normal demagnetization curve derived from the intrinsic curve. The field required to reduce induction B to zero is the normal coercive force H_c. The important practical features of the curve

for application to permanent magnet materials are the numerical values of B_r, H_c, H_{ci}, and the area within the hysteresis loop.

Because a permanent magnet most often is used to provide a flux field in a space outside itself, the material rests within its own field, which is a self-demagnetizing field. Therefore, for practical applications, a magnet designer is interested primarily in the second quadrant of the hysteresis loop, called the demagnetization curve (see Fig. 2). This curve represents the resistance to demagnetization and, in an affirmative sense, the ability of a material to establish a magnetic field in an air gap or adjoining magnetic material.

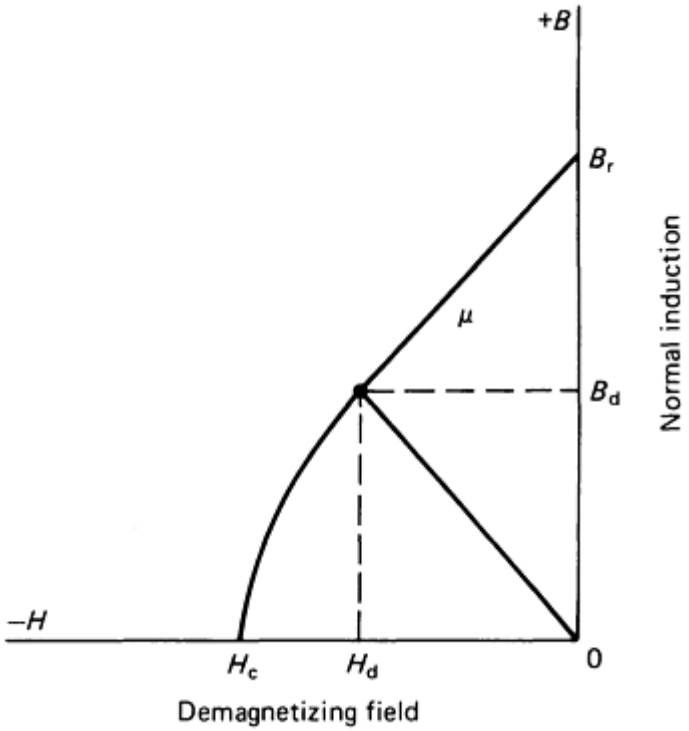

Fig. 2 Normal demagnetization curve for a permanent magnet material

Magnetic Energy. The maximum magnetic energy available for use outside the magnet body is proportional to the largest rectangle that fits inside the normal demagnetization curve. It is indicated by the product $(B_dH_d)_{max}$ and is usually cited as the figure of merit for determining the quality of permanent magnet materials.

A characteristics useful in selecting permanent magnet materials subjected to varying demagnetizing conditions is the permeability (that is, the ratio of the induction to the corresponding magnetizing force) at the operating point:

$$\mu = B_d/H_d \qquad \textbf{(Eq 2)}$$

For example, a straight-line demagnetization curve where $B_r = H_c$ would have the ideal permeability of 1.0; a magnet of such a material would recover spontaneously all flux when a partial demagnetizing field is removed. The corresponding intrinsic curve would be flat out to the knee, and the material would retain maximum energy. Rare-earth alloy and high coercivity hard ferrite magnets come closest to ideal permanent magnet behavior.

Figure 3 is the product curve of *B* and *H* at each point along the demagnetization curve, plotted against *B*. On the demagnetization curve, each value of *B* or *H* involves the other as a coordinate variable. The maximum value of their product--$(B_dH_d)_{max}$--represents the maximum magnetic energy that a unit volume of the material can produce in an air gap. Often, the most efficient design for a magnet is that which employs the magnet at the flux density corresponding to the $(B_dH_d)_{max}$ value.

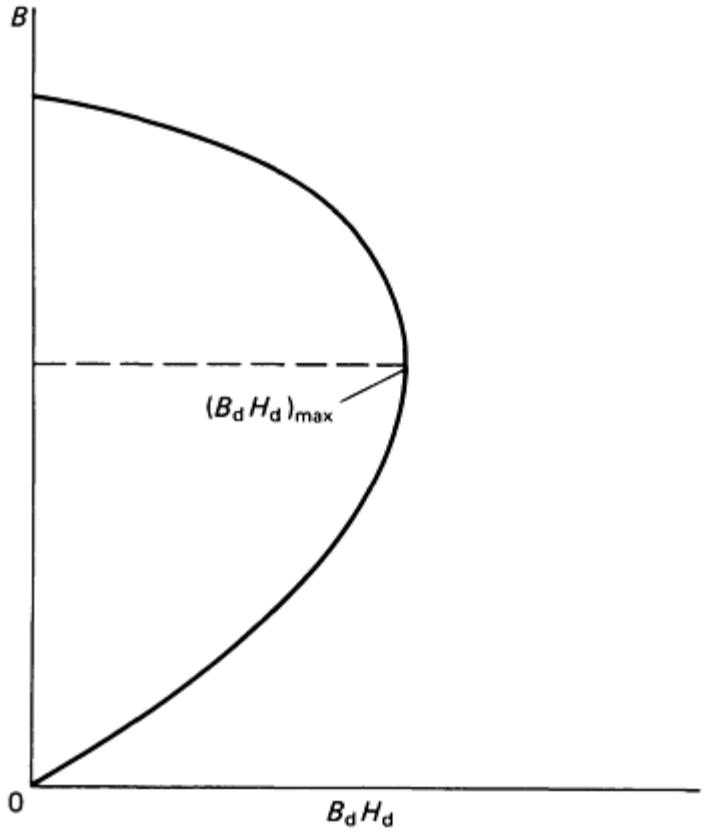

Fig. 3 Typical energy-product curve for a permanent magnet material

The amount of total external magnetic flux available from a magnet operating in an open-circuit condition (that is, some flux both in air or nonmagnetic substance) depends on its shape. This relation is shown in Fig. 4 for one specific shape. The permeability μ is the ratio of the total external permeance B_d to that of the permeance of the space occupied by the magnet, H_d, and is equal to the slope of the demagnetization curve.

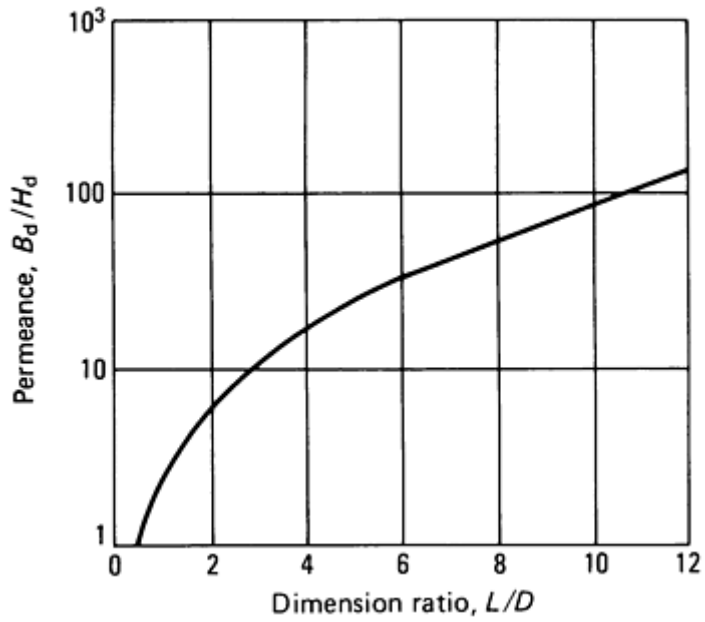

Fig. 4 Relation between magnetic properties and dimensions of straight bar magnets of circular cross section. *L*

is the length of the bar, and *D* is the bar diameter.

An enlarged plot of the first and second quadrants of the intrinsic induction curve is given in Fig. 5.

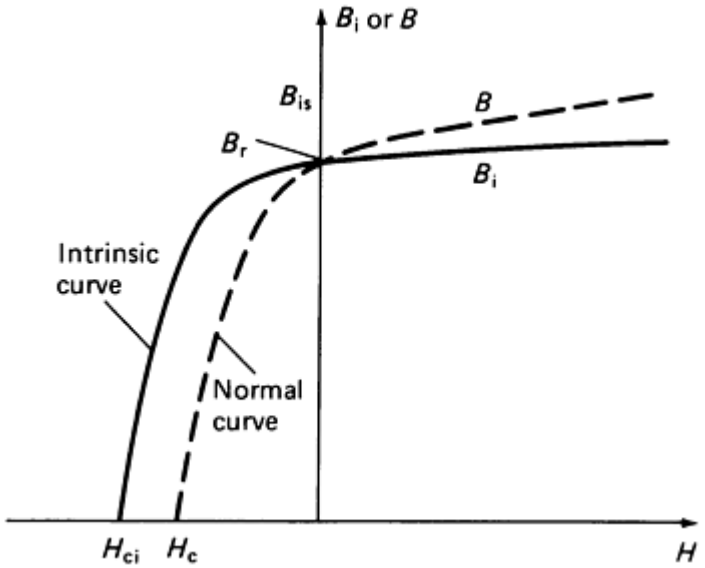

Fig. 5 Intrinsic magnetization curve, B_i, in the first and second quadrants compared with the curve for B

The intrinsic demagnetization curve is of interest to both the materials scientist and the applications engineer. Material scientists are concerned about the effect of composition and processing on the various intrinsic parameters of the material: B_{is}, B_r, and H_{ci}. Applications engineers are concerned about the flux density in an air gap due to both B_i and H. Accordingly, they are interested in the normal induction curve and in the values of B_r, H_c, and $(BH)_{max}$. Design engineers use the intrinsic induction curve to predict performance while the magnet is under the influence of temperature, armature reaction, or other demagnetizing forces.

Lines of constant energy product (B_dH_d) usually are plotted in the second quadrant area of a hysteresis loop. As illustrated in Fig. 6, 7(a), 7(b), 7(c), 8, and 9, they appear as a series of hyperbolic curves superimposed on the rectangular *B-H* grid of the demagnetization curves. The maximum values of external energy are therefore readily available in relation to the demagnetization curve. In this form, the grid constitutes an efficient guide for the design engineer. In practice, a magnet with a fixed air gap would have one fixed B_d/H_d operating point on the demagnetization curve corresponding to the material being used. For variable air gaps, such as are produced by relative movement between the armature and field poles of electrical machinery, the external energy available at the air gap changes continuously, resulting in a so-called minor loop with minimum and maximum values. In practice, the minor loop is plotted on the demagnetization curve to determine location of the loop on the curve, and to evaluate the extent of flux variation within the minor loop cycle. Efficient design of equipment using permanent magnets, such as magnetos, small generators and motors, requires that the minor loop operate near the $(B_dH_d)_{max}$ point.

Magnetically soft materials differ from permanent magnet materials not only in their higher permeabilities, but also, and more significantly, in their much lower resistance to demagnetization. The best magnetically soft materials have H_c values of virtually zero. The hysteresis loop of such a material retraces itself through or near the origin point with each cycle.

Conversely, permanent magnet materials have wide hysteresis loops, characterized by high values of H_{ci}, which range from about 8 to $>1.6 \times 10^3$ kA · m^{-1} (100 Oe to >20 kOe).

Note cited in this section

* *International Electrotechnical Commission specification TC 68 has recommended *J*, the symbol for magnetic polarization, be used in place of B_i because intrinsic induction is also known as magnetic polarization.

Commercial Permanent Magnet Materials

Table 2 lists most of the permanent magnet materials commercially available in the United States and their nominal compositions. Magnetic properties are given in Table 3. Figures 6, 7(a), 7(b), 7(c), 8, and 9 present demagnetization curves associated with the materials listed in Table 2. Physical and mechanical properties are summarized in Table 4. The production of permanent magnet materials is controlled to achieve magnetic characteristics and other properties are allowed to vary according to the manufacturing process used. The selection of materials and the design of permanent magnets for particular applications is a well-defined engineering art; design assistance is available from most producers.

(d) Thermal conductivity: 5.5 W/m · K (38 Btu · in./ft^2 · h · °F).

(e) Specific heat: 380 J/kg · K (0.09 Btu/lb · °F). Thermal conductivity: 15 W/m · K (104 Btu · in./ft^2 · h · °F)

Magnet Steels

Until about 1930, all the commercial permanent magnet materials were quench-hardening steels. Up to about 1910, plain carbon steels containing about 1.5% C were the principal magnet alloys. Alloy steels with up to 6% W were then developed, and later, high-carbon steels with 1 to 6% Cr came into use. Coercive forces for this group of alloys ranged from 3.2 to 5.6 kA · m^{-1} (40 to 70 Oe) (Fig. 6a). The most significant improvement in the quench-hardening steels came in 1917, when the Japanese introduced a cobalt steel containing 36% Co and having a coercive force as high as 20 kA · m^{-1} (250 Oe). The use of magnet steels has declined and today these steels are considered obsolete.

Magnet Alloys

The first advance away from magnet steels came in 1931 with the development of a series of ternary alloys of iron and cobalt plus molybdenum or tungsten. These alloys became known as Remalloy, Cunife, Cunico, and Vicalloy. With the exception of Cunife, these alloys are now obsolete. The magnetic properties of the materials are shown in Fig. 6.

Cunife. Commercial Cunife contains approximately 20% Fe, 20% Ni, and 60% Cu. This composition is in the two-phase region of the phase diagram. The material is quenched from about 1000 °C (1830 °F) to give a homogeneous face-centered cubic (fcc) structure. The quenched specimens are already fully magnetic and contain iron-nickel rich clusters, 5 to 10 nm (50 to 100 μm) in cluster size, in a copper-rich matrix. It is then aged at 650 °C (1200 °F) to develop the amounts of both phases of optimum proportions. It is usually cold worked in stages to maximize directional magnetic properties in the final shape. The nature of the phase diagram, the periodicity of the microstructure and x-ray diffraction effects all support the view that the magnetic structure develops by spinodal decomposition. The coercive force can be accounted for on the basis of shape anisotropy of iron-nickel-rich magnetic regions in a copper-rich nonmagnetic matrix. The material is extremely anisotropic, with the superior magnetic properties in the direction of rolling, a factor that must be considered in magnet design.

Cold working produces a crystallographic texture which is developed strongly by subsequent annealing. The spinodal decomposes along definite crystallographic planes, and the texture is developed by the shape of the particulates. An additional contribution to magnetic texture may arise from straightforward deformation of the partially decomposed spinodal phase. Aging in a magnetic field has no influence on the magnetic properties because the Curie temperature is too far below the decomposition temperature.

The mechanical softness in this alloy system permits easy cold reduction and working, thus leading to many applications in the form of wire or tape. Optimum properties are obtained only after 95% or more cold reduction.

Alnico Alloys

Alnico alloys are one of the major classes of permanent magnet materials. The Alnicos vary widely in composition and in preparation, to give a broad spectrum of properties, costs, and workability. Alnico alloys are sold under a variety of names throughout the world (see Table 1). As a group, Alnico alloys are brittle and hard and can be machined only by surface grinding, electrical discharge machining, or electrochemical milling. They resist atmospheric corrosion well up to 500 °C (930 °F). Magnetic properties are negligibly affected by vibration or shock. Generally, Alnico is superior to other permanent magnet materials in resisting temperature effects on magnetic performance. Typical compositions and properties are summarized in Tables 2, 3, and 4; demagnetization curves are shown in Fig. 7(a), 7(b), 7(c).

Alnicos 1 through 4 are isotropic and generally lower in cost than the other Alnico alloys but are much lower in magnetic characteristics. The remainder of the alloys are generally anisotropic. Maximum properties, and therefore greatest economy, are obtained when the device is designed to make use of oriented material. Optimum properties are achieved by casting and heat treating.

Magnets made by sintering Alnico powders or by bonding are used where small or intricate shapes to precise tolerances are required. Sintered Alnico is produced by blending powders and then pressing and sintering just below the melting temperature in an oxygen-free atmosphere. The sintered alloys have mechanical properties superior to those of cast Alnicos, but the magnetic properties generally are slightly lower. Sintered magnets are given the same heat treatments as cast.

In general, optimum properties are developed by solution treating at 1100 °C (2010 °F), where the alloy is in equilibrium as a body-centered cubic (bcc) phase, followed by cooling at a rapid, but critical, rate. Between 900 and 800 °C (1650 and 1470 °F), the alloy separates into two nonequilibrium bcc phases. One is almost pure iron and the other, a weakly magnetic phase, is roughly FeNiAl. The resulting microstructure is typical of a structure resulting from spinodal decomposition. Various combinations of H_c and B_r can be obtained.

Various other elements are often added to Alnicos. For example, to lessen the deleterious effect of carbon, carbide stabilizers such as titanium or niobium may be added. Titanium and copper increase H_c at the expense of B_r, but niobium increases H_c without decreasing B_r. Increasing the basic cobalt content by about 20% or more results in a major improvement in magnetic performance, because such large amounts of cobalt make it possible to develop a preferred orientation by heat treating the material in a magnetic field. Less striking improvements in H_c and B_r are obtained in nonoriented samples.

The ability of the magnetic field to influence the orientation (and thus the anisotropy) of the decomposing phase originates in the mechanism of decomposition. In processing the most commonly used alloy in this family, Alnico 5, for instance, the molten alloy is cast, then solution treated above 1250 °C (2280 °F). If zirconium and/or silicon is present, the alloy is solution treated at 900 at 925 °C (1650 to 1700 °F). The alloy is then placed in a magnetic field and cooled at a controlled rate from the solution treating temperature. Finally, the alloy is aged at 600 to 500 °C (1110 to 930 °F). An Alnico casting ordinarily can be shaped only by grinding or electrolytic machining, although hot working and certain other very specialized processing techniques are possible. Final finishing generally is done by grinding.

The critical phenomenon in this process is the spinodal decomposition of the high-temperature α-phase into an Fe-Co-rich α-phase and a Ni-Al-rich α'-phase. In the high-cobalt Alnico alloys, heat treating in a magnetic field appears to favor decomposition of parallel compositional waves and to suppress transverse waves. This effect is strongest if aging is carried out just below the intersection, on the phase diagram, of the Curie temperature and the temperature where the spinodal instability sets in. This condition limits the number of alloys that respond to magnetic aging. The addition of cobalt to FeNiAl promotes magnetic aging by moving the Curie temperature and decomposition temperature closer together.

Because the magnetic structure is influenced by crystallographic orientation during its formation, careful development of the proper <100> crystal texture is required to achieve the best properties in the Alnicos. In commercial alloys the magnetic properties of Alnico 5DG, which is a partly oriented material (DG indicates directed grain), are significantly better than those of standard Alnico 5; those of Alnico 5-7, which has almost perfect orientation, are even better.

In the construction of magnets from crystal oriented Alnico, designs are limited by the possible shapes in which a properly oriented magnetic field can be established during heat treatment. (Magnetic fields are easy to create, for instance, in the shapes of straight lines, circles, or arcs of circles.) This is not a major limitation on component design, however, because it can generally be overcome by using segmented magnets or by secondary fabrication of simple cast shapes, or both.

Platinum-Cobalt Alloys

Although platinum-cobalt magnets are expensive, they are useful in certain applications. Platinum-cobalt is isotropic, ductile, easily machined, resistant to corrosion and high temperatures, and has magnetic properties superior to all except the rare earth/cobalt alloys. Best magnetic properties are obtained at an atomic ratio of 50Pt: 50Co. Above about 820 °C (1510 °F) the alloy has a disordered fcc structure. Below this temperature, ordering develops a slightly tetragonal structure. To process this alloy to develop a $(BH)_{max}$ of 72 kJ · m^{-3} (9 MG · Oe), the following treatment is used:

- Heat to 1000 °C (1830 °F) to fully disorder
- Cool at a controlled rate to room temperature
- Age at 600 °C (1110 °F) for about 5 h

The final structure is only partly ordered; its physical structure is without distinction until overaged to the completely ordered structure. Values of $(BH)_{max}$ of more than 80 kJ · m^{-3} (10 MG · Oe), have been achieved by fabricating parts using powder metallurgical techniques and heat treating with essentially the same treatment as that used for cast parts. Typical properties are given in Tables 3 and 4 and the demagnetization curve is shown in Fig. 8. Platinum-cobalt magnets have been replaced by rare-earth materials and are seldom used.

Cobalt and Rare-Earth Alloys

Permanent magnet materials based on combinations of cobalt and the lighter rare-earth (lanthanide) metals are the materials of choice for most small, high-performance devices operating between 175 to 350 °C (345 to 660 °F). These materials are manufactured by powder metallurgy methods and have low-temperature coefficients which can be altered by additions of a heavy rare-earth, such as gadolinium or holmium. Samarium or praseodymium are the best choices for the rare-earth component in commercial rare-earth cobalt permanent magnet materials.

An alloy need not contain only a single lanthanide metal; mixtures are often used. Likewise, a portion of the cobalt can be replaced with copper and iron to obtain desired magnetic characteristics. In some alloys containing copper and iron, some of the samarium is replaced with cerium for cost savings. These are of the $(RE)_2(TM)_{17}$ type, where RE is rare earth and TM is mostly cobalt with some substitution of iron and copper as mentioned.

Sintered $SmCo_5$, $Co_5(RE)$, $(RE)_2(TM)_{17}$ materials with minor elemental additions produce some of the highest magnetic quality permanent magnets. Typical properties of commercially available materials are given in Tables 3 and 4, and demagnetization curves are presented in Fig. 8.

Because of the variety of materials, few standard designations have been developed. The four compositions listed in Table 2 (arbitrarily numbered 1 to 4) represent the range of magnetic quality available from the many producers of these materials.

Bonded permanent magnets utilizing $SmCo_5$ or Sm_2Co_{17} powders likewise are available from a number of magnet producers. Data are presented on selected grades in Tables 3 and 4 and on demagnetization curves in Fig. 6(c). Compression molding is usually favored as the molding method, although injection molding is possible.

It was the discovery of the large magnetocrystalline anisotropy of Co_5Y that initiated the interest in $Co_5(RE)$ alloys as permanent magnet materials. An energy product of nearly 225 kJ · m^{-3} (28 MG · Oe) was achieved in a single particle of Co_5Y. However, no investigator has reported the achievement of a usefully high coercive force in a $Co_5(RE)$ permanent magnet containing a substantial amount of yttrium.

Cerium is by far the most abundant, and potentially the least expensive, of all rare-earth elements. Procedures for preparing large quantities of Co_5Ce have been described in the literature, but this alloy does not make good magnets because of low saturation magnetization and stability problems. However, because cerium-rich misch metal (MM) is at present less expensive than cerium metal, and because $Co_5(MM)$ has some permanent magnet properties superior to those of Co_5Ce, very little effort has been made to develop permanent magnets, with Co_5Ce as the basic magnetic phase. Most development efforts involving cerium metal have been conducted with precipitation-hardening alloys of the 2:17 type, where some of the samarium is replaced with cerium.

Magnetic Properties. Among the binary $Co_5(RE)$ phases, Co_5Pr has the highest potential energy product. Moreover, praseodymium is more than eight times as plentiful as samarium in bastnasite, the major source of rare-earth metals in the United States. The crystal anisotropy of Co_5Pr is much lower than that of samarium cobalt, leading to significantly lower values of H_{ci}. However, several producers substitute praseodymium for up to 50% of the samarium in $SmCo_5$ alloys to get maximum values of residual induction with acceptable levels of H_{ci}.

Sintered cobalt and rare-earth materials are hard and brittle, very much like the Alnicos. Magnets made of these materials often are pressed to final shape to eliminate machining; magnets are also produced by cutting or slicing them from blocks or other simple shapes.

Cobalt and rare-earth materials have coercive forces much higher than those of other permanent magnet materials. Nevertheless, they can be satisfactorily magnetized in fields lower than those necessary to achieve saturation induction. Virgin magnets--that is, magnets that have never been exposed to a magnetizing field after final heat treatment--can be magnetized in fields of about 1.2 $MA \cdot m^{-1}$ (15 kOe).

To obtain anisotropic properties, tooling and dies are designed to compact powders in orienting fields in a manner similar to that used for farrites. Bonded magnets are produced by simply compacting aligned powder mixed with plastic or soft metal binders. Magnetic quality of bonded magnets is lower than that of sintered magnets.

Applications. In general, cobalt and rare-earth magnets cost more than any other type, except platinum-cobalt magnets. Cobalt and rare-earth magnets have replaced most platinum-cobalt types, particularly in microwave applications, where not only the lower price but also the higher coercivity of cobalt and rare-earth magnets are advantageous. The unique combination of properties in these magnets [high H_c, high $(BH)_{max}$, recoil permeability of one, and temperature stability] has led to a variety of new designs in traveling-wave tubes, other charged particle-beam focusing devices, watches, motors and generators, couplers, and magnetic bearings.

Hard Ferrites

Hard ferrites, also known as ceramic permanent magnet materials, are predominantly complex oxides. The ferrite most commonly used for magnets is $SrO{\cdot}6Fe_2O_3$. Prior to the mid-1970s. $BaO{\cdot}6Fe_2O_3$ was produced in major quantities. Ferrites are commonly listed with the chemical composition $MO{\cdot}6Fe_2O_3$, where M represents barium, strontium, or the combination of the two. Various additives such as SiO_2 or Al_2O_3 are beneficial in increasing coercivity and aid in sintering. Hard ferrites have coercive forces three to eight times the coercive forces obtained for most Alnicos. Both sintered and bonded ferrite magnets are used extensively.

A typical sintered ferrite magnet is made by mixing SrO with Fe_2O_3. This mixture is calcined above 1095 °C (2000 °F) to form the complex ferrite oxide compound. After milling into fine particles, the ferrite compound is compacted in a die and sintered at 1200 to 1300 °C (2190 to 2370 °F). Sintering develops a typical ceramic structure machinable only by diamond wheel grinders and slicing tools. Shrinkage during sintering is higher than for sintered metal magnets. About 15% shrinkage occurs, yielding a sintered magnet with a density about 95% of theoretical.

Nonoriented ferrites are almost isotropic. To obtain anisotropic magnets with a resultant twofold to threefold improvement in magnetic properties, the original powdered mixture is then ground to a powder of about 1 μm (40 μin.) particle size. This powder is compacted in a die within an orienting field and finally sintered at 1200 to 1300 °C (2190 to 2370 °F). Similar powder is used to prepare bonded magnets by mixing it with an appropriate proportion of a polymer and pressing, injection molding, or extruding to final shape. Magnetic properties generally are inferior to sintered magnets but dimensional tolerances can be held close and processing costs kept low.

Ceramic permanent magnet materials have high electrical resistivities and are poor conductors of heat. Although ferrites are not affected by high temperatures or atmospheric corrosion, the magnetic properties are more temperature-dependent than they are with other permanent magnet materials. Coercive forces decrease with lowering temperatures; flux density B_d decreases at a rate of 0.19%/°C (0.11%/°F) with rising temperature. The ferrites lose a portion of their magnetic flux to low subzero temperatures, the amount of loss depending on the L/D ratio. For example, the irreversible loss at -57 °C (-70 °F) is 3% when the L/D ratio is 0.09; however, when the L/D ratio is 0.50, no loss occurs. Typical properties are given in Tables 3 and 4 and in the demagnetization curves in Fig. 6(c). Although the $(BH)_{max}$ of the ferrites is relatively low, their low cost and high coercive force make them attractive for applications such as separators, magnetos, motors, speakers, and so on.

Tooling to produce a ferrite magnet to a specific size/configuration is expensive (that is, up to $50,000). Normally the tooling has a large number of cavities and produces a number of pieces in each press cycle. This means the application must use a large quantity of pieces to justify the tooling expense and obtain the lowest cost.

Iron-Chromium-Cobalt Alloys

Anisotropic iron-chromium-cobalt permanent magnet alloys have magnetic properties that are somewhat comparable to Alnico 5. The magnetic hardening of these alloy is performed by tempering after solution treatment. Prior to the tempering cycle the material is ductile and can be machined. The isotropic grades of this alloy have replaced the Remalloy and Vicalloy alloys in many applications. Typical properties are summarized in Table 3 and 4; demagnetization curves are shown in Fig. 8.

Neodymium-Iron-Boron Alloys

Introduced in 1983, neodymium-iron-boron alloy permanent magnet materials have become the material of choice for a wide range of permanent magnet devices and applications. This newest family of permanent magnet materials is based on combinations of neodymium, iron, and boron. Processing of these magnets has been accomplished by two different techniques:

- Conventional powder metal sintering
- Consolidation of rapidly solidified materials

Praseodymium has been substituted for neodymium with favorable results. Likewise, additions of aluminum, dysprosium, gallium, and other elements are made to obtain desired magnetic characteristics.

Conventional Powder Metallurgy Processing. The powder metallurgy process for producing permanent magnets consists of alloy preparation, premilling, milling, particle alignment/pressing, sintering/heat treatment, grinding, coating, and magnetizing. The high reactivity of neodymium or other rare earths and their alloys requires the suppression of contamination during alloy preparation and processing. In particular, oxidation by O_2 or H_2O or both must be kept to minimum through all fine powder handling and sintering stages. Any oxidation of the alloy occurring during processing depletes the alloy of the rare-earth components and shifts the composition of the rich side of the phase diagram. This usually results in the production of an alloy having unfavorable magnetic qualities.

To obtain powder compacts with maximum magnetization, the powder is magnetically aligned and pressed. The powder compaction is performed by die pressing or by isostatic pressing. A maximum energy product of 360 kJ $\cdot$ m^{-3} (45 MG $\cdot$ Oe) has been reported (Ref 1). When die pressing, the aligning field is established in the cavity with its magnetic axis either in the direction of pressing or at right angles. Multicavity tooling is generally used.

Isostatic pressing normally carried out on powders prealigned in a pulsed field capable of producing much higher fields than used in the die pressing method. This improves the degree of particle alignment and results in higher unit magnetic properties than those obtained for die-pressed pieces.

Because of their high iron content, neodymium-iron-boron magnets are susceptible to corrosion and require a corrosion-resistant coating for the many applications. Presently, electrophoretic coating by a cathodic process is widely used. This is a multistage procedure consisting of surface cleaning and pretreatment. An epoxy coating approximately 25 μm (1000 μ in.) thick is typical of this process more suitable for larger pieces, where the cost of holding the individual piece during the coating process is not prohibitive. Other organic and metallic coatings are also used.

Data are presented on selected grades of commercially available materials in Tables 3 and 4 and on demagnetization curves in Fig. 9. A graph depicting the full range of sintered neodymium-iron-boron available is shown in Fig. 10. It is amazing to see much a proliferation of materials in only a 6-year period. Powders made by this method will not produce a usable bonded magnet.

Rapidly Solidified Material Consolidation. One major American automobile manufacturer utilizes a patented process to produce neodymium-iron-boron magnets. The process involves the use of rapidly solidified ribbons having a uniform, finely crystalline microstructure consisting primarily of the $Nd_2Fe_{14}B$ phase.

Isotropic magnets can be made by cold compaction of the rapidly solidified powder with a resin binder or by hot pressing to full density. Because of the extremely fine grain size, field alignment and compaction of milled isotropic ribbons is extremely difficult and not practical. Anisotropy can be achieved by hot deformation. Energy products of 320 kJ · m^{-3} (40

MG · Oe) have been achieved by this method. Data on epoxybonded, hot-pressed, and hot-formed magnets produced from rapidly solidified neodymium-iron-boron alloys are found in Table 3 and 4 and on demagnetization curves in Fig. 9.

All permanent magnet materials are temperature dependent. A change in temperature causes the working point on the operating slope (see Fig. 11) to change. As long as the working point stays within the linear region of the demagnetization curve, the changes in flux density are reversible. In all other cases, any change in flux density is irreversible and can only be regained by remagnetization. To avoid irreversible changes in the flux density through temperature variations, the working point must remain within the linear section of the demagnetization curve. The large temperature coefficient of coercivity of neodymium-iron-boron materials causes the linear region to shrink, or a knee begins to appear on the demagnetization curve. Material scientists have not been successful in altering the temperature coefficients of the alloy. The solution to keeping the demagnetization curve linear has been to develop alloys with high intrinsic coercive forces. The design engineer must consider the operating point, operating temperature, and any external demagnetizing force when selecting a specific material grade.

Selection and Application

Permanent magnets are superior to electromagnets for many uses because they maintain their fields without an expenditure of electrical power and without the generation of heat.

Tables 3 and 4 and Fig. 6, 7(a), 7(b), 7(c), 8, and 9 give nominal properties only. Even under the most carefully controlled manufacturing conditions, some variation from these nominal values must be expected and considered in practical application. Figures 12 and 13 and examples of variations in energy values for two magnet materials.

Economic Considerations

Cost per pound is seldom considered in selecting a magnet material. Cost per unit of magnetic energy is more significant and is more often the basis of comparison. Alnico 5 is one of the more expensive of the Alnico group by the pound, but because of its superior magnetic properties is the most economical Alnico alloy for many applications. Alnico 6 and Alnico 5DG are both slightly, but not significantly, more costly by the pound than Alnico 5. Alnico 2 costs about 35% less per pound than Alnico 5, but is significantly more costly on the basis of magnetic energy.

Magnet prices for all alloys are strongly influenced by size, shape, quantity purchased, and method of manufacture (cast, sintered, or wrought). A significant increase in price may also be associated with a stringent tolerance requirement.

All of the magnet parameters are important and need to be considered when designing a specific magnetic circuit. The overriding consideration is to make the trade-offs necessary to obtain the best overall design for the system in which the magnetic circuit operates. This means that for some systems the neodymium-iron-boron magnet may be the material of choice and prove to be the most economical one.

Optimum Alloy Usage

Table 5 classifies various permanent magnet materials in relation to the properties relevant to the specific application. The number and range of applications utilizing permanent magnets has increased dramatically, making a full listing impractical. Table 6 lists the more predominant applications.

Table 5 Classification of permanent magnetic materials on the basis of application-relevant properties

Property	Performance: High ←					→ Low
Energy (density)	NdFeB	(RE)Co	Alnico, FeCrCo	Ferrites	FeCoVCr	AlNi
$(BH)_{max}$, kJ · m^{-3} (MG · Oe)	320 (40)	...	...	...	...	8 (1)
Stability against demagnetization	(RE)Co	NdFeB		Ferrites	Alnico, FeCrCo	FeCoVCr
H_{ci}, kA · m^{-1} (Oe)	2000 (25 000)	...		...	...	8 (100)
μ_{rec}	1.0	...		...	...	10
Hysteresis loss	Alnico, FeCoVCr, FeCrCo					
Reversible temperature variation	Alnico, FeCoVCr	FeCrCo		(RE)Co	NdFeB	Ferrites
$\alpha(\phi_r)$, %/K	−0.01	...	...	...	...	−0.2
Curie temperature,	Alnico, FeCrCo		(RE)Co, FeCoVCr	Ferrites		NdFeB
°C (°F)	900 (1650)		...	...		300 (570)
Stability with high-temperature operation	Ferrites		Alnico, FeCoVCr, FeCrCo	(RE)Co		NdFeB
Possibility for choosing a preferred direction (PD)	Alnico, FeCrCo		(a) Ferrites; (RE)Co; NdFeB			FeCoVCr, FeCrCo,
PD cause	Magnetic field with heat treatment		Magnetic field with shaping by pressing or injection molding			Mechanical deformation

Physical strength (stability with handling)	FeCoVCr, FeCrCo	NdFeB	Alnico, AlNi	Ferrites		(RE)Co
Economy, relative cost per unit of magnetic energy, $	Ferrites 1		Alnico, FeCrCo ...	NdFeB 5	(RE)Co ...	FeCoVCr 20

Table 6 Applications of permanent magnet materials

Application	Recommended material	Primary reason for selection	Alternative material	Condition or reason favoring selection of alternative material
Aircraft magnetos, military or civilian	SmCo	Maximum energy per unit volume	Cast Alnico 5	Availability or cost restraint
Alternators	SmCo	Compactness and reliability	Ferrite	Where space is available for a larger volume of material of lower magnetic energy and cost
			Alnico	
Magnetos for lawn mowers, garden tractors, and outboard engines	Ferrite	Adequate magnetic energy at lower cost than Alnico	Alnico	Higher energy material is required
			NdFeB	
Small dc motors	Bonded ferrite	Shape favors fabrication; adequate magnetic energy at lower cost	Bonded NdFeB	Higher magnetic energy is required
			Sintered ferrite	
Large dc motors	SmCo	Maximum energy per unit volume	NdFeB	Where lower cost is required, operating temperature is low
Automotive dc motors	Ferrite	Adequate magnetic energy at lower cost than alternate materials	Bonded NdFeB	Higher magnetic energy and less weight
Automotive cranking motors	Ferrite	Adequate magnetic energy at lower cost than alternate materials	Bonded NdFeB	Higher magnetic energy and less weight

Voice coil motors (computers)	NdFeB	High energy	SmCo	Availability
Acoustic transducers	Ferrite	Low cost	NdFeB	Higher magnetic energy allows smaller size and weight
Magnetic couplings (small gap)	Ferrite	Adequate magnetic energy at lower cost	Bonded NdFeB	Higher torque is required
Magnetic couplings (large gap)	NdFeB	High energy	SmCo	High operating temperature
Transport systems	NdFeB	High energy	SmCo	Availability
Separators	Ferrite	Adequate magnetic energy at lower cost	NdFeB	High magnetic energy required
Magnetic resonance imaging	NdFeB	High energy	Ferrite	Where space is available for a larger volume of material of lower energy
Magnetic focusing systems	NdFeB	High energy	SmCo	High operating temperatures or low-temperature coefficient is required
Synchronous hysteresis motors	Isotropic FeCrCo	Shape favors fabrication from wrought material	Cobalt steel	Availability
Holding devices	Ferrite	Adequate magnetic energy at low cost	Alnico	Where holding force versus temperature must not vary over wide ranges
Ammeters and voltmeters	Alnico	Low temperature coefficient	Not available	
Watt-hour meters	Alnico 5 or 6	Low temperature coefficient	Not available	

Alnico 5 was for many years the material recommended for most applications. The development of the hard ferrite material provided the design engineers with a lower cost option for many existing applications and made possible new ones. Permanent magnet dc-motor development became active, and large magnetic separators arrived. Ferrite separators were critical to the success of a new age in low-grade iron ore mining. Then engineers began replacing the Alnico in magnetos and loud speakers. Some problems arose along the way, but hard ferrites became the dominant permanent magnet material and still hold that position.

When samarium cobalt was introduced, many doubted that such a high-price material would ever be used in any volume production. New applications and conversion from existing alloys to the samarium-cobalt type eliminated these doubts. For a specific group of applications, these alloys are the only viable choice.

Neodymium-iron-boron permanent magnet materials have already been established as the material to use in voice coil motors and other devices. Figure 14 projects the 1988 world market for permanent magnet materials.

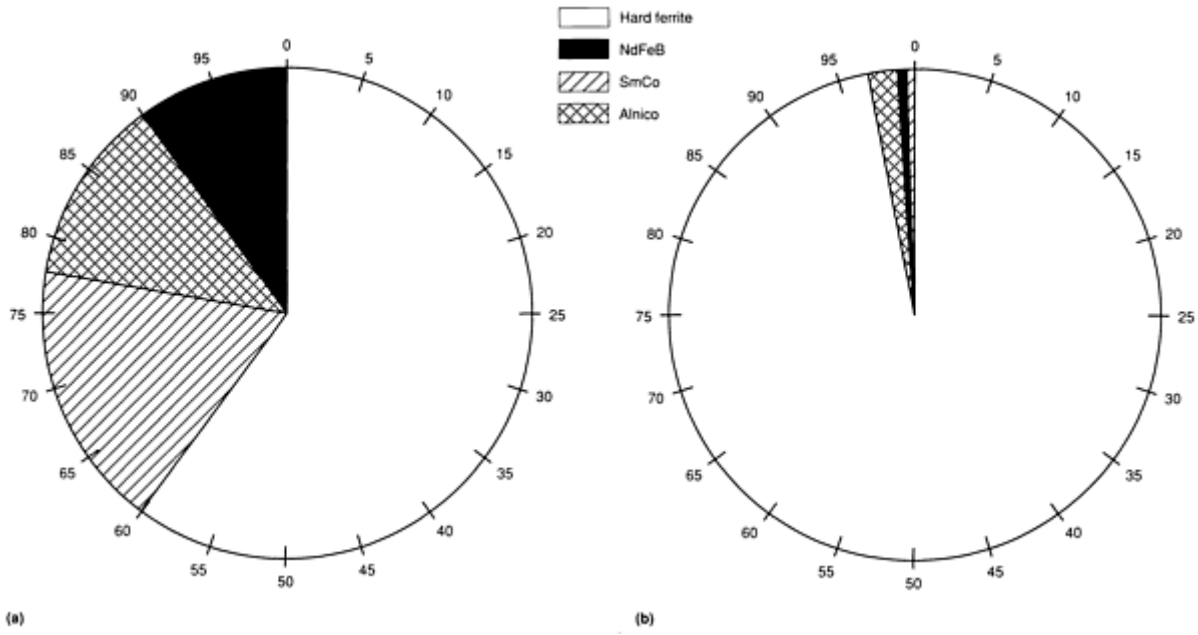

Fig. 14 Breakdown of global permanent magnet market in terms of monetary value (a) and product weight (b). Source: Ref 2

Hysteresis Applications. In most applications, permanent magnets are used to supply flux in an air gap and operate only in the second quadrant of the hysteresis loop. In a few specialized applications, notably hysteresis torque devices, it is necessary to consider the entire hysteresis loop in evaluating a magnetic material.

In hysteresis torque devices, the driving force is provided by a rotating magnetic field. The rotor is usually a thin-wall cylinder magnet that is not premagnetized but that can be magnetized by the rotating field. Immediately after starting, the induced poles rotate within the rotor, subjecting the material to repeated transversals of the hysteresis loop. Hysteresis causes the induced rotor poles to lag behind those of the applied field, producing an accelerating torque. The torque developed is proportional to the area of the hysteresis loop through which the magnet is driven.

If torque were the only requirement, the hysteresis material chosen would be a magnet with the largest possible hysteresis loop (and therefore the largest hysteresis loss). However, two other factors must be considered. Because the applied field must be capable of magnetizing the rotor, there is a practical limit to the coercive force that can be used.

Materials that are very high in coercive force seldom are used for these applications. For example, Alnico 6 develops the largest hysteresis loss, as indicated in Fig. 15, which shows hysteresis loss as a function of magnetizing force for various permanent magnet materials. Therefore, Alnico 6 would produce the greatest amount of torque. However, to produce this torque would require a magnetizing force of more than 80 kA $\cdot$ m^{-1} (1 kOe), a magnetizing force that is not practical for most applications.

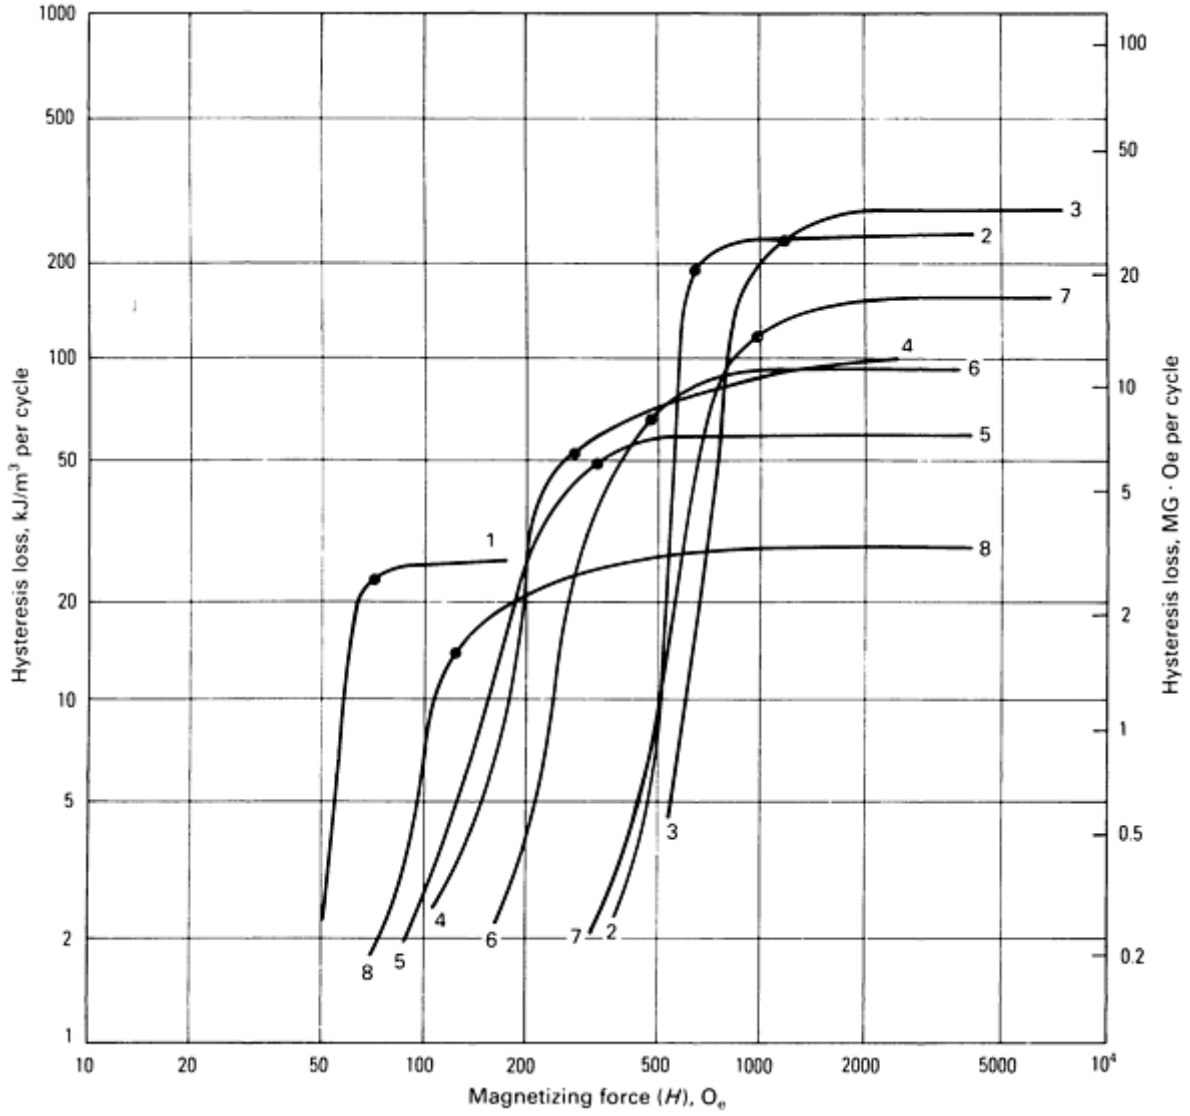

Fig. 15 Hysteresis loss versus magnetizing force for various permanent magnet materials. Data points indicate maximum efficiency, 1, P-6 alloy; 2, cast Alnico 5; 3, cast Alnico 6; 4, Vicalloy; 5, 17% Co steel; 6, 36% Co steel; 7, cast Alnico 2; 8, 3% Cr steel

Because the efficiency of the motor is determined by the magnetic characteristics of the rotor, the shape of the hysteresis loop is important. A convenient measure of this shape is the energy factor, η. The energy factor is defined as the ratio of the area of the hysteresis loop to the area of a rectangle drawn through the extremes (peak *B* and *H*) of the curve and ranges from 0.5 to 0.75. Two materials may have the same intercepts in terms of induction at a given magnetizing force, yet have different energy factors.

In operation, materials are not magnetized to saturation, but operate within a minor hysteresis loop. The actual loop is determined not only by the material, but also by the intensity of the magnetizing field. If only a small field is available, greater torque is developed by a low-energy material that is operated near its saturation value than by a higher-energy material that is little affected by the small applied field.

There is one value of magnetizing force for each material at which it operates most efficiently--that is, at which it produces maximum torque for a given magnetizing force. In Fig. 15, this point is marked with a dot on the curve for each material. The efficiency of a hysteresis material is the ratio of hysteresis loss to magnetomotive force required. Peak efficiencies of commonly used materials are:

Alloy	Efficiency
P-6	0.330
Cast Alnico 5	0.304
Cast Alnico 6	0.202
Vicalloy	0.197
17% Co Steel	0.158
36% Co steel	0.142
Cast Alnico 2	0.124
3.5% Cr steel	0.117

The materials referenced above are in limited use and thus may be difficult to purchase. The material currently being utilized in hysteresis applications is isotropic iron-chromium-cobalt (Fig. 16).

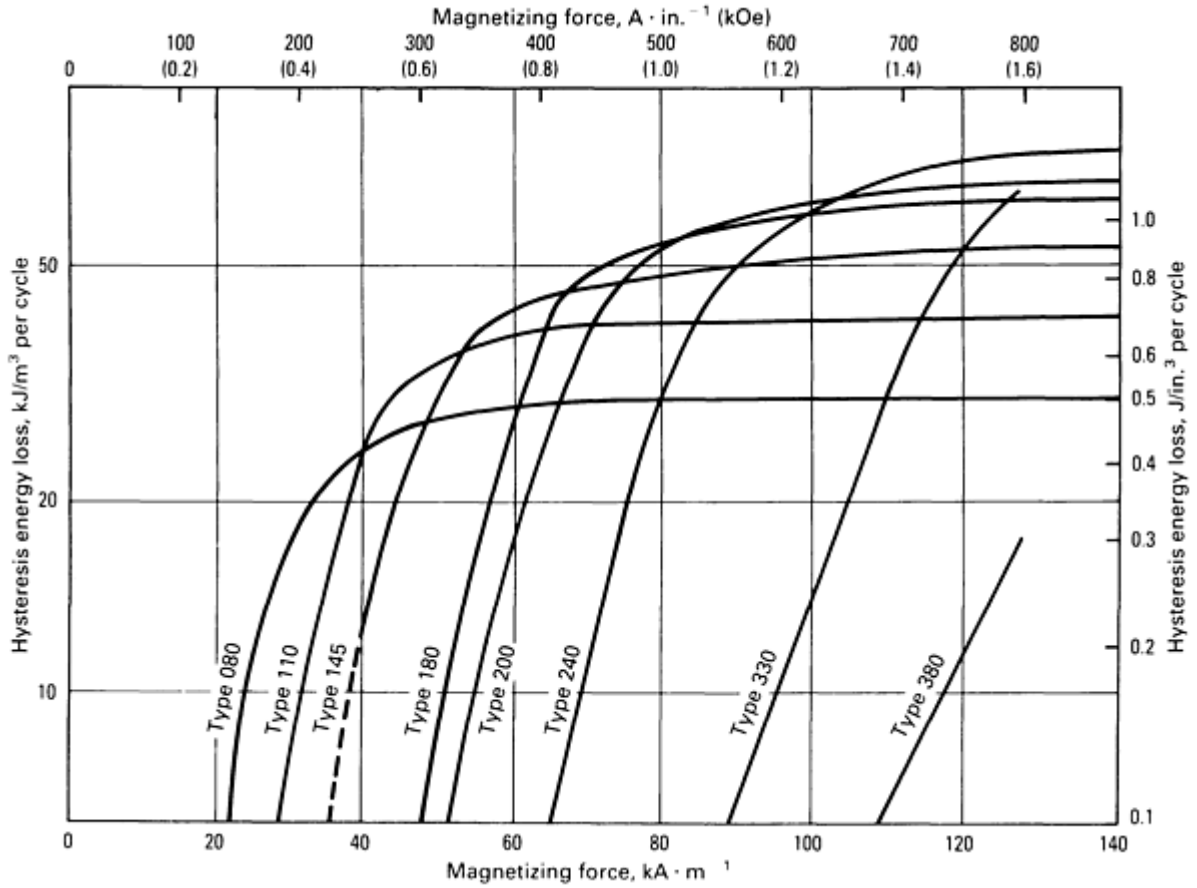

Fig. 16 Hysteresis energy loss versus magnetizing force of isotropic iron-chromium-cobalt alloys

Stabilization and Stability. There is an important group of permanent magnet applications where the accuracy or performance of the device is drastically affected by very small changes (1% or less) in the strength of the magnet. These applications include braking magnets for watt-hour meters, magnetron magnets, special torque motor magnets, and most dc panel and switchboard instrument magnets. Operation of these devices requires extreme accuracy over a moderate range of conditions, or moderate accuracy over an extreme range of conditions.

If the nature and magnitude of the conditions are known, it often is possible to predict the flux change. It also may be possible, by exposing the magnet to certain influences in advance, to render the magnet insensitive to subsequent changes in service. For many years, permanent magnets in instruments have exhibited long-term stability of the order of one part per thousand (0.1%). More recently, investigations in conjunction with inertial guidance systems for space vehicles have shown that longterm stability of the order of one to 10 ppm (0.0001 to 0.001%) can be achieved. This incredible stability of a magnetic field achieved with modern permanent magnets contrasts sharply with the instability of very early (steel) permanent magnets, in which both structural and magnetic changes caused a significant loss of magnetization with time.

Irreversible Changes. Losses in magnetization with time can be classified as either reversible or irreversible. Irreversible changes are defined as changes where the affected properties remain altered after the influence responsible for the change has been removed. For example, if a magnet loses field strength under the influence of elevated temperature and if the flux does not return to its original value when the magnet is cooled to room temperature, the changes is considered irreversible. Full flux is restored by remagnetizing unless metallurgical changes permanently altered the hysteresis loop.

Changes in Metallurgical State. Irreversible changes begin to occur at different temperatures for different alloys. These changes usually depend on both time and temperature, and thus short exposures above the recommended temperatures may be tolerated. These changes may take the form of growth of the precipitate phase, such as in Alnico and Cunife; precipitation of another phase, such as γ precipitation in Alnico; an increase in the amount of an ordered phase,

such as in platinum-cobalt; an increase in grain size, as in $SrO{\cdot}6Fe_2O_3$; oxidation, as occurs with metals, or reduction, as occurs with oxides; radiation damage; cracking; or changes in dimensions.

Typical permanent changes in H_c due to changes in metallurgical structure are shown in Fig. 17. Results for the steels and Alnico 5 were obtained on samples that initially were in the optimum magnetic state. The remainder of the materials were aged, starting from their quenched, as-cast, or as-prepared state, as indicated in the figure. The temperature at which changes in properties first become noticeable corresponds to the beginning of metallurgical changes; this temperature corresponds closely to the maximum temperature to which each material can be exposed, even after aging to the optimum magnetic state.

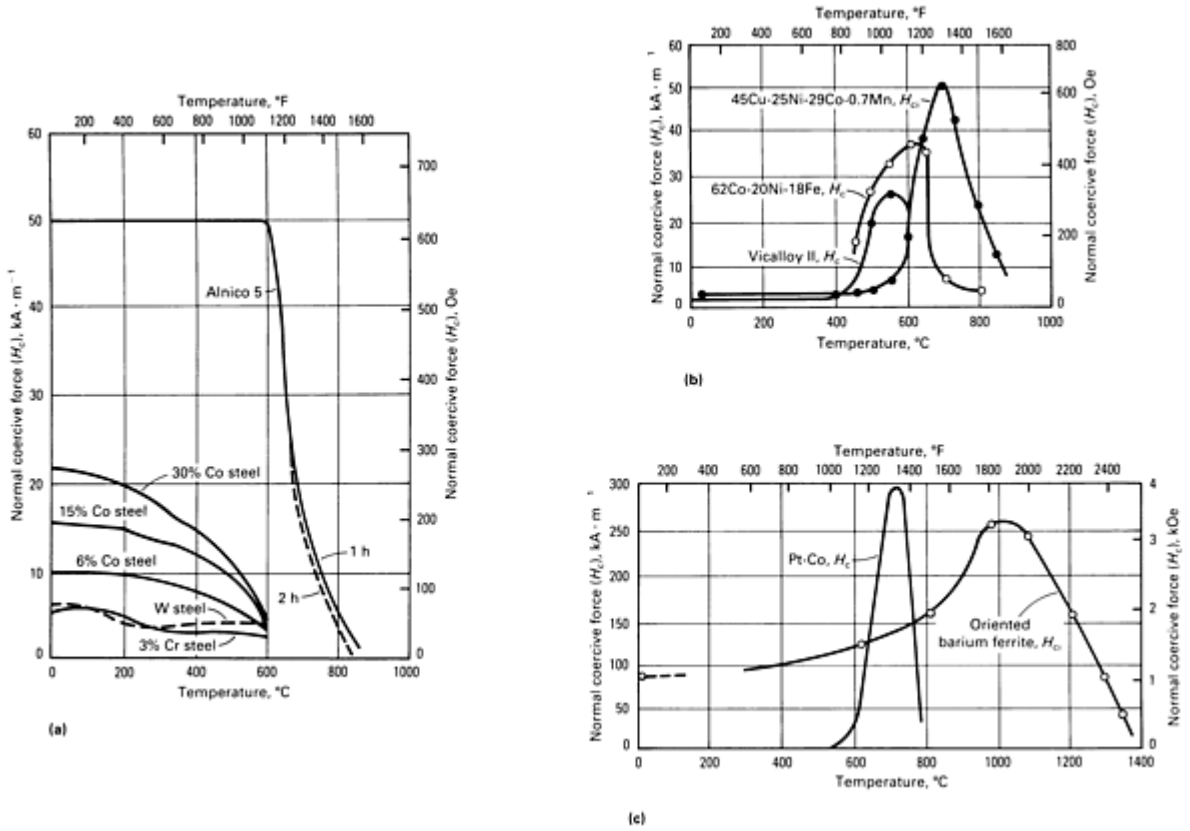

Fig. 17 Irreversible changes in H_c and H_{ci} for various permanent magnet materials

Irreversible metallurgical changes often can be counteracted, and original properties restored, by a suitably chosen thermal treatment. For example, if Alnico 5 has become degraded by exposure to 700 °C (1290 °F), it may be solution treated at 1300 °C (2370 °F), cooled in a magnetic field, and aged at 600 °C (1110 °F) to reattain the optimum metallurgical structure.

A nuclear environment is known to cause changes in metallurgical structure and thus may cause changes in magnetic properties. Permanent magnet materials tested were not affected by neutron (n) irradiation at levels below about 3×10^{17} n/cm^2 (2×10^{18} n/in.^{2}). Results of later work at levels up to 10^{20} n/cm^2 (6×10^{20} n/in.^{2}) showed some degradation. The Alnicos are not affected by radiation up to 5×10^{20} n/cm^2 (3×10^{21} n/in.^{2}) at neutron energies greater than 0.4 eV, and up to 2×10^{19} n/cm^2 (1×10^{20} n/in.^{2}) for neutron energies greater than 2.9 MeV. Radiation effects were found to be independent of temperature, but high temperatures tended to counteract radiation effects.

Tests have been done on $SmCo_5$, Sm_2Co_{17}, and neodymium-iron-boron magnets irradiated at up to 8×10^{19} n/cm^2 (5×10^{20} n/in.^{2}) by several national laboratories. These tests showed that Sm_2Co_{17} was found to be less sensitive by a factor of 10 to neutron irradiation than $SmCo_5$ material. Neodymium-iron-boron proved to be extremely sensitive to ionizing radiation, losing over 50% of its flux at 4×10^4 Gy (4×10^6 rad). The lower Curie temperature of neodymium-iron-boron probably accounts for its sensitivity to radiation.

Temperature Effects. The properties of a magnet vary with temperature in a manner that usually can be predicted. The variation of B_{is} with temperature can be calculated from theory, provided detailed knowledge of the crystallographic and magnetic structure of the magnetic phase is available. In many other instances, such information is not yet available, but direct measurements of B_{is} versus T have been made. Examples of such curves for many permanent magnet materials are shown in Fig. 18. The curves in Fig. 18 include some that represent changes in B_r with T, which depend extensively on properties of the system, such as particle size, sample shape, demagnetizing fields, and domain structures. Changes with temperature must be determined experimentally for the specific magnet and configuration of interest. Typical reversible and irreversible changes are given in Tables 7 and 8 as a function of the length-to-diameter ratio for a number of permanent magnet materials.

(a) In the case of the low-temperature irreversible loss occurring in oriented barium ferrite, only the smallest dimension ratio resulting in no irreversible loss at -60 °C (-75 °F) is shown. This is the recommendation of a major producer to avoid catastrophic loss. The minimum dimensional ratio will depend upon the lowest temperature to be encountered.

(a) H_{ci} = 1440 kA · m^{-1} = 18 kOe.

(b) At 140 °C (285 °F)

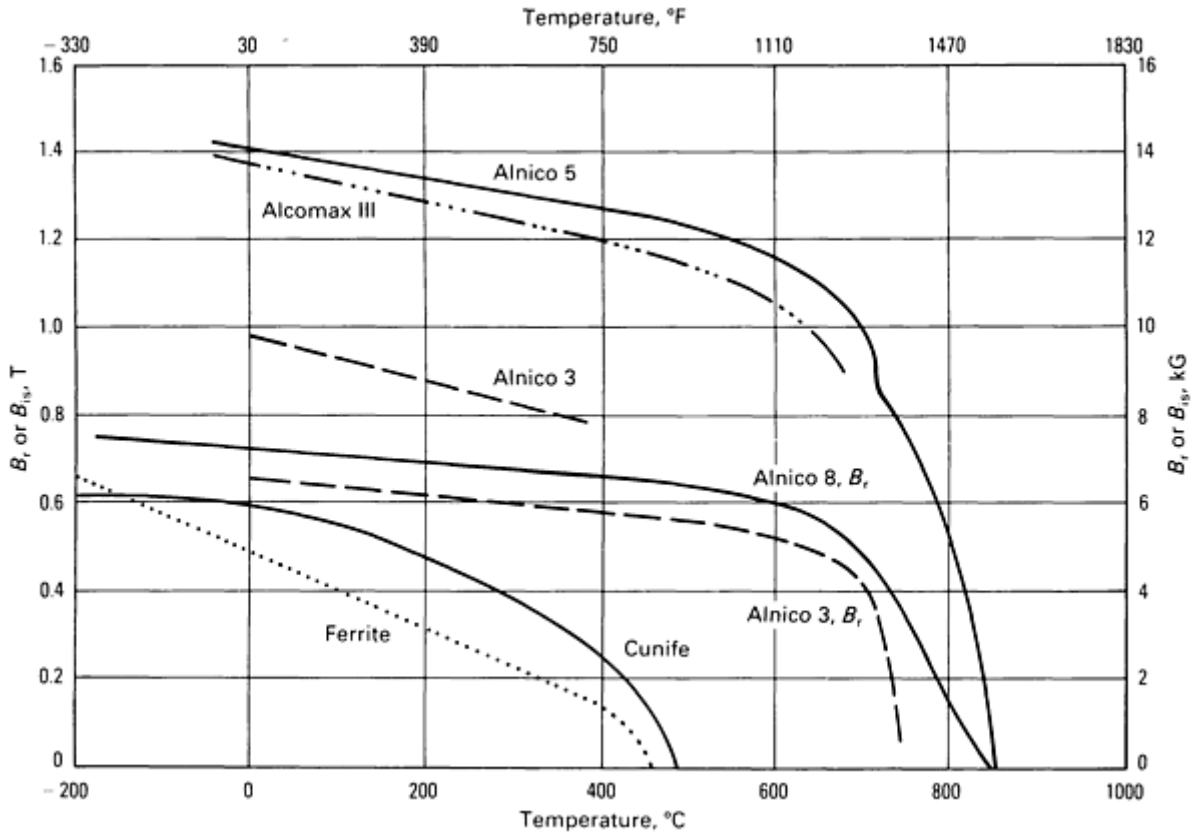

Fig. 18 Temperature dependence of saturation magnetization, B_{is}, or remanence B_r, for various permanent magnet materials.

Changes in H_{ci} with temperature can be predicted from the changes with temperature of anisotropy and magnetization. This assumes knowledge of the physical origin of all anisotropies contributing to H_{ci}. Experimental results are shown for many magnets in Fig. 19. For a case where uniaxial anisotropy predominates, as in $SrO{\cdot}6Fe_2O_3$, good agreement between calculated and experimental results is obtained. In a case where shape anisotropy is dominant, calculated and experimental results also are in good agreement, especially when the small crystal anisotropy contributions are considered. In the case of Alnico, crystal anisotropy is more in evidence. In addition, there is greater uncertainty as to the effect of the so-called nonmagnetic phase, especially at lower temperatures where the nonmagnetic phase may contribute appreciable magnetization. In the case of steels, the temperature dependence based on the inclusion mechanism is difficult to predict.

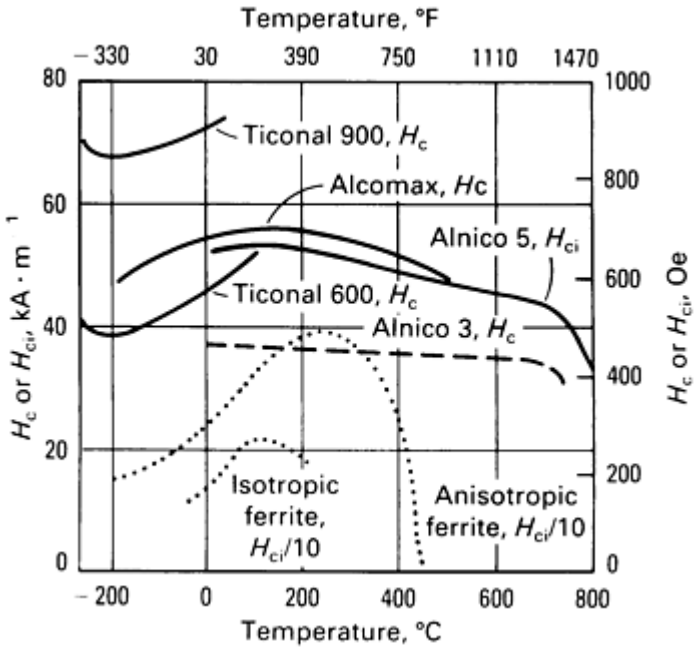

Fig. 19 Temperature dependence of normal coercive force H_c, and intrinsic coercive force, H_{ci}, for various permanent magnet materials

Demagnetization curves may change in both shape and peak values with changes in temperature. Families of demagnetization curves at various temperatures are shown in Fig. 20 for Alnico and hard ferrite.

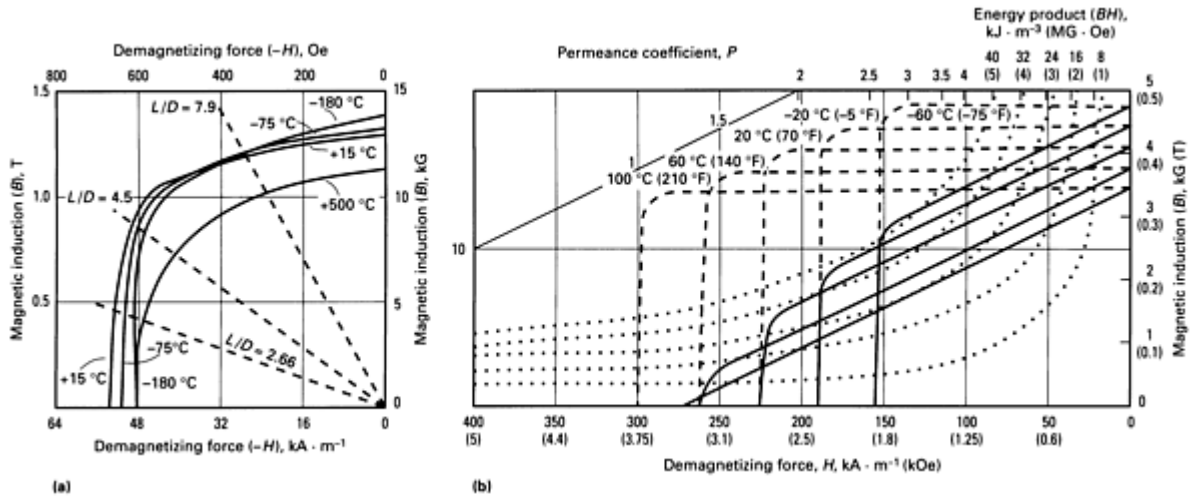

Fig. 20 Demagnetization curves for Alcomax (a) and for oriented ferrite (b) at various temperatures

Changes in magnetic state may be caused by temperature effects, such as ambient temperature changes of statistical local temperature fluctuations within the material; mechanical effects, such as mechanical shock or acoustical noise; or magnetic field effects, such as external fields, circuit reluctance changes, or magnetic surface contacts. In all of these situations, the loss of magnetization may be restored by remagnetizing.

Mechanical shock and vibration add energy to a permanent magnet, and decrease the magnetization in the same manner as discussed for the case of thermal energy. The only differences is that energy imparted thermally to the magnet is precisely *kT*, where *k* is the Boltzmann constant and *T* is the temperature, whereas the energy imparted mechanically

usually is not known. Thus, repetitive shocks or continual vibration should decrease the magnetization by the same logarithmic relations as for thermal effects, but where time is replaced, for example, by number of impacts.

Little work has been done regarding stabilization to minimize mechanical effects because it is seldom found necessary. It is generally conceded that modern permanent magnet materials are not affected by mechanical shock.

Reversible Changes. A loss of magnetization caused by a disturbing influence, such as temperature or an external magnetic field, is considered reversible if the original properties of the magnet return when the disturbing influence is removed.

Time Effects at Constant Temperature. In ferromagnetic materials, the intensity of magnetization does not instantly attain its equilibrium value when the applied field is suddenly changed. This time dependence may be due to eddy current effects or to reversible or irreversible magnetic viscosity. In general, eddy current effects are important only for a very short time--normally, less than a second after a change in the applied field. Such effects are not considered here. Reversible magnetic viscosity has been shown to be due to ionic diffusion in the crystal lattice and thus has a time-temperature dependence characteristic of diffusion processes. The time constant is:

$$\tau = \tau_{\infty} \exp(E/RT) \qquad \textbf{(Eq 3)}$$

where τ_{∞} is the time constant at infinite temperature, R is the reluctance (the reciprocal of permeance) and E is the activation energy, normally 0.1 to 1 eV. The time constant appears to be important only in magnetically soft materials, and only at high frequencies.

Irreversible magnetic viscosity is important to the stability of permanent magnets. Irreversible magnetic viscosity is due to the influence of thermal fluctuations on magnetization or the domain process responsible for magnetization. The effect of thermal agitation has been considered in terms of the energy required to activate irreversible domain processes. The time-temperature dependence of magnetization was shown to be given by:

$$M(t) = S \ln t \qquad \textbf{(Eq 4)}$$

where $S = \lambda N M_s kT$. Here, N is the number of blocks, or regions of magnetization M_s per unit volume; and λ is the constant probability density of energy E of all these blocks. Because these factors are all relatively independent of temperature (except near the Curie temperature), S is nearly directly proportional to T. The results of experiments are in agreement with this equation, as shown in Fig. 21. Aging at room temperature results in losses in magnetization for many materials, as shown in Fig. 22.

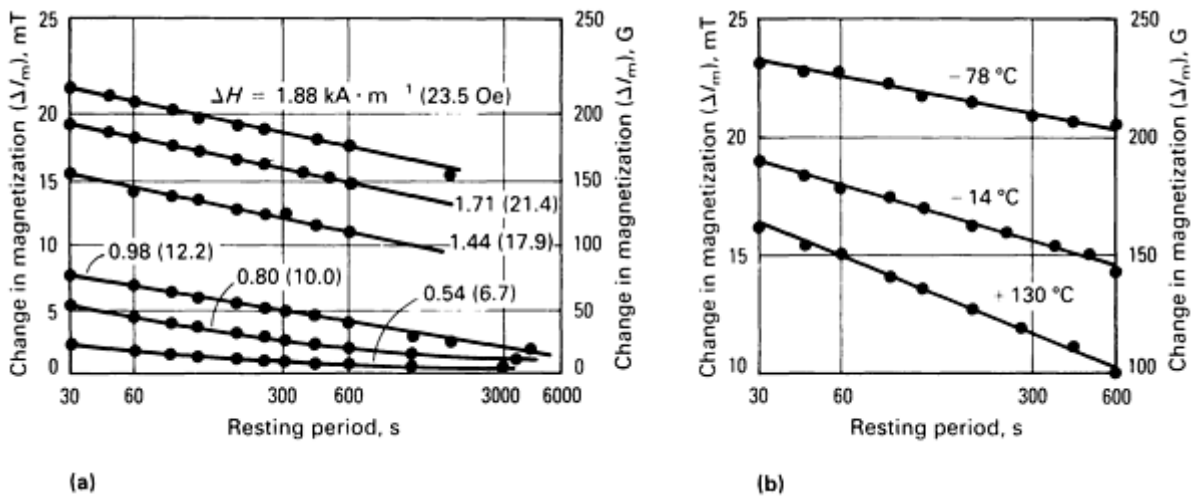

Fig. 21 Changes in magnetization, Δ*H*, with time for Alnico magnets. (a) At -14 °C (7 °F). (b) For Δ*H* = 1.71 kA · m^{-1} (21.40 Oe)

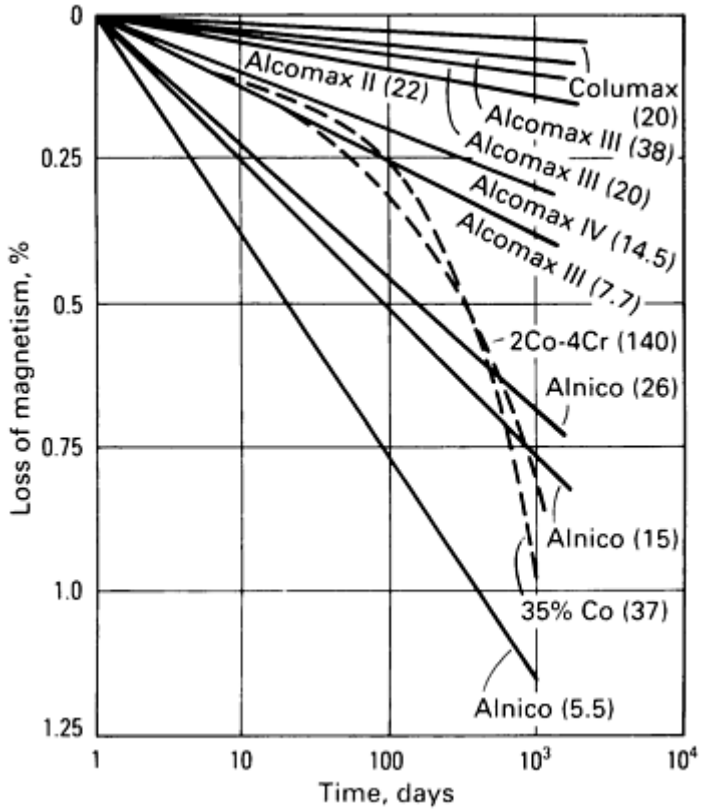

Fig. 22 Changes in magnetization with time at room temperature for various permanent magnet materials. Numbers in parentheses are working points, *B*/*H*.

Effects of Temperature Variations. Various permanent magnet materials undergo changes in magnetization as the temperature is cycled above and below room temperature (see Fig. 23). For a long bar operating above $(BH)_{max}$ (that is, $B/H = 35$), as in Fig. 23(a), the change in M is reversible. For a shorter bar operating below $(BH)_{max}$, as in Fig. 23(b), the first cooling cycle results in a substantial loss in magnetization. After the initial low-temperature exposure, the changes in M are reversible, but at a level below the initial magnetization. Results on an even shorter bar are shown in Fig. 23(c). These data suggest that by proper choice of dimensions, a reversible coefficient of approximately zero could be achieved over a limited range of temperature.

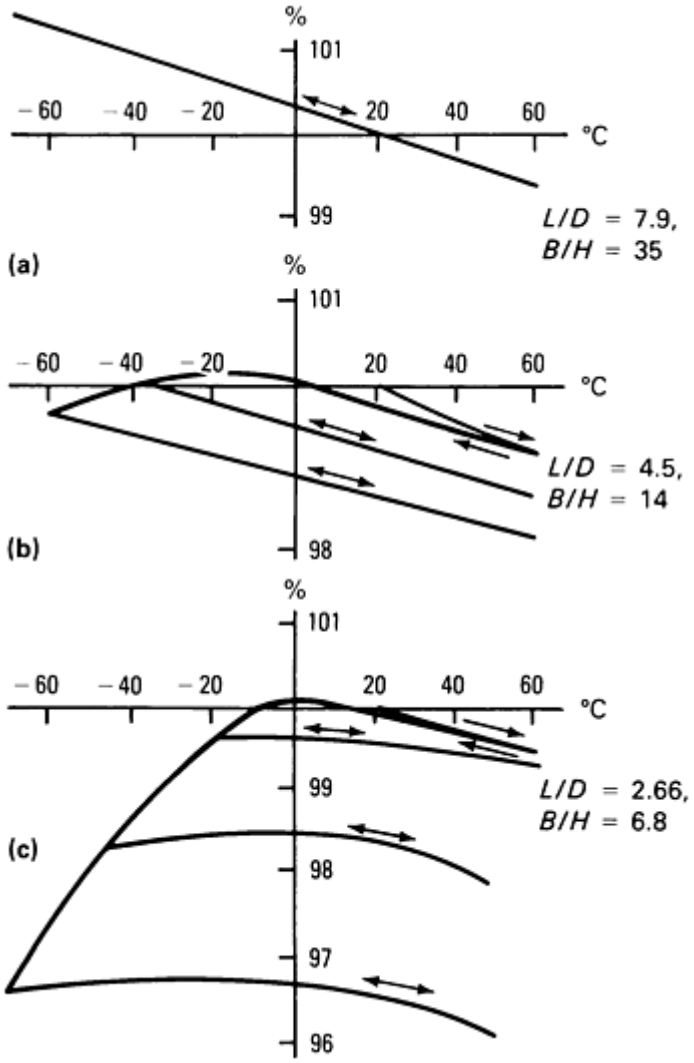

Fig. 23 Temperature variation for Alcomax III bars of various length-to-diameter ratios and working points

Design Considerations. Stability can have a significant influence on choice of magnet material, as well as on component shape and magnetic circuit arrangement. For example, the rather drastic change in coercive force of oriented hard ferrite with temperature (Fig. 19) requires special considerations in design. Here, the lowest permeance coefficient (*B*/*H*) that can be used is established by stability considerations rather than by magnetic circuit analysis.

For the more widely used permanent magnet materials, reversible changes in magnetization are encountered by cooling below room temperature (Table 7). Because the reversible remanence changes are closely approximated by a straight line, a reversible temperature coefficient is listed. The values of the temperature coefficient vary with the material. When the values of the coefficient are very small, they may be of a different sign for different magnet shapes. Consequently, it is often possible to carefully design magnet shape to yield very small variations in remanence with temperature. Similar changes may result upon heating above room temperature (Table 8). It is important to distinguish between irreversible losses and reversible changes. It is common practice prior to use to cycle a magnet between the temperature extremes to be encountered in service. Nearly all of the irreversible loss is encountered in one temperature cycle, but in some instances four or five cycles may be necessary.

In applications that are extremely sensitive to magnetization changes, it is very common to use a temperature compensating circuit to counteract reversible changes over the operating temperature range. Temperature-sensitive iron-nickel alloys are used as magnetic shunts for this purpose. A shunt is mounted beside the permanent magnet and simply diverts flux from the air gap as the temperature decreases. Temperature compensation by shunting requires overdesign of the magnet to allow for the loss in flux through the shunt at low operating temperatures.

Exposure at Very High Temperatures. There is considerable interest in using permanent magnets at temperatures approaching the Curie temperature of the permanent magnet material. The anisotropic Alnico 5 and Alnico 6 have been considered for use at 500 to 700 °C (930 to 1290 °F). At these temperatures, metallurgical effects as well as irreversible and reversible temperature effects are present. Alnico 5 exposed to 700 °C (1290 °F) for 20 h resulted in the reduction of $(BH)_{max}$ and H_c to approximately one half of their initial values. It is possible to program such changes into equipment and devices to allow permanent magnets to function for a limited time at extreme temperatures.

Stress Effects. Some magnets subjected to tension or compression show large changes in properties. This is especially true of Vicalloy, as shown in Fig. 24, and Cunife, as shown in Fig. 25. The changes are reversible, often even after considerable deformation has occurred. The changes are due to the contribution that stress makes to the total anisotropy of the system.

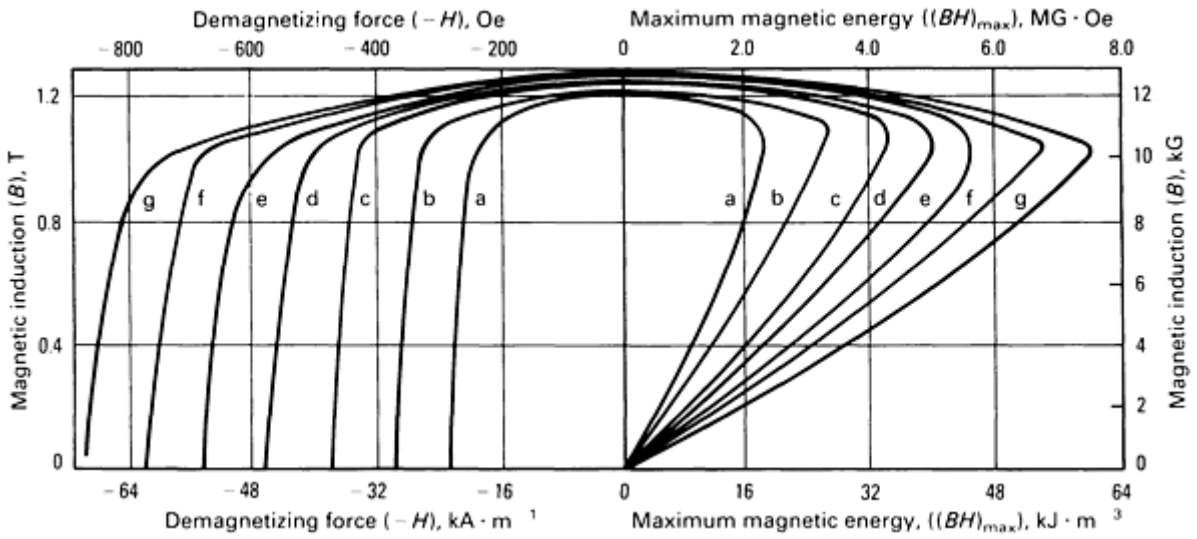

Fig. 24 Effect of stress on the magnetization curves for Vicalloy. Applied stresses: a, 0; b, 500 MPa (73 ksi); c, 990 MPa (144 ksi); d, 1490 MPa (216 ksi); e, 1990 MPa (289 ksi); f, 2490 MPa (361 ksi); g, 2990 MPa (434 ksi)

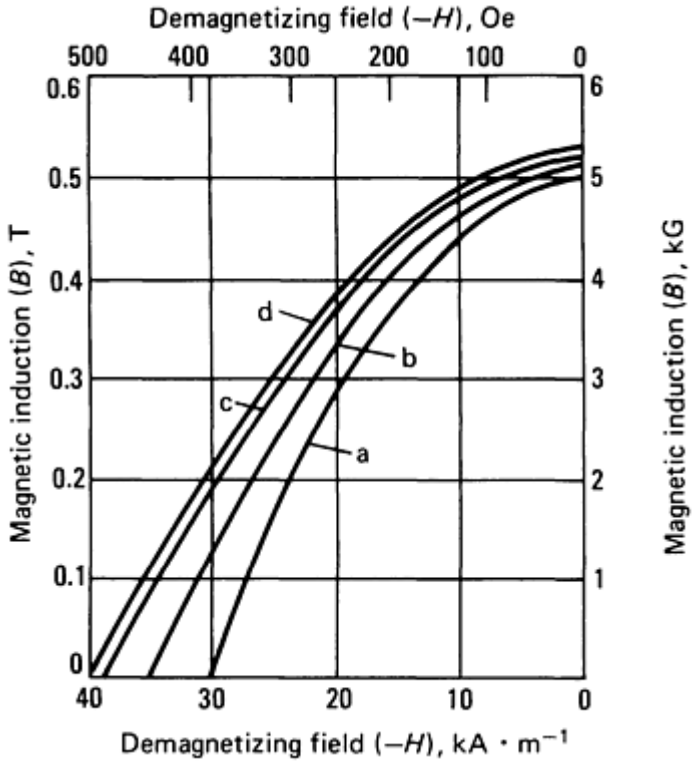

Fig. 25 Effect of stress on the magnetization curves for Cunife. Applied stresses: a, 0; b, 385 MPa (56 ksi); c, 570 MPa (83 ksi); d, 635 MPa (92 ksi)

Magnetization Prior to use. Magnets are magnetized in applied fields supplied by dc or pulsed-current electromagnets. Where practical, saturating magnetizing fields are recommended to gain full use of magnetic potential energy (see Table 9). Most magnets are demagnetized by heating to the Curie temperature or by applying an ac or dc field to reduce the measured induction to zero. Materials such as Alnico and samarium cobalt cannot be demagnetized by exposure to their Curie temperature because the metallurgical changes alter the permanent magnet properties.

Table 9 Recommended magnetizing fields, demagnetizing methods, and maximum service temperature

Permanent magnet material	Magnetizing field		Demagnetizing method	Maximum service temperature	
	kA · m^{-1}	kOe		°C	°F
Steels, Cunife, Vicalloy, Remalloy	80	1	ac field	100	210

(c) Not available

Partial demagnetization may be needed to reduce the flux density B_d to some calibrated level, or to prestabilize against anticipated magnetic losses. These losses can occur due to external demagnetizing forces, such as in electric motors, or by temperature cycles. Partial demagnetization is accomplished by initial exposure to the operating environment or by applying an ac field equivalent to about twice the amount of knockdown anticipated.

Calibration of rare-earth magnets can introduce other difficulties. The process of exposing the magnet to the field levels required to demagnetize the magnet to a specific level is established. The difficulty is due to changes in the flux distribution of the magnet. Such changes may have an adverse effect on flux stability.

Handling of all permanent magnets is best done in the nonmagnetized condition. There is less risk of attracting dirt and chips, of snapping magnetic objects onto the magnet with possible injury, and of partial demagnetization due to mechanical shock. The extremely strong magnetic fields and high mechanical forces developed by rare-earth magnets may create hazards to personnel through chipping, shattering, or pinching on impact. Always make sure that magnetized rare-earth magnets are handled under control when they come near each other or other ferromagnetic materials. Metallic chips and fine particles are susceptible to rapid oxidation (burning) and spontaneous (pyrophoric) ignition.

Metallic Glasses

W.L. Johnson, Keck Laboratory of Engineering, California Institute of Technology

Introduction

METALLIC GLASSES can be prepared by solidification of liquid alloys at cooling rates sufficient to suppress the nucleation and growth of competing crystalline phases. Their discovery in 1960 by Pol Duwez and his colleagues was made possible by the innovation of rapid quenching methods. This article presents a historical survey of the study of metallic glasses and other amorphous metals and alloys from their inception to the present. This includes a discussion of synthesis and processing methods, structure and morphology, and a description of the electronic, magnetic, chemical, and mechanical properties of metallic glasses. In addition, the development of metallic glasses as materials for technical applications will be described.

Historical Introduction and Background

Traditionally, a glass is considered to be a vitrified liquid. This is a liquid that is cooled below its thermodynamic melting point and fails to crystallize, but solidifies nevertheless. In a rather well-defined temperature range below the melting point, an under-cooled liquid undergoes configurational freezing. The viscosity (η) of the liquid rises rapidly with falling temperature in this temperature range to values normally associated with the solid state. An example is shown in Fig. 1(a). For a typical liquid metal, viscosities are measured in units of centipoise. Over a temperature range of tens of degrees, this value rises to 10^{16} poise, a value generally taken to indicate a solid. The heat capacity of the liquid shows an anomaly of the form indicated in Fig. 1(b). The peak in the heat capacity (or the temperature at which the rate of change of viscosity is maximum) is traditionally used to define the glass transition temperature of the undercooled liquid. To experimentally achieve vitrification, crystallization of the undercooled liquid must be avoided.

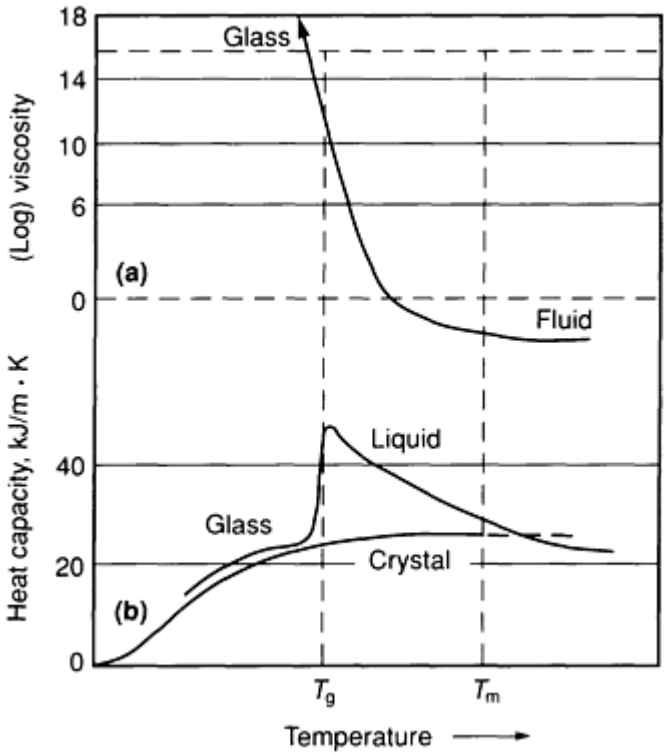

Fig. 1 (a) Temperature dependence of the viscosity of an undercooled melt. (b) Heat capacity of an undercooled melt as a function of temperature. Also shown is the typical heat capacity of the corresponding crystalline solid (at the same composition).

Many naturally occurring minerals, such as volcanic obsidian, exhibit a glassy structure. The earliest evidence of glass synthesis by man was recorded by the historian Pliny in the first century (Ref 1). He writes of a band of Phoenician sailors who about the year 5000 B.C. built a fire over blocks of soda from a ship's cargo. As the fire died, the fused soda sank into the sand, forming a shiny glass rivulet. Remains from Middle Eastern civilizations dating back 5000 years provide direct evidence of glassmaking.

One may naturally ask why the discovery of metallic glasses did not occur until the twentieth century. The answer lies in the ease with which metallic melts undergo crystallization. In contrast to the obsidian and silicate glasses mentioned above, metallic glasses can only be produced when the melt is cooled at high rates. The time required to nucleate and grow crystals in an undercooled melt varies enormously with the nature of the atomic and molecular units that make up the liquid. These units must organize themselves into a crystalline nucleus of critical size in order to initiate the process of crystallization. In metallic melts, where the fundamental units can be viewed as roughly spherical individual atoms, the formation of a crystalline nucleus occurs with relative ease. It is unimpeded by kinetic hindrances that arise when complex, covalently bonded molecular units are organized to form a nucleus (as in materials such as silica, polymers, and so forth). As such, the rate of crystallization in the undercooled melt tends to be relatively high in metallic liquids. The theory of nucleation and growth of crystals in undercooled metals was developed over 40 years ago by Turnbull and others (Ref 2). It was shown that the rate of crystal nucleation and growth is a sensitive function of the degree of undercooling $\Delta T = T_m - T$, where T_m is the thermodynamic melting point. The rate of crystal nucleation at a given ΔT is a rapidly increasing function of ΔT. In metals, this typically permits undercoolings of ~100 K to be achieved with no observable crystallization in laboratory time scales. At greater undercoolings, the crystallization rate rises very rapidly with falling temperature, and copious nucleation and growth of crystals is observed. The rise in the nucleation rate is finally halted when the configurational freezing temperature is approached. Using classical nucleation theory, Turnbull developed a model for the rate of crystal nucleation ($\dot{N}$) (measured as the number of crystalline nuclei/cm^3 · s^{-1}) in metallic melts. He proposed a formula that can be written as:

$$\dot{N} = A \exp[- B/(T - T_g)]\exp(- \Delta G^N/k_B T) \qquad \textbf{(Eq 1)}$$

where A and B are constants, T_g is the glass transition temperature, ΔG^N is the free-energy barrier that opposes the formation of a crystalline nucleus, and k_B is the Boltzmann constant. ΔG^N decreases with increasing undercooling. It roughly varies as:

$$\Delta G^N = C\sigma^3/[\Delta S_F(T_m - T)]^2 \qquad \textbf{(Eq 2)}$$

where C is a geometric constant of order unity, σ is the interfacial energy per unit area between a liquid and a crystal, and ΔS_F is the entropy of fusion per unit volume of liquid. Improvements on this simple formula have been developed (Ref 3), but the version in Eq 2 is adequate for this discussion. These equations lead to a nucleation rate that depends on temperature in a manner illustrated in Fig. 2 for a typical choice of the constants (A, B, C, σ, ΔS_F) and several values of the ratio T_g/T_m. A sharp peak in the nucleation rate as function of undercooling is associated with the rising thermodynamic driving force for crystallization (Δg_{XL}), which is measured as the free energy drop per unit volume on crystallization:

$$\Delta g_{XL} = \Delta S_F(T_m - T) \qquad \textbf{(Eq 3)}$$

This competes against a falling fluidity (the inverse of viscosity):

$$\eta^{-1} \sim \exp[- B/(T - T_g)] \qquad \textbf{(Eq 4)}$$

The maximum rate of nucleation determines the rate at which cooling must be carried out in order to suppress crystallization. As seen in Fig. 2, this maximum rate depends sensitively on the value of T_g compared with the melting point T_m. When T_g/T_m is relatively large (for example, $T_g/T_m = \frac{2}{3}$ in (Fig. 2), the maximum rate of nucleation $\dot{N}$ ~10^{-30} nuclei/cm^3 · s^{-1} occurs when T/T_m ~0.7. When T_g/T_m is only somewhat smaller (for example, $T_g/T_m = \frac{1}{2}$ in Fig. 2), a

maximum rate of $\dot{N} = 10^8$ nuclei/cm$^3 \cdot$ s^{-1} is predicted. The ratio T_g/T_m thus plays a key role in determining whether or not crystallization can be avoided during the quenching of the melt.

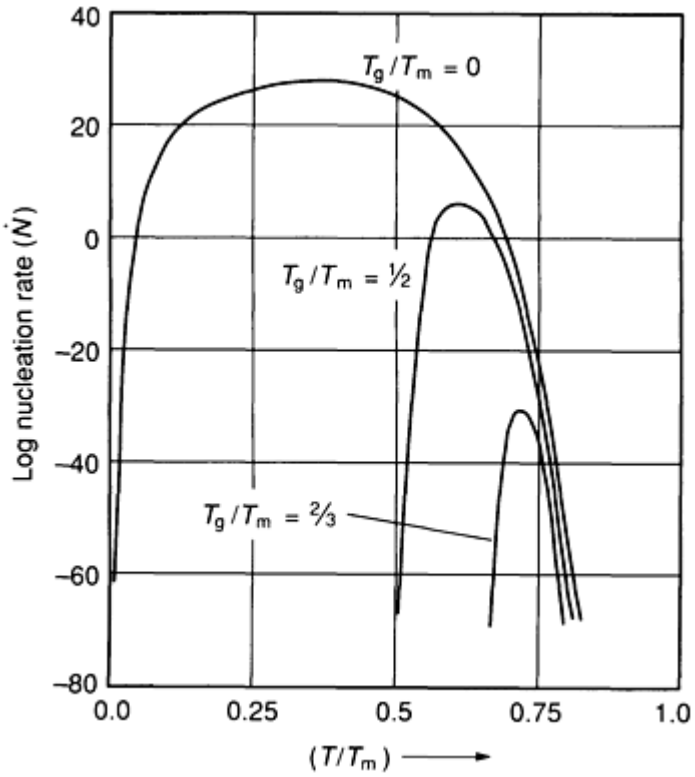

Fig. 2 Temperature dependence of nucleation rate ($\dot{N}$) in an undercooled melt. The nucleation rate is given in units of nuclei/cm$^3 \cdot$ s^{-1}.

In binary alloys where the liquidus and solidus curves fall to relatively low temperatures compared with the melting points of the elemental constituents, the ratio T_g/T_m (here T_m is interpreted as the liquidus/solidus temperature) is larger than in pure metals. Deep-eutectic features in phase diagrams tend to satisfy this condition. As such, compositions lying near deep-eutectic points tend to be good glass-forming compositions. Turnbull pointed out this deep-eutectic criterion during the early 1960s.

Once the nucleation rate is known, the critical cooling rate required for glass formation can be determined. In pure metals, this cooling rate has been estimated to be of the order of 10^{13} K/s. Clearly, this is very difficult to achieve in practical situations. Fortunately, in certain metallic alloys (for example, deep-eutectic alloys), the required rates are more modest, of the order of 10^4 to 10^5 K/s. Although not normally achieved in cooling bulk metallic melts, such rates are feasible under special circumstances. The techniques used to achieve these cooling rates are discussed in detail in the section "Synthesis and Processing Methods" in this article.

The brief discussion above explains why metallic glass formation is normally not observed in everyday experimental situations and answers the question of why metallic glasses were not discovered until the twentieth century. The following section traces the development of special quenching techniques capable of producing metallic glasses. Further, it will be shown that the final glassy state produced by quenching a melt can also be achieved by a variety of other methods in which the parent phase is not a liquid.

It is traditional to refer to materials produced by methods other than melt quenching as amorphous materials. The term amorphous also applies to melt-quenched glasses and is therefore a more general name applied to any material having a structure and physical characteristics similar to those of a configurationally frozen liquid. Specifically which properties of a particular material qualify it as amorphous will be addressed in the sections on structure and properties. The terms amorphous and glassy have become more or less interchangeable. This partially reflects the tendency to view materials in

terms of structure and properties rather than in terms of how they are prepared. In fact, the structure and properties of amorphous solids often depend (albeit in a subtle manner) on the synthesis method used to produce them. As such, the distinction between "glass" and the more general term "amorphous solid" remains somewhat useful.

Synthesis and Processing Methods

Rapid Quenching From the Melt. As mentioned in the previous section, the production of metallic glasses by liquid quenching requires rather high cooling rates. To achieve such rates, heat must be extracted from the melt along a temperature gradient. A molten sample of typical dimension R and initial temperature T_m (the melting point of the material) will require a total cooling time τ (to ambient temperature) of the order of:

$$\tau \sim (R^2/\kappa) \qquad \textbf{(Eq 5)}$$

where κ is the thermal diffusivity of the metal. It is given by $\kappa = K/C$ where K is the thermal conductivity and C is the heat capacity per unit volume. The cooling rate achieved ($\dot{T}$) will be of the order of:

$$\dot{T} = dT/dt = T_m/\tau = (KT_m/CR^2) \qquad \textbf{(Eq 6)}$$

Taking T_m ~1000 K ~1 W/cm $\cdot$ s^{-1} $\cdot$ deg^{-1} (typical of a molten metal) and C ~2 J/cm^3 $\cdot$ deg^{-1} (also typical of a metallic liquid), gives

$$\dot{T} = 500/R^2 \qquad \textbf{(Eq 7)}$$

To achieve cooling rates of 10^6 K $\cdot$ s^{-1}, the sample dimension must be of the order of 100 μm or less. In addition, the achievement of such cooling rates presupposes that the liquid sample can be suddenly brought into intimate thermal contact with a large, thermally conductive mass initially at ambient temperature. This restrictive combination of conditions requires one to produce a thin molten layer and to bring it suddenly into contact with a cold, highly conductive surface.

In 1959, Pol Duwez and his colleagues devised a clever method to accomplish this (Ref 4). A liquid droplet is melted in a nonreactive crucible under an inert atmosphere. The droplet is suddenly subjected to an acoustical shock wave that both atomizes and accelerates the atomized droplets against a cold copper surface at ambient temperature. The individual atomized droplets are of micron dimensions. The device is shown schematically in Fig. 3. This technique is referred to as gun quenching. The droplets impact on the substrate, spread as they slide along, and freeze by heat conduction to the underlying copper strip. This method produces a rather irregular sample, but it has been shown to be capable of achieving cooling rates of 10^6 to 10^8 K $\cdot$ s^{-1}. It was an ideal tool for studying solidification of metals at high cooling rates. With it Duwez *et al.* (Ref 5) produced the first metallic glasses in the gold-silicon binary system.

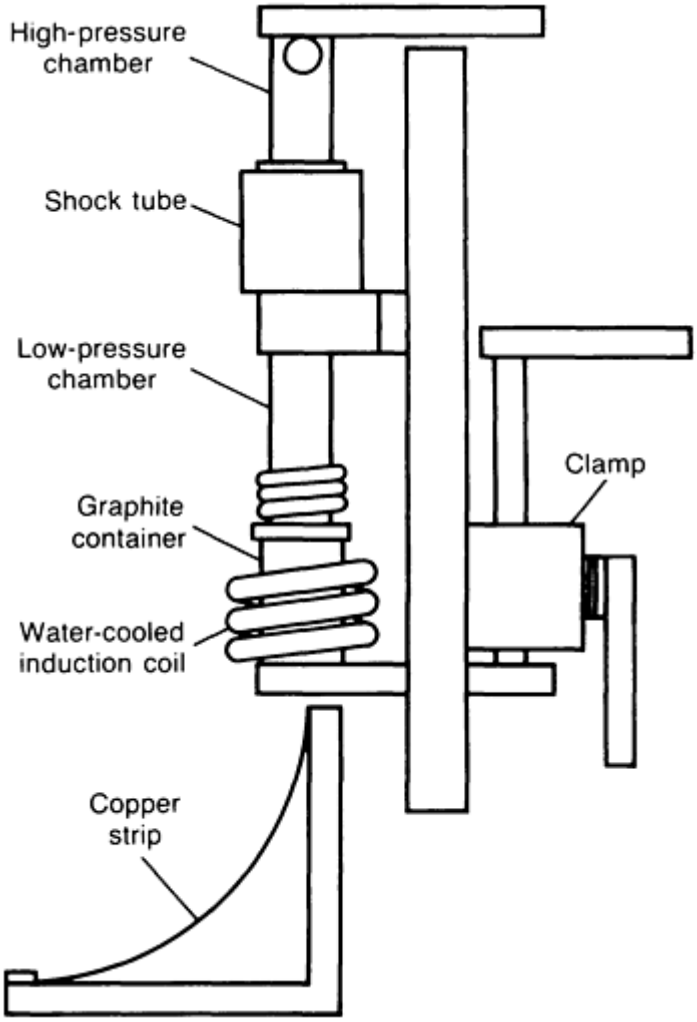

Fig. 3 Schematic showing the gun quenching apparatus used by Duwez *et al.* to carry out rapid solidification experiments. Source: Ref 4

A somewhat refined version of the method, used later by the Duwez group, is illustrated in Fig. 4 and is called the piston and anvil technique. In this method, the droplet is melted and allowed to fall between the faces of an anvil and a pneumatically accelerated piston. The droplet is struck by the face of the piston, carried onto the anvil, and spread by the momentum of the moving piston into a thin layer. The layer subsequently solidifies by conduction of heat onto the piston and anvil surfaces. Cooling rates of the order of 10^5 to 10^6 $K \cdot s^{-1}$ are achieved. The sample produced is a thin foil (the size of a nickel) of thickness ranging from 30 to 50 μm. Owing to their rather uniform thickness, such samples were ideal for scientific studies.

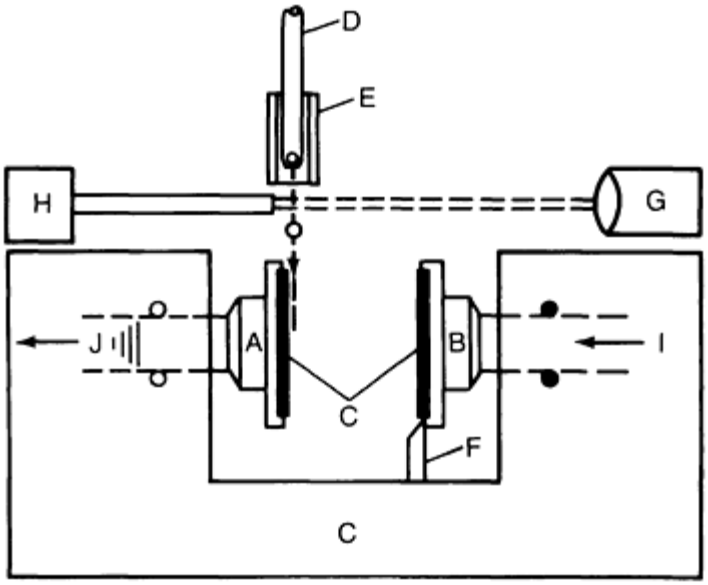

Fig. 4 Schematic drawing of the piston and anvil device used for rapid solidification of liquid drops at cooling rates of 10^4 to 10^6 K/s. The device was developed to produce relatively uniform foils of metallic glass by the Duwez group. The droplet is melted, ejected from the crucible, detected during fall by the photocell, and then quenched by the pneumatically driven piston onto the anvil. Both the gun method and piston and anvil method were used by the Duwez group and by the Giessen and Grant group at M.I.T. during the 1960s to produce samples of glassy metallic alloys for scientific study. Using the rapid solidification methods, the Duwez group found a generic class of metallic glass-forming alloys now referred to as the metal-metalloid systems. These alloys contain about 80 at.% of a transition metal (for example, iron, nickel, cobalt, and so on) and 20 at.% of a metalloid element (for example, silicon, phosphorus, boron, carbon, and so on). The Giessen group discovered a second class of metallic liquids that form glasses at rapid solidification rates. These are referred to as the metal-metal systems. These alloys contain an early transition metal or rare earth element (for example, zirconium, titanium, niobium, tantalum, and so on) alloyed with a late transition element (for example, nickel, cobalt, iron, palladium, and so on). The composition ranges of these glass-forming systems were found to be more varied than those of the metal-metalloid glasses. Both classes of alloys yielded glasses that were stable at room temperature and above. Some of these alloys could be heated to temperatures of the order of 500 °C (930 °F) or more without crystallization on laboratory time scales.

By 1970, it became increasingly apparent that if metallic glasses were to be more than a laboratory curiosity, then a method of continuous fabrication capable of producing larger sample quantities was necessary. Several researchers developed the continuous casting, or melt spinning, processes in response to this need (Ref 6, 7). In these processes, a continuously flowing jet of liquid metal is forced onto the exterior surface of a rapidly rotating substrate wheel. Upon contact with the wheel, the jet spreads onto the surface and solidifies. A solid continuous ribbon is thrown from the wheel in a continuous manner by centripetal force. Multiple-jet casters, in which adjoining jets fuse together on the wheel, were initially developed to produce a wider product.

A major breakthrough in this method was the planar-flow casting technique. Patented by Narasimhan at the Allied Corporation (now Allied-Signal Inc.) (Ref 8), this method involves a broad continuous planar-melt jet produced by a slotted nozzle that flows continuously onto the surface of a rotating drum. In its commercial realization, it leads to the production of uniform sheets of metallic glass having a thickness of ~15 to 150 μm, widths up to ~1 m (40 in.), and essentially unlimited length. The cooling rates achieved by this method are of the same order as those achieved in the original methods of Duwez. The broad sheets of metallic glass produced are ideal for a number of commercial applications. A photograph of such sheets is shown in Fig. 5. The uses of such samples will be discussed further in the section dealing with applications.

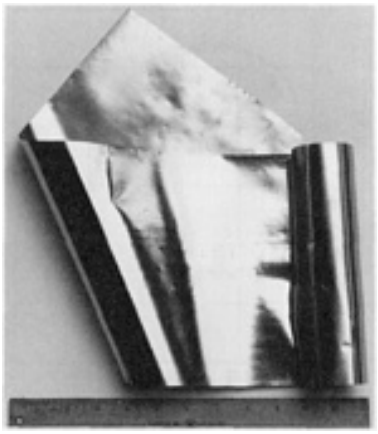

Fig. 5 Sheet of metallic glass prepared using the planar-flow casting method. Such sheets are used to wind power-distribution transformer cores.

Vapor Quenching and Electrodeposition. As mentioned earlier, there are other methods of producing materials that have atomic structures and physical properties similar to those of configurationally frozen liquid. It can be argued that these amorphous solids are in essentially the same metallurgical state as a melt-quenched glass. As such, it is appropriate to review these methods.

The first involves the atom-by-atom deposition of the material onto a substrate. The supply of atoms is provided in several different ways. These include production of metallic vapor by thermal evaporation (such as using electron beam guns), atom-by-atom erosion of a solid target by energetic ions (sputtering), or deposition of metallic ions from an electrolytic solution (electrodeposition and electroless deposition). There are also other variations (such as chemical vapor deposition). All of these methods have in common the fact that the parent material consists of individual atoms (or small atomic clusters) that are deposited atomic layer by atomic layer onto a relatively cold substrate.

The production of amorphous metals by this method was pioneered by Buckel and Hilsch (Ref 9) during the 1950s at the University of Gottingen in Germany. Using thermal evaporation of simple metals (tin, lead, and so forth) and alloys of simple metals (tin-copper, lead-copper, and so forth) they showed that quenching of the metallic vapor onto a cryogenically cooled substrate (T < 10 K) could lead to the growth of an amorphous film. Buckel and Hilsch devised methods such as *in situ* electron diffraction to demonstrate that the structure of these films was similar to that of a liquid. These experiments involved some of the earliest reflection electron diffraction studies of thin films in a high-vacuum chamber. In addition, they developed *in situ* methods for measuring the electrical resistivity of films. Using these methods, they found that the amorphous films became superconducting at temperatures higher than those of the corresponding equilibrium phases. In addition, they were able to show that the amorphous films crystallized at relatively low temperatures. In the case of pure metals (for example, tin, lead, bismuth, and so on), crystallization was observed when the films were heated above ~20 K.

Similar studies of films of pure metals (copper, gold, and so on) and alloy films (copper-gold) formed by quenching on a cryogenic substrate were carried out somewhat later by Mader *et al.* (Ref 10), who pointed out that cryoquenched films of pure noble metals were not amorphous, whereas alloys of noble metals did become amorphous. They attributed this to the fact that alloys of elements having different atomic sizes crystallize with greater difficulty under cryoquenching conditions. They used computer simulation of the deposition process to verify this hypothesis.

Studies of cryoquenched pure metals were extended to the transition elements by Collver and Hammond (Ref 11). They deposited thin films of the 4*d* and 5*d* transition elements onto cryogenically cooled substrates and found that many of the films produced were amorphous. Like Buckel and Hilsch, they observed that amorphous films of pure metals tended to crystallize at temperatures far below room temperature. On the other hand, they discovered that certain amorphous alloy films (for example, molybdenum-rhenium alloys) exhibited far greater stability against crystallization. Some of these films could be heated to room temperature and above (~400 °C, or 750 °F) without crystallization.

Since these early studies, many groups have studied vapor-deposited amorphous alloys (Ref 12). For many alloys, it is unnecessary to cool the substrate in order to obtain an amorphous film. Furthermore, amorphous films so produced often

remain amorphous up to rather elevated temperatures (~700 °C, or 1290 °F). Vapor deposition has become a common method of producing amorphous films for a variety of technical applications. Various methods of producing metallic vapor or atomic scale clusters are currently used. Among these are sputtering, chemical vapor deposition, electron beam evaporation, and so forth. Sputtering utilizes a dc or radio frequency (rf) generated plasma discharge to accelerate inert gas ions into a metal target. The ion impact on the target energizes secondary metal atoms (or ions), which are ejected from the target. These metal atoms are subsequently collected on a substrate and a metal film is grown. The original target is often a metal alloy.

In other cases, two or more elemental targets are simultaneously bombarded (cosputtering) to produce an alloy film. The sputtering method has been perfected with the development of commercially available sputter guns. These guns use magnetic fields to concentrate the inert gas plasma in the vicinity of the target. As such they are often very efficient in producing secondary metal atoms. This variation of sputtering is called magnetron sputtering. In commercially available units, rather high thin-film deposition rates (10 to 100 nm/s) are achievable, and thus reasonably thick films can be deposited in practical time scales.

Chemical vapor deposition employs volatile gases (for example, metal fluorides, metal chlorides, metal carbonyls, and so forth). These gases are heated in a reaction chamber and caused to decompose into a volatile component (chlorine, for example) and pure metal vapor. The volatile component is swept away in the reaction chamber while the metal vapor is deposited onto a substrate. Simultaneous decomposition of two reactants can be used to deposit alloy films. This techniques has been used to form amorphous alloy coatings on complex-shape substrates and irregular surfaces.

Electrodeposition is another atom-by-atom deposition method used to produce amorphous alloy films and coatings. It is much like chemical vapor deposition, except metal ions instead of atoms are obtained by dissolution of metal salts in an aqueous solution. When a current is passed through the electrolytic cell, these metal ions are collected on an anode. A film is built up on the anode as the process proceeds. This method has long been used in commercial plating. For example, electrolytically deposited nickel films have long been used in commercial applications. These films, in fact, often contain (in addition to nickel) substantial amounts of other elements (for example, phosphorus). For sufficiently high concentrations of these other elements, the films are amorphous. It is likely that the earliest amorphous alloy films were made by this process over 60 years ago. Unfortunately, at that time no systematic study of the structure of these films was made.

Solid-State Methods. We have thus far discussed the production of amorphous metals and metallic glasses by quenching of liquid metals or quenching of metallic vapors. An obvious question is whether it is possible to produce an amorphous metal or metallic glass by inducing a crystalline solid to transform to the amorphous state. Such a transformation could be called a crystal-to-glass transformation. As mentioned earlier, the amorphous phase is not an equilibrium phase. Without exception, it is believed that the lowest free-energy state of a solid is a crystalline phase or a mixture of crystalline phases. How, then, can a crystalline metallic solid be induced to transform to the glassy state?

Clearly, the crystalline system must initially be driven away from equilibrium. An excess free energy must be stored in the crystalline system that is sufficient to render it thermodynamically less stable than a competing glassy phase. Figure 6 illustrates the basic principle involved. A nonequilibrium crystalline state is initially created by suitable means. The Gibbs free energy of this state is greater than that of the amorphous state. On the other hand, the equilibrium crystalline state has still lower Gibbs free energy. In order for the nonequilibrium crystalline state to transform to the amorphous phase, kinetics must favor this transformation.

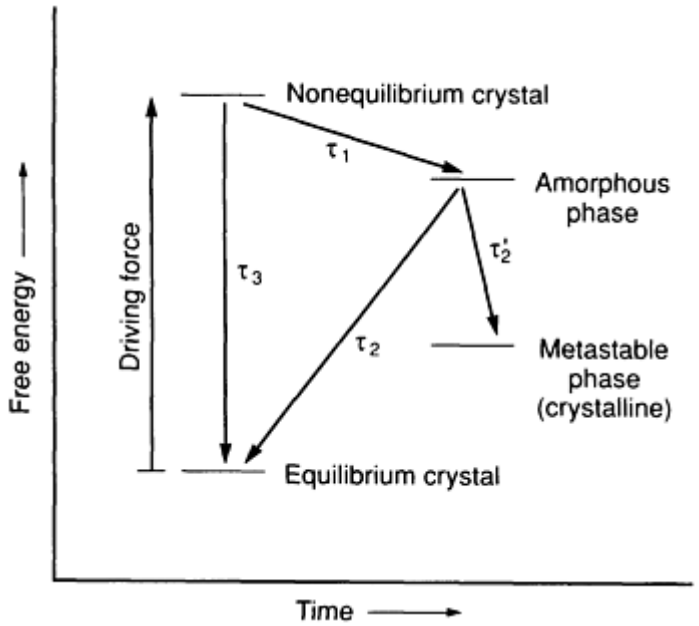

Fig. 6 Illustration of the free-energy relationship and transformation time scales (τ_1, τ_2, τ_3) for a nonequilibrium crystalline solid that undergoes a crystal-to-glass transformation

In Fig. 6, three time constants (τ_1, τ_2, and τ_3) are indicated. These time constants give the characteristics time scale for the respective transformations. In order that the amorphous phase be formed and retained, the transformation from the nonequilibrium crystalline state to the amorphous state must be kinetically preferred over the two other competing transformations:

$$\tau_1 < \tau_2 \text{ and } \tau_1 < \tau_3 \qquad \textbf{(Eq 8)}$$

The first condition ensures that the amorphous state formed will not crystallize to the equilibrium state during the time scale of the experiment; the second condition ensures that the nonequilibrium crystal will not directly transform to the equilibrium crystalline state. In the second condition, the amorphous phase must be metastable during the time scale of the experiment. It is well known that amorphous phases crystallize by a process of nucleation and growth of crystals. The theory of crystallization of an undercooled melt can be applied to the crystallization of the glass. As such, by a suitable choice of kinetic conditions (sufficiently low temperature), one can always ensure that the second condition of Eq 8 is satisfied. Essentially, solid-state amorphization must be carried out below that temperature where the glassy product would normally crystallize. Practically speaking, this requires that the experiments be carried out below the T_g of the amorphous alloy to be produced. In fact, both conditions in Eq 8 can be simultaneously satisfied in a number of actual situations. A few of these situations are discussed in this article; more extensive discussions are available in Ref 10 and 11.

One example of solid-state amorphization is the reaction of two crystalline metals in a diffusion couple to form an amorphous phase. This phenomenon has been observed in numerous binary diffusion couples (Ref 13, 14) and was first reported by Schwarz and Johnson (Ref 15). The example described here is the nickel-zirconium binary couple. Figure 7 is an electron micrograph showing a nickel-zirconium diffusion couple in cross section. The couple was reacted for 6 h at a temperature of 300 °C (570 °F). Between the nickel and zirconium layers, a featureless and uniform gray layer having a thickness of the order of 80 nm has formed. This zone is amorphous. It can be shown that this amorphous phase initially nucleates at the nickel-zirconium interface at grain boundaries of zirconium grains. Apparently, the nucleation barrier for amorphous phase formation is lower than that for formation of the equilibrium intermetallic compounds of the nickel-zirconium binary system. Figure 8 shows an enthalpy of mixing diagram at T = 300 °C (570 °F) for the nickel-zirconium system. Because the enthalpies of mixing in this system are far larger than TS_{mix} (where S_{mix} is the entropy of mixing), the free energy of mixing can be approximated by the enthalpy of mixing.

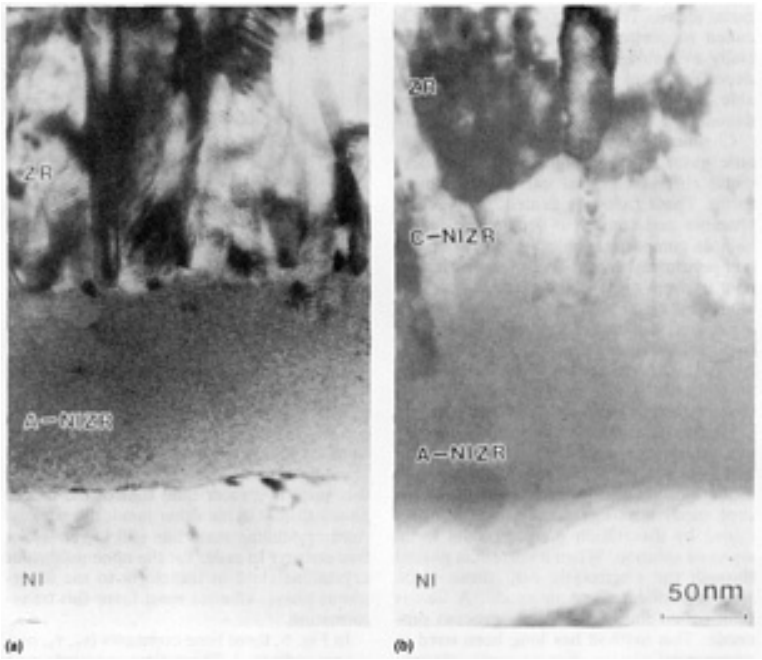

Fig. 7 Electron micrographs showing a cross section of a thin-film diffusion couple consisting of layers of nickel and zirconium. (a) The diffusion couple has been reacted at 300 °C (570 °F) for 6 h. An amorphous interlayer having a thickness of about 80 nm has formed and grown at the nickel-zirconium interface. (b) The diffusion couple has been reacted for 18 h at 300 °C (570 °F). Formation and growth of the amorphous interlayer has now been succeeded by later growth of the crystalline intermetallic compound NiZr.

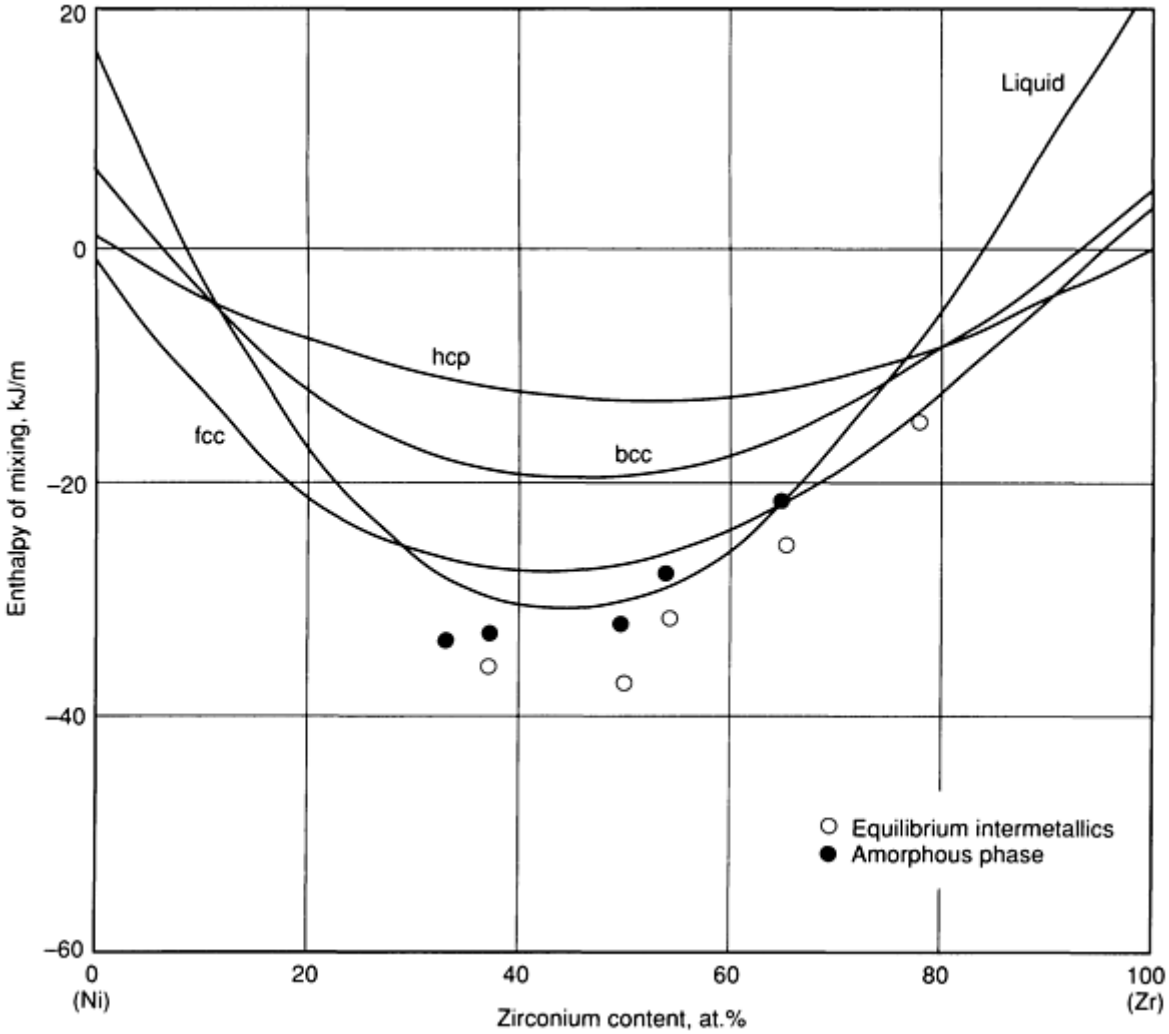

Fig. 8 Enthalpy of mixing versus composition for the nickel/zirconium binary system at a fixed temperature of 300 °C (570 °F). The composition dependence of the enthalpy of mixing of various solid-solution phases (hcp, bcc, and fcc) and the undercooled liquid/amorphous phase are shown. The enthalpy of mixing of the intermetallic compounds is indicated by data points.

In equilibrium, a diffusion couple should ultimately form one or a mixture of two of the terminal solid solutions or equilibrium compounds. These are the lowest free-energy states. On the other hand, the amorphous phase has lower free energy than a physical mixture of the pure metals or their solid solutions. This is precisely the situation described in Fig. 6. The initial free energy of the system is greater than that of the amorphous phase. The free energy of the amorphous phase is greater than that of the ultimate equilibrium phase, which consists of one or a mixture of two intermetallic compounds. In this case one can associate τ_1 with the time required to nucleate and grow the amorphous layer to a certain thickness (for example, 80 nm). The time constant τ_2 is associated with the time required for the amorphous phase to crystallize into one or more of the equilibrium intermetallic compounds, whereas the time constant τ_3 is the time required to nucleate and grow an intermetallic compound in the original diffusion couple. At the temperature where this solid-state reaction is carried out, it is clear that the conditions described by Eq 8 are satisfied.

A second case of solid-state amorphization involves the use of an external driving force to raise the enthalphy (and free energy) of an initially single-phase crystalline material. Irradiation of a crystal by high-energy particles (ions, electrons, and neutrons) has been shown to be an effective means of accomplishing this. The crystal is held at a relatively low temperature, and irradiation induces damage in the crystal in the form of point defects (vacancies, interstitial atoms, and chemical disorder). If the ambient temperature is sufficiently low, recovery of the crystal can be suppressed. The recovery is mediated by the mobility of the defects. Thus the temperature chosen must be sufficiently low to suppress defect mobility. Defect mobility is characterized by a time scale τ_d, which can be identified with τ_3 in Eq 8. If τ_d is sufficiently long compared with the time scale of the experiment, then the defects formed will be trapped in the crystal. Under these

conditions, the defect concentration can be driven far outside of equilibrium limits. The excess enthalpy stored in the crystal in the form of defects then provides the thermodynamic driving force for amorphization. This raises the free energy of the crystal above that of the amorphous phase. If a suitable nucleation site for an amorphous phase exists at the ambient temperature, then a crystal-to-glass transition occurs. Often, the amorphous phase nucleates most easily at extended defect sites in the original crystal (for example, grain boundaries, dislocations, a free surface, or other extended defect). For example, during electron irradiation of the intermetallic compound Ti_3Cu_4, Meshi *et al.* (Ref 16) observed nucleation of the amorphous phase along dislocations. In the absence of extended defects, it may be possible to observe homogenous nucleation of the amorphous phase. Apparently, for a sufficiently damaged crystal, the nucleation barrier for amorphous phase formation becomes very small, or perhaps even vanishes. The amorphous phase then forms without the need for thermal activation. The crystal-to-glass transformation can occur even at cryogenic temperatures under these circumstances. It would appear that the crystal lattice becomes unstable against amorphization for sufficiently high defect concentrations. The mechanism of instability has been a subject of considerable debate. Fecht and the author (Ref 17) have argued that such instability may be relative to an entropy catastrophe. Experimentally, it has been observed that the shear modulus of the crystal is substantially reduced as instability is approached. Figure 9 shows the results of an irradiation experiment by Okamoto *et al.* (Ref 18) in which the shear sound velocity in a Zr_3Al Cu_3Au-type alloy is observed to dramatically decrease during irradiation at cryogenic temperatures. The irradiation ultimately results in amorphization of the crystal.

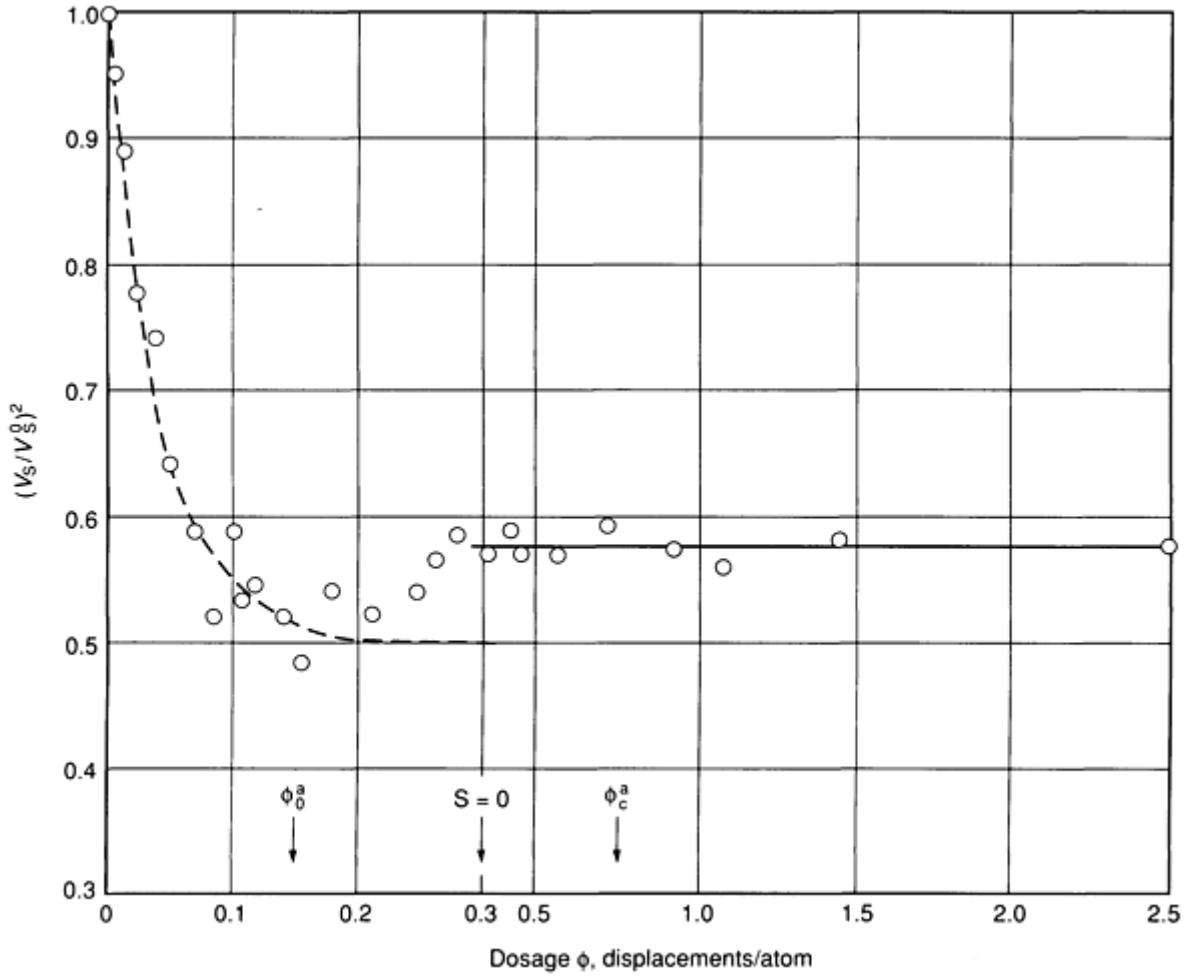

Fig. 9 Relative change in shear sound velocity in crystalline Zr_3Al as a function of irradiation dose by 1 MeV krypton ions. Dosage has been converted to conventional units of irradiation-induced displacements per atom of sample. f_0^a and f_c^a refer to the doses at which the onset and completion of the crystal-to-amorphous transformation occur as observed by electron microscopy. The ratio V_s/V_s^0 is that of the shear sound velocity in the irradiated/unirradiated sample. Source: Ref 18

Severe mechanical deformation of crystalline intermetallic compounds has also been found to result in solid-state amorphization. In this case, repeated deformation of a crystal at relatively high strain rates is carried out in a high-energy ball mill. Dislocations, dislocation walls, grain boundaries (formed by collapse of dislocation arrays), and antiphase boundaries (formed by motion of partial dislocations) are trapped in the crystal in concentrations far in excess of those ordinarily found. This has been observed to result in amorphization of the crystal (Ref 19). This amorphization by mechanical attrition has been found to be an effective means of producing large quantities of amorphous alloy powders.

There are other methods of solid-state amorphization too numerous to detail in the space available here. Amorphization during absorption of hydrogen by a crystal (Ref 20), and mechanical alloying of physical mixtures of metals (Ref 21) are examples. All of these techniques have in common the underlying description implied by Eq 8 and Fig. 6. Equation 8 expresses the kinetic constraints required, and Fig. 6 expresses the fact that a thermodynamic driving force is required if such transformations are to occur.

Structure of Metallic Glasses and Amorphous Metals

Structural Models, Diffraction Experiments, and Crystallization. Because metallic glasses were initially prepared by rapid solidification of a liquid, it is natural to assume that their atomic scale structure is related to that of the liquid phase. On the other hand, glasses are in fact solids in which the configuration of atoms is frozen in much the same manner as it is frozen in a crystalline solid. At temperatures sufficiently low to suppress atomic diffusion, each atom is confined to move in the potential well created by its neighbors. It is often presumed that the local atomic arrangements in glasses resemble those of the corresponding crystal. From these notions, two types of models have historically been put forward to describe the atomic arrangements in metallic glasses. These are loosely called continuous random network and microcrystalline models.

The continuous random network models trace their roots to the work of Bernal and Finney (Ref 22) in the early 1960s. Bernal studied mechanical models of hard spheres packed randomly in an elastic bladder and characterized the atomic arrangements that occur in such hard-sphere packings. For example, he determined the pair correlation function obtained when large samples of "dense randomly packed spheres" were analyzed. The pair correlation function, $\rho(r) - \rho_0$ (ρ_0 = average atomic density), is basically the deviation of the atomic density from its average value as one moves out radially from a typical atom in the packing. Oftentimes it is useful to plot another function, $G(r) = 4\pi r[\rho(r) - \rho_0]$. This function is

called the reduced radial distribution function (see the article "Radial Distribution Function Analysis," in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

For a dense random packing of hard spheres (DRPHS), Bernal and Finney obtained a result that is illustrated in Fig. 10. At the time of their work, x-ray diffraction studies of pure liquid metals had also been carried out, and pair correlation functions of liquid metals were known with reasonable accuracy. The Bernal-Finney DRPHS model was found to give a pair correlation function that agreed remarkably well with that obtained on real liquid metals. The DRPHS model became an accepted model for the structure of liquid metals.

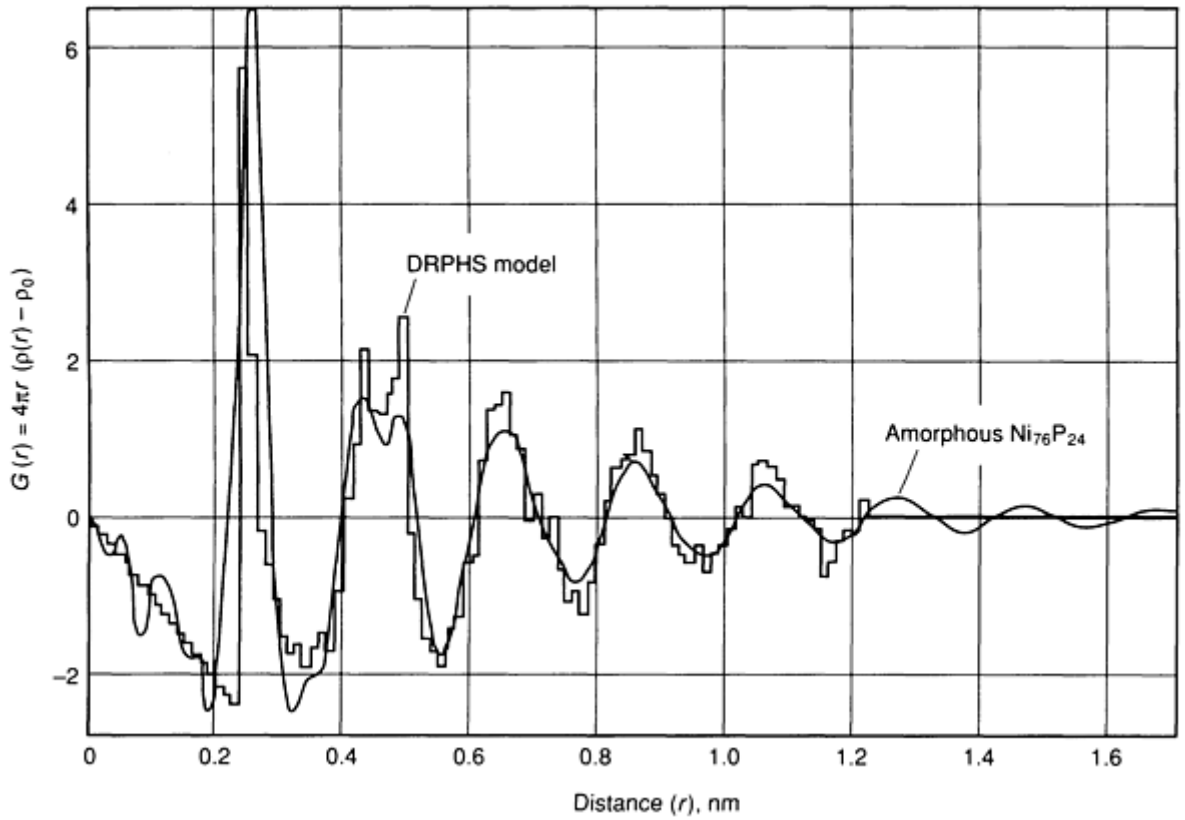

Fig. 10 The reduced radial distribution function for a dense random packing of hard spheres compared with that for the metallic glass $Ni_{76}P_{24}$. Source: Ref 22, 23

In the early 1970s, Cargill (Ref 23) measured the pair correlation functions of several binary amorphous alloys using x-ray diffraction techniques. He attempted to compare these correlation functions to those of Bernal. In addition, he computed the pair correlation function that would be obtained if an assembly of small microcrystals (~1.5 nm in dimension) were brought together. He concluded that the DRPHS pair correlation function provided a far better description of an amorphous $Ni_{76}P_{24}$ alloy than did the correlation function computed for an assembly of microcrystals. Incidentally, he considered microcrystals of phases that appear in the equilibrium phase diagram of the binary nickel-phosphorus system. On this basis, he hypothesized that the structure of metallic glasses was better described as liquidlike than microcrystalline.

Following Cargill's early work, several investigators undertook to improve upon Bernal's DRPHS model by replacing the hard spheres with soft spheres interacting through pair potentials. They used computers to construct and relax large models (containing of the order of 1000 atoms) of randomly packed atoms to obtain more realistic random atomic packing models. Generally speaking, these elaborate computer models were found to give somewhat better agreement with experimental correlation functions of amorphous metals than the simple Bernal hard-sphere model.

This work was extended to binary alloys containing A and B atoms. The pair potentials for AA, BB, and AB interactions were allowed to vary in the computer simulations, and the partial pair correlation functions for AA pairs, BB pairs, and AB pairs could be separately evaluated. It was found possible to reproduce the detailed features of experimental pair

correlation functions of binary amorphous alloys (for example, see Ref 24). Using neutron scattering and isotope substitution techniques, it became possible to experimentally separate the partial pair correlations for the AA, BB, and AB pairs in binary alloys (Ref 25). These separate partial pair correlations could be compared with those obtained in the computer simulations. It was found that not only the total pair distribution but even the partial (AA, BB, and AB) pair correlations in actual alloys could be described by computer simulation provided a suitable choice of pair potentials (AA, BB, and AB) was made. These binary dense random packing models became the standard for describing the structure of metallic glasses.

From the study of partial pair correlation functions it became apparent that binary amorphous alloys frequently exhibit short-range chemical ordering. For example, metal-metalloid glasses containing a transition metal A (for example, gold, nickel, iron, and so forth) and a metalloid element (for example, silicon, germanium, boron, phosphorus, and so forth) and having a concentration near ~20 at.% of the metalloid element were found to possess a common type of chemical ordering. Diffraction studies of partial pair correlation functions showed that the transition metal atoms possessed nearest-neighbor atoms of both the metal and metalloid type, whereas the metalloid atoms had only transition metal atoms as nearest-neighbors. Simply put, nearest neighboring metalloid atoms are excluded in the glassy structure. Such short-range order was inconsistent with the notion that metallic glasses are chemically random.

This discovery led some investigators to explore models for amorphous structure based on assemblies of ordered atomic clusters. For example, it was argued that in $Ni_{80}B_{20}$, $Pd_{80}Si_{20}$, and other similar metal-metalloid glasses, the glass structure could be viewed as being built of trigonal prismatic clusters of nickel atoms surrounding a boron atom, each cluster containing 6 to 9 atoms (Ref 26). It was further argued that these molecular clusters were similar to those observed in crystalline phases of the same composition (for example, Ni_3B). These models might be classified as intermediate between dense random packings and microcrystalline structures. It should be noted, however, that the molecular units that comprise the model contain fewer than, or roughly the same, number of atoms as would be present in one unit cell of the corresponding crystalline phase. As such, the units can hardly be called microcrystals. On the other hand, the ability of these models to reproduce experimental pair correlation functions with high accuracy certainly suggests that the structure of metallic glasses is far from random.

In recent years, the development of ultrahigh-resolution imaging techniques in electron microscopes has further revealed the extent of short-range ordering in metallic glasses. Current electron microscopes are capable of direct imaging with spatial resolution of 0.2 nm or less. This permits direct imaging of lattice planes in crystals. When examined with such instruments, metallic glasses often exhibit remarkable structure on the nanometer scale.

For example, the well-studied metal-metalloid glasses often locally exhibit microcrystal-like structures. An example is shown in Fig. 11 for a $Pd_{75}Si_{25}$ glass. Local features that resemble lattice planes are seen to extend over distances of the order of 2 nm. It is tempting to interpret such features as microcrystallines. Nevertheless, these zones extend over distances of only a few times the lattice constants of the corresponding crystal structures. As such, the zones apparently do not represent a thermo-dynamically stable crystalline nucleus. The regions do not grow spontaneously upon heating. This distinction is important. If the zones are smaller than the dimension of a critical crystalline nucleus, then they will not spontaneously coarsen on heating. In a true microcrystalline alloy, spontaneous coarsening of the grain size would occur upon heating.

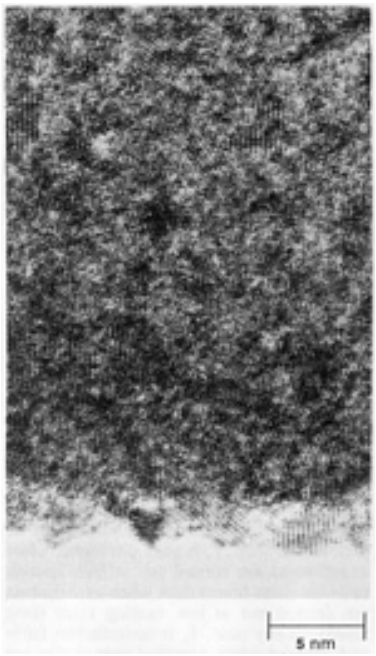

Fig. 11 High-resolution transmission electron micrograph of a thin-film sample of amorphous $Pd_{75}Si_{25}$. Notice the textured appearance on the scale of ~2 nm, as well as the apparent lattice fringes on the same scale.

Spaepen (Ref 27) has used this idea to develop kinetic criteria for distinguishing a glass from a microcrystalline alloy. The nucleation and growth of a crystallite in a liquid or glass is described by nucleation theory. On the other hand, grain coarsening is described by a different kinetic model (Ref 28). By observing the crystallization of a metallic glass during heating at a constant rate or by isothermal annealing, it should be possible to distinguish nucleation and growth of crystals from coarsening of microcrystals. In most actual experiments of this type, the results favor the nucleation and growth kinetics. The microcrystalline-like zones seen in Fig. 11 do not therefore appear to constitute thermodynamically stable crystalline nuclei.

The formation of a stable crystalline nucleus is a thermally activated process that involves surmounting a nucleation barrier. As a consequence, the glass is said to be metastable and distinct from the crystalline state. This type of thermodynamic criterion would seem to provide a clear means of distinguishing glassy structures from micro-crystalline structures. The argument, however, presupposes that a nucleation barrier for crystallization is an essential property of amorphous materials.

From Eq 2, it can be seen that the existence of a nucleation barrier is a consequence of the finite interfacial energy (σ) of the glass/crystal interface. Because melting (and crystallization) are normally assumed to be first-order phase transitions, this would seem to follow. On the other hand, if melting were to be a second-order or continuous phase transition, then a finite interfacial energy might not be required (Ref 17). Under such circumstances, the glass might crystallize without a nucleation barrier and the Spaepen criteria might fail to distinguish a glass from a microcrystalline alloy.

Finally, it should be mentioned that extended atomic ordering in metallic glasses need not necessarily be related to crystallographic ordering. Recent computer studies of undercooled liquids have suggested that icosahedral short-range order may develop in an undercooled liquid metal (Ref 29, 30). Such work suggests that long-range orientational ordering with icosahedral symmetry may even develop without translational symmetry. Such ordering is similar to that observed in the recently discovered quasi-crystals (Ref 31). It is not consistent with ordinary translational symmetry and therefore is unlike the order found in any real crystal. As such, the atomic ordering seen in metallic glasses at the nanometer scale need not be of the same type as that observed in the corresponding equilibrium crystalline phases.

Dependence of Structure on Synthesis Method and Thermal History. In the section "Synthesis and Processing Methods," a variety of methods for preparing amorphous metals were discussed. As mentioned, it is by no means obvious that the structure of a glass prepared by undercooling a liquid is the same as that of a sputter-deposited film or electrodeposited layer of similar composition. This raises a natural question: Does the amorphous phase have a

unique structure in the sense that crystals have a unique structure? In answer to this question, it should be noted that if an attempt is made to measure the entropy of a glass by measuring the heat capacity curve of a liquid in the undercooled regime and then measuring the heat capacity of the glass below T_g, an apparent residual entropy for the glass at $T = 0$ K will be found. This would suggest that a glass can have many equivalent configurations. It would follow that there is no unique glass structure. It might then be asked whether various glass structures are similar. Does the structure depend on the method of synthesis or the thermal history of the glass?

It is found experimentally that the pair correlation functions of alloys prepared by different methods exhibit the same qualitative features. For example, Fig. 12 shows the pair distribution function of several vapor-quenched amorphous pure metal films. The films were quenched onto cryogenically cooled substrates (Ref 32). A comparison with Fig. 10 reveals that these vapor-quenched pure amorphous metal films exhibit all of the essential features of the DRPHS model, the same model that works so well in describing the structure of both liquid metals and amorphous metal-metalloid alloys (Ref 24).

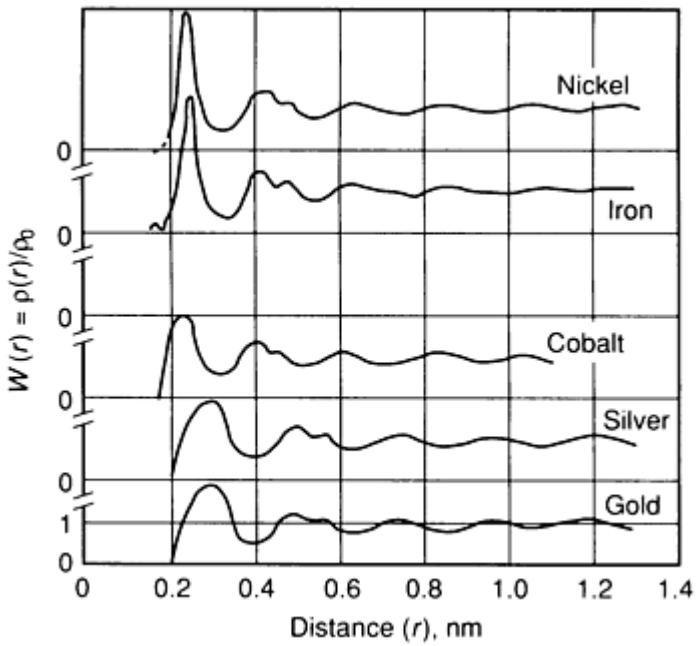

Fig. 12 The pair distribution function (W), of several pure amorphous metals prepared by vapor deposition onto a cryogenically cooled substrate. Notice the similarity with the pair correlation function of Bernal shown in Fig. 10. Source: Ref 32, 33

Comparative studies of sputtered, vapor-quenched, electrodeposited, and liquid-quenched alloys (Ref 33) have generally shown that alloys of the same composition prepared by different methods have similar pair correlation functions. It would seem that the short-range atomic ordering of amorphous alloys is at least qualitatively well defined and rather independent of the method of preparation of the sample. On the other hand, there do seem to be systematic differences. For example, the maxima and minima in the pair correlation functions appear to be somewhat less pronounced in alloys prepared by vapor quenching than those of alloys prepared by liquid quenching. This suggests that sputtered or vapor-quenched alloys are somewhat more disordered. The density of vapor-quenched alloys is often found to be somewhat less (~1 to 3%) than that of the corresponding liquid-quenched alloys. All of these facts suggest subtle differences in various amorphous structures.

In addition to structural differences related to synthesis, it is also found that the pair correlation function of a single amorphous alloy sample changes on thermal annealing at temperatures below T_g. This structural relaxation phenomenon in amorphous alloys is of importance and has been studied in detail for liquid-quenched metallic glasses by numerous investigators (Ref 34). Structural changes on annealing have been found to be both irreversible and reversible. A sample quenched from the liquid state by rapid solidification exhibits subtle but irreversible changes in structure on reheating to temperatures below T_g. These structural changes have been found to be accompanied by a slight densification of the order of a few tenths of 1%. When the annealing is repeatedly and alternately carried out at two different temperatures below T_g, smaller but reversible structural change can also be observed. The effect of these reversible and irreversible structural changes on the physical properties of metallic glasses is discussed in more detail in the following sections.

Finally, it should be pointed out that when thin films and sputtered samples are annealed below T_g, the structural changes that occur tend to be in the direction of achieving a structure more similar to the liquid-quenched structure. The same films tend to densify on annealing, achieving an ultimate density closer to that of liquid-quenched samples. We could summarize these observations by saying that amorphous samples prepared by different methods have a tendency to relax toward a common structure upon annealing at temperatures near T_g.

Thermodynamic Properties

The Glass Transition and Crystallization. As mentioned previously, the glass transition is a phenomenon that occurs when a liquid is undercooled and undergoes configurational freezing to a solid. This is accompanied by a dramatic increase in viscosity and a dramatic drop in atomic mobility (Fig. 1a). The heat capacity of the liquid is observed experimentally to exhibit a maximum (Fig. 1b). Below this maximum, the glassy solid exhibits a falling heat capacity much like that of an ordinary crystalline solid.

In general, the ease with which crystallization occurs in metallic melts makes direct observation of the glass transition rather difficult. Chen and Turnbull were the first to directly observe the glass transition in liquid gold-silicon glass-forming alloys (Ref 35). They pointed out the importance of this observation in establishing that the liquid-quenched alloys of Duwez were indeed like conventional glasses.

The ability to observe the glass transition upon heating of metallic glasses generally depends upon the heating rate employed. The necessity of avoiding nucleation and growth of crystals upon heating generally requires that a rather high heating rate be used. The experimentally observed glass-transition temperature T_g (as indicated, for example, by the heat capacity maximum) is itself found to depend slightly on the heating rate. Table 1 lists the glass-transition temperatures of several common metallic glasses. The values are typically obtained by locating the maximum in the heat capacity during heating in a differential scanning calorimeter. At higher heating rates, T_g is observed to be slightly displaced (by a few degrees) to higher temperatures. Because the glass transition is a kinetic phenomenon, this is not surprising.

Table 1 Glass transition temperature (T_g) and crystallization temperature (T_x) of metal-metal and metal-metalloid metallic glasses

Alloys	T_g, K	T_x, K

$Au_{81}Si_{19}$	292	320
$Au_{55}Pb_{22.5}Sb_{22.5}$[(a)]	312.9	337.3
$Ni_{80}P_{20}$	622	640
$Pd_{80}P_{20}$	610	630
$Pd_{77.5}Cu_{6.0}Si_{16.5}$[(b)]	645	. . .
$Pd_{77.5}Cu_{6.0}Si_{16.5}$[(c)]	666	. . .
$Pd_{77.5}Cu_{6.0}Si_{16.5}$[(d)]	690	. . .
$Fe_{80}P_{13}C_{7}$	705	730
$Fe_{80}B_{20}$(Metglas 2605)	>713	713
$Zr_{50}Cu_{50}$	707	755.5
$Zr_{35}Cu_{65}$	781	815
$Zr_{72}Ni_{28}$	642	671
$Zr_{60}Ni_{40}$	713	751
$Zr_{36}Ni_{64}$	834	864
$Ta_{80}Si_{10}B_{10}$	. . .	1225
$(Ta_{0.3}W_{0.7})Si_{10}B_{10}$	. . .	1450
$W_{40}Re_{40}B_{20}$	. . .	1300

Note: Unless otherwise indicated, heating rate was 10 to 30 K/s.

(a) Heating rate was 20 K/s.

(b) Heating rate was 10 K/s.

(c) Heating rate was 10^3 K/s.

(d) Heating rate was 10^5 K/s. Data compiled from a large number of sources

The values listed in Table 1 correspond to typical heating rates (10 to 30 $K \cdot s^{-1}$) employed in differential scanning calorimetry. It has been argued that an ideal glass transition would be observed in the limit where the heating rate vanishes. This has led to speculation regarding the possible existence of an underlying thermodynamic phase transition. Theories of the ideal glass transition have been developed. The earliest of these is the Gibbs Dimarzio theory (Ref 36), which was based on the concept of the disappearance of free volume with lowering temperature in the undercooled liquid. Cohen and Turnbull have further developed this theory (Ref 37).

More recently, Cohen and Grest (Ref 38) have developed a theory that combines the free-volume concept with percolation theory. In this rather sophisticated theory, the glass transition corresponds to the percolation of liquidlike atomic cells throughout the solid structure. The liquidlike cells consist of atoms with a shell of nearest neighbors that defines a local volume exceeding some critical volume. When these cells percolate throughout the structure, the solid develops fluidity. Because theories of the glass transition refer to a transition observed in the limit of very slow cooling rates, they cannot in general be compared with experimental data.

Generally speaking, the viscosity, atomic diffusion constant (see below), and other phenomena that involve atomic rearrangements all exhibit the same temperature dependence in the vicinity of the glass transition. This is not surprising because the same types of atomic jumps are required for all of these processes. In particular, the nucleation and growth of crystals in the glass are controlled by the same types of atomic jumps. Near T_g, the rates of these atomic jumps increase precipitously (see Fig. 1a). In metallic glasses, crystallization rates tend to become significant at temperatures in the vicinity of T_g. Often, a crystallization temperature (T_x) is defined for metallic glasses. In reality, the crystallization temperature depends on the time scale of an experiment and cannot be precisely defined. T_x is generally higher when experiments are carried out at high heating rates (or short times) than when experiments are carried out at low heating rates (long times). In any case, T_x is nevertheless fairly well defined when practical time scales are considered. The rate of nucleation of crystals in a metallic glass is described by the same classical nucleation theory used to describe nucleation of crystals in the undercooled melt (see Fig. 2). It clearly is a very rapidly increasing function of temperature in the vicinity of T_g. Table 1 contains a list of observed crystallization temperatures for several common metallic glasses of both the metal-metal and metal-metalloid type. Notice that only in cases where $T_x > T_g$ is possible to measure both. For the metallic glasses in Table 1, T_x is generally rather close to T_g. This reflects the fact that when atomic mobility becomes appreciable (near T_g), crystallization occurs with relative ease.

Heat Capacity and Two-Level Systems. The specific heat at constant pressure (c_p) of metallic glasses has many features in common with that of crystalline metals. Both electronic and lattice contributions are observed. The heat capacity vanishes at very low temperatures, increases over an intermediate temperature range, and saturates at a value near the Dulong-Petit value (3R/mol where R is the gas constant) at higher temperatures (below but near T_g). Near T_g, an anomalous increase is observed as previously discussed. As in crystalline metals, the electronic contribution to the heat capacity is linear with temperature:

$$c_p^e = \gamma T \qquad \textbf{(Eq 9)}$$

and can be used to determine the electronic density of states at the Fermi level (Ref 9). At low temperatures, it can be clearly separated from a lattice heat capacity of the form:

$$c_p^1 = \beta T^3 \qquad \textbf{(Eq 10)}$$

which can be associated with the usual Debye contribution. Measurement of the coefficient βcan, as in crystalline materials, be used to determine a Debye temperature for the amorphous phase (Ref 40). In general, the Debye temperature (θ_D) is found to be somewhat lower in amorphous materials than in the corresponding crystalline state. This is thought to

reflect a decrease in the shear sound velocity in glasses compared with crystals. Direct sound velocity measurements in metallic glasses (Ref 41) show a reduction of about 15% in the shear sound velocity of the glass compared with that of the crystal at the same composition.

Prior to 1972, this was thought to be a rather complete picture of the thermal excitations in metallic glasses. At this time, Anderson *et al.* (Ref 42) and Phillips (Ref 43) independently proposed a model to explain an anomalous low-temperature contribution to the heat capacity of nonmetallic glasses. In insulating glasses, this small anomalous contribution takes a linear form:

$$c_p^a = \gamma^a T \qquad \textbf{(Eq 11)}$$

where the superscript "a" stands for anomalous. Because insulating glasses have no conduction electrons, this contribution to the heat capacity cannot be electronic in origin. Anderson and Phillips proposed that it arises from atomic configurations called two-level systems. They proposed that these two-level systems would contribute an excess linear contribution to the lattice heat capacity at low temperatures.

In fact, experiments show that γ^a is rather small. It is typically between one and two orders of magnitude smaller than the γ that arises from electronic excitations in metals. In the case of amorphous metals, this anomalous contribution is obscured by the electronic heat capacity. As such, it was originally thought that this contribution could not be measured in amorphous metals.

This problem was overcome by Graebner (Ref 44), who recognized that in a superconducting metallic glass far below T_c (the superconducting transition temperature) the ordinary electronic heat capacity is exponentially reduced. As such, he was able to demonstrate an anomalous and linear nonelectronic contribution arising from two-level systems. It is now widely recognized that the anomalous linear heat capacity at low temperatures arising from two-level systems is a general feature of glasses that distinguishes them from crystalline solids. Two-level systems also influence the low-temperature behavior of the thermal conductivity and the attenuation of sound at low temperatures. These effects are characteristic of amorphous metals (Ref 45).

Thermal Transport. The thermal conductivity of metallic glasses at room temperature is generally of the same order of magnitude as crystalline alloys. It is typically dominated by electronic transport. The high degree of atomic disorder results in substantial electron scattering and a short electron mean free path. As such, the magnitude of the thermal conductivity at ambient temperatures tends to be similar to that observed in very disordered crystalline alloys. On the other hand, at cryogenic temperatures the thermal transport properties of metallic glasses tend to exhibit unusual features that are associated with the aforementioned two-level systems (Ref 45). The two-level excitations scatter long wave-length phonons, leading to a characteristic T^2 dependence of the thermal conductivity at very low temperatures (<1 K).

As in the case of the heat capacity, this lattice contribution to the thermal conductivity can be isolated from the electronic contribution by using a superconducting amorphous metal at temperatures well below the superconducting transition temperature (Ref 45).

Atomic Diffusion. Below the glass transition temperature, atomic diffusion constants of metallic glasses are presumably small because the atomic diffusion that is characteristic of a liquid metal is rapidly frozen out as the glass transition sets in. Several investigators have studied atomic diffusion in metallic glasses at temperatures below T_g (Ref 46, 47). In general, it has been found that the diffusion constant D follows as Arrhenius law:

$$D = D_0 e^{-Q/T} \qquad \textbf{(Eq 12)}$$

over the limited ranges of temperatures investigated. Values of activation energy Q are found to be similar to those found for self-diffusion in crystalline metals. The values of D tend to range from 10^{-14} to 10^{-20} $cm^2 \cdot s^{-1}$ over temperatures ranging from T_g down to temperatures at which D is not measurable by available experimental techniques (typically ~100 °C, or 180 °F, below T_g).

Deviations from Arrhenius behavior have been observed in a few experiments carried out over larger temperature ranges. This is thought to indicate that the atomic jumps observed in diffusion in glasses involve a distribution of activation energies (a distribution of Q) rather than a single, well-defined activation energy, as would be characteristic of vacancy

jumping in crystals. Further, the activation energy to create a vacancylike defect in a glass would vary from one atomic site to another. As such, the apparent activation energy would be expected to decrease with decreasing temperature, leading to deviations from a simple Arrhenius law. Attempts to develop a theory of atomic self-diffusion in metallic glasses have been based on the concepts of vacancylike defects (Ref 46). In the case of impurity diffusion by small atoms like hydrogen, the diffusion is believed to proceed by an interstitial mechanism in much the same manner as the interstitial diffusion of hydrogen carbon, nitrogen, and so on, in crystalline metals (Ref 48).

Mechanical Properties

Several good reviews of the mechanical properties of metallic glasses can be found in the literature (see, for example, Ref 49, 50, 51, 52). Here, only a brief description of some of the important features will be given.

Deformation Mechanisms: Homogeneous and Inhomogeneous Flow. Metallic glasses undergo deformation under an applied stress τ via two different mechanisms, homogeneous and inhomogeneous deformation. Homogeneous deformation occurs at low stresses (typically $\tau < \mu/100$, where μ is the yield stress of the material) and at relatively low temperatures compared to T_g. At sufficiently low stresses, the flow is essentially Newtonian viscous flow. At higher temperatures (near T_g) or higher stress levels ($\tau > \mu/50$), deformation occurs inhomogeneously through the formation of localized shear bands.

The overall behavior has been described by Spaepen and Taub (Ref 50) using an Ashby deformation map (Fig. 13). As can be seen in Fig. 13, the mode of deformation also depends on the rate of deformation. Higher strain rates are associated with inhomogeneous deformation. At sufficiently high strain rates, deformation becomes inhomogeneous at all temperatures below T_g.

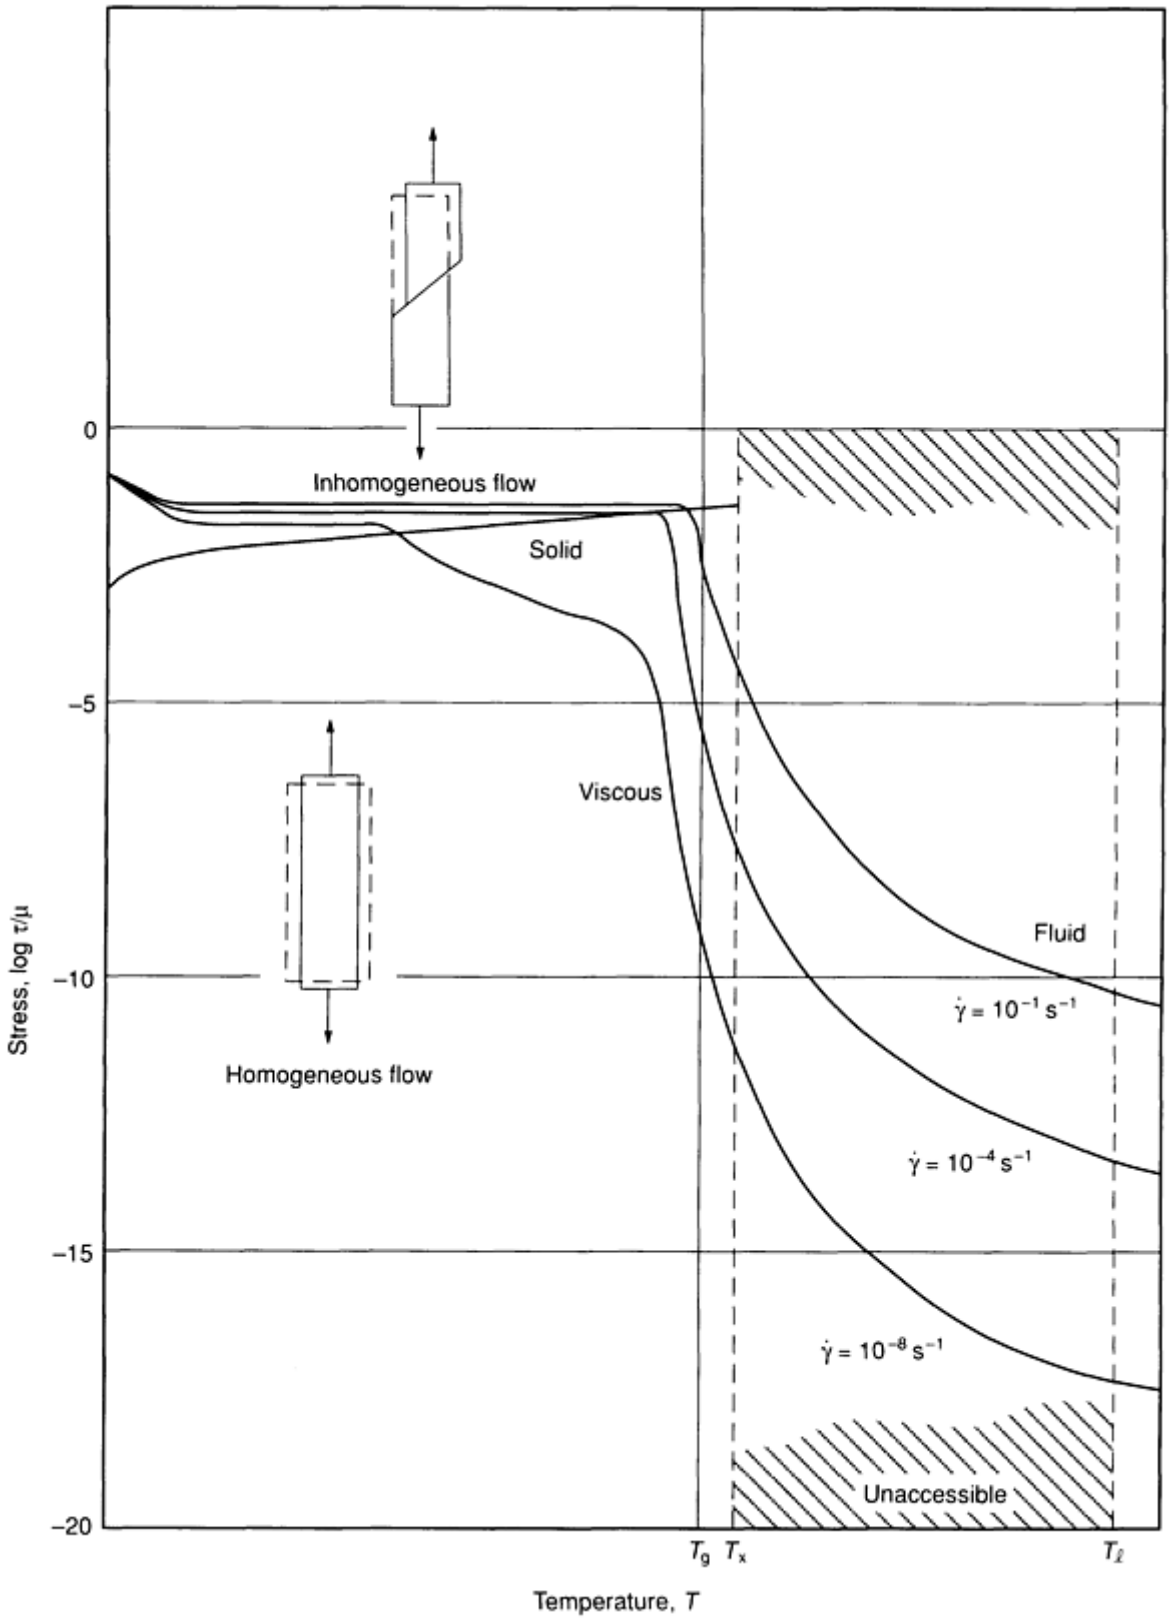

Fig. 13 Ashby flow map for a metallic glass showing the temperatures and stress levels (applied stress τ versus yield stress μ) that result in homogeneous/inhomogeneous flow. The strain rate is denoted by γ; the liquidus temperature is T_l.

Inhomogeneous deformation occurs in localized shear bands. The individual shear bands are typically 20 to 40 nm in dimension. Total plastic strains of the order of 10 or more may occur within an individual shear band. The overall plastic

strain of the specimen depends on the density of shear bands. The deformation mechanism within an individual shear band is believed to be fluidlike. The transition to fluid behavior within the band is believed to be triggered by the stress-driven creation of free volume, adiabatic heating, or some combination of the two.

Yield Strength, Hardness, and Elastic Constants. The elastic constants of metallic glasses are quite similar to those observed in the corresponding crystalline materials. The bulk modulus is typically reduced by a few percent, whereas the shear modulus is typically 15% smaller than in the corresponding crystalline material. Young's modulus is typically somewhat smaller than that of the corresponding crystalline material.

By contrast, values of yield strength (σ_y) and hardness (H) are typically much greater than those of ductile crystalline solids. In fact, the yield strengths of metallic glasses compared with their elastic constants place them among the strongest of known solids.

A typical measure of the relative strength of a solid is the ratio of yield strength to Young's modulus (σ_y/E). This ratio is typically 0.02 for metallic glasses, which yield plastically in a tensile test. By comparison, iron whiskers have a value of 0.05, and aluminum nitride (AlN) fibers exhibit a value of 0.02. These values approach the theoretical maximum-attainable yield strength. The hardness of metallic glasses corresponds to the yield strength:

Glass composition	Vickers hardness, kg/mm^2	Yield strength, MPa (ksi)	Young's modulus, GPa ($psi \times 10^6$)
$Pd_{77.5}Cu_6Si_{16.5}$	500	1570 (227)	88.2 (12.8)
$Fe_{80}B_{20}$	1100	3626 (526)	166.6 (24.2)
$W_{40}Re_{40}B_{20}$	2400	>7840 (>1136)	. . .

Generally, it is found that $H/\sigma_y \sim 3$ for metallic glasses. This suggests that refractory glasses such as $W_{40}Re_{40}B_{20}$ should have yield strengths of the order of >7840 MPa (1136 ksi). Unfortunately, because metallic glasses are very susceptible to brittle fracture, their practical applications are limited.

Failure, Fracture Toughness, and Embrittlement. Metallic glass ribbons that are free of imperfections fail in tension in an essentially plastic manner. Failure tends to coincide with yielding, and it typically occurs along a plane oriented at 45° to the axis along which the stress is applied. This is characteristic of a ductile failure mechanism. The coincidence of failure with yielding shows that metallic glasses do not work harden. When the fracture surface of a failed ribbon is examined, a characteristic veinlike pattern is typically observed (Ref 50). This pattern is thought to be characteristic of a fluidlike instability. A similar pattern is produced when a layer of viscous fluid is sandwiched between two solid surfaces that are subsequently pulled apart. Taub and Spaepen (Ref 50), for example, have discussed the nature of this fluidlike instability and compared it with those originally described by Saffman and Taylor (Ref 53). This failure mechanism is an essentially plastic mechanism. The failure occurs by plastic deformation.

Imperfections in real metallic glasses often cause failure to occur by brittle fracture (Ref 50, 52). Brittle fracture occurs when the tensile stress at a stress concentrator, such as a microcrack, reaches the theoretical fracture stress of the material (σ_{th}) before shear-induced plastic flow can blunt the crack and relieve the stress. In metallic glasses containing defects such as crystallites (which act as stress concentrators), brittle fracture is frequently observed to occur. At very low temperatures, where the viscosity is very high, brittle failure is also a more prominent mechanism of failure.

Many metallic glasses also exhibit an annealing embrittlement effect when subjected to annealing temperatures below T_g and below that which would be required to initiate crystallization. This has been attributed to various mechanisms by

different authors. Densification and loss of free volume upon such annealing causes an accompanying rise in viscosity. This encourages embrittlement. Other authors have attributed the annealing embrittlement to microsegregation or clustering of metalloid elements (in metal-metalloid glasses). Metallic glasses containing high concentrations of metalloid elements are especially prone to annealing embrittlement (Ref 54). Finally, it is interesting that the embrittlement effect in metal-metalloid glasses can be reversed by neutron irradiation (Ref 55). In the same experiment, neutron irradiation was observed to result in lowered density of the glass. This suggests that the loss of free volume is related to the embrittlement.

Metallic glasses generally exhibit rather low fracture toughness. This is presumably related to their high strength (Ref 52). It is also clear that samples containing imperfections such as crystallites exhibit lower values of fracture toughness than samples free of such imperfections. For defect-free samples, the fracture toughness of iron-base metallic glasses has been found to be consistent with that observed in steels when the higher yield strength of metallic glasses is taken into account. Figure 14 compares the plane-strain fracture toughness values of an 18% Ni maraging steel and an AISI 4340 alloy steel as a function of yield strength with fracture toughness values for two commercial iron-base metallic glasses produced in ribbon form.

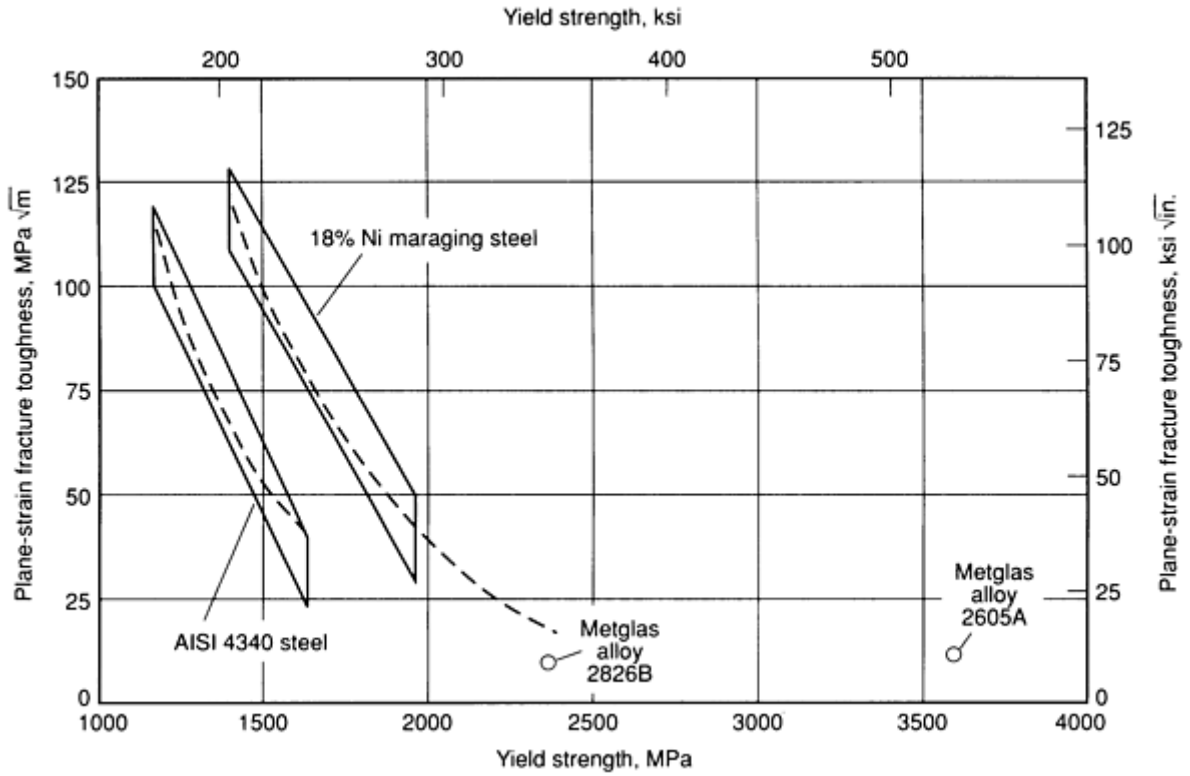

Fig. 14 The plane-strain fracture toughness of two ferrous metallic glasses compared with that of two steels. The lower fracture toughness of the metallic glasses is consistent with their higher yield strength. Source: Ref 52

Electronic and Magnetic Properties

Electrical Transport Properties. Metallic glasses exhibit electrical transport properties that are characteristic of metals (Ref 56, 57). The electrical resistivity (ρ) at ambient temperature ranges from about 50 μΩ· cm to about 250 μΩ· cm. In contrast to crystalline metals and alloys, where ρ decreases rapidly with decreasing temperature, ρ varies little with temperature for metallic glasses. Furthermore, ρ increases with temperature in some metallic glasses and decreases with temperature in others. This behavior is generally quite similar to that found in the corresponding liquid alloy. Extrapolation of metallic glass resistivities to higher temperatures is in fact found to join rather smoothly to the resistivity curve of the liquid alloy. The resistivity values for a number of metallic glasses are shown in Fig. 15. The temperature dependence of the resistivity can be generally characterized by a temperature coefficient of resistivity (α), defined as $\alpha = \rho^{-1} (d\rho/dT)$, where ρ and $d\rho/dT$ are conventionally measured at ambient temperature. This coefficient takes on values ranging from -2×10^{-4} to 2×10^{-4}.

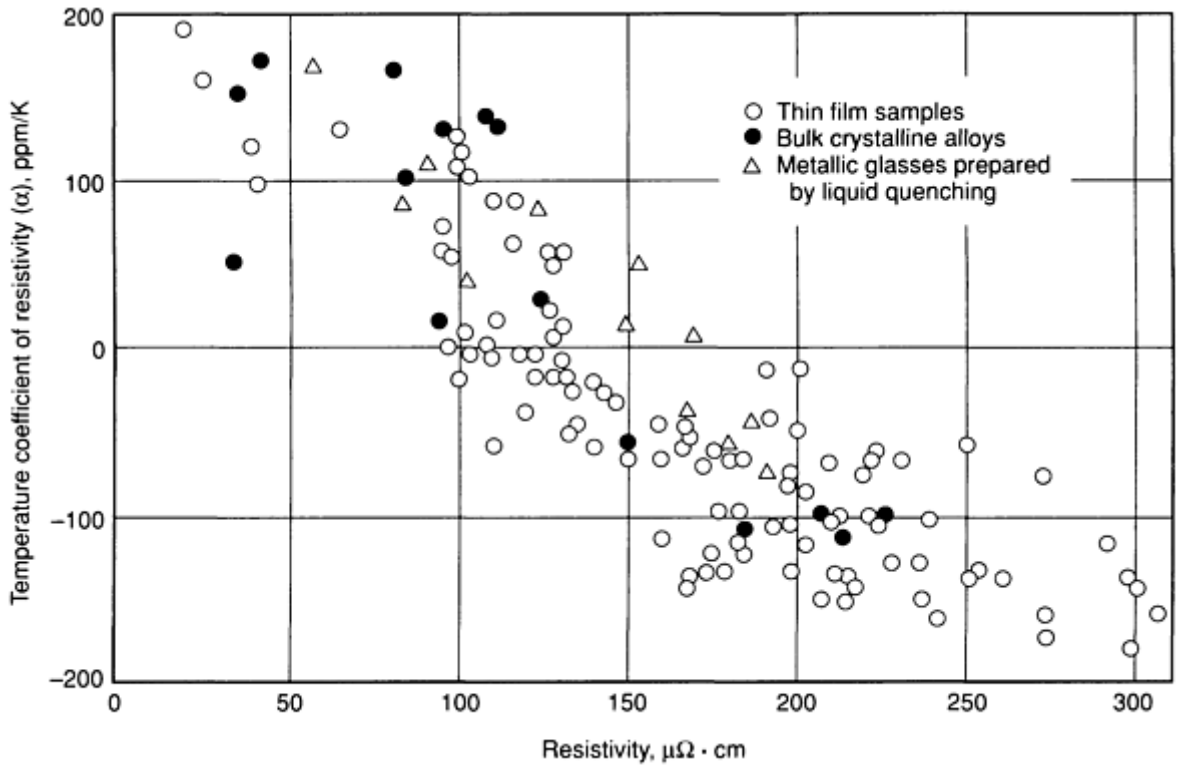

Fig. 15 The Mooij correlation relating the temperature coefficient of resistivity (α) to the absolute value of resistivity at ambient temperature for a large number of metallic samples. Metallic glasses with absolute resistivity less than ~150 μΩ· cm have positive values of α, whereas those with resistivity greater than this tend to have negative values of α.

An interesting correlation has been observed between α and the absolute value of ρ it is referred to as the Mooij correlation (Ref 58). This correlation is also illustrated in Fig. 15. The Mooij correlation is in fact found to apply generally to all metallic solids and is related to the behavior of electrical resistivity in the limit where the electron mean free path approaches atomic distances. In metallic glasses, where atomic disorder leads to strong electron scattering, resistivities are typically high and the change in the sign of α is common.

Theories of electrical conductivity in metallic glasses are basically an extension of earlier theories developed to describe electron scattering in liquid metals. The reader is referred to the above-mentioned review articles for more details.

Other electronic transport properties of metallic glasses that have been studied in detail are the Hall coefficient, thermopower, and magnetoresistivity. The Hall coefficient is found to have both positive and negative signs in metallic glasses. As in the case of crystalline metals, this has been interpreted to indicate electronlike and holelike conduction mechanisms.

The thermopower of metallic glasses is essentially linear with temperature, although low-temperature anomalies have been observed that are related to electron-photon scattering and to electron localization effects. Magnetoresistivity is generally positive (resistivity increases with the application of a magnetic field).

Magnetic Properties. Many metallic glasses contain atoms that carry a magnetic moment. Metal-metalloid glasses containing iron, nickel, and cobalt are examples. In the early 1960s, shortly after the discovery of metallic glasses by Duwez, the question naturally arose as to whether such materials could undergo a transition to the ferromagnetic state as temperature was lowered. At the time, it was not clear whether the development of ferromagnetic order of atomic spins in solids required an underlying crystalline lattice. The disordered atomic structure of metallic glasses implies that the exchange interactions between neighboring spins should vary according to the local atomic environment. It is not clear whether such disorder would suppress ferromagnetism. The answer to this question came in the course of studies of the glass $Fe_{78}P_{12}C_{10}$ by the Duwez group (Ref 59). Magnetic measurements on this glass clearly revealed that it undergoes a ferromagnetic transition at temperatures near 400 °C (750 °F) and develops a spontaneous magnetization. Since this initial discovery, ferromagnetism has been found in a large variety of metallic glasses (Ref 60, 61, 62).

The first systematic studies of the ferromagnetic properties of metallic glasses containing ferrous-group metals were carried out by Mizogouchi *et al.* (Ref 63). Figure 16 is taken from their work and shows the variation of the Curie temperature of several series of ferrous-group metallic glasses of overall composition $TM_{80}P_{10}B_{10}$, where TM stands for a ferrous transition metal (chromium, manganese, iron, cobalt, or nickel) or a combination of two such metals. The horizontal axis in the figure represents the average number of valence electrons for the transition metal component (for example, 8 for Fe, 9 for Co, and so on). It can be seen, for example, that iron-cobalt-base glasses have the highest Curie temperatures and that the Curie temperature of the glasses is generally somewhat lower than that of crystalline transition metals or solid solutions of transition metals that contain no metalloids. This depression in Curie temperature can at least in part be explained by the dilution effect of the metalloid elements. The atomic disorder in metallic glasses may also play a role. In general, there exists no first-principles theory of the Curie temperature.

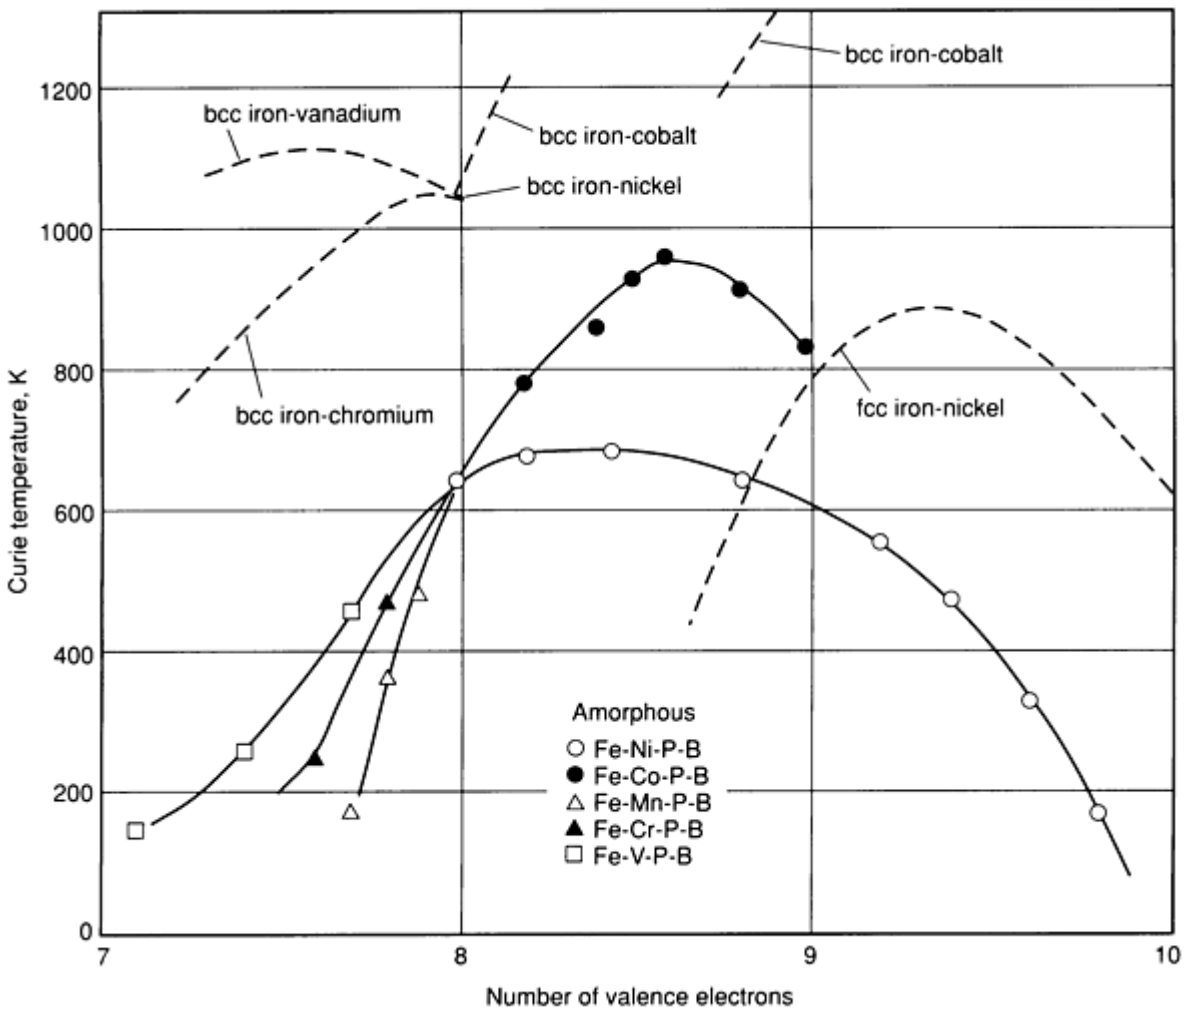

Fig. 16 Ferromagnetic Curie temperatures of several ferrous-group metallic glasses as a function of the total valence of the metallic component. All the alloys have fixed metalloid concentrations of 10 at.% P and 10 at.% B. Also shown are trends in the Curie temperature for related crystalline solid solutions of two transition metals. A similar trend in Curie temperatures is observed in corresponding crystalline solutions of the ferrous-group metals. Source: Ref 63

The saturation magnetic moment of ferromagnetic metallic glasses varies in a systematic way with the valency of the transition metal component, reaching a maximum of about 2 Bohr magnetons per transition metal atom in iron-cobalt-base metal-metalloid glasses. Again, these saturation magnetizations are somewhat lower than those of corresponding crystalline alloys even when the dilution effect of metalloid elements is taken into account. This reduction in saturation magnetization again seems to be associated at least in part with the disorder in the local atomic environments in metallic glasses. Variations of the saturation moment with metalloid element concentration and type have also been studied. It is believed that electron charge transfer effects between transition metal and metalloid atoms can account for many of these systematic variations.

The ferrous-group metal-metalloid elements have been found to exhibit a very low intrinsic magnetic anisotropy. The intrinsic anisotropy is related to the local atomic structure, and unlike crystal field anisotropies, it is random in direction. This random atomic scale anisotropy varies on a scale of about 1 nm, and in the ferrous-group metal-metalloid glasses its magnitude is exceedingly small. On scales larger than this, these glassy magnets are intrinsically very homogeneous. This leads to a very low intrinsic coercive force (H_c). In the absence of surface defects (which couple to magnetic domain walls via the demagnetizing field), internal stresses (which lead to magnetoelastic coupling of the magnetization to the stress field), second-phase precipitates (crystallites), or induced anisotropies, the coercive force of these amorphous magnets is among the smallest found in any magnetic material. For ferrous-group metallic glasses, typical values of H_c in high-quality stress-free ribbons are often found to lie in the range of a few millioersteds (mOe). This property has made metallic glasses very attractive for applications requiring a soft magnetic material.

When a soft magnetic material is subjected to an ac magnetic field, the energy dissipated by the induced changes in the magnetization is related not only to the coercive force but also to eddy current loss arising from the changing magnetization within the sample. Eddy current loss is proportional to the conductivity of the material. Because amorphous metals have relatively low electrical conductivity, these ac losses are expected to be smaller than those in corresponding crystalline materials. The combination of low coercive force and low conductivity is ideal for applications in ac transformers (see the section "Technology and Applications" in this article).

Amorphous alloys typically exhibit magnetostriction effects comparable in magnitude to those observed in similar crystalline materials. These magnetoelastic effects are related to the coupling of stress fields in the material to the magnetization. Internal stress fields raise the coercive force of the material. In melt-quenched ribbons, quenched-in internal stresses couple to the magnetization. These stresses can typically be eliminated by an appropriate annealing treatment (Ref 61), resulting in restoration of the intrinsic coercive force. Annealing in a magnetic field or cold working of the material are both found to produce induced magnetic anisotropies. Using these techniques, special features (such as a large remanance magnetization) can be produced.

Amorphous Superconductors. Superconductivity in amorphous metals was first reported by Buckel and Hilsh in their work on thin films of simple metals (for example, tin, lead, and bismuth) quenched onto cryogenically cooled substrates (Ref 9). They found, for example, that the semimetal bismuth became a superconducting metal when quenched onto a liquid-helium-cooled substrate to form an amorphous phase. The critical superconducting transition temperature (T_c) of amorphous metallic bismuth was reported to be 6 K. These amorphous bismuth films were observed to crystallize on heating to ~20 K. This absence of thermal stability against crystallization made further study very difficult. Later studies by Collver and Hammond (Ref 11) extended these results to cryoquenched films of transition metals. They found, for example, that amorphous molybdenum films became superconducting at nearly 7 K, whereas the superconducting transition temperature of crystalline molybdenum was less than 1 K. By contrast, amorphus niobium had transition temperatures of only about 6 K, whereas crystalline niobium had a transition temperature of 9.3 K. Both amorphous molybdenum and niobium films were found to crystallize near 40 to 50 K. Certain superconducting transition metal alloys (for example, $Mo_{50}Re_{50}$, with T_c ~8 K) were found to be stable against crystallization upon heating to room temperature.

Superconductivity in bulk metallic glasses prepared by rapid quenching methods was first reported by the author and colleagues (Ref 64) for the alloy $La_{80}Au_{20}$ with T_c of 3.6 K. Later work showed that a variety of metallic glasses exhibit superconductivity. Metal-metalloid glasses based on molybdenum, ruthenium, rhenium, and niobium were found to

exhibit superconductivity. One well-studied series of alloys, $Mo_{80-x}Ru_xB_{20}$ (with $20 < x < 60$), exhibits T_c ranging from 5 K to 7 K. The superconducting properties of these metallic glasses were studied in detail.

Amorphous superconductors have many special features that arise from the high degree of atomic disorder present in the amorphous phase (Ref 65, 66). As mentioned earlier, this disorder leads to strong electron scattering and a short electron mean free path (of the order of interatomic distances). For superconductors, this leads to a rather small superconducting coherence length (ξ). For typical amorphous superconductors, ξ ranges from about 4 nm to about 10 nm. By contrast, crystalline metals have coherence lengths of about 50 to 100 nm.

On the other hand, the London penetration depth (λ) for amorphous superconductors is typically quite large. The short coherence length and large penetration depth influence many of the properties of amorphous superconductors. For example, amorphous superconductors are extreme type II superconducting materials with very small lower critical fields (H_{c1}) and very large upper critical fields (H_{c2}).

Superconductivity in the mixed state persists to very high magnetic fields. The upper critical fields of the superconducting metallic glass $Mo_{52}Ru_{32}B_{16}$ and an amorphous $Mo_{30}Re_{70}$ thin film are shown in Fig. 17, where it is compared with the high-field crystalline superconductor Nb_3Sn. The latter material is used to construct high-field superconducting magnets. Even though they possess a lower transition temperature, the amorphous superconductors have a comparable critical field at low temperatures.

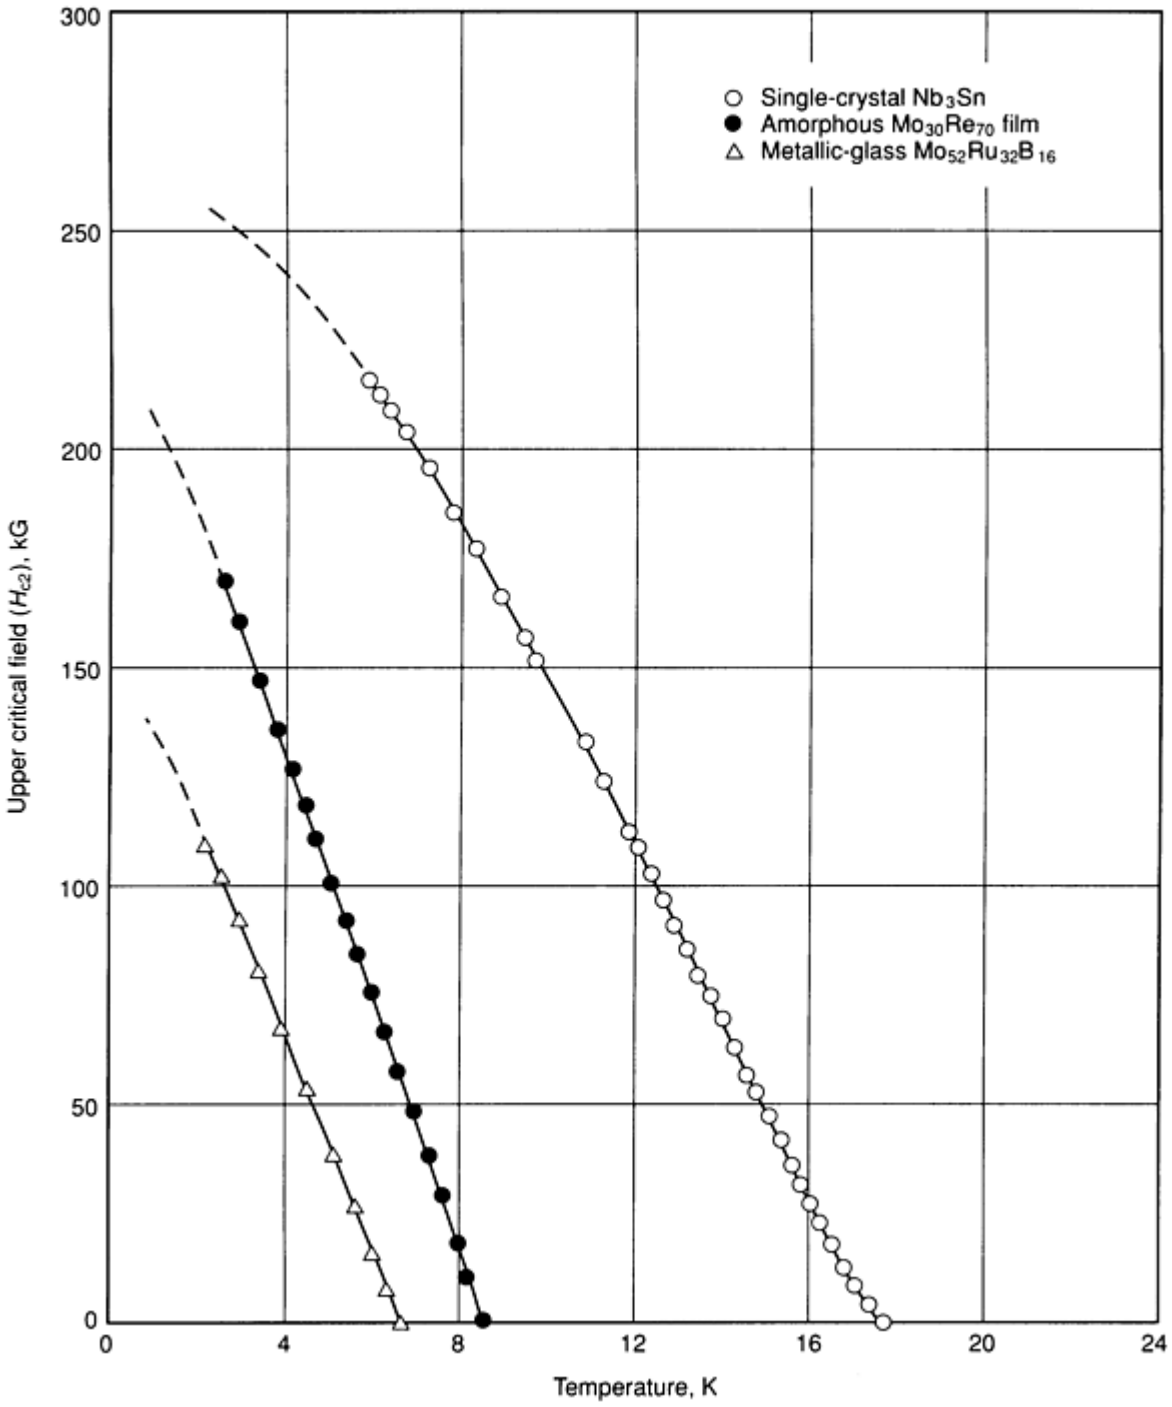

Fig. 17 The upper critical field (H_{c2}) as a function of temperature for the amorphous superconductors $Mo_{52}Ru_{32}B_{16}$ and $Mo_{30}Re_{70}$ compared with that of crystalline Nb_3Sn, a commercially used high-field superconductor

Crystalline inclusions and other inhomogeneities in amorphous superconductors result in pinning of magnetic flux vortices in the mixed state (between H_{c1} and H_{c2}). As a consequence, such inclusions can enhance the critical current density (J_c) of the superconductor in the presence of an applied magnetic field. Using this phenomenon, amorphous superconductors can be engineered to carry current densities of the order of 10^5 A/cm^2 (6.4×10^5 A/in.^{2}) in magnetic fields of the order of 50 to 100 kOe. These parameters have prompted consideration of metallic glass superconducting ribbons as high-field superconducting materials. The relatively modest transition temperatures of amorphous superconductors (<9 K) have thus far prevented their application. More detailed information on superconductivity can be found in the Section "Superconducting Materials" in this Volume.

Chemical Properties

As previously discussed, metallic glasses and other amorphous metals have an atomic scale structure similar to that of liquid metals. This structure has been described earlier in terms of continuous random packings. The continuous nature of the structure implies the absence of spatially extended defects such as grain boundaries or dislocations, which commonly occur in crystalline materials. Computer simulation studies in which dislocationlike defects were introduced into a model metallic glass structure showed that these defects undergo spontaneous relaxation and are subsequently difficult to recognize (Ref 67). In crystalline or polycrystalline metals, such extended defects oftentimes serve as chemically distinct sites at which surface reactions such as oxidation preferentially occur. The absence of well-defined extended defects in amorphous metals results in a chemically more uniform surface, which in turn leads to interesting chemical properties. For example, certain metallic glasses have been found to have excellent corrosion resistance in a variety of chemically hostile environments.

Ferrous metal-metalloid glasses containing modest amounts of chromium and molybdenum (for example, $Fe_{72}Cr_8P_{13}C_7$ and $Fe_{75}Mo_{15}P_{13}C_7$) have been found to undergo spontaneous passivation and exhibit high resistance to corrosion in strongly corroding solutions such as 12 *M* hydrochloric acid (Ref 68). Such alloys are found to have corrosion resistance significantly better than that of stainless steels containing similar amounts of chromium. This is attributed to the chemical and structural homogeneity of the metallic glass on the atomic scale.

Despite the absence of extended defects, amorphous metals do possess structural fluctuations on the scale of atomic distances. Each local atomic environment is distinct and different. As such, the local electronic orbital configurations of surface atoms tend to vary over the surface, and the surface exhibits a distribution of chemically active sites. This feature leads to interesting catalytic properties. For example, amorphous iron-nickel-metalloid alloys have been used for catalytic synthesis of hydrocarbons by hydrogenation of carbon monoxide (Ref 69).

Technology and Applications

As will be described in this section, metallic glasses are being used in an increasingly wide variety of applications. Figure 18 shows a number of components that utilize amorphous metals.

Fig. 18 Various parts that use metallic glasses. Most prominently featured are two spools of as-cast amorphous alloy for high-frequency and antitheft applications. Also shown (right side) are four wound magnetic cores made from amorphous alloy ribbon. Several high-frequency epoxy-encapsulated small cores are shown in the foreground. Such cores are used in switch-mode power supplies, magnetic amplifiers, chokes, and other electronic devices to be incorporated in electronic assemblies such as the one shown. At the lower right are bar code markers containing a strip of metallic glass. In the background is a woven blanket of metallic glass used in magnetic shielding. Courtesy of H.H. Liebermann, Allied-Signal Inc.

Soft Magnetic Materials. The homogeneity, low coercive force, and relatively high permeability of ferrous amorphous alloys are attractive features in many magnetic applications. The innovation of the planar flow casting method for producing uniform sheets of metallic glass in widths ranging up to 1 m (40 in.), thicknesses of 30 to 50 μm, and essentially unlimited lengths has resulted in the commercialization of metallic glasses as a core material for power-distribution transformers. Distribution transformers are used by the utility companies in the final voltage step-down in the network that supplies power to residences, stores, offices, and small industries.

These transformers are put into service for a period of 25 to 40 years, and during that time the primary coil is continuously energized. The significance of this duty pattern lies in the fact that the core material in the transformer is cycled at a frequency of 50 or 60 Hz continuously during the lifetime of the transformer. During each cycle, energy is lost to the magnetic core material. In addition, the alternating field produces eddy currents and accompanying losses within the transformer. Core losses are essentially determined by the coercive force, whereas the eddy current losses are proportional to the electrical conductivity of the material and inversely proportional to the thickness of the individual sheets of magnetic material from which the core is wound.

The low electrical conductivity of metallic glasses compared with conventional crystalline core materials (grain-oriented silicon steels) makes amorphous metals extremely attractive for reducing eddy current losses. The low coercive forces compared with competing crystalline materials reduce core loss. Taken together with the fact that the continuous planar

flow casting process leads to low fabrication costs, these features have led to the introduction of metallic glasses into the commercial transformer core market (Ref 70).

The use of amorphous metals in this application can reduce energy losses, thereby reducing costs. For a single transformer of typical size (a power output of 25 kVA), a conventional iron-silicon transformer can be designed to 98.7% efficiency at full load but generate 85 W of core loss independent of the loading. Over a lifetime of 35 years, this loss amounts to 2.6×10^4 kWh. At a cost of $0.06/kWh, this amounts to over $1500. Table 2 illustrates one analysis of losses for several types of transformers. The reduction in core losses arising from the incorporation of metallic glass as the core material is substantial.

Table 2 Core losses and coil losses in a conventional silicon steel and several metallic glass power-distribution transformers

Type/company	Capacity, kVa	Core loss, W	Coil loss at full load, W
Conventional grain-oriented silicon steel	25	85	240
Alloy 2605S (Allied-Signal)	25	16	235
General Electric	25	18	330
Osaka Transformers	30	30	390
Takaoka Electrical	20	18.9	348

Source: Ref 70, 71

It should be noted that the coil losses in Table 2 refer to a fully loaded transformer. During periods of no load, these losses are essentially eliminated, whereas the core losses occur continuously and are weighted far more heavily in a total cost analysis. The innovation of metallic glass transformers has provided new impetus for the development of more efficient conventional iron-silicon transformers. A complex set of economic factors will ultimately determine how widespread the use of metallic glass transformers will become.

The use of metallic glasses as soft magnetic materials is increasing in a number of other applications. These include inductive components such as saturable reactors, inverter transformers, and chokes for magnetic switches (used in power supplies for pulsed high-power lasers). Other applications in the areas of magnetic sensors and transducers are also currently under development. Many of these applications exploit the low coercivity combined with induced magnetic anisotropy effects. Induced anisotropies (by magnetic annealing) allow tailoring to achieve saturation at very low fields and other characteristics. These features are important in many magnetic applications.

Brazing Materials. Metallic glasses essentially melt to a fluid at temperatures near T_g. In typical metal-metalloid glasses, compositions are chosen that lie near deep eutectic features in the equilibrium phase diagram. As such, the liquidus and solidus curves of the equilibrium alloys often plunge to relatively low temperatures at glass-forming compositions. For example, in iron-base and nickel-base metal-metalloid glasses, the equilibrium solidus curves generally lie in the temperature range of 700 to 1100 °C (1300 to 2000 °F) at the glass-forming compositions. On the other hand, the T_g of the glass typically lies at still lower temperatures, ranging from 300 to 500 °C (570 to 930 °F). The fact that these alloys melt at such low temperatures and that some conventional brazing alloys have glass-forming compositions has been exploited in their use as brazing materials. For example, ribbons and sheets of nickel-base metal-metalloid glasses having T_g near 300 °C (570 °F) are used for specialized low-temperature brazing. The availability of thin sheets that can be cut to a variety of shaped preforms to fit the joining surfaces has made this a successful commercial product for making brazed joints with excellent strength and integrity.

Coatings. The high yield strength and hardness of many metallic glasses and amorphous metals and the observed corrosion resistance of those containing chromium, molybdenum, and other transition elements suggest possible applications as protective wear and corrosion-resistant coatings. Some preliminary studies in this area have been encouraging. For example, sputter deposition of molybdenum-boron-ruthenium and molybdenum-iron-chromium-boron-phosphorus amorphous alloys onto steel substrates to thicknesses of only a few microns was found to lead to substantial improvement of both the wear and corrosion resistance of the steel (Ref 72). Losses in sliding wear under specified loading conditions were reduced by several orders of magnitude (compared with the uncoated surface), and corrosion resistance in various hostile chemical environments was also significantly improved. A key factor in corrosion resistance is the avoidance of micro-cracks and other defects in the amorphous coating, which act as sites for preferential chemical attack. With regard to wear resistance, it was also noticed in the above studies (Ref 72) that the sliding friction coefficient of the amorphous coating was exceedingly small. When compared with a crystalline coating of comparable hardness, the amorphous coating exhibits substantially reduced wear. The wear rate divided by the hardness at a particular load (during, for example, sliding wear) is a good indication of the intrinsic wear characteristics of a surface. Based on the limited data available, it appears that low sliding friction is associated with intrinsically lower wear rates for amorphous coatings when compared with crystalline coatings of comparable hardness.

Recently, it has been observed that certain glass-forming alloys in their equilibrium crystalline form, when subjected to sliding wear under sufficient load, undergo a crystal-to-amorphous transformation in a thin surface layer (of the order ~1 μm in thickness). When this transformation occurs, a substantial reduction in the sliding friction is observed along with an accompanying reduction in wear rate (Ref 73). The mechanism by which the surface layer in the wear scar transforms to the amorphous state is likely related to the observation of amorphization induced by mechanical attrition and mechanical alloying. These phenomena appear to be a fertile ground for future research.

Reinforcing Fibers. The high yield strength of metallic glasses has led to a number of applications as reinforcing fibers in composite materials. A simple example is in the area of reinforcing concrete. Metallic glass fiber can be easily and cheaply produced by a variation of the melt-spinning process in which the melt stream is steadily broken up. The incorporation of only a few volume percent of metallic glass fibers in concrete has been observed to increase the overall work required to cause fracture by 100 times. This substantial improvement in fracture toughness is achieved at a modest increase in cost. Other attempts have been made to introduce metallic glass fibers and ribbons in metal matrices (Ref 74). Others have considered the use of metallic glass ribbons in plastic composites, as belting in radial tires, and so forth. Some refractory metal-metalloid glasses have tensile yield strengths in excess of 7 GPa (10^6 psi); therefore, fibers of these materials are expected to compete with those of the most refractory materials currently used in fabricating composites.

Bulk Metallic Glasses. The high yield strength, hardness, and other properties of some metallic glasses have also led to interest in producing bulk amorphous materials for certain applications. Because rapid solidification techniques require that one dimension of the sample be relatively small in order to achieve the high cooling rates required to bypass crystallization, the production of bulk three-dimensional materials can only be accomplished by consolidation of prequenched powders or ribbon materials. Production of metallic glass powders in large quantities has been demonstrated using variations of the rapid quenching method whereby the liquid is atomized into small droplets and cooled, for example, by thermal conduction in a fluid medium. Spray atomization, high-velocity gas jet atomization, and other methods have been employed successfully for this purpose. When droplet sizes below ~50 μm are achieved, cooling rates adequate for glass formation can be obtained in many alloys. Another simple method of powder production is to crush metallic glass ribbons by grinding or milling. Low temperatures (liquid nitrogen cooling) and hydrogenation of the ribbons are often used during the milling process in order to promote brittle fracture of the ribbon material. Several companies have used this method to produce commercial quantities of powder-flake material. Mechanical alloying is an ideal and relatively inexpensive method of producing metallic glass powder materials in large quantities; this method has only recently been exploited. All of these powder production methods lead to precursor materials that can be subsequently used as the input material for consolidation techniques.

Several consolidation methods have been successfully applied to metallic glass powders. These include shock consolidation, explosive forming, sintering at temperatures below T_g, hot extrusion near T_g, and hot rolling near T_g. In the shock consolidation method (Ref 75), an intense shock wave is produced by a supersonic flyer plate that impacts onto a green powder compact. As the shock front moves through the green compact, densification occurs and energy is preferentially dissipated on the particle boundaries. If the shock intensity and duration are properly chosen, interparticle melt layers are adiabatically formed as densification occurs. This is followed by a quench of the molten zones by heat conduction to the still-cold particle interiors. This rapid quench is sufficient to retain the glassy structure. Successful consolidation requires proper choices of powder grain size, shock intensity (typical peak pressures of the order of 1 Mbar are required), and duration (shock front durations of tens of microseconds). Bulk metallic glasses have been achieved by

this method with densities approaching 99% or more of the intrinsic density. Such specimens exhibit bulk mechanical properties that approach the intrinsic values found for high-quality ribbons.

Explosive forming is similar to shock consolidation. The primary difference lies in the fact that a controlled and shaped shock front is generated. This is accomplished by surrounding the green compact by a suitably shaped explosive charge that burns in a temporal sequence, producing a spatially and temporally controlled shock front. Cline and Hopper (Ref 76) were the first to demonstrate successful consolidation of rods, cylinders, and other shapes using this method.

Recently, Shingu (Ref 77) has exploited the metastability of metallic glasses against crystallization at temperatures near T_g to develop hot extrusion and rolling methods of consolidation that use the homogeneous fluidlike flow of metallic glasses at these elevated temperatures. His hot-rolling method is illustrated schematically in Fig. 19. In this method, the sample is enclosed in a jacket and heated to a temperature near T_g, where fluidlike viscosity is achieved. It is then rolled, formed, and quickly quenched to low temperature. Under favorable circumstances, nucleation and growth of crystals do not occur during processing. A fully consolidated glass is then achieved with density, strength, and so on, approaching the intrinsic values. This method of consolidation has been applied to a number of metal-metalloid and metal-metal glasses.

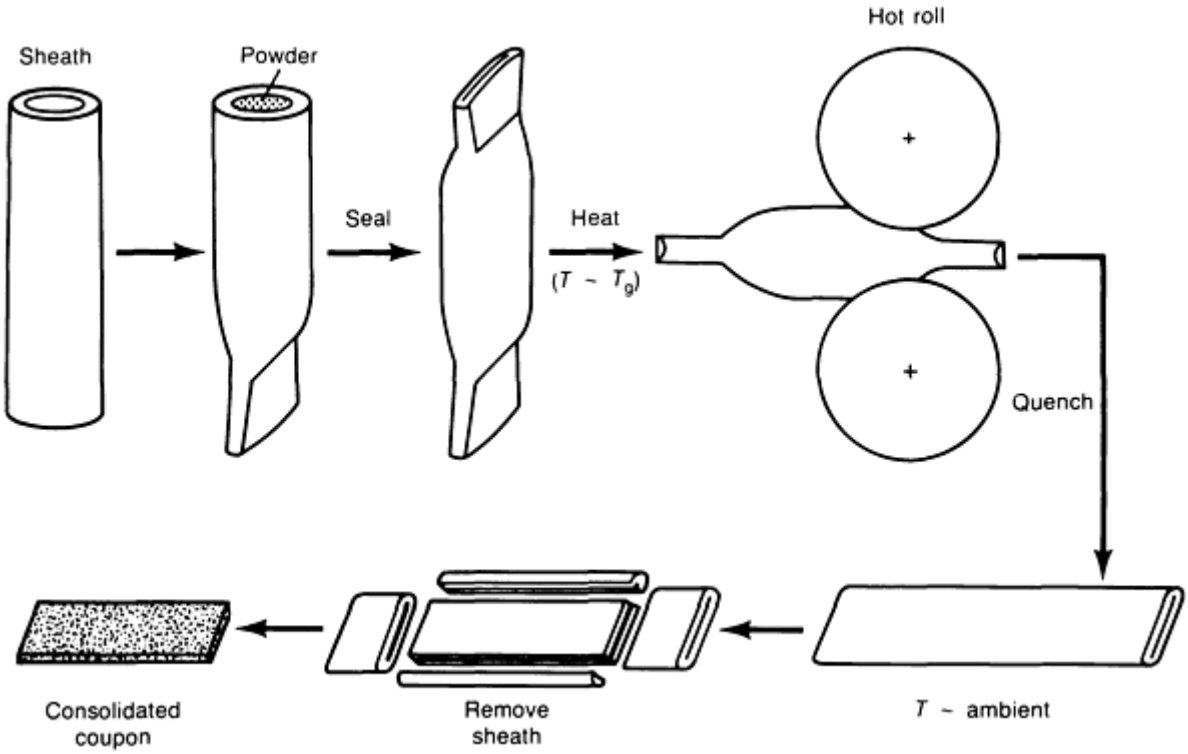

Fig. 19 Schematic illustration of the method used by Shingu to consolidate metallic glass powders into bulk materials. The sheathed sample is heated to temperatures near its glass transition by immersion in a hot salt bath. The heated sample is rolled and then quenched in water. The final consolidated specimen is removed from the sheath. Source: Ref 77

Controlled Crystalline Microstructures. Amorphous metals and alloys are interesting precursor materials for the production of crystalline materials with controlled microstructure. The nucleation and growth of crystalline phases from an amorphous matrix at temperatures near T_g can be controlled with high precision. Starting with an amorphous precursor material, microcrystalline alloys can be produced with controlled grain sizes and with phase distributions not achievable in conventionally processed alloys. For example, this technique has been used to produce ultrafine-grain iron-neodymium-boron alloys with grain sizes that are optimized to achieve hard magnetic properties (Ref 78, 79). Optimum permanent magnet materials are actually achieved by starting with a rapidly quenched material that already possesses an ultrafine grain structure due to nucleation and growth of crystals during the rapid quench.

Future Developments. As the properties of metallic glasses and amorphous metals become better characterized, and as economical synthesis and processing methods become available, it is certain that other applications will be developed.

The ultimate commercial future of metallic glasses and amorphous alloys will depend in part on economic factors. On the other hand, the unique structural, mechanical, electronic, magnetic, and chemical properties of these materials are certain to lead to as yet unexplored areas of technical application. Metallic glasses have a relatively short (30-year) history compared with the majority of currently used engineering materials. It is reasonable to believe that the evolution of this class of engineering materials is still in its relatively early stages.

Electrical Resistance Alloys

Revised by Robert A. Watson, The Kanthal Corporation; Bo Jönsson, Kanthal AB; George A. Fielding, Harrison Alloys, Inc.; Donald V. Cunningham, Emerson Electric, Wiegand Division; C. Dean Starr, C. Dean Starr, Inc.

Introduction

ELECTRICAL RESISTANCE ALLOYS include those types used in instruments and control equipment, heating elements, and devices that convert heat generated to mechanical energy. In this article they are classified as Resistance Alloys, Heating Alloys, and Thermostat Metals. The primary focus will be on metals used in these three classes, although some mention is also made of nonmetallic materials used in similar applications.

Resistance Alloys

The primary requirements for resistance alloys are uniform resistivity, stable resistance (no time-dependent aging effects), reproducible temperature coefficient of resistance, and low thermoelectric potential versus copper. Properties of secondary importance are coefficient of expansion, mechanical strength, ductility, corrosion resistance, and ability to be joined to other metals by soldering, brazing, or welding. Availability and cost are also factors.

Nominal compositions and physical properties of metals and alloys used to make resistors for instruments and controls are listed in Table 1.

Table 1 Typical properties of electrical resistance alloys

Basic composition, %	Resistivity[(a)], nΩ · m[(b)]	TCR, ppm/°C[(c)]	Thermoelectric potential versus Cu, µV/°C	Coefficient of thermal expansion[(d)], µm/m · °C	Tensile strength[(a)]		Density[(a)]

(a) At 20 °C (68 °F).

(b) To convert to Ω· circ mil/ft, multiply by 0.6015.

(c) Temperature coefficient of resistance is $(R - R_0)/R_0\ (t - t_0)$, where R is resistance at t °C and R_0 is resistance at the reference temperature t_0 °C.

(d) At 25 to 105 °C.

(e) Shunt manganin

Resistance alloys must be ductile enough so that they can be drawn into wire as fine as 0.01 mm (0.0004 in.) in diameter or rolled into narrow ribbon from 0.4 to 50 mm ($\frac{1}{64}$ to 2 in.) wide and from 0.025 to 3.8 mm (0.001 to 0.15 in.) thick.

Alloys must be strong enough to withstand fabrication operations, and it must be easy to procure an alloy that has consistently reproducible properties. For instance, successive batches of wire must have closely similar electrical characteristics: if properties vary from lot to lot, resistors made of wire from different batches may cause a given model of instrument to exhibit widely varying performance under identically reproduced conditions, or may cause large errors in a given instrument when a resistor from one batch is used as a replacement part for a resistor from another batch.

Coefficients of expansion of both the resistor and the insulator on which it is wound must be considered because stresses can be established that will cause changes in both resistance and temperature coefficient of resistance. It is equally important that consideration be given to the choice between single-layer and multiple-layer wound resistors, because of the difference in rate of heat dissipation between the two styles.

In design of primary electrical standards of very high accuracy, cost of resistance material is not a consideration. For ordinary production components, however, cost may be the deciding factor in material selection.

Resistors

Resistors for electrical and electronic devices may be divided into two arbitrary classifications on the basis of permissible error: those employed in precision instruments in which over-all error is considerably less than 1%, and those employed

where less precision is needed. The choice of alloy for a specific resistor application depends on the variation in properties that can be tolerated.

In many electronic devices, resistors whose error in resistance value is 5 to 10% are entirely satisfactory. Most resistors for this classification are made of carbon. Carbon resistors are not discussed in this article. Here, we are concerned chiefly with metallic resistors such as wirewound precision resistors and potentiometers, resistance thermometers, and ballast resistors.

Some applications of resistance materials require devices with large temperature coefficients of resistance, either positive or negative. A device of this type is called a thermistor. Thermistors are made almost exclusively of ceramic semiconductor materials.

Precision resistors (those with less than 1% error) require careful material selection. The ideal material for a precision resistor should have a temperature coefficient of resistance equal to zero for the temperature range over which the resistor will operate. In addition, to ensure freedom from thermoelectric effects, it should have a small or negligible thermoelectric potential versus copper, which is the material normally used for the connecting conductor. Temperature differentials may exist among various junctions between a resistance wire and a connecting wire, resulting in a network of thermocouples that can cause parasitic electromotive forces in the circuit; this effect is especially critical in precise dc circuits. In an apparatus where extreme precision is required, it is advisable to make the connecting wires of the same material as the resistors or to design the apparatus so that all dissimilar-metal junctions are at the same operating temperature.

Selection of material for, and specific dimensions of, a precision resistor must include consideration of equipment size and heat-dissipation characteristics. Temperature excursions from the ambient or from a specified operating temperature may be undesirable, because they may cause net changes in resistance that will affect the stability or accuracy of the instrument. The magnitude of the change in resistance can be calculated using the temperature coefficient of resistance. For example, a resistor made of a low-resistivity material could be several times larger than one made of a higher-resistivity material and yet achieve the same total resistance. The larger resistor would have a much greater surface area and therefore could dissipate much more heat, and thus, despite its low resistivity, would attain a lower steady-state temperature than would be possible for a small, high-resistivity resistor operating under the same conditions. Alloys used for precision resistors generally have resistivities ranging from 0.5 to 1.35 $\Omega mm^2/m$ (300 to 800 $\Omega \cdot$ circ mil/ft).

Resistance thermometers are commonly made of copper, nickel, or platinum; these devices are precision resistors whose resistance change with temperature is stable and reproducible over specified ranges of temperature. For resistance thermometers, the larger the temperature coefficient of resistance of the material, the greater the accuracy and ease of measurement. Temperature coefficients of relatively pure metals are greatly affected by small amounts of impurities. In fact, one of the most sensitive tests of the purity of a metal is measurement of its temperature coefficient of resistance, which decreases sharply with increasing impurity or alloy content.

Ballast resistors are used extensively in industrial circuits to maintain constant currents over long periods of time. In such an application, a ballast resistor must be able to dissipate energy in such a way as to control current over a wide range of voltages. Wires with the proper temperature coefficient of resistance can be made to change resistance rapidly with changes in current, due to self heating, in such a manner that the current in the circuit will remain nearly constant even when there are fluctuations in voltage across the circuit. Because ballast resistors operate at elevated temperatures, mechanical properties are important also. Typical materials used in ballast resistors are pure iron, pure nickel, and nickel-iron alloys such as 71Ni-29Fe (See Table 1).

Reference resistors and virtually all other applications of resistance alloys demand temperature coefficients of resistance lower than ±20 ppm/°C (±20 $\mu\Omega/\Omega \cdot$ °C). This requirement stems from the fact that, for these applications, resistance errors resulting from the small changes in ambient temperature that are continually taking place cannot be tolerated. In the most demanding of these applications, resistors often are mounted in thermally insulated containers and are carefully maintained at a temperature slightly above the maximum anticipated ambient temperature.

The most important requirement of a resistor used as a reference standard is that its value be predictable within narrow limits over long periods of time. Many reference resistors exhibit a nearly linear change in resistance with time. Hence, resistance between dates of calibration can be determined by interpolation; resistance at future points in time can be determined by extrapolation, but undue reliance should not be placed on extrapolated values. Figure 1 shows the change in resistance with time for a 10-kΩ resistor made of a Ni-Cr-Al-Cu alloy.

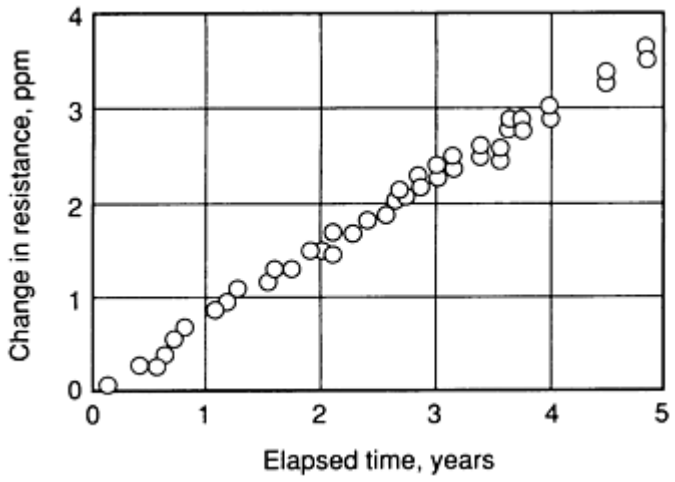

Fig. 1 Change in resistance of a 10-kΩ resistor with time

Stability, or the ability to maintain a specific value of resistance within narrow limits over a long period of time, is an important requirement of materials for precision resistors and reference resistors. Principal sources of instability are:

- Relief of residual stresses during service
- Time-dependent or time-temperature-dependent metallurgical changes, such as precipitation, of a second phase
- Corrosion or oxidation
- Humidity

Effect of Stress Relief. Residual stresses often are relieved at room temperature over long periods of time through a process known as stress relaxation. Stress relaxation alters the resistance of a coil at a rate of change that increases with the original level of residual stress. For this reason, only carefully preannealed wires are used for precision resistors. Stresses induced during winding, weaving, or other operations in fabrication of resistors from preannealed wire must be kept to a minimum. Thorough annealing of finished resistors is not always possible because the wires may be enameled or may be coated with a textile insulation of only moderate resistance to heat. Textiles limit the maximum temperature to about 140 °C (285 °F), and the highest rated enamels have a 220 °C (430 °F) maximum temperature that can be used for stress relieving finished resistors.

Figure 2 shows the effect of residual stress on the stability of a manganin alloy subjected to different amounts of cold work. The top curve illustrates that a low-temperature stress-relieving treatment substantially eliminates the stresses that would, in time, have been eliminated due to natural relaxation at room temperature.

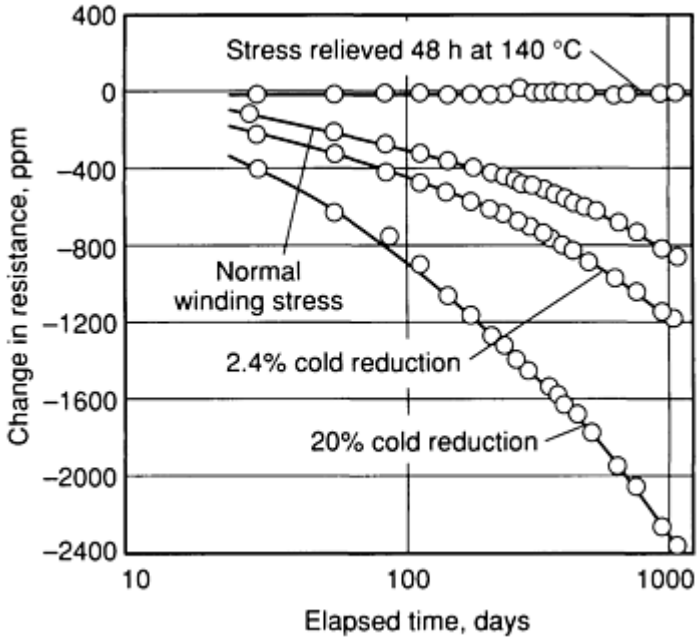

Fig. 2 Change in resistance of manganin resistors upon aging at room temperature

Resistors represented by the top curve were stress relieved at 140 °C (285 °F) for 48 h to stabilize their resistance within about 20 ppm of the nominal value. Resistors not stress relieved, as represented by the other curves, continue to change in resistance almost indefinitely. For most modern, hermetically sealed precision resistors annealed at 140 °C (285 °F), the change in resistance does not exceed 10 ppm/year, and for many it does not exceed 5 ppm/year. However, resistors made of manganin that are used as reference standards require greater stability, and stress relief at 140 °C (285 °F) is not adequate. One-ohm resistors of the best grade (the double-wall type) are treated as follows. A coil of wire is wound on a steel mandrel and annealed at about 500 °C (930 °F) in a protective atmosphere for 6 h or more. The coil is removed and slipped over an insulated tube of the same diameter as the mandrel, and then is hermetically sealed using a second tube slightly greater in diameter. In most resistors of this type, the change in resistance does not exceed 1 ppm/year.

Effect of Metallurgical Stability. The second factor affecting stability of precision resistors is the metallurgical stability of the alloy being used as the resistance element; any metallurgical change will be detrimental. All resistance alloys are single-phase solid-solution alloys; thus, the changes in resistance that occur are relatively small but not insignificant. Changes in resistance are caused by internal changes such as long-range order-disorder reactions in 71Ni-29Fe alloys, short-range order or clustering in quaternary nickel-chromium alloys, and even minor ordering in manganin alloys. Accordingly, resistance of these alloys is affected by heat treatment and by rates of cooling from heat-treating temperatures. Power resistors that can operate as high as 300 °C (570 °F) can in effect be heat treated during service. The net effect during service can be an increase in resistance for nickel-chromium alloys, a decrease for manganin, and either an increase or decrease for nickel-iron alloys.

Effect of Corrosion. The third factor affecting stability of resistors is corrosion and/or oxidation. Corrosion of the resistance element will decrease its effective cross section, resulting in a corresponding increase in resistance. If the corrosive attack is selective, changes will occur in temperature coefficient of resistance and thermal emf, as well as in resistivity. These corrosive effects may be minimized by protecting the wire with an enamel or plastic coating. One relatively common source of corrosive attack, but one that is often overlooked, is flux residue at soldered or brazed joints. Another less obvious cause of instability is the presence of tin-containing solder. Intergranular stress corrosion, believed to originate during thermal stress-relieving treatments, may cause open circuits.

Effect of Humidity. The fourth factor affecting the stability of enameled wire-wound resistors is humidity. The change in resistance is dependent on enamel thickness, wire diameter, and change in the amount of moisture to which the resistor is exposed. Increasing the moisture for a given resistor will cause a positive change in resistance, whereas decreasing the moisture causes a negative shift. This factor can be eliminated where it is physically possible to hermetically seal the resistor.

Combinations of these four factors--residual stresses, metallurgical instability, corrosion or oxidation, and humidity--account for the complex changes in resistance that often occur in resistors.

Solderability or Joining. The ease with which alloys can be soldered, brazed, or welded is an important consideration in selection of materials for precision resistors. Improperly brazed or soldered joints frequently cause resistance instability in the circuit. Metals to be soldered must be cleaned prior to tinning so that solder can completely wet the surfaces and maintain electrical continuity. For copper-nickel alloys this is relatively simple because protective oxide coatings are not formed on these alloys. Nickel-chromium alloys must be tinned immediately after cleaning and before an inherent protective oxide forms.

Pressure Coefficients of Resistance. The resistance value of a resistor may change if the hydrostatic pressure on the resistance element is changed; for manganin this change is about 23 pΩ/Ω · Pa (0.16 pΩ/Ω · psi). Sealed resistors may also be affected by changes in external pressure. In a double-wall one-ohm resistor, for example, a change in pressure on the inner tube will cause a change in tube diameter, thus altering the length of wire wound on the tube. The magnitude of the resistance change depends in part on the thickness of the wall, and for commercial resistors is typically less than the hydrostatic pressure coefficient (PCR) of manganin. Unsealed resistors wound on mica cards containing air bubbles may have pressure coefficients several times greater than that predicted from the hydrostatic pressure coefficient of the alloy. This effect is important only if there is a large change in pressure, which would be most likely if there were a large change in elevation above sea level.

Types of Resistance Alloys

Copper-nickel resistance alloys, generally referred to as *radio alloys,* have very low resistivities and moderate temperature coefficients of resistance (TCR), as shown in the first four listings in Table 1. Resistivity of radio alloys increases, and TCR decreases, as nickel content increases. Thermal emf is negative with respect to copper, the magnitude being directly proportional to nickel content. All radio alloys can be readily soldered or brazed. Those with 12 and 22% nickel have high enough resistance to permit welding. Because of their high copper contents, radio alloys have low resistance to oxidation and thus are restricted to applications involving low operating temperatures. They are used chiefly for resistors that carry relatively high currents, and for this reason rapid dissipation of heat from the surface of the resistor is desirable. In this application, resistor temperature may vary over a wide range, but temperature changes are relatively unimportant.

Copper-manganese-nickel resistance alloys, generally referred to as manganins, have been adopted almost universally for precision resistors, slide wires and other resistive components with values of 1 nΩ or less, and are also used for components with values up to 100 kΩ.

Originally, manganin was the name of a specific alloy, but the term is now generic and covers several different compositions (see Table 1). All manganins are moderate in resistivity (from 380 to 480 nΩ · m, or 230 to 290 Ω· circ mil/ft) and low in TCR (less than ± 15 ppm/°C).

Manganins are stable solid-solution alloys. The electrical stability of these alloys, verified by several decades of experience, is such that their resistance values change no more than about 1 ppm per year when the material is properly heat treated and protected. Manganin-type alloys are characterized by rather steep, parabolic relations between resistance and temperature (see Fig. 3). This severely restricts the range of temperature over which resistance is stable, thus limiting the use of manganins to devices for which operating temperatures are both stable and predictable. For some applications, the maximum of the parabola (peak, or peak temperature) is kept near room temperature by controlling composition, minimizing the effects of small changes in ambient temperature. The temperature coefficient of commercial manganin is usually less than ± 10 ppm/°C for an interval of 10 °C (18 °F) on either side of the peak.

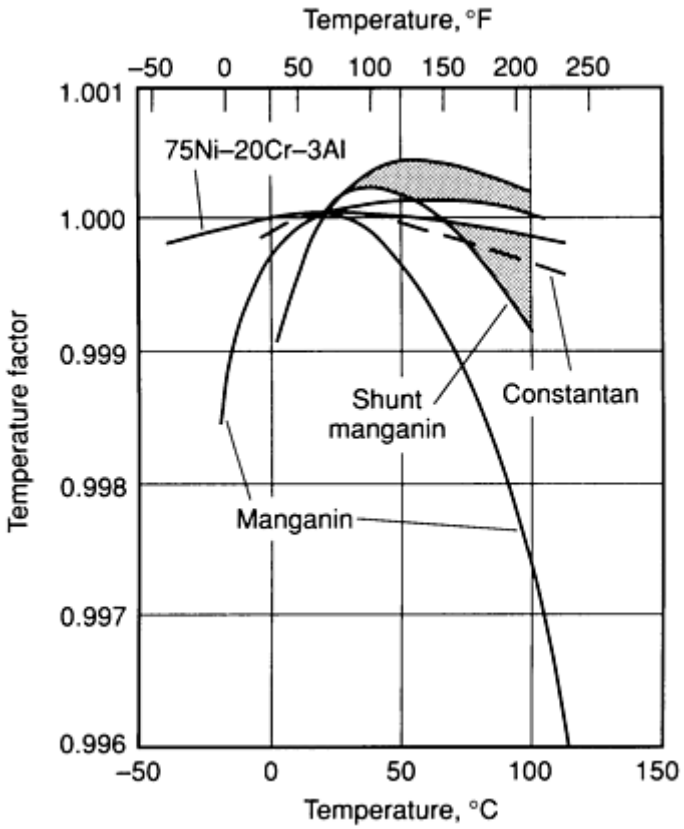

Fig. 3 Variation of resistance with temperature for four precision resistor alloys. To calculate resistance at temperature, multiply resistance at room temperature by the temperature factor.

When instruments are designed for operation above ambient temperature, the chemical composition of the manganin is chosen so that the peak will occur in the operating temperature range. So-called "shunt manganin," which carries high currents and consequently gets hot in use, usually has a peak temperature from 45 to 65 °C (115 to 150 °F).

Manganins are susceptible to selective oxidation or preferential corrosive attack. This may occur during heat treatment, wire manufacture, or coil fabrication. Selective oxidation results in formation of a copper-rich (manganese-depleted) zone on the wire. This copper-rich sheath has the effect of greatly increasing the temperature coefficient of resistance and raising the peak temperature well beyond the range where any precision resistor would ordinarily be used.

The resistivity of manganin--roughly 500 nΩ · m (300 Ω· circ mil/ft) at 25 °C (77 °F)--is adequate for most instrumentation purposes. The thermoelectric potential versus copper is very low, usually less than -2 μV/°C from 0 to 100 °C (32 to 212 °F).

Constantan, like manganin, has become a generic term for a series of alloys that have moderate resistivities and low temperature coefficients of resistance. Nominally, constantans are 55Cu-45Ni alloys, but specific compositions vary from about 50Cu-50Ni to about 65Cu-35Ni. The temperature coefficient of conventional constantan can be held within ±20 ppm/°C of ambient temperature. However, the difference in TCR between the low (-55 to 25 °C, or -67 to 77 °F) and high-temperature ranges (25 to 105 °C, or 77 to 220 °F) is about 20 ppm. Thus, the specification is ±20 ppm/°C over one temperature range or ±40 ppm/°C over both ranges. A variation of constantan with 3% Mn improves the flatness of the resistance temperature curve and provides a TCR of ±20 ppm/°C from -55 to 105 °C (-67 to 220 °F). All constantans contain iron and cobalt in addition to manganese.

The temperature coefficient of resistance of constantan is very low and parabolic like that of manganin, but remains flat over a much wider range (Fig. 3). Other properties are given in Table 1; specific property values vary somewhat with composition. Constantans are considerably more resistant to corrosion than manganins.

Use of constantans as electrical resistance alloys is restricted largely to ac circuits, because thermoelectric potential versus copper is quite high for these materials (about 40 μV/°C at room temperature). However, if the circuit voltage is high enough to overshadow thermoelectric effects, constantans may be used in dc circuits as well.

Nickel-Chromium-Aluminum Resistance Alloys. Nickel-chromium alloys containing small amounts of other metals--usually aluminum plus either copper, manganese, or iron--have resistivities about $2\frac{1}{2}$ to $3\frac{1}{2}$ times that of manganin. Ni-Cr-Al resistance alloys have been adopted almost universally for the construction of wire-wound precision resistors having resistance values of about 100 kΩ, and are also used for resistors with values as low as about 100 Ω. The temperature coefficients of resistance of these alloys are vastly superior to those of manganin and constantan, being less than ±20 ppm/°C between -55 and 105 °C (-67 and 220 °F). The difference in TCR between the hot region (25 to 105 °C) and the cold region (-55 to 25 °C) is about 20 ppm/°C for constantan (and about 10 ppm/°C for newer constantan), but only about 5 ppm/°C for the original quaternary Ni-Cr-Al alloys, and only 1 ppm/°C for the new quaternary alloys. The high resistivity and low TCR of Ni-Cr-Al alloys are obtained by an order-disorder type of heat treatment at approximately 540 °C (1000 °F). Therefore, if desired, the temperature coefficient can be decreased without resorting to melt selection, which is required for alloys that do not respond to heat treatment. The availability of smaller temperature coefficient ranges is dependent on wire size and alloy composition. Table 2 gives the available commercial ranges. Electrical stability of quaternary Ni-Cr-Al alloys is excellent--1 to 10 ppm/year or less. Their thermoelectric potential versus copper is also excellent--about 1 μV/°C at temperatures from 0 to 100 °C (32 to 212 °F).

Table 2 Temperature coefficient of resistance of nickel-chromium-aluminum base alloys as a function of wire diameter

Wire diameter		**Alloy I[(a)]**	**Alloy II[(b)]**
mm	**in.**		
		Both ranges (-55 to 25 °C, and 25 to 105 °C)	
>0.287	>0.0113	±20	±10
0.25-0.0787	0.010-0.0031	±10	±8
0.07-0.013	0.00275-0.0005	±5	±3
		One range (-55 to 25 °C, or 25 to 105 °C)	
>0.287	>0.0113	±15	±10
0.25-0.0787	0.010-0.0031	±7	±5

(a) Alloy I, 75Ni-20Cr-3Al-2(Cu, Fe, or Mn).

(b) Alloy II, 72Ni-20Cr-3Al-5Mn

As indicated in Table 1, the mechanical properties of Ni-Cr-Al alloys are higher than those of manganin and constantan. Wires made of Ni-Cr-Al alloys are available in diameters as small as 0.01 mm (0.0004 in.), whereas wires of copper-base alloys such as constantan are seldom produced in diameters smaller than 0.025 mm (0.001 in.). Because the resistance of a wire varies inversely with the square of its diameter, it is possible with small-diameter Ni-Cr-Al wires to produce miniature resistors that are exceedingly high in resistance.

The Ni-Cr-Al alloys resist oxidation better than other commercial electrical resistance alloys. This is an advantage in resistors that are not covered with enamel, teflon, or other coatings. It is a disadvantage for making acceptable soldered or brazed joints, because it necessitates greater care in joint preparation. However, suitable soldered or silver-brazed connections can be made readily using appropriate fluxes.

Other Precision Resistance Materials. In high-resistance precision resistors, where TCR limits are less stringent, 80Ni-20Cr alloys may be used. 80Ni-20Cr alloys have temperature coefficients from four to sixteen times the nominal value for Ni-Cr-Al alloys. Other similar alloys, such as Ni-Cr-Fe alloys, are used primarily to accomplish specific design objectives because they permit designers to vary wire diameter and wire coatings in order to accommodate design constraints, such as severe space limitations. All of these precision resistance alloys have low thermoelectric potentials versus copper at temperatures from 0 to 100 °C.

Aside from electrical resistance and temperature coefficient, several other design factors must be taken into consideration in selection of precision resistance metals for specific applications. For example, pure nickel (99.8%) is used in precision instruments that require a high positive temperature coefficient; pure copper is used for compensating resistors in precision instruments where the temperature coefficient of moving coils must be matched; and pure platinum is used for heating elements in thermocouple-type ac-to-dc converters as well as for precision resistance bulbs. Aluminum is seldom used as a resistor metal, but because of its favorable ratio of weight to resistance it is often used in windings for the moving coils of permanent-magnet electrical instruments.

Alloys such as 71Ni-29Fe and pure metals such as nickel and platinum have low resistivities and high-temperature coefficients. For these metals, it is important that operating temperature be specified carefully, because the temperature coefficient varies quite sharply with temperature (see Table 3).

Table 3 TCR values for 71Ni-29Fe and pure nickel determined using various reference temperatures

Reference temperature, °C	Temperature range, °C	TCR, ppm/°C
71Ni-29Fe alloy		
20	20-100	4500
25	25-100	4300
Nickel (99.9% purity) (270)		
0	0-100	6730
20	20-100	6150
25	25-100	6000
Nickel (99% purity) (205)		

0	0-100	5250
20	20-100	4750
25	25-100	4620

Although their high-temperature coefficients eliminate them from use in ordinary precision resistors, pure metals are useful in other applications such as temperature-measurement instruments and ballast devices.

Semiprecision Resistance Alloys. The alloys in Table 1 other than those previously discussed are used chiefly for rheostats and potentiometers. These semiprecision resistance alloys are not made to the rigid specifications that apply to manganins, constantans, or quaternary Ni-Cr-Al alloys. For these alloys, long-term stability generally is not critical, and such factors as thermal emf versus copper and temperature coefficient of resistance are relatively unimportant.

Semiprecision resistance alloy wires are produced in diameters ranging from a lower limit of 0.013 mm (0.0005 in.)--a lower limit of 0.02 mm (0.0008 in.) for certain Cu-Ni alloys--to an approximate maximum of 6.35 mm ($\frac{1}{4}$ in.). Above 0.078 nn (0.0031 in.), wires are made only in standard B&S gages; below 0.078 mm, both standard B&S gages and intermediate sizes are available. Also, ribbon and strip usually are available in thicknesses from 0.013 to 6.35 mm (0.0005 to $\frac{1}{4}$ in.). Ribbon and strip in thicknesses near the lower end of the foregoing range usually are available only as cold rolled stock, and those in thicknesses near the extreme upper end of the range usually are available only as hot rolled stock.

Dimensional tolerances are seldom specified for applications in which resistivity and electrical resistance per unit length, rather than physical dimensions, are of primary importance. Typical tolerances on resistance per unit length are:

- For hot rolled ribbon rods, ±8
- For cold rolled ribbon, ±5%
- For cold drawn round wire finer than 0.05 mm (0.002 in.), ±10%
- For cold drawn wire 0.05 to 0.1 mm (0.002 to 0.004 in.), ±8%
- For cold drawn wire 0.1 mm (0.004 in.) and heavier, ±5%

Closer tolerances are available.

Thermostat Metals

A thermostat metal is a composite material (usually in the form of sheet or strip) that consists of two or more materials bonded together, of which one may be a nonmetal. Because the materials bonded together to form the composite differ in thermal expansion, the curvature of the composite is altered by changes in temperature; this is the fundamental characteristics of any thermostat metal. A thermostat metal is, therefore, a complete, self-contained transducing system capable of transforming heat directly into mechanical energy for control, indicating, or monitoring purposes.

In applications such as circuit breakers, thermal relays, motor overload protectors, and flashers, the change in temperature necessary for operation of the element is produced by the passage of current through the element itself--in other words, the change is produced by I^2R heating. In certain other applications, any increase in the temperature of the thermostat element caused by I^2R heating is objectionable, and a thermostat metal with low electrical resistivity is required.

For circuit breakers and similar devices, there are thermostat metals that differ in electrical resistivity but are similar in other properties. This allows a manufacturer to design a complete series of circuit breakers of different ratings in which the thermostat elements are all of the same size but have different electrical resistance. Resistivity is varied by

incorporating a layer of a low-resistivity metal between outer layers of two other metals that have high resistivities and that differ widely in expansion coefficient.

In one series of commercial thermostat metals with resistivities ranging from 165 to 780 nΩ · m (100 to 470 nΩ · circ mil/ft) at 24 °C (75 °F), high-purity nickel is used for the intermediate layer. In a series with resistivities from 33 to 165 nΩ · m (20 to 100 Ω· circ mil/ft), high-conductivity copper alloys are employed for the intermediate layer.

The use of a manganese-copper-nickel alloy having a resistivity of 1745 nΩ · m (1050 Ω· circ mil/ft) for one of the outer layers has extended the practical upper resistivity limit of thermostat metals to 1620 nΩ · m (975 Ω· circ mil/ft) at 24 °C.

Tolerances on resistivity at a standard temperature vary from ±3 to ±10%, depending on the type of thermostat metal and its resistivity.

About 30 different alloys are used to make over 50 different thermostat metals. Most of these 30 alloys are nickel-iron, nickel-chromium-iron, chromium-iron, high-copper, and high-manganese alloys.

Thermostat metals are available as strip or sheet in thicknesses ranging from 0.13 to 3.2 mm (0.005 to 0.125 in.) and widths from 0.5 to 300 mm (0.020 to 12 in.). They are easily formed into the required shapes. Thermostat metals usually are selected on the basis of the temperature range in which they are required to operate. They are available for various operating ranges between -185 and 540 °C (-300 and 1000 °F). Properties and typical bimetal combinations for several temperature ranges are given in Table 4.

Table 4 Properties of thermostat metals frequently selected for some common service temperatures

Temperature range of maximum sensitivity		Composition		Resistivity at 24 °C (75 °F)		Flexivity[(a)]	
°C	°F	High-expanding side	Low-expanding side	nΩ · m	Ω· circ mil/ft	µm/m · °C	µin./in. · °F
-20 to 150	0-300	75Fe-22Ni-3Cr	64Fe-36Ni	780	470	26.3	14.6
-20 to 200	0-400	75Fe-22Ni-3Cr	Pure Ni	160	95	8.3	4.6
		72Mn-18Cu-10Ni	64Fe-36Ni	1120	675	38.5	21.4
120-290	250-550	67Ni-30Cu-1.4Fe-1Mn	60Fe-40Ni	565	340	16.6	9.2

(a) At 40-150 °C (100-300 °F). See ASTM B 106 for standard test method for determining flexivity of thermostat metals.

Heating Alloys

Resistance heating alloys are used in many varied applications·from small household appliances to large industrial process heating systems and furnaces. In appliances or industrial process heating, the heating elements are usually either open helical coils of resistance wire mounted with ceramic bushings in a suitable metal frame, or enclosed metal-sheathed elements consisting of a smaller-diameter helical coil of resistance wire electrically insulated from the metal sheath by compacted refractory insulation. In industrial furnaces, elements often must operate continuously at temperatures as high as 1300 °C (2350 °F) for furnaces used in metal-treating industries, 1700 °C (3100 °F) for kilns used for firing ceramics, and occasionally 2000 °C (3600 °F) or higher for special applications.

The primary requirements of materials used for heating elements are high melting point, high electrical resistivity, reproductible temperature coefficient of resistance, good oxidation resistance, absence of volatile components, and resistance of contamination. Other desirable properties are good elevated-temperature creep strength, high emissivity, low thermal expansion, and low modulus (both of which help minimize thermal fatigue), good resistance to thermal shock, and good strength and ductility at fabrication temperatures.

Table 5 gives physical and mechanical properties, and Table 6 presents recommended maximum operating temperatures for resistance heating materials for furnace applications. Of the four groups of materials listed in these tables, the first group (Ni-Cr and Ni-Cr-Fe alloys) serves by far the greatest number of applications.

Table 5 Typical properties of resistance heating materials

Basic composition	Resistivity[(a)], $\Omega \cdot mm^2/m$[(b)]	Average change in resistance[(c)], %, from 20 °C to:				Thermal expansion, µm/m · °C, from 20 °C to:			Tensile strength		Density

Nonmetallic heating-element materials				
Silicon carbide	2410	4370	1600	2900
Molybdenum disilicide	(b)	(b)	1700-1800	3100-3270
$MoSi_2$ + 10% ceramic additives	(b)	(b)	1900	3450
Graphite	3650-3700(c)	6610-6690(c)	400(d)	750(d)

Element	Vacuum	Pure H_2	City gas
Mo	1650 °C (3000 °F)	1760 °C (3200 °F)	1700 °C (3100 °F)
Ta	2480 °C (4500 °F)	Not recommended	Not recommended
W	1650 °C (3000 °F)	2480 °C (4500 °F)	1700 °C (3100 °F)

(a) Recommended atmospheres for these metals are a vacuum of 10^{-4} to 10^{-5} mm Hg, pure hydrogen, and partly combusted city gas dried to a dew point of 4 °C (40 °F). For the recommended temperatures in these atmospheres, see the entries for Mo, Ta, and W at the end of this table.

(b) Decomposes before melting at 1740 °C (3165 °F) for $MoSi_2$, and 1825 °C (3315 °F) for $MoSi_2$ + 10% ceramic additives.

(c) Graphite volatilizes without melting at 3650 to 3700 °C (6610 to 6690 °F).

(d) At approximately 400 °C (750 °F) (threshold oxidation temperature), graphite undergoes a weight loss of 1% in 24 h in air. Graphite elements can be operated at surface temperatures up to 2205 °C (4000 °F) in inert atmospheres.

The ductile wrought alloys in the first group have properties that enable them to be used at both low and high temperatures in a wide variety of environments. The Fe-Cr-Al compositions (second group) are also ductile alloys. They play an important role in heaters for the higher temperature ranges, which are constructed to provide more effective mechanical support for the element. The pure metals that comprise the third group have much higher melting points. All of them except platinum are readily oxidized and are restricted to use in nonoxidizing environments. They are valuable for a limited range of application, primarily for service above 1370 °C (2500 °C). The cost of platinum prohibits its use except in small, special furnaces.

The fourth group, nonmetallic heating-element materials, are used at still higher temperatures. Silicon carbide can be used in oxidizing atmospheres at temperatures up to 1650 °C (3000 °F); three varieties of molybdenum disilicide are effective up to maximum temperatures of 1700, 1800, and 1900 °C (3100, 3270, and 3450 °F) in air. Molybdenum disilicide heating elements are gaining increased acceptance for use in industrial and laboratory furnaces. Among the desirable properties of molybdenum disilicide elements are excellent oxidation resistance, long life, constant electrical resistance, self-heating ability, and resistance to thermal shock. Nonmetallic heating elements described are considerably more fragile as compared to metal heating alloys.

Nickel-Chromium and Nickel-Chromium-Iron Alloys. The resistivities of Ni-Cr and Ni-Cr-Fe alloys are high, ranging from 1000 to 1187 nΩ · m (600 to 714 Ω· circ mil/ft) at 25 °C. Figure 4 shows that the resistance changes more

rapidly with temperature for 35Ni-20Cr-45Fe than for any other alloy in this group. The curve for 35Ni-30Cr-35Fe (which is no longer produced) is similar, but slightly lower. The other four curves, which are for alloys with substantially higher nickel contents, reflect relatively low changes in resistance with temperature. For these alloys, rate of change reaches a peak near 540 °C (1000 °F), goes through a minimum at about 760 to 870 °C (1400 to 1600 °F) and then increases again. For Ni-Cr alloys, the change in resistance with temperature depends on section size and cooling rate. Figure 5 presents values for a typical 80Ni-20Cr alloy. The maximum change (curve A) occurs with small sections, which cool rapidly from the last production heat treatment. The smallest change occurs for heavy sections, which cool slowly. The average curve (curve B) is characteristic of medium-size sections.

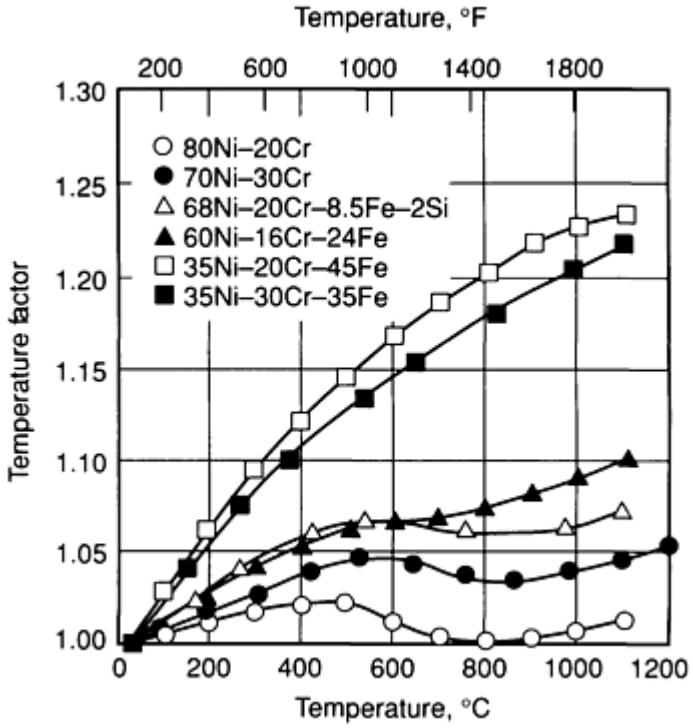

Fig. 4 Variation of resistance with temperature for six Ni-Cr and Ni-Cr-Fe alloys. To calculate resistance at temperature, multiply resistance at room temperature by the temperature factor.

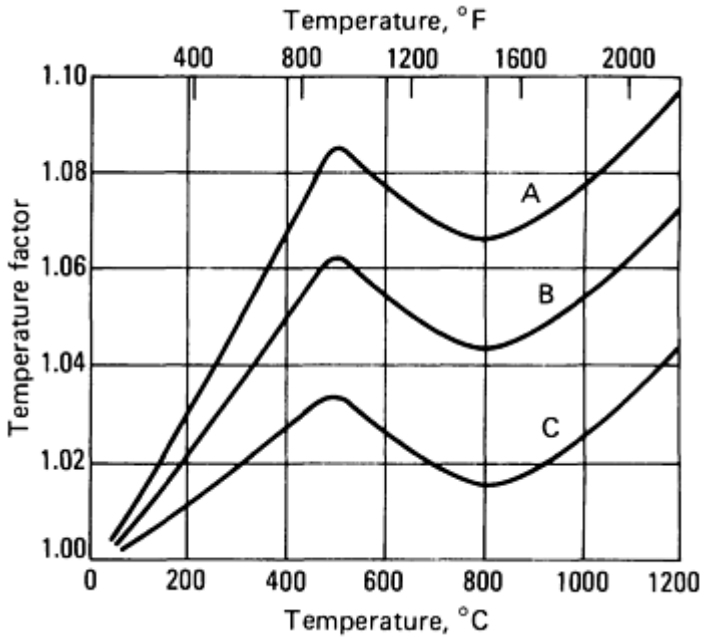

Fig. 5 Variation of resistance with temperature for 80Ni-20Cr heating alloy. Curve A is for a specimen cooled rapidly after the last production heat treatment. Curve C is for a specimen cooled slowly after the last production heat treatment. Curve B represents the average value for material as delivered by the producer. To calculate resistance at temperature, multiply the resistance at room temperature by the temperature factor.

Iron-Chromium-Aluminum Alloys. Fe-Cr-Al heating alloys are higher in electrical resistivity and lower in density than Ni-Cr and Ni-Cr-Fe alloys. Resistivity of Fe-Cr-Al alloys depends on both aluminum and chromium contents, with aluminum being predominant (see Fig. 6).

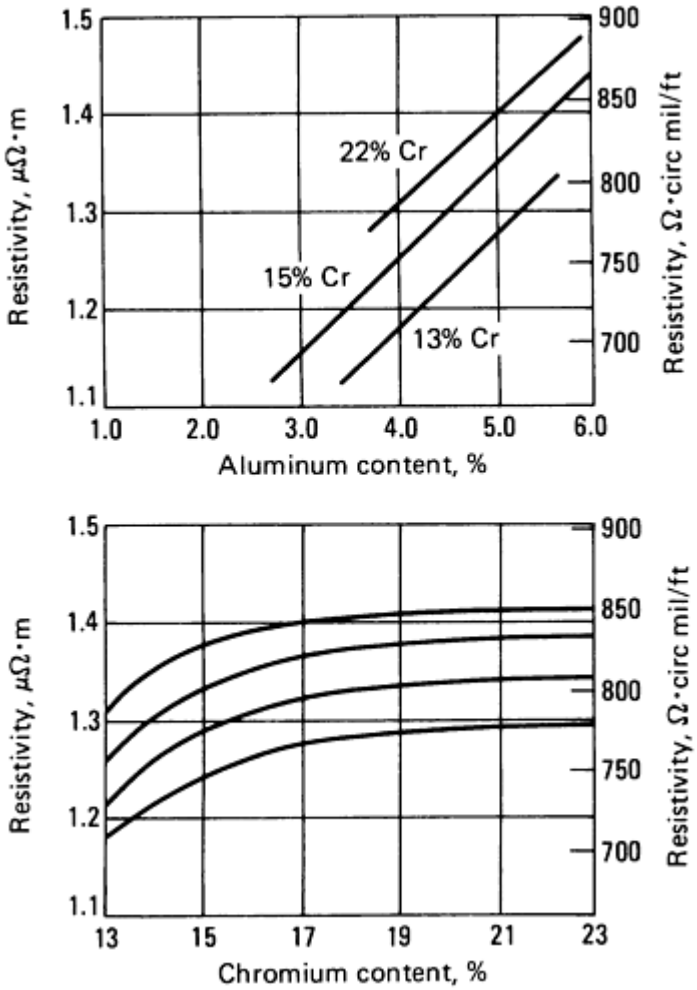

Fig. 6 Effects of aluminum and chromium on resistivity of Fe-Cr-Al heating alloys

These alloys have excellent resistance to oxidation at elevated temperatures because reaction with atmospheric oxygen forms a protective layer of relatively pure alumina. At about 1200 °C (2200 °F), this oxide consists of nearly pure Al_2O_3. This gray-white protective skin has extremely high dielectric strength. The electrical resistivity of aluminum oxide is 10^{12} Ω· m at room temperature, and at about 1100 °C (2000 °F) it is still 10^4 Ω· m. Under normal operating conditions, deterioration of the oxide surface layer, and the resulting aluminum depletion, are fairly slow provided that there is no contact with certain refractories at temperatures above 980 °C (1800 °F). The time required for a 10% change in resistance varies from 75 to 100% of heater life (time to burnout), depending on the particular melt, the size of the heater, and the operating temperature.

Tensile strength of Fe-Cr-Al alloys is relatively low, as shown in Table 7. Because of this low strength, the weight of the lower terminal in straight-wire testing causes the wire to stretch; consequently, life test on Fe-Cr-Al alloys are conducted

using U-shape specimens. Life of heaters made from Fe-Cr-Al alloys is also influenced by the fact that these alloys exhibit large increases in resistance with time as a result of their grain-growth characteristics.

Table 7 Elevated-temperature tensile strength of selected resistance heating materials

Heating material	Tensile strength at:							
	425 °C (800 °F)		650 °C (1200 °F)		870 °C (1600 °F)		1100 °C (2000 °F)

Iron-chromium-aluminum alloys undergo a metallurgical change that causes brittleness after cyclic exposure to high temperatures. As a result, when heaters made of these alloys fail, repair is more difficult than with nickel-chromium alloys. However, new Fe-Cr-Al material has been developed that overcomes several of the disadvantages of the traditional Fe-Cr-Al materials. This new Fe-Cr-Al material is produced with powder metallurgical techniques and results in an alloy that has higher hot strength, as well as having a hot resistance change with time, no worse than nickel-chromium.

Figure 7 presents data on life of 74.5Fe-20Cr-5Al-0.5Co wire 0.40 and 0.29 mm (0.0159 and 0.0113 in.) in diameter at a series of temperatures. With Fe-Cr-Al alloys, as with Ni-Cr alloys, life of a heater of given size decreases as temperature increases.

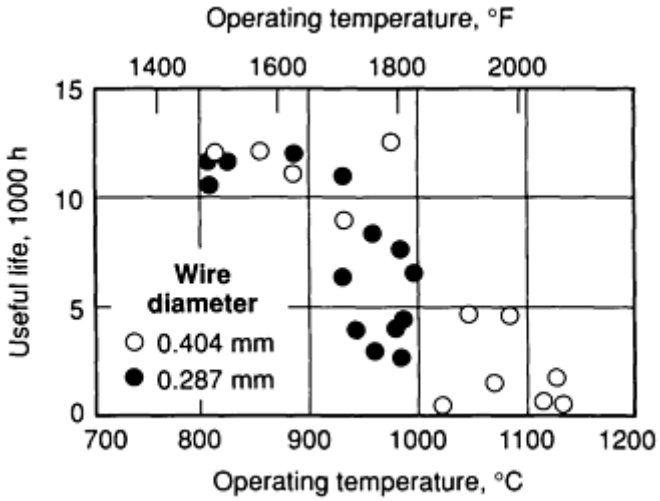

Fig. 7 Total life versus temperature for two sizes of 74.5Fe-20Cr-5Al-0.5Co wire. The alloy included 0.5% Co, which served as a means of identification years ago by one manufacturer.

Pure metals used as heating alloys (see Table 5) have very low resistivities and very high-temperature coefficients of resistance. The tensile strengths of molybdenum and tungsten are quite high, even at elevated temperatures, and that of tantalum is medium (see Table 7). Above 800 °C (1500 °F), all three of these refractory metals are substantially stronger than Ni-Cr, Ni-Cr-Fe, and Fe-Cr-Al alloys at any given temperature.

Platinum can be used for temperatures up to 1500 °C (2750 °F) because it has excellent resistance to oxidation in air. Molybdenum, tantalum, and tungsten must be kept below 400, 500, and 300 °C (750, 930, and 570 °F), respectively, because they are subject to catastrophic oxidation in air at moderate and elevated temperatures.

Nonmetallic Materials. Of the nonmetallic heating materials, graphite and silicon carbide are much higher in resistivity than wrought metallic heating materials. The temperature coefficient of resistance of these materials is negative. Molybdenum disilicide elements have relatively low resistivity at room temperature and a very high positive temperature coefficient of resistance.

All of these materials have low tensile strengths. However, because the resistivity of silicon carbide is so high, silicon carbide elements are made in large cross sections in order to reduce resistance to reasonable values, and as a result these elements can withstand relatively high mechanical loads. Graphite has poor oxidation resistance and should not be used above 400 °C (750 °F). Silicon carbide, however, has excellent oxidation resistance and can be used at temperatures up to 1600 or 1650 °C (2900 or 3000 °F).

Two materials composed of about 90% molybdenum disilicide and 10% refractory oxides have been produced. One has a maximum operating temperature of 1700 °C (3100 °F), while the other serves at temperatures up to 1800 °C (3270 °F).

Pure molybdenum disilicide is too brittle for practical use as an electric heating element. Addition of metallic and ceramic binding agents reduces this brittleness to a practical level. Sintering in the presence of a liquid phase then produces a material that is essentially free of porosity. The high resistance to thermal shock of $MoSi_2$ has enabled $MoSi_2$ elements to undergo, without damage, a test in which they were cycled from room temperature to 1650 °C (3000 °F) through 20,000 cycles.

The excellent high-temperature performance of molybdenum disilicide elements is brought about by the chemical reaction that takes place on the element surface.

Above 980 °C (1800 °F), the material reacts with oxygen to form a silicon dioxide (quartz glass) coating, which protects the base material against chemical attack including further oxidation. This film is "self-healing:" surface cracks developed by mechanical damage are covered by a new coating of quartz glass when the element is again heated above 980 °C (1800 °F) in air.

Design of Open Resistance Heaters

Regardless of which heating alloy is selected, design of the heating element is important. One of the most important rules is to allow for unhindered expansion and contraction so as to avoid concentration of stresses as the temperature changes.

For service at lower temperatures, particularly from 400 to 600 °C (750 to 1100 °F), formed heating elements are used in ovens. In this construction, a heater support is made of two high-alloy rods spaced approximately 300 mm (12 in.) apart in a frame made of angle sections. The rods, whose length is determined by rated electrical input, contain spool insulators around which is wound a ribbon element made of a heating alloy. In a similar alternative construction, the ribbon element is replaced by a continuous helical coil of 5-gage or smaller wire.

Ribbon sizes for oven heaters range from 0.09 to 0.20 mm (0.0035 to 0.008 in.) thick, and from 9.5 to 16 mm ($\frac{3}{8}$ to $\frac{5}{8}$ in.) wide. Oven heaters are rated to give maximum output at a watt density of approximately 8 kW/m^2 (5 W/in.^{2}). (Watt density is obtained by dividing total power input to the elements by total surface area of the heater.) For 120- or 240-V oven heaters operating under normal conditions, expected life of Ni-Cr elements in air is three to five years (depending on temperature, atmosphere, and cyclic conditions).

For furnace temperatures up to 1175 °C (2150 °F), sinuous loop elements generally are formed from ribbon having a width-to-thickness ratio of about 12 to 1 and dimensions varying from 0.76 to 3.2 mm (0.030 to 0.125 in.) in thickness and from 13 to 38 mm ($\frac{1}{2}$ to 1 $\frac{1}{2}$ in.) in width. The dimensions for various temperature ranges are listed in Table 8. Round rods of resistance material also may be formed into elements. Rod-type elements have been used by several furnace manufacturers.

Table 8 Typical length and spacing of loops in Ni-Cr, Ni-Cr-Fe, and Fe-Cr-Al heating elements

760-1100	1400-2000	40 min	1.5 min	55 min	2.25 min	450	18

(a) Loop spacing is the lineal distance between centers for two adjacent bends on the same side of the element.

(b) Loop length is the overall lineal distance from one side of the element to the other. For elements over 300 mm (12 in.) in loop length, the loops must be separated or supported by additional insulators. Two end supports or one hanger and a bottom guide separator are sufficient for elements under 300 mm (12 in.) in length.

Dimensional relationships of loops are important in achieving the desired combination of uniform furnace temperature and long heater life. Recommended loop dimensions for various locations within a furnace are shown in Table 8 for several different ranges of operating temperature. Ribbon size and watt density are correlated with operating temperature in Table 9. When designed in accordance with these recommendations, Ni-Cr elements have life expectancies of up to seven years at temperatures of 540 to 925 °C (1000 to 1700 °F), two to five years at 980 to 1100 °C (1800 to 2000 °F), and one to two years at 1100 to 1175 °C (2000 to 2150 °F).

Table 9 Typical ribbon size and electrical capacity of Ni-Cr, Fe-Cr-Al, and Ni-Cr-Fe heating elements

Maximum operating temperature		**Size of ribbon**				**Power density**	
		Min thickness		**Width**			
°C	**°F**	**mm**	**in.**	**mm**	**in.**	**kW/m^2**	**W/in.^{2}**

925-1100	1700-2000	2.3	0.090	20-40	$\frac{3}{4}$ -1 $\frac{1}{2}$	15.5	10

Iron-chromium-aluminum heating elements used for temperatures up to 1300 °C (2350 °F) also may be made from ribbon. However, Fe-Cr-Al ribbon must be formed into short, sinuous loops having a loop spacing of 50 mm (2 in.) or

less, and requires better loop support than Ni-Cr ribbon. In the design of heating elements, for maximum life the designer should consider factors such as the lowest practical voltage, maximum cross-sectional area, and lowest watt density consistent with design and reasonable cost.

Refractory Supports. Ceramic refractories that come in contact with heating elements may influence selection of heating alloys. Below 1000 °C (1825 °F), protective oxides that form on the surfaces of Ni-Cr, Ni-Cr-Fe, and Fe-Cr-Al alloys do not react with ceramic oxides, including refractory grades of SiO_2, Al_2O_3, CaO, Na_2O, MgO, K_2O, and ZrO_2. Above 1000 °C, pure MgO, Al_2O_3, and ZrO_2 are recommended. Many ordinary refractory-grade materials become conductive at such temperatures; the sodium and potassium contents of the refractory material should be low to prevent this. Sulfur-containing refractories should not be used with Ni-Cr, Ni-Cr-Fe, or Fe-Cr-Al alloys. Refractories also must be as low as possible in ferric oxide, if they are to be used with Fe-Cr-Al resistance elements.

Use of molybdenum, tungsten, or platinum heating elements at temperatures above 1200 °C (2200 °F) necessitates use of pure oxide refractories. High-purity alumina (99%) and magnesia are the most satisfactory. Zirconia becomes conductive above 1300 °C (2350 °F); silica decomposes and embrittles platinum at about 1200 °C (2200 °F). Consequently, neither zirconia nor silica can be used at or above these temperatures.

In cyclic temperature applications, some alloys elongate continuously and at the same time continuously decrease in cross-sectional area. Iron-chromium-aluminum alloys do this even in the absence of applied external force. A popular but unproved explanation of this growth is as follows: first, the alloy oxidizes at elevated temperature; on cooling, the high compressive strength of the oxide layer forces the weaker core to elongate; on reheating, the oxide is weak in tension so that it cracks, and reoxidation takes place; thus growth continues in a cyclic manner. Growth is detrimental because it causes large changes in resistance, so suitable steps must be taken in the design of high-temperature elements to minimize cyclic growth.

Iron-chromium-aluminum heating alloys must be adequately supported for use at temperatures near 1300 °C (2350 °F).

Nickel-chromium alloys, which exhibit little or no growth, do not require special support at their maximum operating temperatures, which are 200 °C (360 °F) lower than those of Fe-Cr-Al alloys (1400 °C versus 1200 °C). Although all electrical heating alloys have low tensile properties at high temperatures, Ni-Cr and Ni-Cr-Fe alloys have higher strength at elevated temperature than do Fe-Cr-Al alloys. For example, 80Ni-20Cr tested at 1100 °C (2000 °F), and a strain rate of 3.3 mm/m · s (0.2 in./in. · min) exhibited yield and tensile strengths of 41 and 48 MPa (6 and 7 ksi), respectively. An Fe-Cr-Al alloy tested under identical conditions exhibited values of only 12 and 16 MPa (1.8 and 2.3 ksi). The new P/M Fe-Cr-Al alloy has values of about 20 MPa (2.9 ksi).

One way of establishing allowable stresses in heating elements is to define allowable stress as the load that will produce 0.1% creep in 1000 h or 1% creep in 10,000 h. For 80Ni-20Cr, this load is 1.4 MPa (200 psi) at 1100 °C (2000 °F). For the P/M formed Fe-Cr-Al product, the load is 0.8 MPa (116 psi) at 1100 °C (2000 °F).

Fabrication of Open Resistance Heaters

Annealed wire, rod, or ribbon of any common nickel-chromium heating alloy can be bent at room temperature around a mandrel whose diameter equals the diameter or thickness of the stock. Some difficulty has been experienced in making such bends in 80Ni-20Cr alloys, because these alloys tend to strain age during forming if they have been heated in the range 100 to 200 °C (200 to 400 °F) between forming stages.

Iron-chromium-aluminum alloys are harder at room temperature, and somewhat more difficult to form, than Ni-Cr alloys. They can be shaped into heating elements by techniques must like those used for making elements from Ni-Cr alloys, but heavy-gage material may require preheating to 150 °C (300 °F) to facilitate forming of sharp radii.

Joining. Nickel-chromium and nickel-chromium-iron alloys are readily joined by welding. Preferred processes include resistance welding, gas-shielded metal-arc welding, and oxyfuel gas welding. Filler metal of essentially the same composition as the base alloy should be used. These alloys can be brazed, but heating elements are seldom joined in this way because brazing introduces a zone whose melting temperature is lower than that of the base metal.

Iron-chromium-aluminum alloys are weldable, but they should be welded as quickly as possible to prevent grain growth. Postheating, which sometimes is done for stress relief, must be done at a temperature low enough to prevent grain growth. A temperature range of 700 to 800 °C (1290 to 1470 °F) is recommended.

Sheathed Heaters

Nickel-chromium (80Ni-20Cr), nickel-chromium-iron (60Ni-16Cr-22.5Fe-1.5Si), and iron-chromium-aluminum alloys are extensively used as heating elements in sheathed heaters, where compacted granular magnesium oxides provides electrical insulation between a wire element and a metallic sheath. This construction permits operation at high watt density without rapid degradation. Various grades of magnesium oxide are available for use at different temperature levels.

Insulation resistance and heater life are affected by factors such as chemical and physical characteristics of the insulation, operating temperature, and atmospheric conditions within the heater sheath. In a sheathed heater helix, strain aging can lead to nonuniform stretching during forming of the helix, which in turn can lead to hot spots in service. Penetration of oxidation products into the insulating layer of magnesium oxide may occur, causing a reduction in insulation resistance with prolonged cyclic testing or use. This can result in excessive electrical leakage to the metal sheath and failure. In the preparation of element wire and fabrication of heaters, care must be taken to ensure uniformity of cross section and to avoid surface damage that could shorten service life.

In the design of sheathed heaters, it must be recognized that the operating temperature of the internal heating element is considerably higher than that of the external sheath. Selection of heater material is based on expected operating temperature and environment. Electrical-grade, fused magnesium oxide is used as insulation in most sheathed heaters. The MgO is approximately 94% pure; however, higher purity can be obtained if required. The melting point of MgO is approximately 2750 °C (5000 °F), which is far above the melting point of metal resistor alloys or sheath materials. Electrical insulating properties of MgO decrease with increase in temperature. Consideration must be given to the dielectric strength of MgO at operating temperature when designing metal-sheathed heaters. Iron-chromium-aluminum alloys should only be used either when the tube temperature is below 700 °C (1290 °F), or when the wire temperature is below 850 °C (1560 °F).

Service Life of Heating Elements

Maximum service temperature is one the most important factors governing service life of heating elements. Whether the temperature is constant or intermittent also has a marked effect. Data from accelerated laboratory testing (Fig. 8) illustrate the effects of temperature on 80Ni-20Cr heating elements. The graph shows a rapid decrease in element life as temperature increases above 1120 °C (2050 °F).

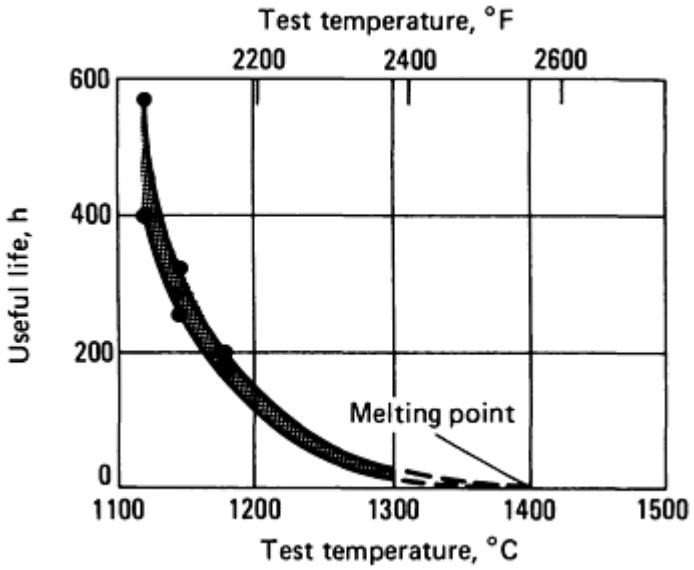

Fig. 8 Variation in useful life with temperature in cyclic testing of 80Ni-20Cr heating elements. Life is defined as time to burnout or to 10% change in electrical resistance, whichever occurs first. Tests were conducted in accordance with ASTM B 76; specimens were at temperature for 2 min out of every 4-min cycle.

The life of a heating element is dependent upon many factors. These include method of melting, composition, environment, and other design parameters. Manufacturers of heating elements use an ASTM life test to control their product. Even under simplified and closely controlled test conditions, there is still a variation in element life, as shown by the data in Fig. 9 for 56 identical specimens of 80Ni-20Cr tested at 1175 °C (2150 °F) in air. In actual service, the construction of a resistor, environment, and the operation per se can vary so greatly that direct correlation with the ASTM life test is not possible. Thus, manufacturers of wire and ribbon use the ASTM test as an internal control test, whereas manufacturers of devices or appliances use test appropriate to the unit being evaluated.

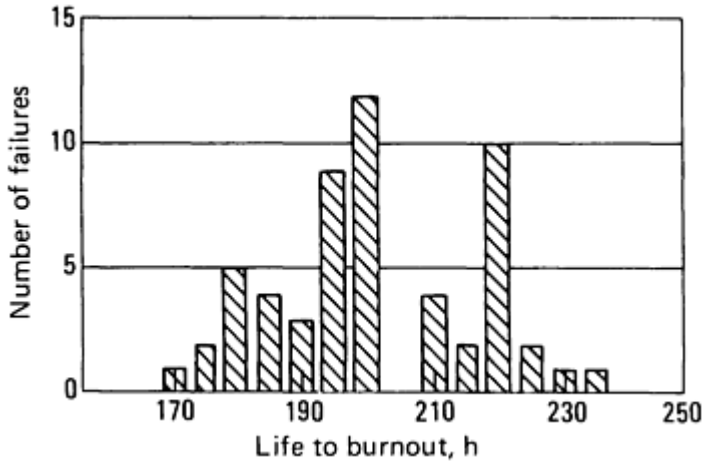

Fig. 9 Distribution of life to burnout in 56 identical tests of 80Ni-20Cr elements at 1175 °C (2150 °F)

The life of a heating element increases with ribbon thickness or wire diameter, as shown in Fig. 10. In some applications, heaters may be required to operate for 10 to 15 years without element failure. Predictions, based on data from accelerated life test, that elements will achieve such extended service lives are not reliable. Often, maximum heater temperatures must be lowered considerably from those normally given in data sheets, in order to ensure exceptionally long element life.

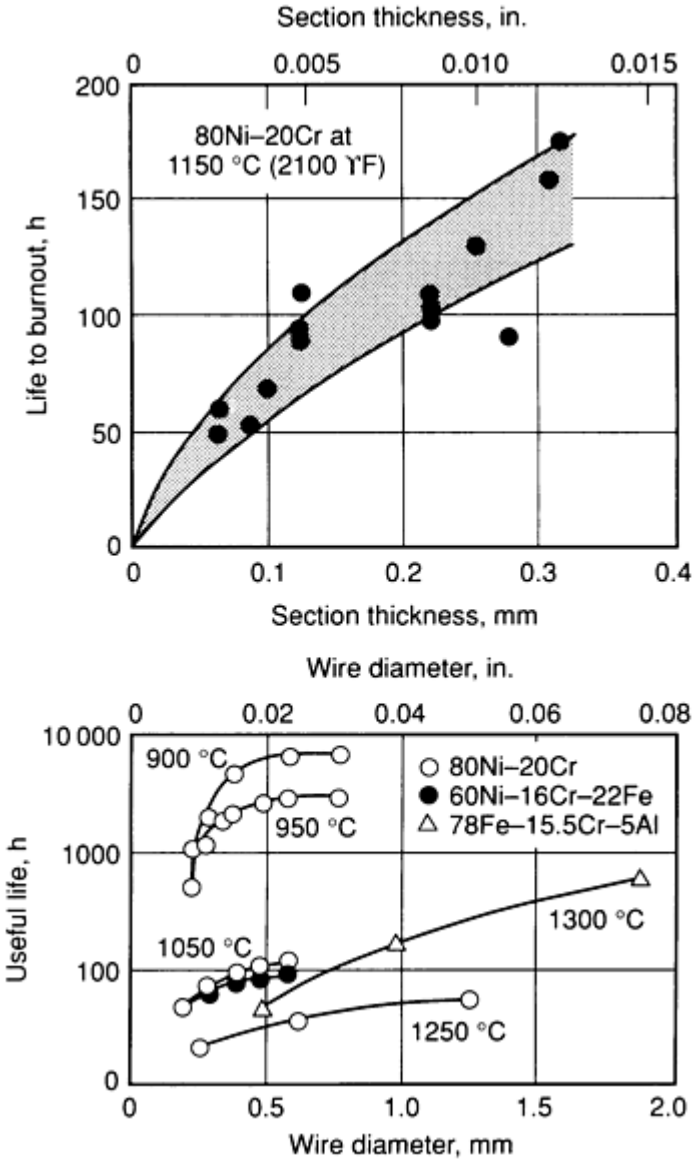

Fig. 10 Variation of heater life with section thickness or wire diameter. Life is defined as time to burnout or to 10% change in resistance, whichever occurs first.

Oxidation resistance of alloys used for heating elements is critical. In addition to the inherent oxidation resistance necessary for any alloy used at elevated temperatures, heating alloys also must have adherent oxides that resist spalling during temperature cycling. Because elements are heated electrically to attain temperature, oxidation and spalling in a localized area result in a local increase in resistance with consequent increase in local temperature, which creates a hot spot and shortens the life of the element. Because localized oxidation or spalling increases total resistance only slightly, the current through elements remains essentially constant, and I^2R heating causes an increase in temperature only in the region of increased resistance.

The effect of composition on the life of heating-element alloys is evaluated by both static and cyclic testing. In static testing, the element is heated to an elevated temperature and held for a prescribed time, and the weight gain or loss due to oxidation is measured. In cyclic testing, the elements is alternately:

- Heated to an elevated temperature and held for a prescribed time
- Cooled to ambient temperature and held for an equal time

The weight loss in percent, or total testing time in hours (total life), is used as a measure of the quality of the alloy. Either low weight loss or long life is desired. For heating elements used with a fixed voltage, life is defined as the time in hours to burnout or to a 10% increase in total resistance, whichever occurs first. Any increase in total resistance results in a decrease in power and consequently a decrease in temperature.

Figure 11(a) compares two alloys that were continuously oxidized in air at 1175 °C (2150 °F). Cylindrically coiled strips 0.13 by 9.5 by 250 mm (0.005 by 0.375 by 10 in.) were used. Oxidation was evaluated by determining the thickness of the oxide layer. Figure 11(b) presents test results for the same two alloys oxidized under similar conditions, except that heating was intermittent.

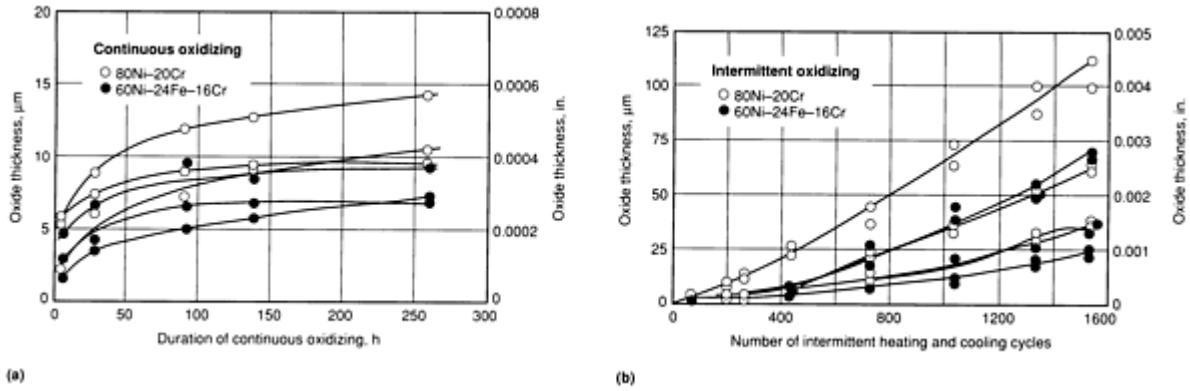

Fig. 11 Typical rates of oxidation at 1175 °C (2150 °F) for two common heating alloys. In both continuous tests (a) and intermittent tests (b), cylindrically coiled strips 0.13 by 9.5 by 250 mm (0.005 by $\frac{3}{8}$ by 10 in.) were heated in air. In the intermittent oxidizing tests, power was cycled 7.5 min on and 7.5 min off.

Chemical composition of heating-element alloys in the first two groups in Table 5 is carefully controlled to achieve resistance to intermittent oxidation in oxidizing environments. Figure 12 presents data on weight loss of Ni-Cr-Fe alloys as nickel-plus-chromium content is increased from just over 20% almost 100%. In practice, nickel-plus-chromium content is maintained above 50% to inhibit the oxidation and spalling that lead to large weight changes in high-iron compositions. Figure 13 shows the weight gain in Ni-Cr alloys after continuous oxidation for 100 h at 1100 °C (2000 °F). Increasing the chromium content of Ni-Cr alloys causes a substantial decrease in oxidation rate. Minimum weight gain is obtained at about 30% Cr.

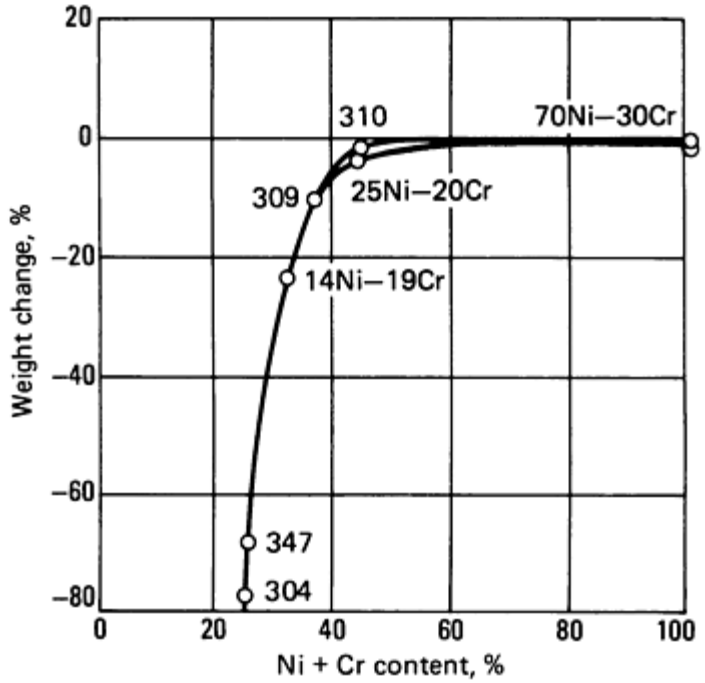

Fig. 12 Intermittent oxidation of Ni-Cr, Ni-Cr-Fe, and stainless-steel heating elements in air. Weight change was determined after 400 h in a cyclic test at 980 °C (1800 °F) where the power was cycled 15 min on and 15 min off.

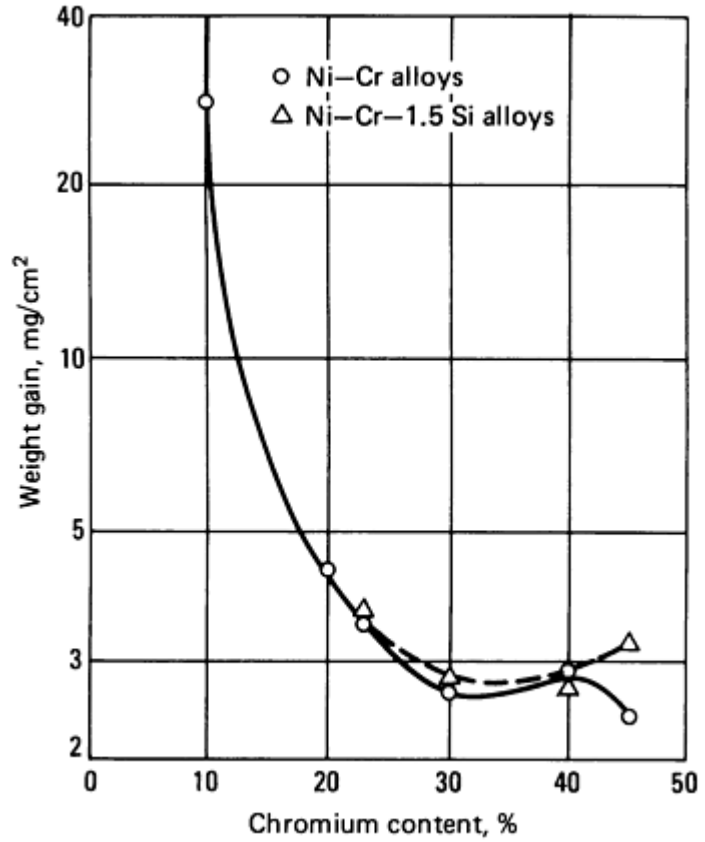

Fig. 13 Continuous oxidation of Ni-Cr heating alloys held 100 h at 1100 °C (2000 °F)

Minor chemical constituents are important in governing life at elevated temperatures. Close control of minor elements, especially silicon, has substantially increased life of Ni-Cr heating alloys. An example of the effect of silicon on the life of 80 Ni-20Cr alloys is shown in Fig. 14.

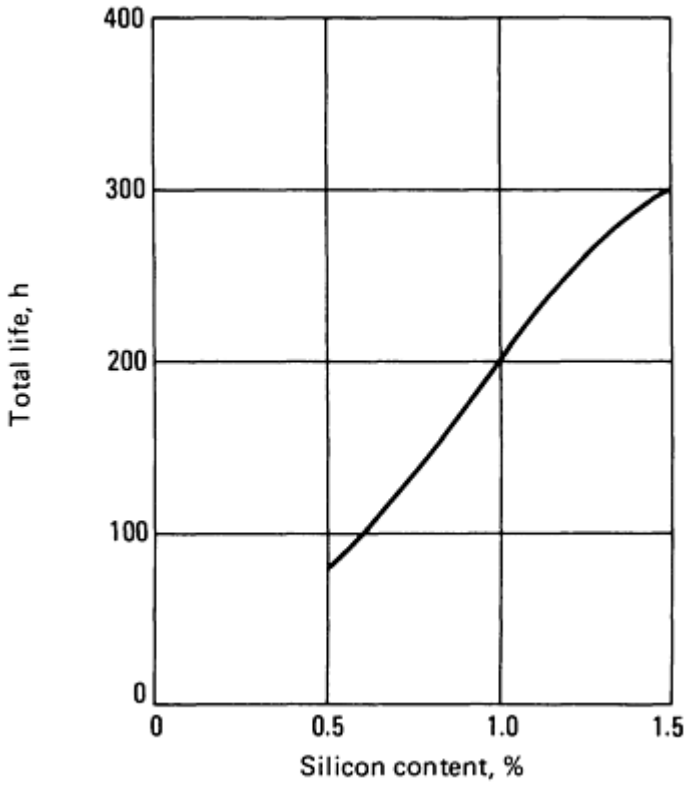

Fig. 14 Total life versus silicon content for 80Ni-20Cr alloys. Total life was determined for 0.64 mm (0.025 in.) diam wire in intermittent tests in air at 1175 °C (2150 °F).

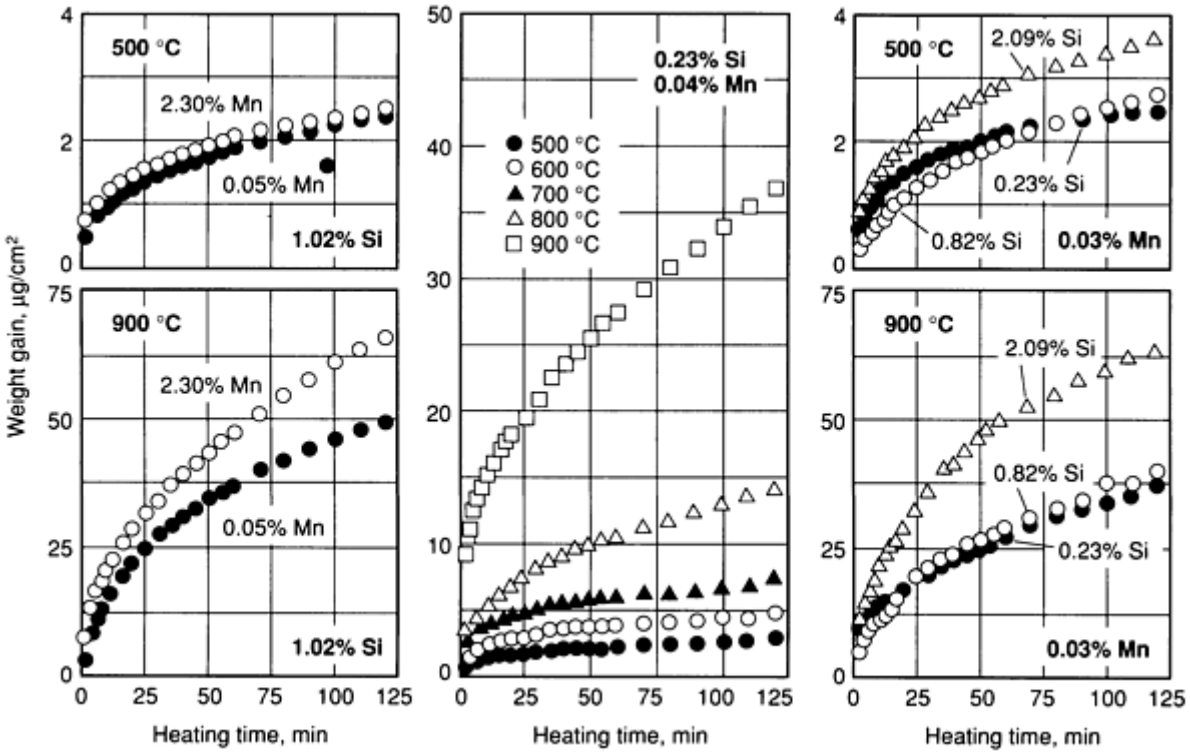
The five graphs in Fig. 15 show the effects of manganese and silicon contents on rate of oxidation of 80Ni-20Cr alloys under the conditions of time and temperature indicated. Specimens for these tests were first polished with emery papers through No. 0000. They were tested in oxygen at a pressure of 10 kPa (76 mm Hg), which constitutes accelerated testing. Such tests performed under controlled conditions give some useful information, but they cannot necessarily be correlated with element life for any specific application. Element life is related to oxide stability and adherence under actual conditions of use; life is affected by furnace atmosphere, temperature cycling, and contact with other materials (such as refractories).



Mn	Si	Cr	Ni	Fe	Al	C	Useful life, h
2.30	1.02	20.00	bal	0.25	0.13	0.06	105
0.05	1.02	20.00	bal	0.25	0.15	0.06	106
0.04	0.23	20.00	bal	0.25	0.20	0.06	63
0.03	2.09	20.00	bal	0.25	0.17	0.06	124
0.03	0.82	20.00	bal	0.25	0.15	0.06	178

Fig. 15 Effects of silicon and manganese contents on continuous oxidation of 80Ni-20Cr alloys. Alloys can be identified in the table and in the graphs, by manganese and silicon contents. Specimens were first polished with emery papers through No. 0000 and then tested in pure oxygen at 10 kPa(0.1 atm, technical), which constitutes accelerated testing.

Addition of 1% Nb to 80Ni-20Cr increases resistance to preferential oxidation of chromium, commonly called "green rot." Green rot occurs when Ni-Cr alloys are exposed to environments with low partial pressures of oxygen at temperatures from 870 to 1040 °C (1600 to 1900 °F); maximum oxidation rate occurs at 955 °C (1750 °F). Green rot is most common in 90Ni-10Cr alloys used in thermocouples. However, it can occur in 80Ni-20Cr alloys exposed for long periods of time. Although green rot in 70Ni-30Cr alloys is theoretically possible, it has not occurred during testing in which such alloys have been exposed for over fifteen years.

Addition of niobium to a 35Ni-20Cr-45Fe alloy stabilizes the carbon by forming niobium carbides. If carbon is tied up in this manner, heating elements remain ductile when stressed during service.

Atmospheres

Based on element temperature, Table 10 rates serviceabilities of various heating-element materials as good, fair, or not recommended for the temperatures and atmospheres indicated. Element temperatures are always higher than furnace control temperatures; the difference depends on watt-density loading on the element surface. Thus, when furnaces are operated near maximum element temperature in the more active atmospheres, watt-density loading should be lower and element cross-sectional area should be higher.

Table 10 Comparative life of heating-element materials in various furnace atmospheres

Note: Inert atmosphere of argon or helium can be used with all materials. Nitrogen is recommended only for the nickel-chromium group. Temperatures listed are element temperatures, not furnace temperatures.

(a) Special 80Ni-20Cr elements with ceramic protective coatings designated for low voltage (8 to 16 V) can be used.

(b) Must be oxidized first.

(c) Special molybdenum heating elements with $MoSi_2$ coating can be used in oxidizing atmospheres.

(d) Good with pure H_2 only

With the exception of molybdenum, tantalum, tungsten, and graphite, commonly used resistor materials have satisfactory life in air and in most other oxidizing atmospheres.

Oxidizing Atmospheres. Nickel-chromium and nickel-chromium-iron alloys are the most widely used heating materials in electric heat-treating furnaces. The 80Ni-20Cr alloys are more commonly used than the 60Ni-16Cr-20Fe or the 35Ni-20Cr-45Fe types. In fact, most electric-furnace manufacturers provide 80Ni-20Cr elements as standard, both because they permit a wider range of furnace temperatures and because it is usually more economical to stock only a limited number of heater materials. The 80Ni-20Cr alloys permit a wider range of operating temperatures because they have the greatest resistance to oxidation, and therefore can be used at higher temperatures than other Ni-Cr and Ni-Cr-Fe alloys. Heating elements of lower nickel content are required for certain special applications, such as where an oxidizing atmosphere contaminated with sulfur, lead, or zinc is present.

The iron-chromium-aluminum alloys are widely used in furnaces operating at 800 to 1300 °C (1500 to 2350 °F). In general, Ni-Cr heating elements are unsuitable above 1150 °C (2100 °F) because the oxidation rate in air is too great and the operating temperature is too close to the melting point of the alloy, although some Ni-Cr elements have been used at elements temperatures up to 1200 °C (2200 °F). The Fe-Cr-Al elements historically have been recommended for operation in air. Recent use in many reducing atmospheres indicates that the performance of Fe-Cr-Al elements is comparable to Ni-Cr resistance elements in most environments. In addition, Fe-Cr-Al elements can generally be used at higher temperatures than Ni-Cr elements

For temperatures above 1300 °C (2350 °F), silicon carbide or molybdenum disilicide elements are employed in industrial furnaces. Here again, maximum life of heating elements is obtained in air. These nonmetallic materials give fair service life in slightly reducing atmospheres at temperatures up to 1300 °C (2350 °F) for SiC and 1500 °C (2750 °F) for $MoSi_2$. They can be used in both oxidizing and slightly reducing atmospheres more commonly than Fe-Cr-Al elements, which are recommended only for service in air or inert atmospheres.

Platinum has been used in some small laboratory furnaces up to 1480 °C (2700 °F) in air. Because of the high cost of platinum, it is used only in special applications where silicon carbide cannot worked into the furnace design. Platinum is restricted to service in air and cannot be used in reducing atmospheres. Although the initial cost of platinum is high, it has a high salvage value.

Elements made of 90% molybdenum disilicide and 10% refractory oxide mixtures perform well at continuous temperatures of 1700 and 1800 °C (3100 and 3270 °F) (depending on type) in air and in other oxidizing or inert atmospheres.

Carburizing Atmospheres. Unpurified exothermic (type 102) and purified exothermic (type 202) atmospheres are less harmful than endothermic (type 301) or charcoal (type 402) atmospheres, which are higher in carbon potential. The higher-carbon-potential atmospheres have a tendency to carburize Ni-Cr alloys, especially at higher temperatures. Chromium is a strong carbide former and may pick up enough carbon to lower the melting point of the alloy, causing localized fusion in the heating element. For this reason, in reducing atmospheres of high-carbon potential, it is safer to limit the operating temperature of 80Ni-20Cr to about 1000 °C (1850 °F).

Unprotected heating elements made of Ni-Cr alloys are not recommended for use at more than 30 volts in enriched endothermic carburizing or carbonitriding (type 309) atmospheres. Short life of heating elements in these types of atmospheres may be caused by carbon deposits on the element or refractory and by carburization of the element alloy. Carbon deposits may also short out extension wires and terminals, and cause them to melt. In recent years, a coated Ni-Cr heating element has been developed for use in carburizing atmospheres; in this element, the alloy is protected with a high-temperature ceramic coating that resists carburization. The element is designed to operate at low voltage (8 to 10 volts) to prevent arcing at the terminals in carbon-impregnated brick-work.

In recent times, when more and more carburizing furnaces are being converted from fossil fuels to electricity, it has been found that molybdenum disilicide can operate safely in both carburizing and reducing atmospheres at element temperatures up to 1500 °C (2700 °F). This makes it possible to eliminate the radiant tubes often used to protect metallic heating elements, thereby greatly increasing the efficiency of these furnaces by allowing faster recovery when a cold charge is placed in the furnace. Radiant tubes form a thermal barrier that slows heat transfer from the heating elements to the charge.

Reducing Atmospheres. In conventional heat-treating terminology, a reducing atmosphere is one that will reduce iron oxide on steel. Reducing atmospheres are of several types, as shown in Table 11.

Table 11 Types and compositions of standard furnace atmospheres

See Table 10 for comparative life of heating elements in these atmospheres.

Type	Description	Composition, vol%					Typical dew point	
		N_2	CO	CO_2	H_2	CH_4	°C	°F
Reducing atmospheres								
102[(a)]	Exothermic unpurified	71.5	10.5	5.0	12.5	0.5	27	80
202	Exothermic purified	75.3	11.0	. . .	13.0	0.5	-40	-40
301	Endothermic	45.1	19.6	0.4	34.6	0.3	10	50
502	Charcoal	64.1	34.7	. . .	1.2	. . .	-29	-20
501	Dissociated ammonia	25	. . .	. . .	75	. . .	-51	-60
Carburizing atmospheres								
307	Endothermic + hydrocarbon	No standard composition					. . .	. . .

(a) This atmosphere, refrigerated to obtain a dew point of 4 °C (40 °F), is widely used.

With the exception of dry hydrogen and dissociated ammonia (type 501), all atmospheres listed as reducing in Table 10 are oxidizing to Ni-Cr and Fe-Cr-Al alloys. Even hydrogen or dissociated ammonia will selectively oxidize chromium in a Ni-Cr alloy unless the gas is extremely dry. The type of oxide produced in "reducing" atmospheres is entirely different from that produced in air. The oxide produced in air is a green-to-black, impervious type that retards further oxidation of the underlying metal. It is usually a combination of Cr_2O_3 and $NiO\text{-}Cr_2O_3$. The oxide produced on Ni-Cr elements in reducing atmospheres is green and porous and allows the atmosphere to internally oxidize the base metal. This type of attack, frequently referred to as green rot, takes place over a limited temperature range--870 to 1040 °C (1600 to 1900 °F)--in any atmosphere that is oxidizing to chromium and reducing to nickel, and occurs as particles or stringers of Cr_2O_3 surrounding metallic nickel.

Among the listed reducing atmospheres, type 501 has the smallest effect on Ni-Cr heating elements. At temperatures above 1100 °C (2000 °F), a Ni-Cr element will have better life in dry hydrogen than in air, because oxidation in air occurs more rapidly at elevated temperatures. Wet hydrogen, on the other hand, will cause preferential oxidation, and, around 950 °C (1750 °F), green rot will occur.

Graphite heating elements have been used for laboratory applications at temperatures near 1370 °C (2500 °F) in atmospheres free from O_2, CO_2, and H_2O. Silicon carbide elements give fair life in some reducing atmospheres; however, the maximum operating temperature is lower than for operation in air.

The poorest life for silicon carbide elements is obtained in hydrogen or dissociated ammonia. All atmospheres, including air, must be relatively dry; wet atmospheres shorten the life of silicon carbide elements. Silicon carbide is not recommended for use in carburizing atmospheres because it absorbs carbon, thus reducing electrical resistance and overloading the power supply.

Molybdenum disilicide heating elements can be safely used in carbon monoxide environments at 1500 °C (2730 °F), in dry hydrogen at 1350 °C (2460 °F), and in moist hydrogen at 1460 °C (2660 °F). As a rule of thumb, any combination of temperature and atmosphere that does not attack silica glass is compatible with molybdenum disilicide.

Atmosphere Contamination. Sulfur, if present, will appear as hydrogen sulfide in reducing atmospheres and as sulfur dioxide in oxidizing atmospheres. Sulfur contamination usually comes from one or more of the following sources: high-sulfur fuel gas used to generate the protective atmosphere; residues of sulfur-base cutting oil on the metal being processed; high-sulfur refractories, clays, or cements used for sealing carburizing boxes; and the metal being processed in the furnace. Sulfur is destructive to Ni-Cr and Ni-Cr-Fe heating elements. Pitting and blistering of the alloy occur in oxidizing atmospheres, and a Ni-S eutectic that melts at 645 °C (1190 °F) may form in any type of atmosphere. The higher the nickel content, the greater the attack. Therefore, if sulfur is present and cannot be eliminated, Fe-Cr-Al elements are preferred over those made of nickel-base alloys.

Lead and zinc contamination of a furnace atmosphere may come from the work being processed. This is a common occurrence in sintering furnaces for processing powder metallurgy parts. In the presence of a reducing atmosphere, lead will vaporize from leaded bronze powders (such as those used to make sintered bronze bushings) and attack the heating elements, forming lead chromate. Metallic lead vapors are even more harmful than sulfur to Ni-Cr alloys, and will cause severe damage to a heating element in a matter of hours if unfavorable conditions of concentration and temperature exist. Higher-nickel alloys are affected more than lower-nickel alloys. Elements made of 35Ni-20Cr-43.5Fe-1.5Si give satisfactory life for sintering lead-bearing bronze powders at 845 °C (1550 °F) in reducing atmospheres; 80Ni-20Cr elements give poor life in this application.

Zinc contamination results from zinc stearate used as a lubricant and binder when P/M compacts are pressed. The zinc stearate volatilizes when the compacts are heated and may carburize the heating element. (Brazing of nickel silvers, which contain at least 18% Zn, also results in a high concentration of zinc vapors in the furnace atmosphere.) Zinc vapors, which alloy with Ni-Cr heating elements and result in poor life, may be eliminated at the higher sintering temperatures by using a separate burn-off furnace at 650 °C (1200 °F), with heating elements protected by full muffle, by sheathing, or by a high-temperature ceramic protective coating. If these precautions are not feasible, silicon carbide elements (which are not affected by sulfur, lead, or zinc contamination) should be used at both low and high temperatures when contamination is anticipated.

The Ni-Cr, Ni-Cr-Fe, Fe-Cr-Al, and molybdenum disilicide heating elements should not be used in the presence of uncombined chlorine or other halogens.

Vacuum Service. For vacuum heating, 80Ni-20Cr elements have been used at temperatures up to 1150 °C (2100 °F). The 80Ni-20Cr alloys generally are not satisfactory much above 1150 °C (2100 °F), because the vapor pressure of chromium is high enough for chromium to vaporize from the elements, resulting in poor life, contamination of the material being processed, and loss of vacuum. Because of this, watt density must be kept low, especially at higher temperatures.

In vacuum heating, the estimated maximum operating temperature at which weight loss by evaporation from refractory-metal heating elements will not exceed 1% in 100 h is:

Metal	Temperature

	°C	°F
Tungsten	2550	4620
Tantalum	2400	4350
Molybdenum	1900	3470
Platinum	1600	2910

Molybdenum disilicide heating elements are not suitable for use in high vacuum.

Properties of Electrical Resistance Alloys

80Ni-20Cr

Commercial Name

Common name. 80-20 alloy

UNS designation. NO6003

Specifications

ASTM. B 344 and B 267

DIN. 17470 (Material number 2.4869)

Chemical Composition

Composition limits. 19 to 21 Cr, 1 Fe max, 1.0 Mn max, 0.15 C max, 0.75 to 1.75 Si, 0.01 S max, bal Ni

Applications

Typical uses. Electric heating elements for household appliances, industrial process heating, and industrial furnaces; fine-wire resistors for electronic applications

Precautions in use. Avoid sulfur-bearing and reducing atmospheres at high temperatures and furnace cements containing phosphoric acid or with high sulfur content.

Mechanical Properties

Tensile properties. Annealed: tensile strength, 790 MPa (115 ksi); elongation, 25 to 35% in 50 mm or 2 in.; reduction in area, 55%. Hard: tensile strength, 1380 MPa (200 ksi); elongation, 0 to 1% in 50 mm or 2 in.; reduction in area, 0 to 1%. See also Table 12.

Table 12 Variation of tensile properties of 80Ni-20Cr wire with temperature

Annealed wire 0.72 mm (0.0285 in.) in diameter

Temperature		Tensile strength		Elongation, %
°C	°F	MPa	ksi	
20	68	860	125	30
425	800	725	105	22

650	1200	620	90	20
870	1600	205	30	17
1040	1900	97	14	15

Hardness. Annealed: 85 to 90 HRB. Hard: 100 to 105 HRB

Elastic modulus. Tension, 215 GPa (31×10^6 psi)

Structure

Crystal structure. fcc

Mass Characteristics

Density. 8.4 g/cm^3 (0.30 lb/in.^{3}) at room temperature

Thermal Properties

Liquidus temperature. 1390 °C (2530 °F)

Coefficient of linear thermal expansion. 17.3 μm/m · K (9.6 μin./in. · °F) at 20 to 1000 °C (68 to 1830 °F)

Specific heat. 450 J/kg · K (0.107 Btu/lb · °F) at room temperature

Thermal conductivity. 13.4 W/m · K (7.7 Btu/ft · h · °F) at 100 °C (212 °F)

Electrical Properties

Electrical conductivity. Volumetric, 1.6% IACS at 25 °C (77 °F)

Electrical resistivity. 1.080 Ω· mm^2/m (650 Ω· circular mil/ft) at 20 °C (68 °F); temperature coefficient, 80 μΩ/Ω · K at -65 to 150 °C (-85 to 300 °F). See also Fig. 16.

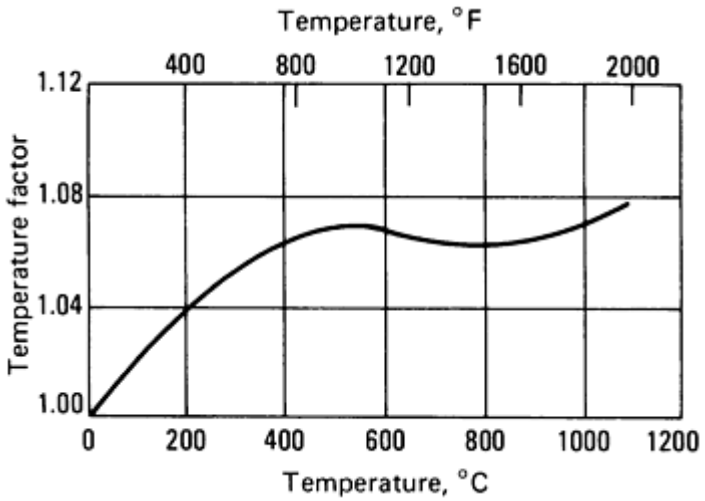

Fig. 16 Electrical resistance versus temperature for 80Ni-20Cr. To find resistance at any given temperature, multiply resistance at room temperature by the temperature factor.

Chemical Properties

General corrosion behavior. Highly resistant to oxidizing atmospheres up to 1200 °C (2200 °F). It is subject to corrosion in sulfur-bearing atmospheres at elevated temperatures and in certain reducing atmospheres at around 925 °C (1700 °F).

Fabrication Characteristics

Weldability. Can be soldered, brazed, or welded using oxyfuel-gas, carbon-arc, or resistance methods

Heat treatment. Annealing only

Annealing temperature. 870 to 1040 °C (1600 to 1900 °F)

Reduction between anneals. 65%

Hot-working temperature. 1205 °C (2200 °F)

70Ni-30Cr

Commercial Name

Common name. 70-30 NiCr

UNS designation. N06008

Specification

DIN. 17470 (Material number 2.4658)

Chemical Composition

Composition limits. 29 to 31 Cr, 1 Fe max, 1.0 Mn max, 0.15 C max, 0.75 to 1.75 Si, 0.01 S max, bal Ni

Applications

Typical uses. Elements for industrial furnaces. Particularly good in reducing atmospheres. Not subject to "green rot"

Precautions in use. Avoid sulfur-bearing atmospheres and using furnace cements containing phosphoric acid or with high sulfur contents. Do not use in pure N_2.

Tensile properties. Annealed: tensile strength, 825 MPa (120 ksi); elongation, 36 to 40% in 50 mm or 2 in.; reduction in area, 50%; Hard: tensile strength, 1380 MPa (200 ksi); elongation, 0 to 1% in 50 mm or 2 in.

Structure

Crystal structure. fcc

Mass Characteristics

Density. 8.11 g/cm^3 (0.29 lb/in.^{3}) at room temperature

Thermal Properties

Liquidus temperature. 1365 °C (2490 °F)

Coefficient of linear thermal expansion. 17 μm/mm · K (9.4 μin./in. · °F) at 20 to 1000 °C (68 to 1830 °F)

Specific heat. 460 J/kg · K (0.110 Btu/lb · °F) at room temperature

Thermal conductivity. 13.7 W/m · K (7.9 Btu/ft · h · °F) at 100 °C (212 °F)

Electrical properties

Electrical conductivity. Volumetric, 1.5% IACS at 25 °C (77 °F)

Electrical resistivity. 1.18 Ω· mm^2/m (710 Ω· circular mil/ft) at 25 °C (77 °F); temperature coefficient, 90 μΩ/Ω · K at 20 to 100 °C (68 to 212 °F)

Chemical Properties

General corrosion behavior. Highly resistant to oxidizing atmospheres up to 1260 °C (2300 °F). Not subject to preferential oxidation ("green rot") in reducing atmospheres. It is subject to corrosion in sulfur-bearing atmospheres at elevated temperatures.

Fabrication Characteristics

Weldability. Can be soldered, brazed, or welded using oxyfuel-gas, carbon arc, or resistance methods

Heat treatment. Annealing only. Annealing temperature 870 to 1120 °C (1600 to 2050 °F)

Reduction between anneals. 60%

60Ni-22Fe-16Cr

Commercial Name

Common name. 60Ni-16Cr alloy

UNS designation. N06004

Specifications

ASTM. B 344 and B 267

DIN. 17470 (Material number 2.4867)

Chemical Composition

Composition limits. 57 Ni min + Co, 14 to 18 Cr, 1.0 Mn max, 0.75 to 1.75 Si, 0.15 C max, 0.01 S max, bal Fe

Applications

Typical uses. Heat-resisting elements for heating devices such as toasters, percolators, waffle irons, flat irons, ironing machines, heater pads, hair driers, permanent wave equipment, and hot water heaters. Electrical usage in high-resistance rheostats for electronic equipment, oxidized wire with high-resistance coating for close-wound rheostats, potentiometers, and thermocouples. Corrosion-resisting usage in dipping baskets for acid pickling and cyanide hardening, automatic pickling machine parts, filters, enameling racks, containers for molten salts

Mechanical Properties

Tensile properties. Sand cast: tensile strength, 450 MPa (65 ksi); elongation, 2% in 50 mm or 2 in.; reduction in area, 2%. Annealed: tensile strength, 690 MPa (100 ksi); elongation, 30% in 50 mm or 2 in.; reduction in area, 47%. Hard: tensile strength, 1345 MPa (195 ksi); elongation, 0 to 2% in 50 mm (2 in.). See also Table 13.

Table 13 Nominal tensile properties of 60Ni-22Fe-16Cr at elevated temperatures

Temperature		Cast material			Wrought material		
		Tensile strength		Elongation, %	Tensile strength		Elongation, %
°C	°F	MPa	ksi		MPa	ksi	
20	68	450	65	2.0	725	105	30
540	1000	325	47	2.1	365	53	12
650	1200	295	43	2.3	260	38	13
760	1400	255	37	2.5	200	29	23

Hardness. Sand cast: 92 HRB. Annealed: 83 HRB

Structure

Microstructure. fcc

Metallography. Rough polish with emery paper through 000; use levigated alumina on polishing cloth to finish. Etching for grain size: Marble's reagent preferably or aqua regia (3 HCl, 1 HNO_3); sometimes less HCl is used and sometimes it is diluted to 50% with water, depending on the worked or annealed condition of the alloy. Use aqua regia for microstructure. Upon completion of polishing, this alloy often exhibits a cold-worked film obscuring the true structure, and hence must be repolished on the last stage and re-etched. This is common to other stainless austenitic materials. Usual method of reporting grain size--grains per sq mm

Mass Characteristics

Density. 8.25 g/cm_3 (0.298 lb/$in._3$) at 20 °C (68 °F)

Patternmaker's shrinkage. 2.0%

Thermal Properties

Liquidus temperature. 1375 °C (2510 °F)

Coefficient of linear thermal expansion. 17.0 μm/m · K (9.4 μin./in. · °F) at 20 to 1000 °C (68 to 1830 °F)

Specific heat. 450 J/kg · K (0.107 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 13.4 W/m · K (7.7 Btu/ft · h · °F) at 100 °C (212 °F)

Electrical Properties

Electrical conductivity. Volumetric, 1.5% IACS at 25 °C (77 °F)

Electrical resistivity. 1.125 Ω· mm^2/m (675 Ω· circular mil/ft) at 25 °C (77 °F); temperature coefficient, 150 μΩ/Ω · K at 20 to 100 °C (68 to 212 °F). See also Fig. 17.

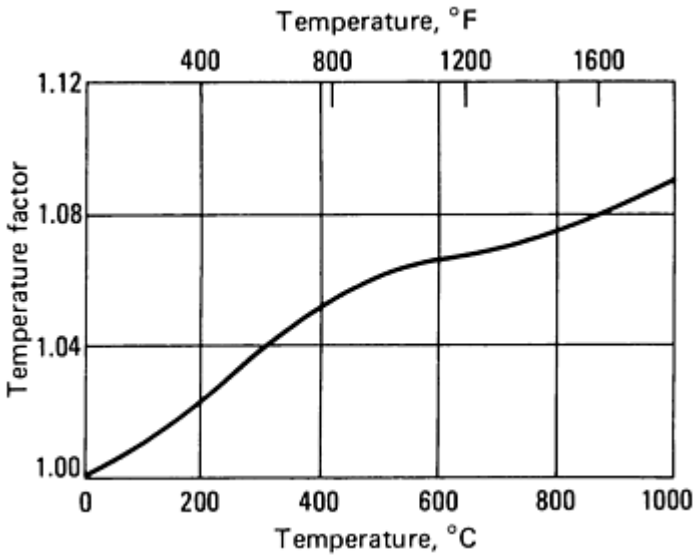

Fig. 17 Electrical resistance versus temperature for 60Ni-22Fe-16Cr. To find resistance at any given temperature, multiply resistance at room temperature by the temperature factor.

Chemical Properties

Corrosion testing. Strauss test, using changes in both weight and electrical resistance as criteria for evaluation

Resistance to specific corroding agents:

Corrosive agent	Resistance
Acid, acetic	Resistant

Acid, hydrochloric	Moderate general attack
Acid, lactic	Resistant
Acid, nitric	Resistant
Acid, phosphoric	Moderate general attack when hot
Acid, sulfuric	Resistant
Air	Resistant
Alcohol, ethyl	Resistant
Alcohol, methyl	Resistant
Ammonia	Resistant
Ammonium nitrate	Resistant
Carbon dioxide	Resistant
Carbon tetrachloride	Resistant
Copper sulfate	Moderate intergranular attack
Foodstuffs	Resistant
Fruit products	Resistant
Hydrogen sulfide	Severe general attack when hot
Lead and its compounds	Severe attack when hot
Milk	Resistant
Mineral oils	Resistant
Motor fuel	Resistant
Oxygen	Resistant

Petroleum products	Resistant when cold
Photographic solutions	Resistant
Potassium hydroxide	Resistant
Potassium nitrate	Resistant
Sodium carbonate	Resistant
Sodium hydroxide	Resistant
Sodium nitrate	Resistant
Sugar	Resistant
Sulfur	Severe general attack when hot
Sulfur dioxide	Severe general attack when hot
Water, distilled	Resistant
Water, rain	Resistant

Fabrication Characteristics

Formability. Suited to forming by hot and cold rolling, forging, drawing, pressing, and bending

Weldability. Soft solder with 50Pb-50Sn, using HCl plus Zn flux. Silver braze (silver solder) with low-melting-point filler metals, using borax flux and a neutral flame. Braze with low-brass filler metal, using borax flux. Oxyfuel-gas weld with 60Ni-24Fe-16Cr filler metal, using no flux and a neutral or carburizing flame

Casting temperature. Sand and ingot. 1510 to 1540 °C (2750 to 2800 °F)

Annealing temperature. 760 to 1090 °C (1400 to 2000 °F)

Reduction between anneals. 75% max in area

Standard finishes. Castings are sandblasted, forgings pickled, and wrought mill products given various finishes.

37Ni-21Cr-2Si-40Fe

Commercial Name

Common name. 37-21 alloy

Chemical Composition

37 Ni, 20-21 Cr, 1.0 Mn max, 2.0 Si, bal Fe

Application

Typical uses. This alloy has a lower resistivity than 60Ni-16Cr at room temperature, but it has a higher temperature coefficient. It finds use as heating elements in appliances.

Mechanical Properties

Tensile properties. Annealed: tensile strength, 585 MPa (85 ksi); elongation, 25 to 35% in 50 mm or 2 in.; Hard: tensile strength, 1135 MPa (165 ksi); elongation, 0 to 1% in 50 mm or 2 in.

Structure

Microstructure. fcc

Metallography. Same as 60Ni-22Fe-16Cr

Mass Characteristics

Density. 7.95 g/cm^3 (0.29 lb/in.^{3}) at room temperature

Thermal Properties

Liquidus temperature. 1380 °C (2515 °F)

Coefficient of linear thermal expansion. 19.0 μm/m · K (10.6 μin./in. · °F) at 20 1000 °C (68 to ±830 °F)

Specific heat. 460 J/kg · K (0.110 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 13.0 W/m · K (7.5 Btu/ft · h · °F) at 100 °C (212 °F)

Electrical Properties

Electrical conductivity. Volumetric, 1.6% IACS at 25 °C (77 °F)

Electrical resistivity. 1.08 Ω· mm^2/m (650 Ω· circular mil/ft) at 25 °C (77 °F); temperature coefficient, 240 μΩ/Ω · K at -65 to 150 °C (-85 to 300 °F)

Chemical Properties

Corrosion testing. Same as 60Ni-22Fe-16Cr

Fabrication Characteristics

Formability. Suited to forming by hot and cold rolling, forging, drawing, pressing, and bending

Weldability. Soft solder, silver braze, and braze with same methods as 60Ni-24Fe-15Cr alloy; Oxyfuel-gas weld with 37Ni-42Fe-21Cr filler metal, using no flux and a neutral or carburizing flame

Casting temperature. 1525 to 1550 °C (2775 to 2825 °F)

Annealing temperature. 760 to 1175 °C (1400 to 2150 °F)

Reduction between anneals. 75% max

Hot-working temperature. 980 to 1260 °C (1800 to 2300 °F)

Standard finishes. See 60Ni-22Fe-16Cr.

35Ni-43Fe-20Cr

Commercial Name

Common name. 35Ni-20Cr alloy

Specifications

ASTM. B 344

Chemical Composition

Composition limits. 34 to 37 Ni, 18 to 21 Cr, 1.0 Mn max, 0.25 C max, 3.0 Si max, 0.03 S max, bal Fe

Applications

Typical uses. Although 35Ni-43Fe-20Cr has lower electrical resistivity than 60Ni-22Fe-16Cr near room temperature, it has a higher temperature coefficient. It is normally used at temperatures up to 815 °C (1500 °F) for heavy-duty rheostats, low-priced electrical appliances, and resistors operating in cracked gas atmospheres. It is not subject to "green rot" and is used as heating elements in industrial electric furnaces operating below 1040 °C (1900 °F).

Mechanical Properties

Tensile properties. Sand cast: tensile strength, 425 MPa (62 ksi); elongation, 2% in 50 mm or 2 in.; reduction in area, 2%. Annealed: tensile strength, 585 MPa (85 ksi); elongation, 30% in 50 mm or 2 in.; reduction in area, 45%. Hard: tensile strength. 1205 MPa (175 ksi); elongation, 1 to 2% in 50 mm (2 in.). See also Table 14.

Electrical Properties

Electrical conductivity. Volumetric, 1.7% IACS at 25 °C (77 °F)

Electrical resistivity. 1.0 Ω· mm^2/m (610 Ω· circular mil/ft) at 25 °C (77 °F); temperature coefficient, 310 μΩ/Ω · K at 20 to 500 °C (68 to 930 °F). See also Fig. 18.

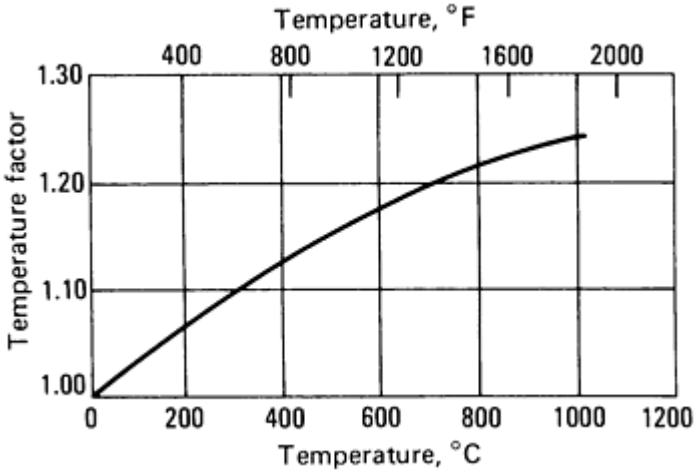

Fig. 18 Electrical resistance versus temperature for 35Ni-43Fe-20Cr. To find resistance at any given temperature, multiply resistance at room temperature by the temperature factor.

Chemical Properties

Corrosion testing. Same as 60Ni-22Fe-16Cr

Fabrication Characteristics

Formability. Suited to forming by hot and cold rolling, forging, drawing, pressing, and bending

Weldability. Soft solder, silver braze, and braze with the same methods as for 60Ni-22Fe-16Cr alloy. Oxyfuel-gas weld with 35Ni-43Fe-20Cr filler metal, using no flux, and a neutral or carburizing flame

Casting temperature. 1525 to 1550 °C (2775 to 2825 °F)

Annealing temperature. 760 to 1090 °C (1400 to 2000 °F)

Reduction between anneals. 75% max

Hot-working temperature. 980 to 1260 °C (1800 to 2300 °F)

Standard finishes. See 60Ni-22Fe-16Cr.

Constantan
45Ni-55Cu

Chemical Composition

Composition limits. Variable; several specific compositions--all having an approximate nominal composition of 42 to 45 Ni, bal Cu--are commonly supplied. Composition limits of both major and minor constituents are varied to suit the specific application.

Applications

Typical uses. This alloy has about the highest electrical resistivity, the lowest temperature coefficient of resistance, and the highest thermal emf against platinum of any of the copper-nickel alloys. Because of the first two of these properties, it is used for electrical resistors, and because of the latter property, for thermocouples.

Precautions in use. Maximum temperature for resistor use is 500 °C (930 °F); maximum temperature for thermocouple use is 900 °C (1650 °F).

Mechanical Properties

Tensile properties. Wrought: tensile strength, annealed, 415 MPa (60 ksi); cold worked, 930 MPa (135 ksi). Cast: tensile strength, 380 MPa (55 ksi); yield strength, 145 MPa (21 ksi); elongation, 32% in 50 mm or 2 in.; reduction in area, 4%

Shear strength. 295 MPa (43 ksi)

Hardness. 75 to 85 HRB, 48 to 54 HRB

Impact resistance. Charpy: 41 J (30 ft · lbf)

Mass Characteristics

Density. Wrought: 8.9 g/cm^3 (0.32 lb/in.^{3}) at 20 °C (68 °F). Cast: 8.6 g/cm^3 (0.31 lb/in.^{3})

Patternmaker's shrinkage. 2.1%

Thermal Properties

Liquidus temperature. 1280 °C (2330 °F)

Solidus temperature. 1220 °C (2225 °F)

Coefficient of linear thermal expansion. 14.9 μm/m · K (8.3 μin./in. · °F) at 20 to 100 °C (68 to 212 °F); 16.3 μm/m · K (9.0 μin./in. · °F) at 20 to 500 °C (68 to 930 °F); 18.8 μm/m · K (10.4 μin./in. · °F) at 20 to 1000 °C (68 to 1830 °F)

Specific heat. 395 J/kg · K (0.094 Btu/lb · °F) at 20 °C (68 °F)

Thermal conductivity. 21 W/m · K (12.3 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical resistivity. 0.5 to 0.525 Ω· mm^2/m (300 to 315 Ω· circular mil/ft) at 20 °C (68 °F); temperature coefficient, ±20 μΩ/Ω · K at 25 to 150 °C (77 to 300 °F). The coefficient may be either positive or negative, depending on small variations in composition and on variations in the amount of cold work. In any event, the value of the coefficient is small.

Thermoelectric potential. The basic alloy is modified by additions of manganese and iron to give slightly different emf characteristics in thermocouple service, as specified by different pyrometer manufacturers. For more detailed information on this subject, see the article in this Volume entitled "Thermocouple Materials."

Fabrication Characteristics

Formability. Suited to forming by hot and cold rolling, forging, drawing, pressing, and bending

Weldability. Can be welded, brazed, and soldered by conventional methods

Casting temperature. Minimum: 1350 °C (2460 °F)

Annealing temperature. 870 to 980 °F (1600 to 1800 °F)

Reduction between anneals. 80% max

Hot-working temperature. 870 to 1120 °C (1600 to 2050 °F)

22Cr-5.3Al-Fe Balance

Chemical Composition

Typical 22Cr-5.3Al-balance Fe. Nominal aluminum content will vary from 4.5 to 5.8%. Values given below for 5.3% Al

Applications

Typical uses. Electric resistance heating elements in industrial and laboratory furnaces as well as in household appliances

Precautions in use. Keep the material as clean as possible prior to the first firing, which forms the protective oxide. Choose suitable support materials for use at the highest temperatures.

Mechanical Properties

Tensile properties. Annealed: tensile strength, 690 MPa (100 ksi); elongation, 15 to 25% in 50 mm or 2 in.; Hard: tensile strength, 1035 MPa (150 ksi); elongation, 0 to 1%

Curie point. 600 °C (1100 °F)

Mass Characteristics

Density. 7.15 g/cm^3 (0.259 lb/in.^{3}) at room temperature

Thermal Properties

Liquidus temperature. 1500 °C (2730 °F)

Coefficient of linear thermal expansion. 15 μm/m · K (8.3 μin./in. · °F)

Specific heat. 460 J/kg · K (0.11 Btu/lb · °F) at room temperature

Thermal conductivity. 16 W/m · K (9.25 Btu/ft · h · °F) at 20 °C (68 °F)

Electrical Properties

Electrical resistivity. 1.39 μΩ· m (835 Ω· circular mil/ft) at 20 °C (68 °F)

Chemical Properties

General corrosion behavior. Highly resistant to oxidizing atmospheres up to 1400 °C (2550 °F). Affinity for oxygen and subsequent oxide formation is so great that only a small partial pressure of oxygen is necessary for oxide to form. Pre-oxidation of element can assist in obtaining maximum life of the heating element. Does not react as severely as nickel to sulfur attack. Oxide can provide sufficient dielectric for use of close-wound coils in small appliances.

Fabrication Characteristics

Weldability. Can be welded using resistance welding. TIG or carbon arc recommended for larger elements

Heat treatment. Annealing only

Annealing temperature. 850 °C (1560 °F)

Minimum reduction between annealing. 35%

Molybdenum Disilicide $MoSi_2$, $MoSi_2$ + 10% Ceramic Additives

Chemical Composition

Composition limits. 90% $MoSi_2$, 10% metal and ceramic additives

Applications

Typical uses. Electric resistance heating elements in industrial and laboratory furnaces. Normally supplied in hairpin shape consisting of terminals twice the diameter of the hot zone. Most common hot zone diameters are 3, 6, and 9 mm (0.12, 0.24, 0.35 in.). Will operate in oxidizing atmospheres at temperatures of 1700 °C (3100 °F) for $MoSi_2$, and 1800 °C (3275 °F) for $MoSi_2$ + 10% ceramic additives. Also usable at lower temperatures in reducing atmospheres. For maximum recommended service temperatures, see Table 15.

Table 15 Maximum service temperatures for $MoSi_2$ heating elements

Atmosphere	Temperature	
	°C	°F
Air	1700[(a)]	3100[(a)]
Nitrogen	1590	2900
Argon, helium	1450	2640
Dry hydrogen	1350	2460
Moist hydrogen[(b)]	1460	2660
Carbon dioxide	1590	2900
Carbon monoxide	1450	2730

Sulfur dioxide	1590	2900
Cracked, partly burnt ammonia[c]	1400	2550
Methane	1350	2460

(a) For "1700 °C" material; for "1800 °C" material, maximum service temperature is 1800 °C (3270 °F).

(b) Dew point 15 °C (60 °F).

(c) Approximately 8% H_2

Precautions in use. Avoid elemental chlorine, other halogens, and high vacuum environments.

Mechanical Properties

Tensile strength. 195 MPa (28 ksi) at room temperature

Compressive strength. 2350 MPa (340 ksi) at room temperature

Hardness. Knoop: 1280 at 20 °C (68 °F), decreasing to 640 at 700 °C (1290 °F)

Elastic modulus. Tension, 410 GPa (59×10^6 psi) at room temperature

Bending strength. 345 MPa (50 ksi) at 20 °C (68 °F), 135 MPa (19 ksi) at 1100 °C (2010 °F)

Structure

Crystal structure. Pure $MoSi_2$: body-centered tetragonal

Mass Characteristics

Density. 5.6 g/cm^3 (0.202 lb/in.^{3}) at room temperature

Thermal Properties

Incipient melting temperature. 2050 °C (3720 °F). Decomposes before melting at approximately 1740 °C (3165 °F) for $MoSi_2$, and 1825 °C (3315 °F) for $MoSi_2$ + 10% ceramic additives

Coefficient of linear thermal expansion. 7.1 to 8.8 μm/m · K (3.9 to 4.9 μin./in. · °F) at 20 to 1500 °C (68 to 2730 °F)

Specific heat. 420 J/kg · K (0.10 Btu/lb · °F) at 20 °C (68 °F)

Electrical Properties

Electrical resistivity. For $MoSi_2$ + 10% ceramics:

Temperature		1700 °C material μΩ· m	1800 °C material μΩ· m
°C	°F		
20	68	465	440
1370	2500	4800	4570

1650	3000	6060	5750

Thermoelectric potential. In microvolts versus Pt: 5.13 T, + 1.88 × 10^{-2} T^2 - 5.22 × 10^{-6} T^3

Temperature of superconductivity. 1.3 K

Emissivity. 0.34 at 370 °C, 0.60 at 1370 °C, 0.75 to 0.80 at 1500 °C in air due to formation of SiO_2 coating

Chemical Properties

General corrosion behavior. In normal use, material has a SiO_2 glass coating, and any combination of temperature and atmosphere that is harmful to quartz glass will deteriorate the elements.

Fabrication Characteristics

Sintering temperature. 1620 °C (2950 °F)

Hot-working temperature. $MoSi_2$, 1450 to 1700 °C (2640 to 3090 °F); $MoSi_2$ + 10% additives, 1500 to 1800 °C (2730 to 3270 °F)

Electrical Contact Materials

Revised by Yuan-Shou Shen, Engelhard Corporation; Pat Lattari and Jeffrey Gardner, Texas Instruments, Inc.; Harold Wiegard, J.M. Ney Company

---

Introduction

ELECTRICAL CONTACTS are metal devices that make and break electrical circuits. Contacts are made of either elemental metals, composites, or alloys that are made by the melt-cast method or manufactured by powder metallurgy (P/M) processes. Powder metallurgy facilitates combinations of metals which ordinarily cannot be achieved by alloying.

A majority of contact applications in the electrical industry utilize silver-type contacts, which include the pure metal, alloys, and powder metal combinations. Silver, which has the highest electrical and thermal conductivity of all metals, is also used as a plated, brazed, or mechanically bonded overlay on other contact materials--notably, copper and copper-base materials. Other types of contacts used include the platinum group metals, tungsten, molybdenum, copper, copper alloys, and mercury. Aluminum is generally a poor contact material because it oxidizes readily, but is used in some contact applications because of its good electrical and mechanical properties and its availability and cost.

Acknowledgements

The editors would like to express their thanks to Hendrick Slaats of Engelhard Corporation and Ernest M. Jost of Chemet Corporation for their helpful suggestions during the review of this article.

Selection Criteria

Electrical contact materials are used in diverse service conditions, and no metal has all the desired properties required to accomplish the objectives of different contact applications. The usefulness of an electrical contact material also depends on a variety of electrical and mechanical properties, service life, load conditions, and economics. The choice of contact materials in particular applications is discussed in the section "Recommended Contact Materials" in this article.

The desirable properties of electrical contact materials include such characteristics as high electrical conductivity to minimize the heat generated during passage of current; high thermal conductivity to dissipate both the resistive and arc heat developed; high resistance to chemical reactions in all application environments so as to avoid formation of insulating oxides, sulfides, and other compounds; and immunity to arcing damage on the making and breaking of electrical contact. The melting point of electrical contact materials should also be high enough to limit arc erosion, metal transfer, and welding or sticking, but low enough to increase resistance to reignition in switching. (When the melting point is high, contacts continue to heat gas in the contact gap after the current drops to zero, thus facilitating reignition). Other important characteristics of electrical contact materials include:

- Vapor pressure should be low to minimize arc erosion and metal transfer
- Hardness should be high to provide good wear resistance, yet ductility should also be high enough to ensure ease of fabrication
- Purity of the material should be maintainable at a level that ensures consistent performance. Finally, the material should be available at low cost and should not present an environmental hazard in use or in the necessary fabrication process

Circuit Characteristics. Proper choice of electrical contact materials depends on whether the current is alternating or direct, whether the circuit voltage or amperage is high or low, and whether the voltage at contacts during interruption of the circuit is high or low. Whether the load is inductive, capacitive or resistive, or is a motor load, is also important. Allowance should be made for overload, where such a condition can be expected, and attention should be given to the method or arc suppression. Consideration must also be given to potential hazards during service life of the electrical contact. For example, failure of a railroad signal to open might cause a fatal accident, although failure to close would only be troublesome. For such applications, carbon-to-metal contacts are employed because they cannot become welded together, even under the most adverse conditions.

Mechanical Factors. A basic factor in the selection of a contact material is the force required to close a contact of a given material. For example, platinum, palladium, and gold are used where reliable closure with low force is required.

Other mechanical factors affecting the contact force or the selection of a contact material include:

- The nature of the contact force
- The frequency of operation
- The speed of opening and closing of the contact
- The manner in which the contact is made (wipe, slice, or butt)
- The degree of chatter on opening or closing
- The size of contact gap when the contact is fully opened
- The method of operation--whether by cam, simple lever or push button, electromagnet, or bimetal thermostatic control

Environmental factors influencing selection of a contact material are type of atmosphere, ambient temperature, and whether contacts are exposed to ambient atmosphere or enclosed in a hermetically sealed, artificial environment such as might be specified for use in outer space. Atmospheric pressure and minor contaminants that are present affect contact life and, in some instances, may cause a sharp decrease in service life. Gases may cause tarnishing, as does the presence of humidity, airborne salts, dust, and organic vapors.

Service Life. The required service life for contacts varies according to the application. This may range from a few operations, on missiles and detection systems, to 100 million cycles in automotive vibrators or 40 years in telephone relays. Likewise, the dormant time between successive openings or closings may vary widely--from milliseconds or microseconds in vibrators to months or years in alarms and similar safety devices.

Failure Modes of Make-Break Contacts

In an electric make-break switching device, there are two different types of contacts: arcing contacts and sliding contacts. The arcing contact points, which usually consist of a pair of thin shaped slabs, perform the actual duty of making, carrying, and breaking the current. Arcing contacts differ from sliding contacts in that the moving member of the switching device travels perpendicular to the contact surfaces. As a result, arcs generated during opening and closing actions always strike and consequently damage the conducting surfaces.

Arcing, except in a circuit with an extremely low potential or low current, is a major factor--if not the main factor--causing failure of contact points.

When a pair of contacts opens in a live circuit, an arc is often generated between the contact pair, which remains until they are separated by a certain gap. Relatively less severe arcing occurs when the contacts close. Arcing also occurs when the moving contact bounces away from the stationary contact during closing. The arc causes contact erosion by blowing

away the molten metal droplets, vaporizing the material, and transforming the metal to ion jets. Sometimes the material vaporizes from one contact and then condenses onto the other contact, thereby altering the surface configuration of both contacts. This is known as material transfer.

Welding. When a pair of contacts close, the arcs generated during closing and bouncing of a moving contact melt a small portion of both contacts. On reclosure, solidification of the molten material welds the contact pair in the same manner as fusion welding.

Another type of welding occurs after the contacts are made. To make a pair of contacts more conductive, a mechanical load is always applied on the contact pairs. Theoretically, the load could make two rigid contact surfaces touch at no more than three points. However, the touching points at both surfaces yield either elastically or plastically, resulting in larger areas of contact. These constricted regions carry the current through the contacts and form regions of high current density. Heat is generated in these areas and, if the temperature becomes high enough, the two contact points eventually are welded together.

Occasionally, the strength of the weld exceeds the opening force of the switching device, resulting in catastrophic failure of the entire electrical system because the contacts fail to open on command.

Bridge Formation. When a pair of contacts opens, the contact area gradually decreases because of the gradual lessening of contact pressure. The continuous opening action causes the contact areas to reach a stage at which the current density of the constricted areas is so great that it melts the material in these regions. Continuous separation of the contact points now pulls the molten metal, forming a current-carrying bridge. The temperature of the molten bridge continues to rise as the contact points pull apart. It may become high enough to evaporate the material and finally break the circuit. This "bridge" phenomenon during the opening of a pair of contacts slightly damages the surfaces of the contacts and evaporates some of the bridge material. This generally results in pitting of one contact surface and buildup of material on the other; an uneven continuous transfer may eventually erode one of the contacts. Furthermore, the surface asperities from the continuous bridge formation may interlock the contact pair and interfere with their mechanical separation.

Oxidation of the contact surfaces, which may be accelerated by the heat from arcing, is a serious problem because most metallic oxide films are nonconductive or semiconductive. The oxide film may easily increase contact resistance. In high-current circuits, this may cause excessive contact heating. In low-voltage and low-current circuits, the oxide films can grow so thick that they completely insulate the contact surfaces before the contact bodies erode. This happens more frequently when a pair of contacts operates in a hostile environment such as a polluted industrial atmosphere. Condensed organic polymers also play a role in precious metal contacts at light loads. These polymers come from monomers which evaporate from resins and are polymerized on the active catalytic metal surfaces of contacts.

Property Requirements for Make-Break Arcing Contacts

The four failure modes discussed above determine the requirements of materials for arcing contacts. The most important requirements are listed below. In selecting a material, it is often necessary to reach a compromise that provides adequate properties without jeopardizing essential qualities of the component as a whole, such as reliability, life, and cost.

- *Electrical conductivity:* Because the conduction of electricity between the pair of contacts depends on only a few constricted spots, the higher the electrical conductivity, the less the amount of heat that will be generated by high current density in these spots
- *Thermal properties:* High melting and boiling points decrease evaporation loss caused by high arcing heat. High thermal conductivity disperses the heat rapidly and quenches the arc
- *Chemical properties:* Contact materials should be corrosion resistant so that insulating films (either oxides or other compounds) do not form easily when the contacts operate in a hostile environment
- *Mechanical properties:* The major loads applied to a contact pair are the closing force and the impact between movable and stationary contact points during closing. An induced relative movement between two contact surfaces always exists when closing. In some devices, such as certain types of relays, a wiping motion is purposely designed into the device to destroy any oxide films that form. However, friction between wiping surfaces produces wear of the contacts upon repeated opening and closing. Generally, hard materials are more resistant to wear. However, hard materials often have high contact resistances and low thermal conductivities, both of which contribute to a greater tendency to contact welding. Hard materials also have high tensile strengths, which may or may not be advantageous in

electrical contact applications

- *Fabrication properties:* Contact materials should have the capability of being welded, brazed, or otherwise joined to backing materials. In addition, they should have sufficient malleability to enable them to be shaped, or they should be capable of being formed by P/M techniques

None of the elementary metallic elements used for arcing contacts meets all of the criteria for an ideal contact material. For instance, silver has the best electric and thermal conductivity and good oxidation resistance, but its resistance to arcing and mechanical wear is low. Tungsten resists arcing and withstands mechanical wear, but it has poor conductivity and poor oxidation resistance. Properties of a contact material can usually be improved by combining metals, either by alloying or by powder metallurgy, but improvement often is achieved at the expense of other properties. For example, the alloying element that increases the hardness of silver also decreases its conductivity.

Sliding Contacts

The applications of sliding contacts are usually quite different from those of arcing contacts. Friction, contact temperature, mechanical considerations, and wear also are different.

The fundamental difference between arcing contacts and sliding contacts is that sliding contacts require films on the contact faces to facilitate sliding without seizure or galling; shear must take place within this film with only minor disturbance of both materials. A lubricant of some kind is always necessary. This can be provided by graphite if there is moisture present--such as in an environment having a dew point of about -20 °C (-4 °F) or higher. Alternatively, lubrication can be provided by very thin oil films, although excessive oil vapor causes over-filming. It can also be provided by molybdenum disulfide, and other chalcogenides of molybdenum, tungsten, and niobium. Oxgyen, sulfur, and other contaminants cause increased filming.

In applications in air, a drop in voltage can result from an equilibrium between oxidation and filming (which tend to increase the drop) and fretting or film breakdown and cleaning action (which tend to decrease the drop). In the absence of lubricants, fretting and oxidation are most important. In inert or reducing gases, oxidation is largely eliminated, and the voltage drop decreases until counteracted by mechanical factors. Noble metals that are properly lubricated also minimize voltage drops in air.

Brush contacts generally contain an appreciable amount of metal if they are intended for use in low-voltage (<24 V) applications. Large quantities of brush contacts are used in automotive and related industries as starter brushes and auxiliary motor brushes; copper-graphite is the principal material. Silver-graphite brushes are used primarily in instruments and in outer space applications. Some silver-graphite brushes are used in seam welders and similar equipment.

Oxidation of sliding contacts is similar to that of arcing contacts, except that the surface disturbed by friction oxidizes more rapidly. In most applications in air, the metal surface generates a film that is a complex mixture of graphite, oxide, sulfide, and water, which tends to decrease the conducting area.

The surfaces generated on metal-graphite brushes as they wear are effective cleaning agents in that they abrade films and keep larger areas available for conduction. Even so, it is sometimes advisable to have additional abrasive material in the brushes to prevent over-filming in critical atmospheres.

Because the major factor in friction is the shear strength of any film that is present, the composition of this film, as affected by atmospheric contaminants, is important. Table 1 lists common materials that affect friction in sliding contacts and the mechanism by which they affect contact friction.

Table 1 Effects of atmospheric contaminants on friction between carbon brushes and copper

Contaminant	Effect
CCl_4	Friction becomes high and erratic

Cl_2	Small amounts, friction decreases; large amounts, friction increases
SO_2	Friction increases
H_2S	Small amounts, friction decreases; large amounts (detectable by smell), friction increases
Silicones	With current, friction increases; without current, friction decreases
Steam, H_2O	Friction may increase or decrease
Tobacco smoke	Friction increases
Oil vapor	Small amounts, friction decreases; large amounts, friction increases

Brush Materials. Considering the range of commercially available metal powders, graphites, other lubricants, and processing variables, there are unlimited possibilities for development of suitable brush materials. However, only a limited number of commercial grades have been developed; a list of grades compiled by one supplier appears in Table 2.

Table 2 Properties of metal-graphite electrical contact materials

Composition, %		Approximate density, g/cm^3	Electrical conductivity, % IACS	Applications
Metal	Graphite			
Copper-graphite materials				
30	70	2.60	0.11	Alternators; small auxiliary motors; low-metal, long-life brushes
30	70	2.50	2	Automotive auxiliary and appliance motors
36	64	2.75	3	Automotive heaters and blower motors
40	60	2.75	4	Automotive and other small auxiliary starting motors
40	60	2.75	2.5	Automotive heaters and ac motors
50	50	3.05	0.73	Automotive alternators
50	50	2.97	6	Automotive auxiliary and appliance motors
50	50	3.18	0.83	Industrial truck motors

62	38	3.65	3	Automotive starters. Excellent grade for low-humidity applications; excellent filming properties
65	35	3.15	3	Starters
75	25	3.25	0.51	ac wound motors and rotary converters
95	5	6.30	34	Collector roll brushes
92	8	7.30	41	High-current-carrying brush material for grounding applications
96	4	7.75	42	Automotive starters
Silver-graphite materials				
90	10	7.5	42	Instruments, fuel pumps
50	50	3.4	2	Welding machines, motors
85	3[(a)]	7.8	45	Antenna motors[(b)]
75	20[(c)]	5.2	12	Antenna motors and generators[(b)]

(a) Plus 12MoS_2.

(b) With altitude protection.

(c) Plus 5MoS_2

More brush contacts are made from copper and its alloys than from any other class of material. In applications where copper metals undergo substantial oxidation, silver metals may be used. Tungsten or, more rarely, molybdenum is used where a high melting point is required. Platinum, palladium, and gold are used where reliable closure with low force is required. Brushes clad or electroplated with precious metals, and brushes made of sintered alloys, are important for general applications in power-switching relays.

Interdependence Factors. When contacts are attached to a carrier, which is usually a copper alloy, the properties of the carrier material and the properties of the interface between contact and carrier (that is, the area of bond and the conductivity across the interface) are critical to ultimate performance. The contact carrier serves as a heat sink as well as a structural member and electrical conductor. The overall efficiency of the system depends on the contact, the contact carrier, and the method of attachment, all of which affect the size of the contact required for a specific application. To conserve precious metal, the contact materials, carrier material, and method of attachment must be optimized. Some high-strength, high-conductivity copper alloys are used for carriers because of their structural properties and resistance to softening at brazing temperatures.

The attachment method that provides minimum interface alloying, minimum softening of the carrier, and maximum bond area generally produces the best combination of properties for the contact system as a whole. Common attachment methods include brazing, resistance welding, percussion welding, and resistance induction torch welding. Welding methods provide the most localized heat input and therefore minimize softening of the carrier, which may occur during brazing methods. A more weldable backing such as steel, nickel, or monel is often clad to the precious metal to provide optimum welding compatibility with the carrier. Projections can also be coined or rolled into the contact backing to assist in welding.

Percussion welding does not require a special backing for attachment. However, percussion welding has fallen out of favor due to relatively high cost in comparison with brazing, welding, and mechanical attachment (riveting). The overwhelming majority of contacts in the United States and Europe are brazed, either in strip or part form.

Copper Contact Alloys

High electrical and thermal conductivities, low cost, and ease of fabrication account for the wide use of copper alloys in electrical contacts. The main disadvantage of copper contacts is low resistance to oxidation and corrosion. In many applications, the voltage drop resulting from the film developed by normal oxidation and corrosion is acceptable. In some circuit breaker applications, the contacts are immersed in oil to prevent oxidation. In other applications, such as in drum controllers, sufficient wiping occurs to maintain fairly clean surfaces, thus providing a circuit of low resistance. In some applications, such as knife switches, plugs, and bolted connectors, contact surfaces are protected with grease or coatings of silver, nickel, or tin. In power circuits, where oxidation of copper is troublesome, contacts frequently are coated with silver. Vacuum-sealed circuit breakers use oxygen-free copper contacts (wrought or powder metal) for optimum electrical properties.

In air, copper does not provide high resistance to arcing, welding, or sticking. Where these characteristics are important, copper-tungsten or copper-graphite mixtures are used. However, when used in a helium atmosphere, a Cu-CdO contact performs similarly to an Ag-CdO contact. Copper alloys are used for high currents in vacuum interrupters.

Pure copper is relatively soft, anneals at low temperatures, and lacks the spring properties sometimes desired. Some copper alloys, harder than pure copper and having much better spring properties, are listed in Table 3. The annealing temperature and the elevated-temperature properties of copper can be increased by additions of 0.25% Zn, 0.5% Cr, 0.03% to 0.06% Ag (10 to 20 oz per ton) or small amounts of finely dispersed metal oxides, such as Al_2O_3, with little loss of conductivity. On the other hand, improved mechanical properties are obtained only at the expense of electrical conductivity. Precipitation-hardened alloys, dispersion-hardened alloys, and powder metal mixtures can provide a wide range of mechanical and electrical properties.

Table 3 Properties of copper metals used for electrical contacts

UNS number	Solidus temperature		Electrical conductivity, % IACS	Hardness		Tensile strength			
						OS035 temper		H02 temper

Applications. Copper-base metals are commonly used in plugs, jacks, sockets, connectors, and sliding contacts. Because of tarnish films, the contact force and amount of slide must be kept high to avoid excessive contact resistance and high levels of electrical noise. Yellow brass (C27000) is preferred for plugs and terminals because of its machinability. Phosphor bronze (C50500 or C51000) is preferred for thin socket and connector springs and for wiper-switch blades because of its strength and wear resistance. Nickel silver is sometimes preferred over yellow brass for relay and jack springs because of its high modulus of elasticity and strength, resistance to tarnishing, and better appearance. Sometimes, copper alloy parts are nickel plated to improve surface hardness, reduce corrosion, and improve appearance. However, nickel carries a thin but hard oxide film that has high contact resistance; very high contact force and long slide are necessary to rupture the film. To maintain low levels of resistance and noise, copper metals should be plated or clad with a precious metal.

Silver Contact Alloys

Silver, which has the highest electrical and thermal conductivities of all metals, is the most widely used material in pure or alloyed form for a considerable range of arcing contacts (1 to 600 A). Because of its electrical and thermal conductivity, silver is widely used in contacts that remain closed for long periods of time and, in the form of electroplate, as a coating for connection plugs and sockets. It is also used on contacts subject to occasional sliding, such as in rotary switches, and to a limited extent for low-resistance sliding contacts, such as slip rings.

The various types of silver-base contact materials include:

- Unalloyed silver or silver overlays
- Binary, ternary, and multicomponent silver alloys such as silver-cadmium, silver-copper, silver-copper-nickel, or silver-cadmium-nickel contact materials
- Composite silver-base materials with refractory constituents such as cadmium oxide, magnesium oxide, tin oxide, graphite, tungsten, tungsten carbide, or molybdenum

The composite silver-bases are often made using P/M processes, which allow the combination of constituents that ordinarily cannot be alloyed. However, some silver-base composites with cadmium oxide or magnesium oxide can also be

made by preparing binary alloys of silver and cadmium or of silver and magnesium, then converting the cadmium or magnesium into an oxide by internal oxidation. Contact materials with refractory or oxide constituents are described in the section "Composite Materials" in this article.

This section describes the properties of silver and the silver alloys used as contact materials. Mechanical properties and hardness of pure silver are improved by alloying, but its thermal and electrical conductivities are adversely affected. Figure 1 shows the effect of different alloying elements on the hardness and electrical resistivity of silver. Properties of the principal silver metals used for electrical contacts are given in Table 4.

Table 4 Properties of silver metals used for electrical contacts

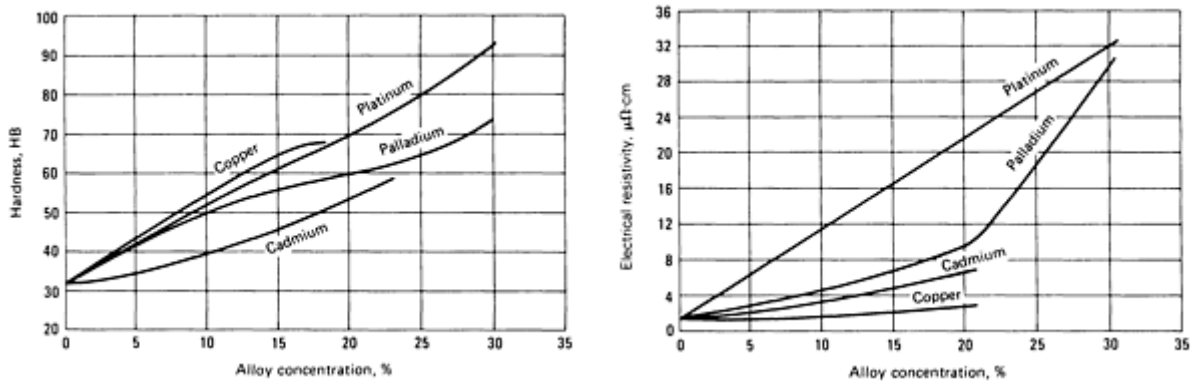

Fig. 1 Hardness and electrical resistivity versus alloy content for silver alloy contacts

Electrical and Thermal Conductivity. Because silver has the highest electrical and thermal conductivities of all metals at room temperature, it can carry high currents without excessive heating, even when dimensions of the contacts are only moderate. Although good thermal conductivity is desired once the contact is in service, such conductivity increases the difficulty of assembly welding unless a higher resistance layer is added by cladding.

In component assemblies, migration of silver through and around electrical insulation may cause failure of the insulation. When in contact with certain materials, such as phenol fiber, and when under electric potential, silver migrates ionically through or across the insulating material, producing thread-like connections that lower the resistance across the insulation. This reduces insulating qualities, and the reduction is even greater if moisture is present in the atmosphere. Insulators must be designed with care to avoid this hazard.

Oxidation Resistance. Silver is used instead of copper chiefly because of its resistance to oxidation in air. In general, silver oxide is not a problem on silver contacts, whether or not the contacts make and break the circuit. However, silver oxide can be produced by exposure to ozone, as well as by other methods. This oxide has high resistivity, is decomposed slowly on heating at about 175 °C (350 °F), is decomposed rapidly at about 350 °C (650 °F) and is removed by arcing. This "self-cleaning" characteristic is most unusual among metals and is a chief reason for the attraction of silver as a contact material.

Silver is vulnerable to attack by sulfur or sulfide gases in the presence of moisture. The resulting sulfide film may produce significant contact resistance, particularly where contact force, voltage, or current is low. Direct current brings silver ions from the matrix into the sulfide where they form connecting bridges. Therefore, particularly at high direct current, the film becomes somewhat conducting. The resistance of a silver sulfide film decreases as temperature increases--Ag_2S decomposes slowly at 360 °C (680 °F) and more rapidly at higher temperatures. In addition, the film may increase erosion and entrap dust.

Limitations of Silver Contacts. Silver will provide a fairly long contact life for make-break contacts and will handle up to 600 A. In pure silver contacts, difficulties sometimes arise from transfer of metal from one electrode to the other, which leads to the formation of buildups on one contact surface and holes in the other. When used in dc circuits, silver contacts are subject to ultimate failure by mechanical sticking as a direct result of metal transfer. The direction of transfer is generally from the positive contact to the negative, but under the influence of arcing, the direction may be reversed. With high currents or inductive loads, it may be desirable to shunt the load with a resistance-capacitance protection network to reduce erosion.

When arcing produces a glow discharge in air, the rate of erosion of silver is unusually high because of a chemical interaction with air to form $AgNO_2$.

For low resistance and low noise levels, the design of the contact device must provide sufficient force and slide to break through any silver sulfide film and maintain film-free metal-to-metal contact at the interface. Connectors should have high slide force and several newtons normal force. Rotary switches that have up to 490 mN (0.11 lbf) normal force and considerable slide should have a protective coating of grease to reduce sulfiding and to remove abrasive particles. In low-noise transmission circuits, silver should not be used on relay and other butting contacts that have less than 195 mN (0.044 lbf) force; other precious-metal coatings, such as gold or palladium, should be used instead of silver.

A silver sulfide film has a characteristic voltage drop of several tenths of a volt. Where this drop is tolerable, silver contacts will provide reliable contact closure. Failure to close, however, may be greater than with other precious metal contacts because of impacted dirt, with a sulfide film acting as a dirt catcher.

For many applications, silver is too soft to give acceptable mechanical wear. Alloying additions of copper, cadmium, platinum, palladium, gold, and other elements are effective in increasing the hardness and modifying the contact behavior of silver. These additions do, however, lower both the electrical conductivity and the oxidation resistance relative to pure silver.

Fine silver (99.9 Ag) has the highest electrical and thermal conductivities of all metals. It has a high current capacity, which limits heat generation, and a high thermal conductivity, which allows contacts to readily dissipate the heat generated by arcing. Silver also has good oxidation resistance, and therefore a low-resistance and low-voltage drop across the contact interface can be maintained.

The low boiling and melting points of silver are disadvantages. Fine silver contacts tend to weld easily, and usually have high erosion loss (see "Silver-Cadmium Alloys" below). The low hardness and low mechanical strength of fine silver result in high rates of mechanical wear.

Fine silver contacts are used in low-current (<20 A) applications such as switches and relays in appliances and automotive products. Because fine silver is very ductile, it can be fabricated into many designs, including contacts in the form of solid, tubular, and composite rivets and solid buttons.

Silver-Copper Alloys. Copper additions improve the hardness of silver appreciably and slightly decrease its conductivity. However, copper decreases the tarnish resistance of silver; hence, the oxidized film increases contact resistance. Switching devices that have silver-copper contacts should have a high closing force and large wiping action to break down the oxide films.

Silver-copper alloys are used in place of fine silver where electrical, mechanical, and atmospheric conditions are compatible. For the same application, silver-copper alloys usually cost less than fine silver.

Addition of a small amount of nickel to a silver-copper alloy (as in Ag-24.5Cu-0.5Ni, for example) makes the oxide film brittle, so that switching devices can use less closing force.

Silver-Cadmium Alloys. Cadmium improves the arc-quenching ability of silver, and also increases its resistivity and mechanical strength. Silver-cadmium alloys are more resistant to arc erosion and welding than fine silver and silver-copper alloys.

Ag-22.6Cd-0.4Ni Alloy. Because of the nickel addition, the oxidation film of this alloy is also brittle. Ag-22.6Cd-0.4Ni is used in electrical gages and automotive voltage regulators, where the closing force is light and where a stable

resistance and low transfer rate are required. It is also used to make positive contact and retard material transfer when paired with Ag-3Pd alloy in polarized low-voltage circuits.

Ag-15Cd alloy, which typically undergoes internal oxidation to form a Ag-CdO composite, is a widely used composition. The Ag-CdO composite (discussed in the section "Composite Materials" in this article) exhibits low welding tendencies at the contact interface and is the material most commonly used to switch light or medium current in ac or dc circuits such as line starters, solenoid relays for automotive starters, and other devices subjected to high-surge current.

Ag-5.5Cd-0.2Ni-7.5Cu alloy has excellent resistance to corrosion and good spring properties. It is used to make current-carrying spring contacts in television tuners, collector rings, and rf switches.

Silver-Platinum Alloys. A small addition of platinum increases the hardness, wear resistance, and corrosion resistance of silver, but concurrently decreases its electrical conductivity. Silver-platinum alloys are used in switching devices having low closing force where cost is not the main concern.

Silver-Palladium Alloys. Palladium improves the wear resistance of silver, but also decreases its conductivity. Silver-palladium alloys are less susceptible to oxidation than fine silver. Ag-3Pd alloy is used as the negative contact paired with Ag-22.6Cd-0.4Ni in low-voltage dc circuits. Silver and palladium form a complete solid solution, and their alloys have very good fabricability.

Silver-Gold Alloys. Gold increases hardness and improves oxidation resistance of silver. The tarnish films on contact surfaces are more stable than those of any other alloy. Ag-10Au is primarily used in ac and dc relays with current capacities less than 0.5 A where high reliability is essential. This alloy is very ductile and can be fabricated in the same manner as fine silver.

Multi-Component Alloys. Ag-0.25Mg-0.20Ni and Ag-0.18Mg-0.20Ni-0.15Cu have similar properties. In low-current dc applications (voltage regulators, thermal gages, and relays), these materials provide low transfer characteristics. Mechanical properties can be improved by internally oxidizing the alloying elements into oxides.

Ag-23Pd-12Cu-5Ni has high hardness (good resistance to wear), better tarnish resistance, and a higher melting point than fine silver. It is limited to light current applications. Because of its high hardness, the alloy is used as brush contacts in potentiometers and other sliding applications. This alloy is also made into disks for composite rivets.

Gold Contact Alloys

Pure gold has unsurpassed resistance to oxidation and sulfidation, but a low melting point and susceptibility to erosion limit its use in electrical contacts to situations where the current is not more than 0.5 A. Although oxide and sulfide films do not form on gold, a carbonaceous deposit is sometimes formed when a gold contact is operated in the presence of organic vapors. The resistance of this film may be several ohms.

When gold is used in contact with palladium or rhodium, very low contact resistances have been reported.

The low hardness of gold can be increased by alloying with copper, silver, palladium, and platinum, but usage is necessarily restricted to low-current applications because of the low melting point.

Properties of gold and its alloys are listed in Table 5. If low tarnish rates and low contact resistance are to be preserved, the gold content should not be less than about 70%.

Table 5 Properties of gold metals used for electrical contacts

(a) Rockwell 15N

Fine Gold. The unique property of fine gold (99.0 Au) as a contact material is its superb tarnish resistance in air. Only platinum is more tarnish resistant, but fine gold is less costly than platinum. Pure gold is very soft and susceptible to mechanical wear, metal transfer, and welding. Pure gold electroplated or roll bonded over a base metal substrate is used in dry circuit connectors and relays to improve reliability. It is widely used in computers and telecommunications equipment were reliability is a major concern.

Au-26.2Ag-1.8Ni and Au-27Ag-3Ni Alloys. Silver and nickel increase the hardness of gold, thereby increasing resistance to mechanical wear and deformation. Au26.2Ag-1.8Ni resists welding and transfer better than pure gold and is used in devices that carry less than 0.5 A current where high reliability is required. The alloy is ductile and has good fabricability. Alloy Au-27Ag-3Ni is more widely used than Au-26.2Ag-1.8Ni.

Au-25Ag-6Pt. Both silver and platinum increase the hardness of gold. Au-25Ag-6Pt is employed in low-current and low-closing-force relays such as those used in telecommunication systems, where high reliability is required. Under conditions of erosion, contacts have long life if the current is limited to 0.4 A. The alloy is also highly satisfactory for use in sliding contacts, such as in rotary switches or low-pressure slip rings, because it has good wear resistance and maintains low contact resistance. It is less susceptible to polymer formation than palladium and, where this is important, its greater cost may be justified.

Au-25Ag and Au-50 Ag. Silver increases the hardness of gold, but decreases its tarnish resistance. Gold-silver alloys are used where a higher degree of reliability is required than can be obtained with silver-base alloys.

Au-5Ag-9Pt-15Cu provides good tarnish resistance as well as high hardness and strength. It is used as a contact where a large wipe is required. It is also used as brush contacts against slip rings made of Au-26.2Ag-1.8Ni.

Au-10Cu. Copper increases the hardness of gold with only a small sacrifice in corrosion resistance. Au-10Cu is used in low-voltage dc devices such as alternators or voltage regulators, and as a positive contact paired with a platinum-iridium negative contact. Under light closing forces, this combination provides a low transfer rate and good anti-welding characteristics.

Au-14.5Cu-8.5Pt-4.5Ag-1Zn. This multiple-component alloys is age hardenable. Compared to other high-gold-content alloys, it can be two to three times harder. The high gold, silver, and copper content make it a low producer of frictional polymers; thus, an excellent material for applications with voltages too low to electrically puncture these films. The combined strength and nobility of this alloy make it the ideal material for sliding contacts, slip rings, and resistance wire. This alloy is the preferred mating material for Pd-30Ag-14Cu-10Au-10Pt-1Zn alloy. Applications also include self-contained cantilever beam contacts.

Precious Metals of the Platinum Group

Platinum and palladium are the two most important metals of the platinum group. These metals have a high resistance to tarnishing, and therefore provide reliable contact closure for relays and other devices having contact forces of less than 490 mN (0.110 lbf). Their high melting points, low vapor pressure, and resistance to arcing make them suitable for contacts that close and open the load, particularly in the range up to 1 A. The low electrical and thermal conductivities of these metals, as well as their cost, generally exclude them from use at currents above about 5 A.

Palladium has an arcing limit only slightly less than that of platinum and gives comparable performance in relays for telephones and similar services handling 1 A or less. Palladium is a satisfactory substitute for platinum in these applications.

Chemical Properties. Platinum has a high resistance to corrosion, including resistance to oxidation, sulfidation, and salt water. It will not form a stable oxide at any temperature.

Palladium is resistance to oxidation at ordinary temperatures. if heated above 350 °C (660 °F), it will oxidize slowly to form an oxide that is stable at room temperature. However, the oxide is decomposed promptly on heating to 800 °C (1470 °F) or by arcing. The oxide is not considered to be a significant factor in the reliability of closure of telephone-type relays.

The presence of organic vapors in the contact area can seriously influence the life and reliability of electrical contacts, particularly the low-force precious metal contacts universally employed in high-reliability low-noise circuits. The damaging organic vapors may arise from coil forms, wire coatings, insulation, soldering flux, potting and sealing compounds, and other organics in associated electrical equipment, as well as from external sources.

Organic contamination may produce two distinctly different forms of contact damage: activation and polymer formation.

Activation is the development of a carbon deposit on the contacting surfaces, formed by the decomposition of the organic contaminant in the arc. This deposit markedly increases arc erosion. The carbon deposits decrease the current needed to sustain an arc and prolong the arcing time. A 95% reduction in contact life may result from activation brought about by the presence of organic vapors. Activation can be reduced or eliminated by using insulating materials that are not sources of organic vapors, by adequate ventilation and, perhaps, by absorbing the organic vapors in a getter such as active carbon.

Polymer formation is the development of a polymer-like insulating brown powder on contacts in dry circuits (those not carrying current on make or break), and may lead to transient open circuits. The insulating brown powder is believed to result from the adsorption of the organic vapor on the contact surface, followed by its polymerization by the friction associated with contact operation. The sliding motion both forms the polymer and pushes it outside the slide area, where it builds up as a brown powder. A transient open circuit occurs when some of the built-up powder falls into the contact area.

Controlled experiments have shown that the type of contact metal influences the amount of polymer formed. The greatest amount of polymer is formed on the platinum metals; lesser amounts are formed on gold and some base metals; polymer does not form on silver.

Elimination of materials that give rise to organic vapors is a possible solution to polymer formation, but one that is difficult to carry out. From a practical standpoint, the problem has been solved in telephone circuits by cladding one of a

mating pair of palladium contacts with a very thin layer of gold. In dry circuits, the one gold surface significantly reduces polymer formation, although in working circuits, the gold soon wears off and exposes the palladium base.

Erosion and Sticking. The arcing current limit for platinum group metals is about 1 A, and contact life is long if the current is kept below this value. With currents higher than 1 A or with inductive loads, it may be desirable to shunt the load or contact with a resistance-capacitance network to reduce erosion, and to reduce failures caused by snagging of pits and build-ups. In general, for equal volumes of contact metal, the life of platinum or palladium contacts is about ten times the life of silver contacts.

Resistance and Noise. Palladium is used almost universally on relays and relay-type switch contacts in telephone systems within the United States for talking circuit transmission. In this service, palladium is essentially noise-free and is used in preference to platinum or gold alloys because it is more economical.

In a few isolated instances, where the palladium talking circuit contacts have been subject to vibration in service, noise troubles have developed because of polymer formation. In these few instances, the difficulty has been met by the use of gold alloys, which greatly reduces the production of polymer.

Fine Platinum. Platinum has higher melting and boiling points (1799 °C, 3270 °F, and 4530 °C, 8186 °F, respectively) than those of gold (1063 °C, 1945 °F and 2970 °C, 5380 °F), and has excellent corrosion resistance.

Fine platinum (99.9 Pt) provides a very low and consistent surface resistance at a wide range of temperatures. Contacts made with platinum remain clear in hostile environments. It is usually used in light-force relays with a current capacity of up to 2 A when reliability is the most important factor.

Properties of platinum and its alloys are listed in Table 6. The effect of alloying on the hardness and electrical resistivity of platinum is shown in Fig. 2.

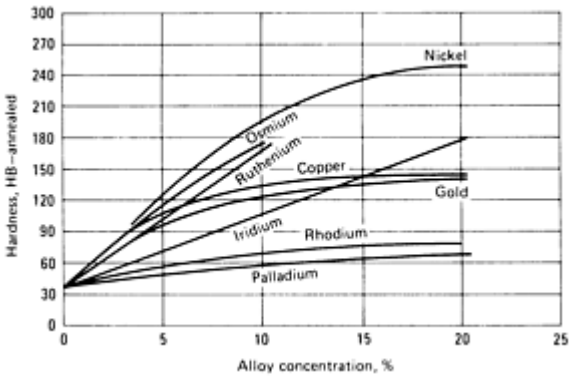

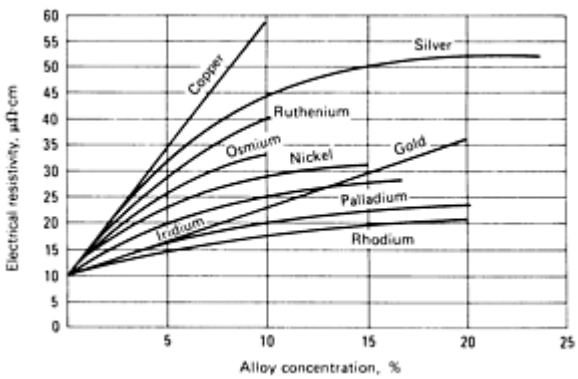

Fig. 2 Hardness and electrical resistivity versus alloy content for platinum contacts

Platinum-Iridium Alloys. Platinum and iridium form a complete solid solution. The physical properties, melting point, hardness, and mechanical strength of Pt-Ir alloys increase almost linearly with the amount of iridium in platinum, without affecting the corrosion resistance of the latter. This group of alloys is used in low-current ac and dc circuits when the mechanical forces are high and high wear resistance and strength are required.

Fabrication of platinum-iridium alloys becomes difficult when the iridium content is high. These alloys are usually used in the form of disks to make composite rivet faces.

Platinum-Ruthenium Alloys. Ruthenium forms a solid solution with platinum up to 79% Ru. Ruthenium increases the hardness, strength, and wear resistance of platinum, but high ruthenium content makes the alloy brittle. To ensure good fabricability, the ruthenium content should not exceed 15%.

Platinum-ruthenium alloys have good tarnish resistance and cost less than platinum-iridium alloys. Pt-Ru alloys are used as positive contacts in low-voltage dc circuits, almost always paired with negative contacts made of tungsten. Pt-Ru alloys can be made into rivets or disks for composite rivets.

Pt-18.4Pd-8.2Ru. This ternary alloy has properties similar to those of platinum-ruthenium and platinum-iridium alloys, but costs less. It is used in low-voltage dc circuits as the positive contact and paired with tungsten as the negative contact. This alloy has poor fabricability and can be used in the form of disks for composite rivets.

Fine Palladium. The oxidation resistance of fine palladium (99.9 Pd) is second only to that of platinum. The boiling point (3950 °C, 7142 °F) and melting point (1552 °C, 2825 °F) are slightly lower than those of platinum. However, palladium costs about one-fourth as much as platinum, and usually replaces platinum when cost is the main concern. Table 6 gives properties of palladium metals. Figure 3 shows the effect of alloying elements on palladium.

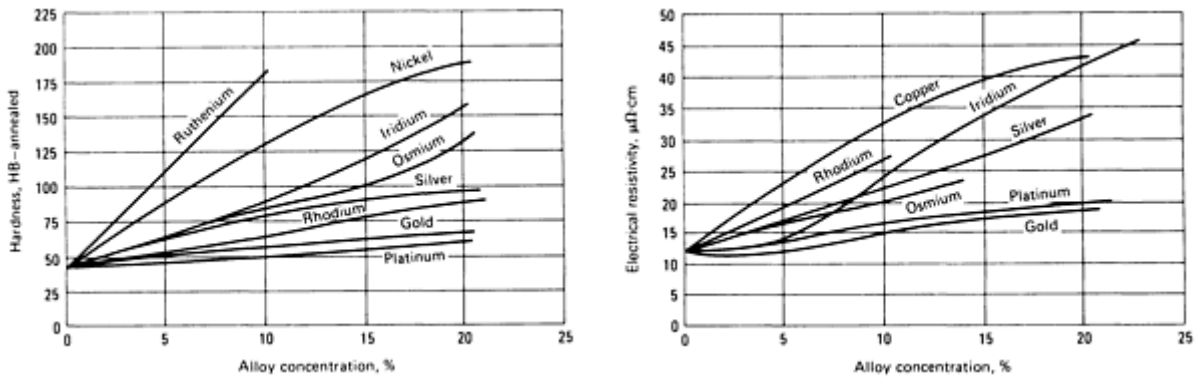

Fig. 3 Hardness and electrical resistivity versus alloy content for palladium contacts

Palladium is used in light-closing-force and low-current applications. It has very good fabricability and can be easily made into rivets or composite rivets.

Palladium-Ruthenium Alloys. Palladium forms only a limited solid solution with ruthenium. Ruthenium increases the hardness of palladium without sacrificing its corrosion resistance. Palladium-ruthenium alloys are used in low-current relays where closing forces are high. These alloys are used mostly as positive contacts paired with tungsten in dc circuits. In some applications, they are used to replace platinum-ruthenium alloys when cost is important. Practically all of the palladium-ruthenium alloys are used in the form of rivets because of their poor fabricability.

Pd-40Cu. Corrosion resistance of Pd-40Cu is good, but it is inferior to that of other precious metals. The alloy has high hardness and is used primarily as brush contacts and in instruments and gases. Because of its very poor headability, it can be used only in disk form to make composite rivets.

Pd-40Ag. Silver improves the hardness of palladium. Pd-40Ag costs less than fine palladium but has the same corrosion resistance against a sulfiding atmosphere. It is used in high-closing-force contacts with less than 1 A current. It has a fair headability, but is used mostly in disk form for composite rivets.

The Pd-40Ag alloy is often clad to base metals for electronic connector applications for increased wear resistance compared to gold alloys. A particular structure of gold diffused into the Pd-40Ag alloy has been found to offer superior properties for electronic connectors used in telecommunications. When clad to copper-base metals this system offers corrosion resistance and wear resistance at lowest cost.

Multiple-Component Alloys. Table 6 lists multiple-component alloys that are designed to increase mechanical properties and decrease cost, with some sacrifice of corrosion resistance.

Pd-9.5Pt-9.0Au-32.5Ag alloy is used for brushes and slide contacts. It has a modulus of elasticity of 115 GPa (17×10^6 psi) and a proportional limit of 930 MPa (135 ksi), which are the highest for precious-metal contacts.

Pd-26Ag-2Ni is used in ac or dc contact devices where operation frequency is high, such as in business machines and computers. In dc circuits, it is also used as a positive contact paired with tungsten.

Pd-30Ag-14Cu-10Au-10Pt-1Zn has one of the highest strength and nobility combinations of all other precious-metal contact materials. This alloy has excellent ductility in the annealed condition, which makes it extremely well suited for forming, drawing, and other deformation processes. After the forming operation, the material is age hardened to achieve desired mechanical properties.

Because this alloy is age hardenable, the mechanical properties can be altered to provide the maximum flexibility to the designer. The age-hardening characteristics also provide resistance to stress relaxation at elevated temperatures, which allows for the use of very low contact forces at elevated temperatures without loss of contact pressure. Before hardening, this alloy has good workability owing to its ductility in the annealed condition. After hardening, it also has superior wear properties as a result of hardness values that approach 400 HV. Applications include potentiometers, brushes, make-break contacts, spring arms, and probes for integrated and printed circuits.

Pd-38Ag-16Cu-1Pt-1Zn is another age-hardenable alloy. It is more economical than Pd-30Ag-14Cu-10Au-10Pt-1Zn because it does not have gold and has less platinum. It has high strength and hardness in the age-hardened condition, providing wear resistance and making it ideal for self-contained cantilever beam contacts. The combined 45% noble and 38% semi-noble content give this alloy good resistance to tarnish and corrosion.

Precious Metal Overlays

Silver, gold, rhodium and, to a lesser extent, platinum and palladium are employed in clad and electroplated contacts. Electrodeposition and cladding compete for many of the same applications. Clad overlays are favored because of their lower porosity, but electrodeposits are slightly less expensive for those applications requiring in very thin layer of precious metal. Electrodeposits frequently have higher hardness than the annealed wrought material; rhodium, which has a deposit hardness in excess of 600 HV in the annealed condition, is an outstanding example. High hardness accounts for the superior wear resistance of electroplated rhodium where rubbing or wiping occurs. Even at a thickness of 0.13 to 0.50 μm (5 to 20 μin.) over silver or base-metal contacts, rhodium improves wear resistance and minimizes tarnishing.

Electroplated gold is employed on silver contacts to minimize tarnishing. Nickel underlayers (barrier coats) are used to prevent migration of silver through the gold plate. Recent studies indicate that migration of silver along nickel grain boundaries is rapid at high temperatures. Hence, a nickel barrier coat is questionable for high-temperature applications. Other work in this area has disclosed that palladium can be substituted for gold as a protective coating for extension of shelf life. Electroplated gold also is used on palladium contacts to minimize polymer formation in dry circuits. However, gold electrodeposits on both silver and palladium contacts soon wear off if the contacts wipe, rub, or arc.

Electroplated silver is sometimes applied to copper-base materials to make less expensive components. Electroplated silver is slightly harder than annealed wrought silver. Palladium and platinum electroplated on silver have improved

tarnish resistance. Platinum, palladium, and gold electroplates are used on silver to prevent the development of conducting filaments in insulating supports.

Clad overlays are used extensively in applications requiring precious-metal thicknesses from 0.025 to 1.3 mm (0.001 to 0.050 in.). These thicknesses cannot be obtained by electroplating. These applications include electromechanical devices operating in current ranges where arcing and subsequent erosion are likely to occur. In these devices, sufficient precious metal must be available to survive the erosion that will occur over the required device cycle life.

Tungsten and Molybdenum

Most tungsten and molybdenum contacts are made in the form of composites with silver or copper as the other principal component. Tungsten, which was one of the earliest metal other than copper and silver adopted for electrical contact applications, has the highest boiling point (5930 °C, or 10,700 °F) and melting point (3110 °C, or 5625 °F) of all metals; it also has very high hardness at both room and elevated temperatures. Therefore, as a contact material, it offers excellent resistance to mechanical wear and electrical erosion. Its main disadvantages are low corrosion resistance and high electrical resistance. After a short period of operation, an oxidized film will build up on tungsten contacts, resulting in very high contact resistance. Considerable force is required to break through the film, but high pressure and considerable impact cause little damage to the underlying metal because of its high hardness. Tungsten contacts are used in switching devices with closing forces of more than 20 N (4.5 lbf) and in circuits with high voltages and currents not more than 5 A, such as automotive ignitions, vibrators, horns, voltage regulators, magnetos, and electric razors. In low-voltage dc devices, tungsten is always used as the negative contact, and is paired with a positive contact made of precious metal.

Tungsten rods or strips that are consolidated by swaging or rolling from sintered powder compacts have very poor ductility. They cannot be cold worked, in contrast to other contact materials. Tungsten disks are usually cut from rods or punched from strips and then brazed directly to functional parts such as breaker arms, brackets, or springs.

Properties such as grain size, grain configuration, and the degree of fibrous structure, which affect contact behavior, are controlled by using special swaging methods and annealing cycles. Tungsten disks usually are supplied with a ground finish, but they can also be electrochemically polished to obtain high-luster surfaces.

The high boiling and melting points of molybdenum--5560 °C (10,040 °F) and 2610 °C (4730 °F), respectively--are second only to those of tungsten and rhenium. Molybdenum is not used as widely as tungsten because it oxidizes more readily and erodes faster on arcing than tungsten. Nevertheless, because the density of molybdenum (10.2 Mg/m^3 or 0.369 $lb/in.^3$) is about half that of tungsten (19.3 Mg/m^3 or 0.697 $lb/in.^3$), use of molybdenum is advantageous where mass is important. Its cost by volume is also lower.

In addition to its use in make-break contacts, molybdenum is widely used for mercury switches because it is not attacked, but only wetted, by mercury.

Like tungsten, molybdenum strips and sheets are made by swaging or rolling sintered powder compacts. Disks made from rods or sheets are brazed to blanks or other structural components. Table 7 lists the properties of tungsten and molybdenum, and Fig. 4 and 5 show the effect of temperature or diameter on various properties.

Table 7 Typical properties of tungsten and molybdenum

Some of the physical properties of tungsten and molybdenum vary considerably with cross-sectional area and grain structure.

Tungsten	
Hardness, HRA (HV)	70 (385)
Modulus of elasticity, GPa (10^6 psi)	
At 20 °C (68 °F)	405 (59)

At 1000 °C (1830 °F)	325 (47)
Density, g/cm^3	19.3

Aluminum

As a contact metal, aluminum is generally poor because it oxidizes readily. Where aluminum is used in contacting joints, it should be plated or clad with copper, silver, or tin. Aluminum should never be used for power applications where arcing is present. For instance, if aluminum contacts were substituted for silver in a motor starter, an explosion due to noninterruption of current on motor-starter de-energization would probably occur on load interruption.

Composite Materials

Composite electrical contacts are made from three categories of materials:

- Those that contain refractory constituents such as tungsten or molybdenum carbide
- Those that contain semirefractory constituents such as cadmium oxide, magnesium oxide, and tin oxide
- Those that contain elements (such as silver and nickel) that do not conventionally alloy but which are formed by P/M processes to produce contact materials with unique properties

The various types of composite contact materials (Table 8) generally have a base material of silver, copper, or refractory metals and their carbides. The refractory-base and silver-base contacts are used in switching devices operated in air. Copper-base composite contacts are used in vacuum and oil switching devices.

Table 8 presents the compositions and properties of various composite contact materials. Because manufacturing methods affect the properties of materials with the same composition, the manufacturing methods are also given in Table 8. The most common methods of producing composite electrical contact materials are described in the section "Composite Manufacturing Methods" in this article.

Data published by contact manufacturers usually include density, hardness, and electrical conductivity (Table 8). These data provide designers of electrical devices with the basic properties of a composite contact. Other properties, such as contact resistance, may depend on operational parameters such as force (Fig. 6).

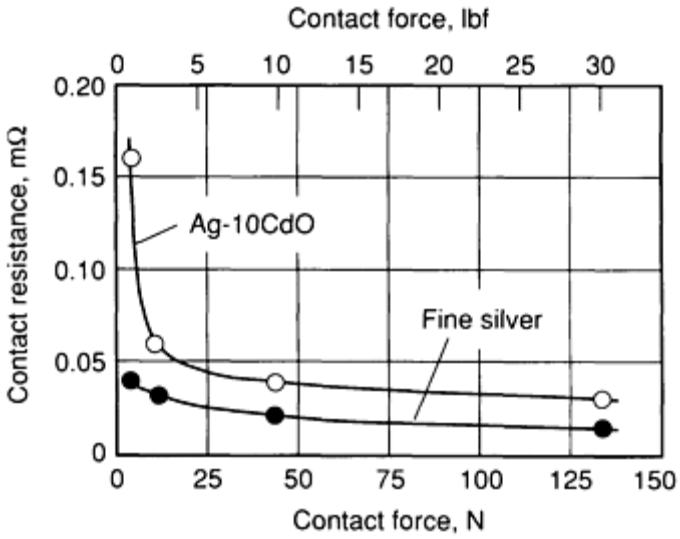

Fig. 6 Contact resistance versus force for fine silver and Ag-CdO contacts. Unarced contacts were 12.7 mm ($\frac{1}{2}$ in.) in diameter with a 38 mm (1 $\frac{1}{2}$ in.) spherical radius. Resistance measurements were made with ac current at 50 A and 60 Hz.

Characteristics that relate directly to failure modes such as arc erosion or material transfer are usually described in a qualitative manner. Very few quantitative data pertaining to these characteristics have been published because these properties depend on several test parameters. For instance, the arc erosion rate is affected by various mechanical factors:

- Opening force and opening speed
- Closing force and closing speed
- Bouncing of the movable contact
- Wiping distance
- Gap between opposing contacts

or electrical factors:

- Current--both amperage and whether ac or dc
- Voltage
- Power factor (inductive/capacitive)

Because each variable can greatly affect the arc erosion rate of a composite, it is virtually impossible to define a universal test to evaluate erosion rate.

Published data on erosion rate and welding frequency usually are collected under very specific conditions. They are valid only for qualitative description in a specific set of circumstances and cannot be extrapolated to suit other applications. The

only means of learning how a composite will perform in a specific application is to test it extensively in the device in which it will be used. Examples of test data are given in Fig. 6, 7, 8, and 9 and in the section "Life Tests" in this article.

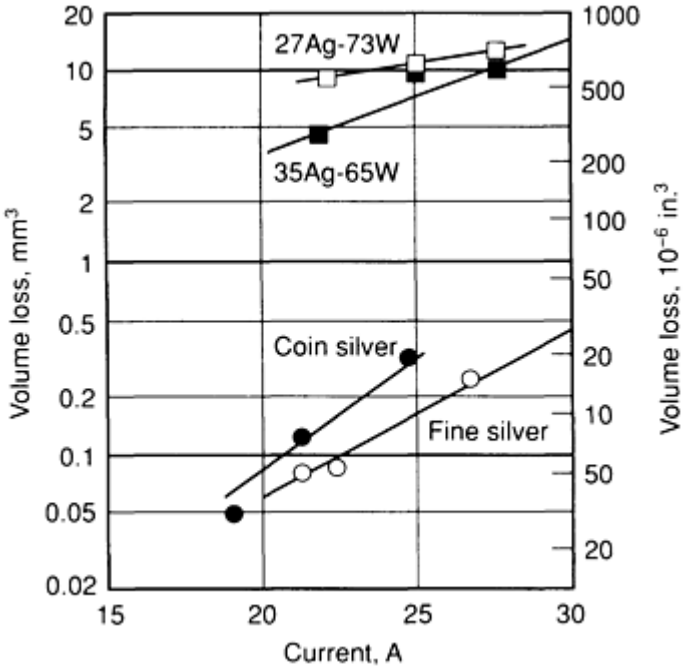

Fig. 7 Contact erosion characteristics of silver and silver-tungsten contacts. Test conditions were 115 V, 60 Hz, and 1.0 power factor for 100,000 operations at 60 operations per minute. Closing and opening speeds were 38 mm/s (1 $\frac{1}{2}$ in./s). Closing force was 980 mN (0.22 lbf) and opening force, 735 mN (0.165 lbf).

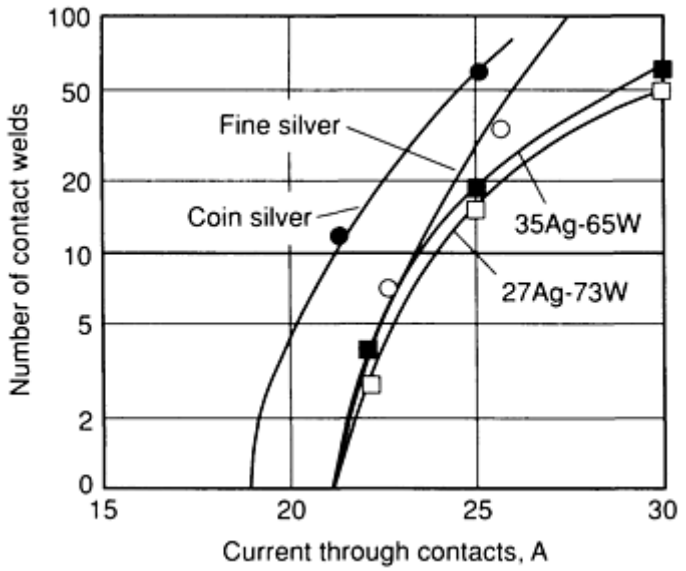

Fig. 8 Contact welding characteristics of silver and silver-tungsten contacts. Operation characteristics are the same as for Fig. 7.

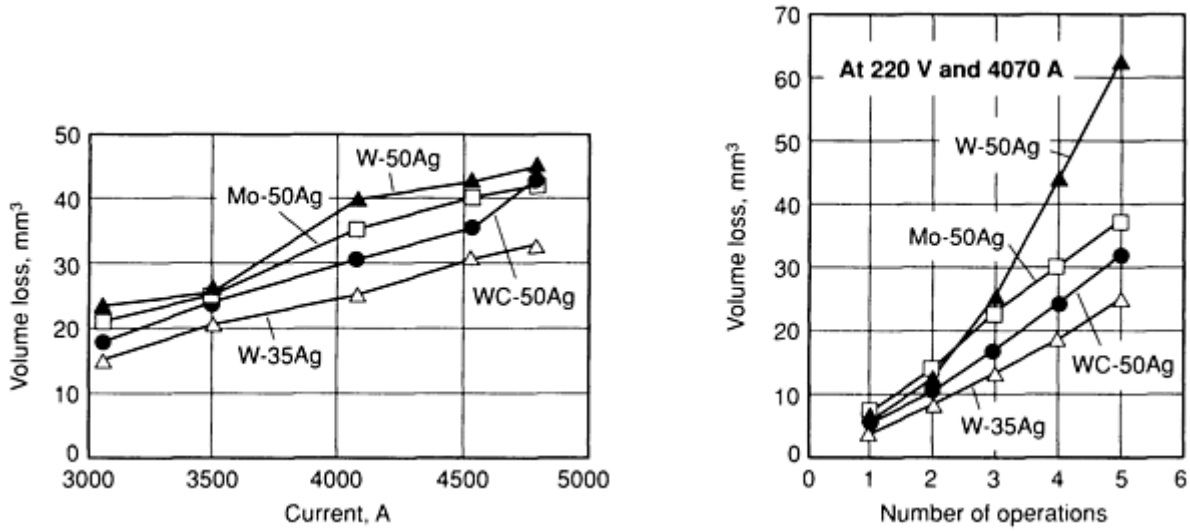

Fig. 9 Results of short-circuit tests on Ag-W, Ag-Mo, and Ag-WC

Refractory Metal and Carbide-Base Composites

Refractory metals and their carbides are distinguished by high melting and boiling points, and high hardness, but poor electrical and thermal conductivities and poor oxidation resistance. In pure elemental form, refractory metals perform well only under low-current conditions.

Forming a composite can compensate for these drawbacks. For example, the development of composite contact materials involving silver or copper with tungsten or molybdenum or their carbides has resulted in materials that can withstand higher currents and more arcing than other contact materials, without experiencing sticking or rapid erosion. The refractory metal content may vary from 10 to 90%, although 40 to 80% usually is used in air- and oil-immersed circuit breaker devices. Refractory metals offer good mechanical wear resistance and resistance to arcing. The silver and copper provide the good electrical and thermal conductivities.

Because silver or copper does not alloy with tungsten, molybdenum, or their carbides, P/M processes are required in fabrication. Depending on the composition, refractory metals containing silver or copper contact materials are made either by pressing and sintering or by the press-sinter-infiltrate method. When infiltration is used, either all refractory metal powder is compacted to shape, or a small amount of silver or copper powder is blended with the refractory metal, compacted, and sintered in a reducing atmosphere. The sintered compact is then returned to the furnace; silver or copper is added to act as the infiltrant.

Most infiltrated composite contacts use silver as the infiltrant because of its excellent thermal and electrical conductivities, as well as its superb oxidation resistance. Copper infiltrant, which costs less but has very poor corrosion resistance, is used for composites that operate in noncorrosive environments such as oil, vacuum, or inert atmospheres. At temperatures above the melting point of the infiltrant, the liquid metal penetrates and fills the interconnecting voids of the pressed and sintered compact. Densities of 96 to 99% of theoretical can be achieved by this process. Infiltrated contact materials find use as current-carrying contacts in air- and oil-immersed circuit breakers, heavy-duty relays, automotive starters, and switches. Lower properties can be obtained by pressing and sintering.

In a material made by infiltration, the function of the infiltrant (silver or copper) is twofold. First, because silver or copper does not alloy with tungsten, molybdenum, or carbides, the conductivity of the composite depends strictly on the volume percentage of infiltrant. Second, during arcing, the high temperature melts the infiltrant; consequently, the heat of fusion absorbs (quenches) a portion of the heat generated by the arc. Theoretically, the skeleton, which is made of a high-melting element, will not begin to melt until all the low-melting component evaporates. The refractory skeleton also prevents molten infiltrant from flowing by capillary action. Because of this, erosion loss of the contact is low. Properties (such as the erosion data in Fig. 7 and 9) of the contact vary with the composition of the composite. A composite with high skeletal composition has high hardness and better wear resistance, but lower current-carrying capacity. On the other hand, a high-silver composite possesses high electrical and thermal conductivities, and undergoes lower temperature rise, but is softer.

Compositions of Refractory Component. There is a lower limit for the composition of the skeleton material. Generally, when the amount of refractory or carbide is less than about 30 vol%, it is difficult to form a sound and uniform skeleton to accommodate the amount of silver. For practical purposes, the skeleton material should amount to a minimum of 50 wt% for tungsten and molybdenum, and 35 wt% for tungsten carbide. Any composite containing lesser amounts than these limits should be made by the press-sinter-re-press method, and should be considered a silver-base composite in which the function of the refractory material is to reinforce the silver matrix. For compounds with 60% or less tungsten, the classical method of mixing the powders, pressing, sintering (generally below the copper melting point), and re-pressing might also be used. Materials with 60 to 80% W are generally produced by infiltration, either of loose tungsten powder or of a pressed and sintered tungsten compact.

Tungsten, tungsten carbide, and molybdenum powders are the most commonly used materials for making skeletons for infiltrated contacts. Composites with tungsten skeletons have the best arc-interrupting and arc-resisting characteristics and the best arc-erosion resistance. Their antiwelding properties are moderate (Fig. 8). High-energy devices usually use silver-infiltrated composites having a tungsten skeleton.

Composites with tungsten carbide skeletons have better resistance to welding, better anticorrosion properties, and more stable contact resistance compared with other infiltrated composites. Devices that handle switching arcs usually use composites based on tungsten carbide skeletons.

For a combination of properties, or sometimes for a special requirement, a skeleton made of a mixture of tungsten and tungsten carbide is used. The blended powder contains either the mixture of tungsten and tungsten carbide or a mixture of tungsten and graphite. In the latter case, the graphite and part of the tungsten react to form tungsten carbide during sintering.

Composites with molybdenum skeletons have relatively low contact resistance and behave well in circuit-interrupting devices. For the same current-carrying capacity, a molybdenum-base composite costs less than the other two, but the antiwelding and anticorrosion properties of molybdenum-base composites are inferior to those with tungsten or tungsten carbide skeletons. Figure 9 compares the erosion characteristics of a molybdenum composite with tungsten and tungsten carbide composites.

Silver-Base Composites

The main advantage of a silver composite over a silver alloy is that the bulk conductivity of a silver composite depends generally on the percentage of silver by volume. An alloying element in solution greatly decreases the conductivity of silver. For instances, the volume of silver in Ag-15CdO composite is less than that in Ag-15Cd alloy, yet the electrical conductivity of the former (65% IACS) is much greater than that of the latter (35% IACS).

In silver composites, the second phase forms discrete particles that are dispersed in the silver matrix. The dispersed phase improves the matrix in two ways. First, it increases the hardness of the composite material in a manner similar to dispersion hardening. Second, in the region where two mating contacts touch upon closure, the second phase particles reduce the surface area of silver-to-silver contact. This greatly reduces the tendency to stick or weld. In cases where the contacts do weld, the second-phase oxide particles (which are weaker and more brittle than silver) behave as slag inclusions and reduce the strength of the weld, allowing the device contact-separating force to pull the contacts apart.

Silver-base composites can be divided into two types: type 1 uses a pure element or carbide as the dispersed phase; type 2 uses oxides as the dispersed phase. In both types, the hardness increases and the conductivities decrease as the volume fraction of dispersed phase increases, and vice versa.

Silver-Base Composites With a Pure Element or Carbide. In type 1, the dispersed phase functions as a hardener and improves the mechanical properties of the silver matrix. The dispersed phase also promotes improved electrical performance such as antiwelding properties. Elements used include tungsten, tungsten carbide, molybdenum, nickel, iron, graphite, and mixtures of these materials.

Silver-Tungsten and Silver-Molybdenum Composites. Silver composites (made by the press-sinter-re-press method using tungsten, tungsten carbide, and molybdenum as the dispersed phases) show electrical conductivities similar to those of infiltrated composites of the same components. However, their mechanical properties are inferior because the dispersed phases do not form a refractory skeleton.

Silver-Nickel Composites. One of the elements typically combined with silver by P/M processes is nickel. Nickel is more effective as a hardening agent than copper; consequently, silver nickel is considerably harder than coin silver. At the

same time, nickel does not increase contact resistance appreciably, particularly in combinations that include 15 wt% Ni or less. Silver nickel is combined in proportions ranging to about 40 wt%.

Composites with nickel as the dispersed phase resist mechanical deformation or peening under impact and possess good antiwelding properties. Silver-nickel composite contacts can be used as both members of a contact pair. Sometimes, a silver-nickel composite is used as the moving contact operating against a stationary contact of a different composite such as silver-graphite.

The combinations most widely used are 60Ag-40Ni and 85Ag-15Ni. These materials are very ductile and can be formed in all of the shapes in which silver contacts are used, including very thin sheets for facing large contact areas. This material is ideal for use under heavy sliding pressures. It does not gall like fine silver and coin silver, but instead takes on a smooth polish. It is therefore suitable for sliding contact purposes, as well as for make-break contacts. Silver nickel can handle much higher currents than fine silver before it begins to weld. It has a tendency to weld when operated against itself. Therefore, it is frequently used against silver graphite.

The 60Ag-40Ni composites is the hardest material in the silver-nickel series. It is the most suitable for sliding contact in which pressure is high. This alloy also has the lowest rate of wear under sliding action. It is less ductile than silver-nickel materials containing less nickel, but it is still sufficiently ductile for all conventional manufacturing processes.

The 85Ag-15Ni composite is the most widely used material in the silver-nickel series. Because of its ideal mechanical properties, 85Ag-15Ni is an ideal material for motor-starting contactors and is superior in this type of application to fine silver, coin silver, and copper. It is also suitable as a general-purpose contact for various types of relays and switches.

The contact resistance of clean 85Ag-15Ni contacts that have not operated under load tend to be slightly lower for fine silver. However, in make-break circuits, silver tends to gradually increase contact resistance. This increase is not necessarily permanent, as contact resistance varies with the effects of arcing on the contacts. Generally, average resistance is higher than the initial resistance before the contacts operate. The contact resistance of 85Ag-15Ni is similar, except that it usually varies within a narrower range. Exhibiting nearly constant contact resistance is more important than possessing low contact resistance.

85Ag-15Ni exhibits a lower contact resistance and is also harder than coin silver.

Another advantage of 85Ag-15Ni is its low flammability; that is, it makes a smaller arc than other materials. In testing of more than 40 contact materials, 85Ag-15Ni exhibited the lowest arc energy. Low arc energy is important in that the ability to break a circuit with as little flame as possible is desirable. This characteristic was primarily responsible for the adoption of 85Ag-15Ni for relays in aircraft electrical systems.

Silver-Graphite Composites. Graphite is also combined with silver by P/M techniques. Graphite in silver-base composites serves as a good lubricant, reducing the damage caused by frictional forces. Silver-graphite composites are used chiefly as sliding or brush contacts. These materials have high resistance to welding and are also used as make-break contacts. In circuit breakers, they are usually paired with silver-nickel composites.

The most frequently used composition is 95Ag-5C, although graphite compositions ranging from 0.25 to 90% with the remainder silver have been used. This material was developed as a circuit breaker contact material. The addition of graphite prevents welding. Frequently, 95Ag-5C is used in combination with silver nickel or silver tungsten contact. It is also used in combination with pure nickel contacts and with fine silver contacts. Silver graphite is soft compared to other types of contact materials, and electrical and mechanical erosion is more rapid.

95Ag-5C has been widely used as a material for contacts in molded-case circuit breakers, sliding contacts, and contact brushes. This material is only moderately ductile and can be rolled into sheets and punched into contacts of various shapes. However, it cannot be headed to make solid rivets or bent to any great extent without cracking. It can be coined to a moderate extent. 95Ag-5C contacts can be individually molded. Depending on size, shape, and quantity, contacts of this material are either punched from rolled slabs, extruded, or individually molded from powders. Copper is combined with graphite as a substitute for silver in certain applications.

A modified form of silver graphite is silver-nickel-graphite. Typical compositions are 88Ag-10Ni-2C and 77Ag-20Ni-3C. These materials are substantially harder than 95Ag-5C and exhibit superior wear resistance, but offer less protection against welding. Like 95Ag-5C, they can be manufactured from slabs or by molding individually.

Composites of silver-iron exhibit good antiwelding and good wear characteristics when used in creep-type thermostat devices. These materials have poor corrosion resistance.

Silver-Base Composites With Dispersed Oxides. Type 2 silver-base composites use semirefractory oxides as the dispersed phase. These silver-base composites are produced by a variety of methods such as internal oxidation, pre-oxidation, and conventional P/M processes (see the section "Composite Manufacturing Methods" in this article).

The semirefractory component of Type 2 silver-base composites includes metal oxides such as CdO, SnO_2, or ZnO. In general, the semirefractory constituents promote nonsticking qualities or provide increased resistance to wear.

The silver-cadmium oxide group of electrical contact materials is the most widely used of all the silver semirefractory contact materials. The addition of 5 to 15% cadmium oxide to silver imparts excellent nonsticking and arc quenching qualities.

Because of its resistance against arc erosion and its low contact resistance which does not increase even after switching, Ag-CdO has proved to be a universally good contact material for many switching devices. Silver-cadmium oxide contact materials are well suited for contactors and motor starters, but are also used in circuit breakers, relays, and switches with medium to low currents.

Ag-CdO material has antiwelding and antierosion properties united with constant resistance, examples of its main advantage of well-combined properties. Another favorable quality is that it has good workability. It can be fabricated by either the internal oxidation (least costly), preoxidation, or P/M methods. The Ag-CdO material can also be cold reduced or rolled quite easily. For instance, Ag-15CdO material can endure more than 70% cold reduction.

Silver-tin oxide, which is used widely in Europe as a contact material, is a class of composite materials that has the potential to replace silver-cadmium oxide composites in many electrical contact applications. However, general comparisons of silver-tin-oxide ($AgSnO_2$) contacts with Ag-CdO contacts are difficult because results may depend on the specific conditions of testing. Previous concerns on the toxicity of CdO, which was one of the motivations for using Ag-SnO_2 contacts, have also been relaxed in Japan and Europe. The toxicity of CdO must be distinguished from the highly toxic nature of cadmium.

Like Ag-CdO contacts, Ag-SnO_2 contacts can be produced by internal oxidation or P/M techniques. One drawback of the Ag-SnO_2 composite is that a third element (such as indium) must be added to achieve internal oxidation when the silver alloys contain more than 4% Sn. The oxidized material also does not allow a high level of cold reduction because of its brittleness. Therefore, a press-sinter-re-press method or extruded method is the most feasible way to fabricate silver-tin oxide, although extruded products are more brittle than extruded Ag-CdO powder of similar compositions. For example, extended Ag-10SnO_2 can be subject to a maximum of 30% cold reduction compared to over 60% for Ag-12CdO.

Another drawback is the higher temperature rise of Ag-SnO_2 contacts (as compared to Ag-CdO) after arcing. This troublesome characteristic has, however, been eliminated with Ag-SnO_2 materials made by P/M methods.

Table 8 lists three grades of commercially available silver-tin oxide composite contact materials. Ag-SnO_2 contact materials cannot be easily brazed or welded. To be able to braze silver-tin oxide contacts, they are made with at least two layers, the contact layer and brazable or weldable fine silver layer. The brazing alloy can be applied separately in the shape of paste, wire, or foil, or it is already clad onto the semifinished product.

Silver-zinc oxide (Ag-ZnO) is another composite material that has been tested and marketed for contact applications. Silver-zinc oxide, like silver-tin oxide composite, cannot take high cold reduction because of the brittleness of the oxidized material. When internal oxidization is used, the maximum zinc content cannot exceed 6% for good oxidation. Typical applications of a commercially available Ag-ZnO composite are listed in Table 8.

Multiple-Component Composites. There is no ideal material to meet all conditions for contact applications. If required by manufacturers of switching devices, contact manufacturers can offer composite materials consisting of as many as four or five components. Most of these composites serve only special purposes. They are not universally accepted and generally cost more. Two common three-component composites are listed in Table 8.

Composite Manufacturing Methods

The methods used to manufacture composite contact materials can be classified into three major categories:

- Standard P/M processes, for producing composites from materials that cannot be conventionally alloyed
- Internal oxidation processes, for producing silver-base composites with dispersed oxides
- Hybrid consolidation, which is a combination of the internal oxidation and P/M consolidation processes

P/M Methods

Infiltration is used exclusively for making refractory metal and carbide-base composite contact materials. Metal powder or carbide powder is first blended to the desired composition with or without a small amount of binder to impart green strength, then is pressed and sintered into a skeleton of the required shape. Silver or copper is then infiltrated into the pores of the skeleton. This method produces the most densified composites, generally 97% or more of theoretical density. Complete densification is not possible because of the presence of some closed pores in the sintered skeleton. After infiltration, the contact is sometimes chemically or electrochemically etched so that only pure silver appears on the surface. The contact thus treated has better corrosion resistance and performs better in the early stages of use.

Press-Sinter. For small refractory-metal contacts (not exceeding about 25 mm, or 1 in., in diameter), a high-density material can be obtained by pressing a blended powder of exact final composition into shape and then sintering it at the melting temperature of the low-melting-point component (liquid-phase sintering). In some cases, an activating agent such as nickel, cobalt, or iron is added to improve the sintering effect on the refractory metal particles. For this process, powders of much finer particle size are required so that more bonding surface exists. However, the skeleton formed by this process is weaker than that formed by the infiltration process. Formation of the skeleton usually shrinks the apparent volume of the refractory portion of the composition, thus bleeding out the molten component onto the surface of the finished contact.

Press-Sinter-Re-press. The press-sinter-re-press process is used for all categories of contact materials, especially those in the silver-base category. Blended powders of the correct composition are compacted to the required shape and then sintered. Afterward, the material is further densified by a second pressing (re-pressing). Sometimes the properties can be modified by a second sintering or annealing. The versatility of this process makes it applicable for contacts of any configuration and of any material. However, it is difficult to obtain material with as high a density as is obtained with other processes. Material thus produced also may have weak bonding between particles.

Press-Sinter-Extrude. Blended powder of final composition is pressed into an ingot and sintered. The ingot is then extruded into wires, slabs, or other desired shapes. The extruded material may be subsequently worked by rolling, swaging, or drawing. Material made by this method is usually fully dense.

The press-sinter-extrude process is used mostly for silver-base composites. Other processes used for manufacturing silver-base composite contacts are direct extrusion or direct rolling of loose powder. Although they appear to be uncommon, they are economically feasible if the equipment is properly designed and built.

Internal Oxidation

Silver-base composites with dispersed metal oxides can be produced by internal oxidation. In this process, a silver alloy (such as a silver-cadmium alloy) is first cast into ingots, which are rolled into strips or fabricated further into the finished product form. The silver-alloy material is then heated in air or oxygen, so that the oxygen diffuses into the alloy and forms metal oxide particles (such as CdO in the case of a Ag-Cd alloy) dispersed in the silver matrix.

Internal oxidation is used in the production of a substantial portion of Ag-CdO composites. The initial Ag-Cd alloy can be internally oxidized either in strip or finished product form. The silver-cadmium alloy is heated between 800 to 900 °C (1470 to 1650 °F) in a furnace with air, oxygen-enriched air, or pressurized oxygen. Under this condition, the oxygen species diffuse into the silver-cadmium alloy and oxidize the cadmium species. Upon the completion of the oxidation, the cross section of the material will display a microstructure of cadmium oxide particles embedded in a silver matrix. Contact parts are punched from the strip and then coined into required shapes.

The size of the CdO particles and the uniformity of their dispersion are dependent on the temperature and the partial pressure of oxygen. Reduced temperature decreases coalescence of cadmium prior to being oxidized and thereby causes a finer dispersion of CdO. Increasing the partial pressure of oxygen in the furnace increases the diffusion rate of oxygen into the silver. This also causes a finer CdO dispersion by reducing the time available for the cadmium to coalesce.

During the internal oxidation of a silver-cadmium alloy, the cadmium species become depleted in zones when the oxygen front moves into the silver-cadmium alloy. The cadmium atoms before the oxygen front immediately diffuse into the zone against the oxygen front. As the oxidation front moves from the surfaces of the strip toward the center, the concentration

of the cadmium species becomes increasingly dilute as compared to the original composition. Hence, after the oxidation is completed, the cross section will display a significant oxide-deficient or -depleted zone in the center of the contact body.

For some applications the presence of the depletion zone is detrimental, requiring its removal or displacement from the center. There are two common methods to achieve this result. In the first, an oxidation barrier, such as ceramic glaze, is applied to one surface so that the oxidation can proceed from only one side. The second method is to laminate two Ag-Cd sheets of the same size and to form a package by welding along the four edges. After oxidation, the sheets are separated. The oxide-deficient zone will appear on one side (the inner side of the package) of each sheet.

Package rolling is another technique for reducing the size of the depletion region. In this method, very thin Ag-Cd sheets are first oxidized. Then a number of sheets (for example, 16 sheets) are stacked together and hot-bond rolled into one slab. The cross section of the final product displays very thin depleted zones equal to the number of sheets.

Hybrid Consolidation

Various hybrid techniques utilize a combination of internal oxidation and P/M methods. These methods are used to produce a finer average oxide size and/or a more uniform distribution of cadium oxides in the matrix of a Ag-CdO composite. Hybrid consolidation methods include:

- Preoxidize-press-sinter-extrude
- Coprecipitation

Table 9 compares Ag-CdO composites manufactured by different methods.

Table 9 Comparison of Ag-CdO material made by different methods

Properties	**Press-sinter-re-press**	**Press-sinter-extrude**	**Internal oxidation**	**Preoxidize-press-sinter-extrude**
Performance characteristics				
Resistance to arc erosion	3	2	1	1
Resistance to sticking and welding	1	1	2	2
Low contact resistance and temperature rise	1	1	1	1
Arc interruption	3	2	1	1
Resistance to corrosion	1	1	1	1
Material characteristics				
High mechanical properties	3	2	2	1
Resistance to annealing	3	2	2	1
Electrical and thermal conductivity	2	1	1	1

Flexibility of composition	2	2	2	1
Uniform cadmium oxide distribution	1	1	3	1

Note: 1 indicates that under most conditions this is the preferred material; 2 indicates that under most conditions the material is preferable to 3, but not as good as 1; 3 indicates that the material may be acceptable, but under typical operating conditions it is not as good as 1 or 2.

The preoxidized-press-sinter-extrude process combines the oxidation process and the press-sinter-extrude process. Commercially, it is called "preoxidized process." The purpose of this method is to redistribute the oxide-deficient center of Ag-CdO composites.

The preoxidized process is used exclusively for making silver-cadmium oxide (Ag-CdO) material. Alloys are reduced to small particles in the shape of flakes, slugs, or shredded foil. These particles are oxidized and then consolidated with the press-sinter-extrude process. Material made by this method is more uniform than the same material made by conventional internal oxidation. Mechanical properties are superior of those of the same material made by the press-sinter-re-press method.

The Ag-CdO particulates are made by one of four methods and then are pressed into ingots, sintered, and extruded according to standard metallurgical method. There are four processes to prepare the particulates:

- *Granulated Wire:* Ag-Cd alloy is first made into wire and oxidized. The oxidized wire is then chopped into granules with a length of about 3 mm ($\frac{1}{8}$ in.)
- *Low-Pressure Water Atomization:* The molten Ag-Cd alloy is atomized by water at a pressure of 100 to 200 kPa (15 to 30 psi). The approximately quarter-inch particulates are in the form of thin twisted flakes. Then the flakes are oxidized for consolidation
- *High-Pressure Water Atomization:* The molten Ag-Cd alloys is atomized with high water pressure, usually higher than 2750 kPa (400 psi). The powder sizes range between 40 mesh (420 μm) and 270 mesh (53 μm). Then the alloy powders are oxidized before consolidation

Coprecipitation. Conventional blending or mechanical mixing of silver and cadmium oxide powders begins by dissolving the proper amounts of silver and cadmium metals in nitric acid. Compounds of silver and cadmium coprecipitate from the solution when the PH value of the solution is changed by adding either hydroxide or carbonate solutions. During subsequent calcination at about 500 °C (930 °F), the compound mixture decomposes to form a mixture of silver and cadmium oxide. Alkali-metal content can be controlled in the ppm range by adequate washing. Controlled amounts of sodium, potassium, and lithium may enhance electrical life. Excessive amounts of these elements can lead to rapid erosion, restrike, and generally poor electrical life. Depending on device design, the range may be from 10 to 300 ppm. Contacts are consolidated from this mixture by conventional P/M methods. The microstructure of contacts made by this method displays a finer particle size and a more uniformly dispersed CdO phase than material made by conventional blending.

Life Tests

Example 1. Wear of Telephone Plugs (Fig. 10). A simulated service test, representing the service of telephone plug bodies, has provided a comparison of the wear properties of 2011-T3 aluminum and half-hard brass rubbing against nickel-silver.

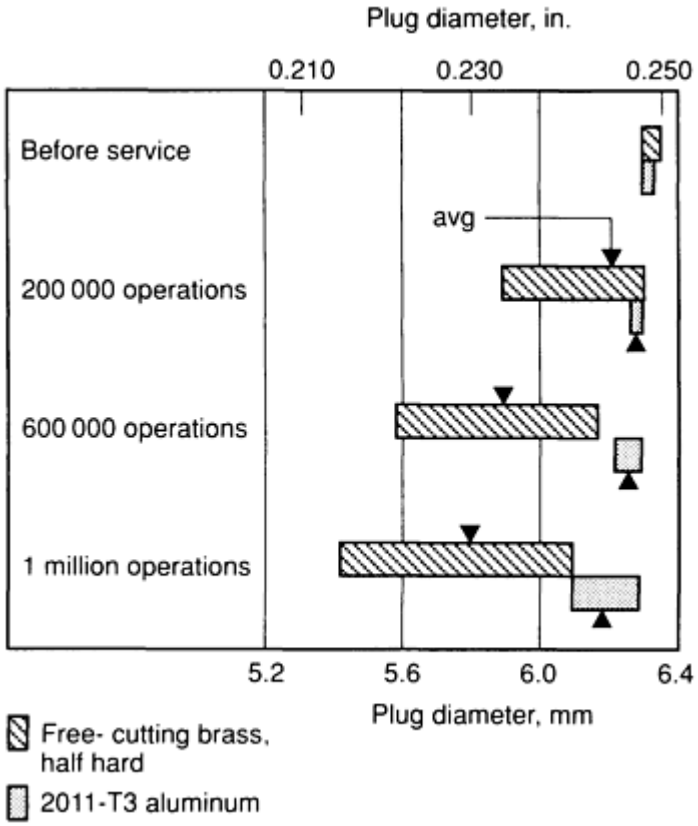

Fig. 10 Wear of aluminum and brass telephone plugs in simulated service. Test plugs were cycled at 30 operations per minute and rotated 35° after each 100,000 operations. Measurements were taken after each 200,000 operations.

The outside diameter of each sleeve was measured at intervals of 60° around the circumference. After the original diameter of approximately 6.32 mm (0.2490 in.) was measured, the plug was mounted on a test fixture designed to simulate normal mating of the plug and corresponding jack. Upon entering the jack, the sleeve rubbed against a nickel-silver spring contact. The test lasted for one million operations at a rate of about 30 per minute. To get more uniform wear, the plugs were rotated about 35° after each 100,000 operations. There was considerably less wear on the aluminum alloy plugs than on the brass, as shown in Fig. 10.

Example 2. Life Tests Using an ASTM Microcontact Tester (Fig. 11). Effect of voltage on contact resistance and contact area for 100,000 operations, using 0.38 mm (0.015 in.) diameter 80Pt-20Ir contacts with a load of 100 mA, is shown in Fig. 11. Tests were made using an ASTM microcontact tester that allowed selection of any make-break contact force up to 49 mN (0.011 lbf). Contacts were protected from dust by a glass cover during testing. In these tests, the make force was 10 mN (0.002 lbf) and the break force was 5 mN (0.001 lbf). Ten readings were taken at each interval, resulting in the spread shown in Fig. 11.

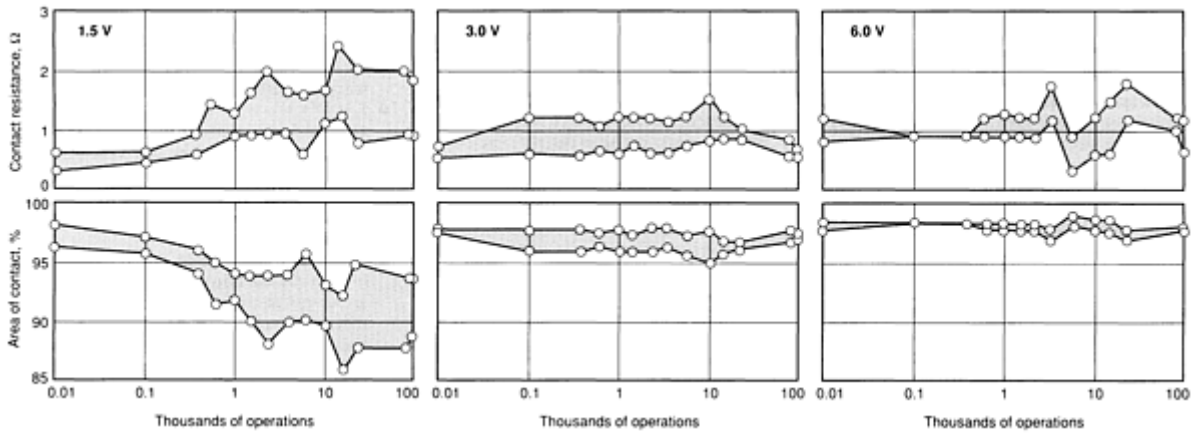

Fig. 11 Effect of voltage on contact resistance and contact area for 80Pt-20Ir contacts 0.4 mm (0.015 in.) thick. (Upper row of graphs) Effect of voltage on contact resistance at a load of 100 mA. Contacts were held in a clamp-type holder and tested in a closed jar. Shaded area represents spread for ten readings. (Lower row of graphs) Effect of voltage on contact area for tests same as above. Initial contact area was 96 to 98%.

Low noninductive voltages had little effect on contact operation. There appeared to be more consistency in the 3 and 6 V readings, and they finished at lower resistance.

Example 3. Life Tests Using a Movable-Coil Relay. An accelerated life test was conducted on five contact materials mounted in a movable-coil type of relay. These contact materials were solid silver, solid 80Pt-20Ir, and gold, ruthenium, and rhodium plated on the platinum-iridium alloy. The moving contacts were two 20 mm (0.80 in.) diam flat disks mounted one on each side of a phosphor bronze strip. The stationary contacts were pointed wire having a 0.075 mm (0.003 in.) radius at the point, mounted in adjusting screws, one on each side of the moving contact. The contacts were operated with a force of about 980 μN (2.2×10^{-4} lbf) on one side and no mechanical load on the other. The electrical load was purely resistive: 1 mA at 9 V dc. Contact resistances were measured using an ohmmeter that operated on 1.5 V, 30 mA, and a force of 29 μN (6.5×10^{-6} lbf). Results of this test support these conclusions:

- If sticking were not a problem, silver would be the best material, having low contact resistance up to 12 million operations. However, silver began to stick after 800,000 operations
- Gold-plated platinum-iridium had low contact resistance, and there was no sticking until about 3.5 million operations
- The three platinum-family metals were similar, each having higher contact resistance than silver or gold from the start. However, platinum-iridium did not increase in resistance as much as the other two and finished with the lowest contact resistance of the three platinum metals

An examination of the contacts at the end of the test revealed that there had been no arcing and that the load was not sufficient to erode the contacts. Thus, failure (high contact resistance) occurred solely because of wear.

Although silver and gold were superior for applications involving frequent make-break, platinum-iridium would still be chosen for use where the relay would be idle for long periods of time, as in a burglar alarm.

Example 4. Life Tests in Circuit Breakers (Fig. 12). Ag-W contacts and the same kind of contacts having silver-enriched surfaces were tested for about five months in circuit breakers to determine how the average maximum temperature of the contacts changed during this simulated service. The current through the contact was 20 A at 120 V, 60 Hz, ac. The breakers were mounted in an enclosure where the temperature was 40 °C (105 °F); outside the enclosure it was 25 °C (77 °F). The breakers were operated in the closed position for $8\ \frac{1}{2}$ h per day from Monday through Friday, but remained open overnight and on weekends (one make and one break per day). The temperature values shown in Fig. 12 are averages of six readings.

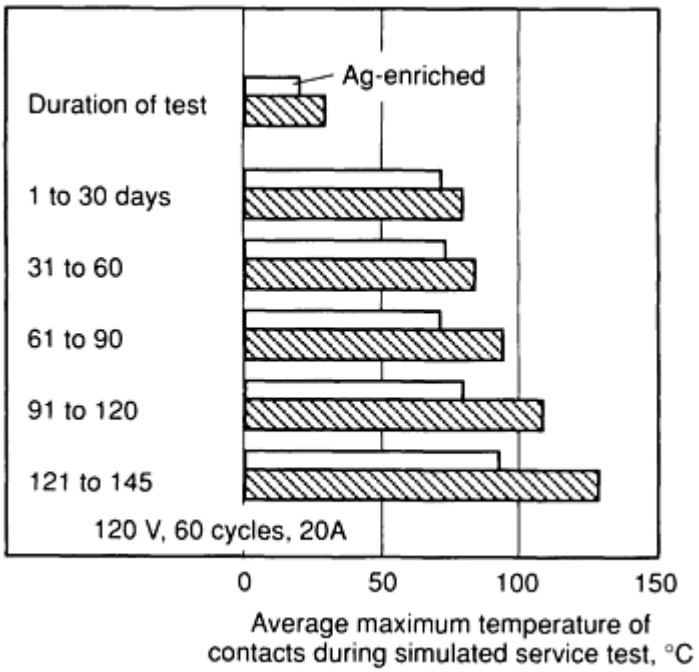

Fig. 12 Effect of time on maximum temperature of Ag-W contacts, compared with similar contacts having silver-enriched surfaces. See text for description of test.

The maximum temperatures for the Ag-W contacts changed almost linearly from 78 to 127 °C (172 to 260 °F) during the period. For the first three months, there was no appreciable change for the silver-enriched contacts. The temperature increases significantly during the fourth and fifth months, reaching about 95 °C (203 °F) at the end of the test. This is 23 °C (42 °F) higher than for the first period, but 32 °C (57 °F) lower than the temperature developed in the same period for the contacts that were not silver enriched.

Effect of Atmosphere. Life tests involving butt contacts have been made for several materials in atmospheres of helium, hydrogen, and air under different operating conditions. Extensive data are presented in Fig. 13. The contacts were subjected to five operations per second, the closing being made magnetically to a closed force of 195 mN (0.044 lbf); the opening was accomplished by a spring to a gap of 0.8 mm ($\frac{1}{32}$ in.).

Fig. 13 Effect of atmosphere and current characteristics on life of contact materials. Tests were performed with a purely resistive load and a rate of five operations per second. Action was entirely butting, the contact being closed magnetically under a force of 20 g (0.2 N, or 0.045 lbf) and opened by a spring to 0.8 mm ($\frac{1}{32}$ in.) width of gap. Welding or open circuit was the criterion of failure. Tests were discontinued after 3.88 million operations.

The criterion of failure was a weld or an open circuit, whichever developed first. If failure did not occur in 3.88 million operations, the test was discontinued.

Not only can the effect of the different atmospheres be determined for any one of the five conditions used, but comparisons can be made of direct and alternating current, variations in current, and variations in frequency. The current conditions were:

Volts	Amperes	Frequency, Hz
28 dc	1	. . .
28 dc	8	. . .
115 ac	5	60
115 ac	5	400
115 ac	30	400

For the direct-current test, none of the ten materials gave long life in air when the current was 8 A. Six materials lasted for the full 3.88 million operations in air when the current was 1 A: fine silver, tungsten, molybdenum, 90Ag-10CdO, 50Ag-50W, and 89Pt-11Ru. Tungsten was the only material to last the full test period when helium was used as the test medium and the direct current was 8 A. Copper, molybdenum, and tungsten lasted the full test period when hydrogen was the test medium and the direct current was 8 A.

The alloy containing 97Ag-3Pt had long life when air and alternating current at 5 A were used, regardless of frequency. The lives of 77Ag-22.4Cd-0.6Ni, 97Ag-3Pt and 90Ag-10CdO, in a hydrogen atmosphere, were increased considerably by increasing the frequency from 60 to 400 Hz. In general, the life of a material was decreased by increasing the current. Fine silver showed a definite superiority over all other materials at 30 A. Copper was a fairly strong rival at 30 A, except in air.

Erosion and Wear. Three simulated tests, the results of which are shown in Fig. 14 and 15, are related to erosion and wear. The following contact materials are dealt with in Fig. 14; fine silver, 90Ag-10Cu, 77Ag-21Cu-2Ni, 77Ag-22.7Cd-0.3Ni, palladium, 35Ag-65W, and 27Ag-73W.

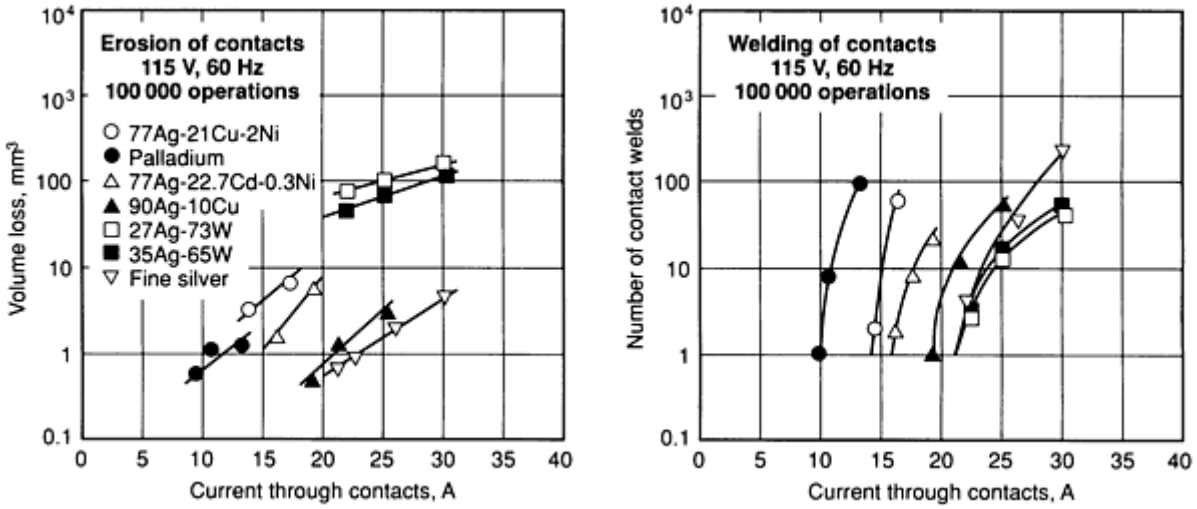

Fig. 14 Comparison of erosion and welding characteristics of selected electrical contact materials. All contacts were butting, with a closing force of 980 mN (0.22 lbf), an opening force of 735 mN (0.165 lbf) and closing and opening speeds of 38 mm/s (1 $\frac{1}{2}$ in./s). Contacts operated at the rate of 60 per minute.

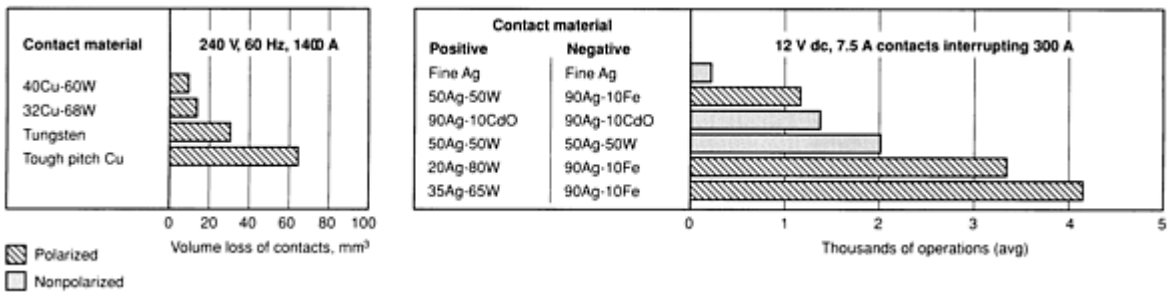

Fig. 15 Contact materials compared for erosion and wear characteristics. (Left) Four contact materials compared for volume loss after 30 operations in 10C transformer oil at a power factor of 70%, maximum arc time of $\frac{1}{2}$ cycle, one operation per minute, using a closing force of 13 N (3 lbf) and an average opening speed of 2.4 m/s (8 ft/s). (Right) Life of polarized contact pairs and nonpolarized pairs based on the number of short circuits observed.

Alternating current at 115 V and 60 Hz was employed, with the test lasting 100,000 operations at the rate of 60 per minute. The contacts were butt-type with closing and opening speeds of 38 mm (1 $\frac{1}{2}$ in.) per second. The closing force was 980 mN (0.22 lbf), and the opening force 735 mN (0.165 lbf).

The number of contact welds was far less for fine silver and for the silver-tungsten sintered products than for palladium. The first two are about the same, but palladium can carry only about 40% as much current through the contact for the same number of contact welds.

The volume loss for fine silver at 25 A is about the same as that of palladium at 12 A. The volume loss for 27Ag-73W and 35Ag-65W is about 100 times that of fine silver at the same amperage.

In Fig. 15, comparison is made of copper, tungsten, 40Cu-60W, and 32Cu-68W, when tested for loss in volume for 30 operations in 10C transformer oil at 240 V, 60 Hz, 1400 A. The volume loss for 40Cu-60W was about two-thirds that for 32Cu-68W, and both were far below that for tungsten or copper.

In the second test, silver, Ag-CdO, and silver-tungsten were used to determine the number of operations required for failure in short circuit in a circuit breaker operating at 12 V dc, 7.5 A, interrupting a 300-A short circuit. A substantial increase in life is realized with a proper polarized combination: Ag-W positive and Ag-Fe negative.

Life of Polarized Contacts. Some information on life of polarized contacts has already been given in connection with erosion and wear (Fig. 15). It was shown that the polarized combination of 20Ag-80W or 35Ag-65W positive and 90Ag-10Fe negative, operating at 12 V dc, 7.5 A, with short-circuit interruption of 300 A, had a longer life than a similar combination where the tungsten content of the sintered contact was as low as 50%.

Test results are shown in Fig. 16 for a device operating with various contact materials in a dc circuit, operating at 12 V, 1.04 A, where polarized contact materials were used, with different materials as positive and negative terminals. The effect of the polarity of the contact materials is clearly demonstrated. Instead of plotting the number of operations obtained with each polarized contact combination, the time required to complete 100 cycle is used. Because sustained arcing affects the temperature rise of the contacts, and also the bimetal element used to make and break the circuit, the time required to complete 100 cycle is a good indication of the effectiveness of different contact of polarity on a given combination.

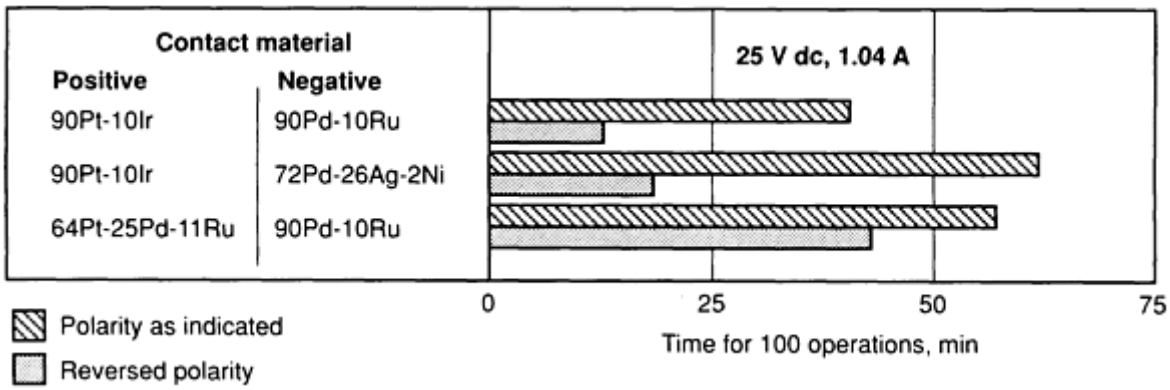

Fig. 16 Effect of composition and polarity on life of some platinum and palladium alloy contacts actuated by a bimetal element. Sustained arcing affects the bimetal, thus indicating effectiveness of contact combinations by time for 100 operations.

Of the materials and combination tested, 90Pd-10Ru positive and 90Pt-10Ir negative gave the shortest time (12 min) for the completion of 100 operations: 90Pt-10Ir positive and 72Pd-26Ag-2Ni negative required the longest time (62 min). It takes less time for 100 cycles when the palladium alloy is positive and the platinum alloy is negative than for the reversed polarity. The time for 100 cycles for the combination 90Pd-10Ru positive and 90Pt-10Ir positive is about one-third that for the same combination with reversed polarity.

Figure 17 shows that polarized contacts, using 50Ag-50WC at both terminals for 24 V dc and 1500 A, have considerably longer life than some other combinations of sintered silver products. Results are also given in this same figure for automotive voltage regulators for 15 V dc, 1.0 A and 15 V dc, 1.8 A. Tungsten-tungsten had a very long life of about 70 million operations when the current was 1.0 A. However, when the current was increased to 1.8 A, the life was reduced to 3 million operations. Positive 90Ag-10Ni and 97Ag-3Pd negative was the best combination tested for the higher amperage but the poorest of all combinations for the lower amperage.

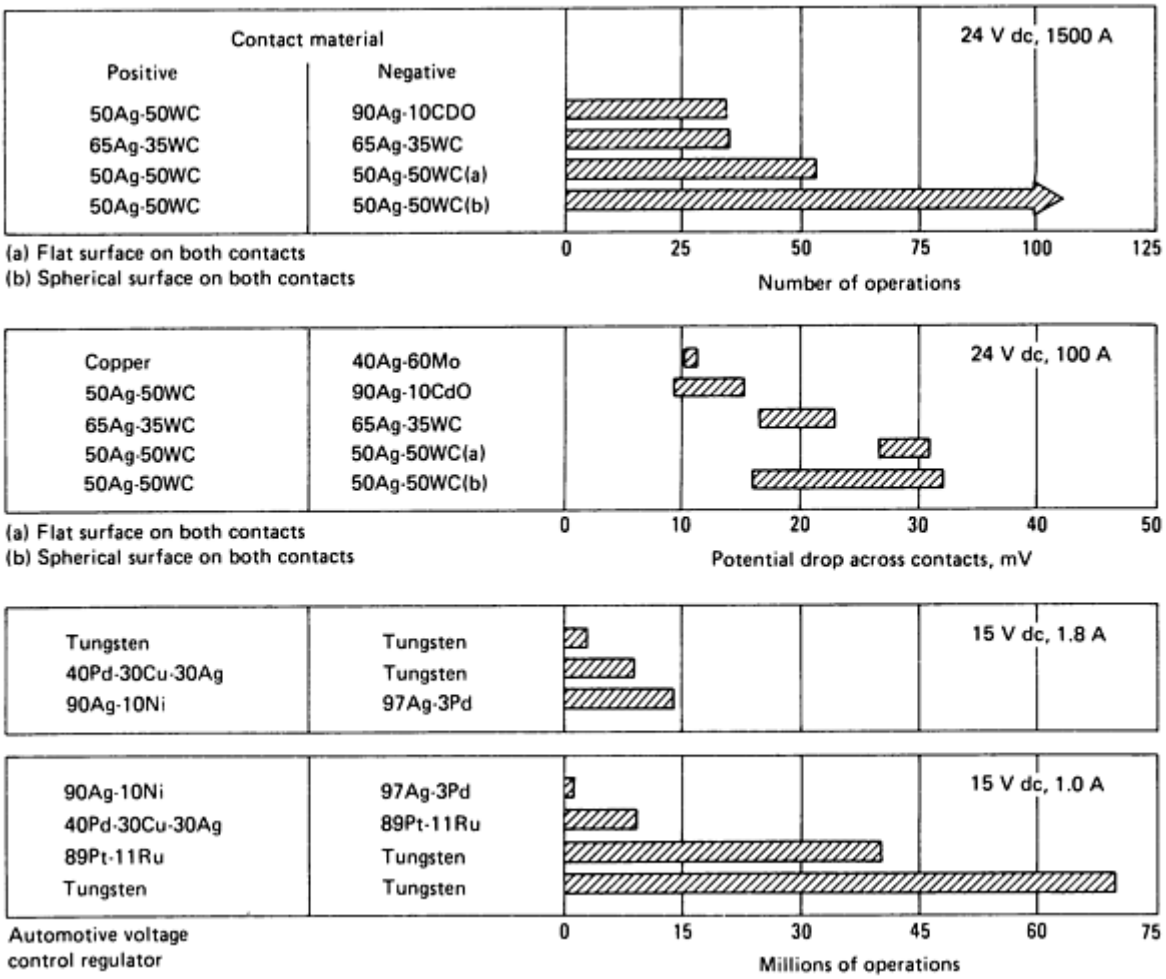

Fig. 17 Effect of composition, combination, and electrical characteristics on contact life of various materials. 24 V dc, 1500 A: A comparison of several polarized contact material combinations for their susceptibility to welding when subjected to an overload of 1500 A at 24 V. The 50Ag-50WC combination with a spherical surface shows considerably longer life than some other combinations of silver sintered products; it did not weld in 100 operations. 24 V dc, 100 A: Shown is the scatter of contact potential after 200,000 operations for several samples of different alloy combinations. Under conditions of relatively high-current, the contact force used in these tests was approximately 2.2 to 2.8 N. 15 V dc, 1.8 A: A comparison of the life of three contact material combinations intended for use in automotive voltage regulators. At this level of amperage, tungsten with tungsten failed because of insulation resulting from oxide formation after 3 million operations. Palladium-copper-silver with tungsten failed as a result of sticking. Silver-nickel with silver-palladium failed from metal transfer. 15 V dc, 1.0 A: Life comparison for four contact material combinations intended for use in automotive voltage regulators. Silver-nickel with silver-palladium made the poorest showing and failed from sticking. Palladium-copper-silver with platinum-ruthenium, and platinum-ruthenium with tungsten-failed from oxide insulation. Tungsten with tungsten, which failed from oxide insulation at 1.8 A, survived about 70 million operations.

Recommended Contact Materials

Fixed and stationary contacts for operations at low frequency are made of less expensive materials such as copper metals and aluminum metals. The ordinary two prong domestic appliance plug is this type in its simplest form. Plug connectors are manually connected and disconnected. There is a little trouble from arcing, pitting, and welding because the current where it will be interrupted before the plug is engaged or removed. The life of the spring is the life of the contact; it is the spring that usually fails. Therefore, spring bronze is used for plugs frequently connected and disconnected that do not need the highest conductivity. Where higher conductivity is needed, silver on copper is better.

For bolted connectors, low contact resistance is important. Silver-coated copper is ideal in a noncorrosive environment. For wet-cell battery terminals, where corrosion is severe, lead against lead is used. Many combinations of metals are used for bolted connectors, corrosivity, conductivity, and cost affecting selection.

Power Circuits. Materials selected for contacts in power circuits (Tables 10, 11, and 12) usually have high electrical and thermal conductivity, and high resistance to arc erosion and to welding or sticking. Because these contacts are relatively large, precious metals like platinum are seldom used except in extremely, copper faced or plated with silver, and aluminum faced or plated with silver are commonly used for stationary contacts carrying high current. Carbon, occasionally mixed with copper or silver in a sintered products, is commonly used for brushes against copper commutators or slip rings for sliding contacts. Occasionally, silver or silver-plated copper is used. Sintered products consisting of tungsten, tungsten carbide, or molybdenum mixed with copper or silver are used for spark gaps and for moving contacts that are required to interrupt high currents at high voltage with heavy arcing.

Table 10 Recommended materials for fixed or stationary contacts for power circuits

Materials are listed in order of decreasing preference.

Alloy	**Advantages**[a]
Plug connectors (1 to 100 A) 1 to 10,000 operations	
Brass	[b], [c]
Bronze	[c], [d], [e]
Sn on Cu	[f], [g], [h]
Plug connectors (100 to 100,000 A) 1 to 10,000 operations	
Cu	[b], [f]
Ag	[f], [g], [h], [i]
Ag on Cu	[b], [f], [g], [h], [i]
Ag on Al	[b], [g], [h], [i]
Cr-Cu	[d], [e]
Blade connectors (10 to 100,00) 10 to 10,000 operations	
Cu	[b], [f]
Ag on Cu	[f], [g], [h]
Bolted connectors (100 to 1000 A) 1 to 100 operations	
Brass	[b], [c]
Bronze	[e], [j]

Sn on Cu	(f), (g), (h)
Bolted connectors (1000 to 1,000,000 A) 1 to 100 operations	
Cu	(b), (f)
Ag on Cu	(f), (g), (h)
Sn on Cu	(f), (g)
Ag on Al	(b), (g), (h)

(a) With fixed or stationary contacts, failure is ultimately caused by deterioration of the contact surface.

(b) Low-cost material.

(c) Material easy to fabricate.

(d) Wear resistance.

(e) Material provides lower contact resistance.

(f) Electrical conductivity.

(g) Surface oxidation resistance.

(h) Material provides lower contact resistance.

(i) Material permits use of low contact force.

(j) Material has higher strength.

Table 11 Recommended materials for sliding contacts for power circuits

Materials are listed in order of decreasing preference.

Alloy	Advantages	Cause of failure
Power brushes (10 to 10,000 A) continuous slide		
Electrographite	(a), (b), (c)	(d)

Carbon graphite	(a), (b), (c)	(d)
Fractional horsepower brushes (1 to 10 A) continues slide		
Electrographite	(a), (b), (c)	(e)
Carbon graphite	(a), (b), (c)	(e)
Resin bonded	(a), (b), (c)	(e)
Aviation brushes (10 to 1000 A) continuous slide		
Electrographite	(a), (b), (c), (f)	(g)
Carbon graphite plus BaF, CdI, MoS_2 for altitude performance	(a), (b), (c), (f)	(g)
Automotive starter brushes (10 to 1000 A) continues slide		
Copper graphite	(a), (b), (h), (i)	(j)
Automotive generator brushes (10 to 100 A) continuous slide		
Electrographite	(a), (b), (c)	(k)
Carbon graphite	(a), (b), (c)	(k)
Automotive auxiliary brushes (1 to 10 A) continuous slide		
Copper graphite	(a), (b), (h), (i)	(l)
Plating generator brushes (100 to 10,000 A) continuous slide		
Copper graphite	(a), (b), (h), (i)	(m)
Alternating-current and slip ring brushes (1 to 1000 A) continuous slide		
Electrographite	(a), (b)	(n)
Carbon graphite	(a), (b)	(n)
Copper graphite	(a), (b), (h), (i)	(n)

Commutators (10 to 10,000 A) continuous slide		
Cu	(a), (h)	(o)
Ag on Cu	(h), (i), (p)	(o)
Silver-bearing Cu	(b), (h), (q)	(o)
Zirconium-bearing Cu	(b), (h), (q), (r)	(o)
Slip rings (10 to 10,000) continuous slide		
Stainless steel	(b), (q)	(o)
Silver copper	(h), (i), (p)	(o)
Bronze	(a), (b), (s)	(o)
Tool steel	(a), (b), (q)	(o)
Wire against slider or trolley wheel (10 to 1000 A) continuous slide or roll		
Bronze wire against bronze wheels	(a), (b)	(t)
Ag-Cu against Ag-W	(b), (h), (i), (p), (u)	(t)
Cd-Cu wire against Cu-C sliders	(h), (p)	(t)
Cd-Sn-Cu wire against hard Cu	(h), (o)	(t)
Steel against cast iron	(a), (b)	(t)
Liquid to collector assembly (10 to 10,000 A) continuous dip		
Mo against Hg	(b), (h), (u)	(v)
Steel against Hg	(a), (b), (q)	(v)
Bearings and swivels (10 to 10,000) intermittent slide		
Brass	(a)	(o)

Steel	(p)	(o)
Cu	(h)	(o)
Ag-graphite	(b), (w)	(o)
Ag	(h), (i), (p)	(o)
Bronze	(b), (q)	(o)
Graphite	(u)	(o)

(a) Low-cost material.

(b) Wear resistance.

(c) High contact resistance for commutation.

(d) Wear, poor commutation.

(e) Wear, arcing.

(f) Suitable for operation in dry air or at altitude.

(g) Wear, dusting, poor commutation.

(h) Electrical conductivity.

(i) Lower contact resistance.

(j) Wear, high resistance.

(k) Wear, arcing, poor performance.

(l) Wear, poor performance.

(m) Wear, dusting, grooving of commutators.

(n) Wear, sparking, grooving.

(o) Wear, arc erosion.

(p) Surface oxidation resistance.

(q) Higher strength.

(r) Higher annealing temperature.

(s) Ease of fabrication.

(t) Wear.

(u) Arc-erosion resistance.

(v) Liquids practically never, solids by arc erosion.

(w) Less sticking and welding tendency

Table 12 Recommended materials for make-break contacts for power circuits

Alloy	**Advantages**	**Cause of failure**
Tap changers (10 to 100 A) no-load make-break, 100 to 100,000 V, 10,000 max operations		
Bronze wiper against brass	(a)	(b)
Cu-Cd against Cu-Cd	(c), (d), (e)	(b)
Brass or bronze against brass or bronze	(a)	(b)
Tap changers (100 to 100,000 A) no-load make-break, 100 to 100,000 V, 10,000 max operations		
Cu	(f)	(b)
Cu-Cd	(f), (h), (i)	(b)
Ag on Cu	(c), (h), (i)	(b)
Ag-Ni	(f), (h)	(b)
Ag-Cu-Ni	(f), (h)	(b)

Cr-Cu	(c), (f), (i)	(b)
Tap changers (10 to 10,000 A) load make-break, 100 to 100,000 V, 10,000 max operations		
Cu-W	(e), (j), (k)	(l)
Cu-WC	(e), (j), (k)	(l)
Ag-graphite	(c), (d), (g) (m)	(l)
Ag-W	(c), (d), (e), (g), (j), (k)	(l)
Ag-Ni	(a), (f), (h), (i)	(l)
Contractors and motor starters (10 to 10,000 A) alternating current, 10 to 100 V, 10,000,000 max operations		
Ag	(c), (d), (g), (j), (o)	(l)
Ag-CdO	(e), (f), (h), (k), (m)	(l)
Ag-Cd	(e), (g), (j)	(l)
Cu	(a), (e), (j)	(l)
Cu-W, Ag-W, Ag-Ni	(e), (f), (h), (k), (m)	(l)
Contactors and motor starters (10 to 10,000 A) direct current, 1 to 1000 V, 10,000,000 max operations		
Ag-CdO	(e), (f), (h), (j), (k)	(l)
Ag-Cd	(e), (i), (j)	(l)
Ag	(c), (d), (g), (i)	(l)
Ag-Ni	(e), (h)	(l)
Ag-W or Ag-Wc	(e), (f), (h), (j), (k)	(l)
Air circuit breakers (10 to 100 A) current-carrying and arcing, 10 to 1000 V, 1,000,000 max operations		
Ag-Cu-Ni	(a), (c)	(n)

Ag-Ni	(e), (h), (j)	(n)
Ag-graphite	(c), (d), (g)	(n)
Ag-W	(e), (f), (h), (j), (k)	(n)
Ag-CdO	(c), (d), (e), (g), (j), (k), (m)	(n)
Air circuit breakers (100 to 1000 A) current-carrying and arcing, 10 to 10,000 V, 100,000 max operations		
Ag-W	(e), (h), (j), (k)	(n)
Ag-CdO	(c), (d), (e), (j), (g), (m)	(n)
Ag-WC	(c), (g), (h), (j)	(n)
Air circuit breakers (100 to 100,000 A) current-carrying only, 100 to 100,000 V, 10,000 max operations		
Cu	(a), (c)	(n)
Ag on Cu	(c), (d), (g), (m)	(n)
Ag-Ni	(e), (h)	(n)
Ag-graphite	(c), (d), (g), (h), (m)	(n)
Air circuit breakers (1000 to 1,000,000 A) arcing tip only, 100 to 100,000 V, 10,000 max operations		
Cu-W	(a)	(n)
Ag-W, Ag-WC, Ag-Mo	(h), (j), (k)	(n)
Magnet steel	(a)	(n)
Oil circuit breakers (10 to 10,000 A) current-carrying and arcing, 1000 to 100,000 V, 100,000 max operations		
Cu-W	(a)	(n)
Ag-W	(d), (e), (g)	(n)
Ag-Mo	(c), (g), (m)	(n)

Oil circuit breakers (100 to 10,000 A) current-carrying only, 1000 to 1,000,000 V, 10,000 max operations		
Cu	(a), (f)	(n)
Ag on Cu	(c), (d), (g)	(n)
Ag-Ni	(f), (h)	(n)
Oil circuit breakers (100 to 1,000,000 A) arcing tip only, 1000 to 1,000,000 V, 10 000 max operations		
Cu-W	(a)	(n)
Cu-WC	(k)	(n)
Ag-W	(c), (d), (g)	(n)
Ag-Mo	(c), (d), (e), (g)	(n)
Spark gaps (10 to 1,000,000 A) 100 to 1,000,000 V, 1,000,000 max operations		
W	(j)	(n)

(a) Low-cost material.

(b) Surface deterioration, wear.

(c) Electrical conductivity.

(d) Lower contact resistance.

(e) Less sticking and welding tendency.

(f) Higher strength.

(g) Surface oxidation resistance.

(h) Wear resistance.

(i) Ease of fabrication.

(j) Arc-erosion resistance.

(k) Resistance to transfer and pitting.

(l) Sticking arc erosion.

(m) Allows low contact force.

(n) Arc-erosion, material transfer and pitting, or overheating

(o)

Liquid metals are seldom used in power circuits, but mercury and the sodium-potassium eutectic are used against solid contacts where a circuit must be completed between a stationary part and one involving an unusual type of motion, or where currents of more than 100,000 A must be "collected" from rotating equipment, as is accomplished with the liquid eutectic.

Brushes. A cursory examination of Table 11 shows that sliding power contacts have a wide range of application. Although the list is not complete, it covers machines with current ranges from 1 to 10,000 A. Even with this broad application range, there is one condition that must be satisfied in any successful sliding contact. Somewhere between the two surfaces that are moving relative to each other, there must be a film or region in shear that prevents seizing or welding of clean surfaces. Trouble ensues when the film disappears in plating generators because of low humidity, or when the film can no longer be formed because of lack of oxygen and moisture, as in aircraft flying at high altitudes. Under normal conditions, this film is inherent.

Lubricants added to the brush material also help in preventing cold welds. In certain power stations operating at room temperature in the wintertime, the relative humidity must be kept above 25% to prevent rapid wear and dusting of brushes. In aircraft applications, adjuvants are helpful in maintaining this film. The identity of such films has not been clearly established. Graphite is most effective, but it requires the presence of considerable moisture and oxygen.

There are no simple rules for selecting materials for brushes, but the usual practice is to start with a material in the correct resistance range. If this is unsuitable the reasons for failure, which might be poor commutation, overfilming, high wear, or arcing, must be considered and brush properties improved.

For many functions, it is imperative to select contact materials that do not contribute unduly to high-frequency radio noise, as may be generated by sliding contacts and brushes. Such noise may be minimized by having low or uniform contact resistance between brushes and rings, a condition that can be effected through the use of graphite, silver-graphite, gold-graphite, or other noble metal brushes against alloys of silver, gold, or platinum, or against graphite. A good expedient is to use two or more brushes against a single ring to have parallel circuits, the ultimate being fiber brushes, molybdenum, or some other metal that gives the effect of many separately supported parallel contacts. In most applications, silver-graphite brushes containing from 5 to 50% graphite are used against silver rings. At high altitude, silver-graphite must have a protecting adjuvant to prevent the rapid wear that may ensure in dry rarefied air.

Circuit Breakers. Contact materials recommended for use in air circuit breakers having a maximum current rating of 800 A and a maximum voltage rating of 600 V are:

Stationary contact	Moving contact

Silver-tungsten	Silver-tungsten
Silver-WC	Silver-WC
Silver-molybdenum	Silver-WC
Silver-nickel	Silver-molybdenum
Fine silver	Silver-tungsten
Silver-molybdenum	Silver-tungsten

Vibrators have severe requirements as contact materials because of the high localized temperature caused by the rapidly repeated making and breaking of contact. As a result, only a small amount of current at low voltage can be handled if the operation is continuous and reasonable life is expected. Contact materials recommended for vibrators are listed in the first group of Table 13.

Table 13 Recommended materials for light power and engineering contacts of current range of 0.1 to 30 A

Materials are listed in order of decreasing preference.

Alloy	Advantages	Cause of failure	Applications
Electromagnetic vibrators (0.1 to 30 A)[a]			
W-0.5 Mo Pd-Ag-Ni-W Pt-Ru-W Ag-Mo Au-Pt-Ir	[b], [c], [d], [e], [f]	[g]	Automotive voltage regulators, bells, buzzers, horns, radio vibrators
Thermomechanical thermostats (0.1 to 30 A)[h]			
Ag	[f], [i], [j], [k], [l], [n]	[m]	Household heating and cooling, cooking, electric blankets
Ag-Pd	[e], [j], [k], [l]		
Ag-Cd	[b], [c]		
Hg-Pt	[j]		
Hg-Mo	[b], [c], [e], [j]		
Ag-CdO	[b], [c], [e]		
Pt-Ir	[d], [j], [k], [n]		

Au	(j), (k), (n)		
Manual or electromagnetic snap-action switches (0.1 to 30 A)[o]			
Bronze	(f), (l), (p)	(q)	Lighting, appliances, engineering equipment
Ag-CdO	(b), (c), (e)		
Ag	(f), (i), (j), (k), (l), (n)		
Pt	(d), (j), (k), (n)		
Au	(j), (k), (n)		
Electromagnetic relays (0.1 to 30 A)[r]			
Ag-CdO	(b), (c), (e)	(s)	Control systems, engineering equipment, lighting, appliances
Ag	(i), (j), (k), (n)		
Ag-Cu	(b), (d), (f)		
Ag-Cu-Ni	(d), (f)		
Pd	(j), (k), (n)		

(a) Fast action with force of 0.137 to 4.45 N ($\frac{1}{2}$ to 16 oz). Contact, butting plus slight wipe, 1 to 110 V; 1 billion max operations.

(b) Less sticking and welding tendency.

(c) Arc-erosion resistance.

(d) Wear resistance.

(e) Resistance to transfer and pitting.

(f) Low-cost material.

(g) Wear, welding transfer, and arcing (open).

(h) Slow or fast action with 2.7 N (10 oz) max force. Contact, butting to considerable wipe, 300 V max; 100,000 max operations.

(i) Electrical conductivity.

(j) Lower contact resistance.

(k) Surface oxidation resistance.

(l) Ease of fabrication.

(m) Arcing, welding and contamination by dust.

(n) Allows low contact force.

(o) Fast action with 0.2 to 4.45 N (1 to 16 oz) force. Contact, butting to wipe, 300 V max; 1 million max operations.

(p) Spring properties.

(q) Arcing (open), and welding.

(r) Fast action with 0.2 to 4.45 N (1 to 16 oz) force. Contact, butting to considerable wipe. 300 V max; 1 million max operations.

(s) Wear (open), some welding (closed)

Automobile horns usually operate for only a short length of time at each operation. They carry 10 to 20 A with a closing force of 25 to 30 N (6 to 7 lbf). Tungsten is almost universally used as the contact material because of the combination of good conductivity and high melting point. The high pressure is needed to break down an oxide film that develops.

Tungsten is also used for contacts in radio vibrators that operate in a protected environment with low current and pressure for comparatively long periods of time. Silver and silver alloy points are used in buzzers that operate with very low current for short periods of time. Platinum or gold is used in critical applications, such as fire alarms, where reliability is essential.

Voltage Regulators. A wide range of contact materials is used in automotive voltage regulators because even minor differences in alternator field circuits or in suppression devices can have a marked effect on contact life. Generally, regulator contacts are polarized, the substance with the higher melting point being specified for the side that ordinarily loses material. A most successful contact combination is a tungsten negative contact against platinum-ruthenium positive contact. Other commonly used materials are tungsten against tungsten at higher voltage with good environmental protection; silver alloys against palladium alloys where cost is important; and gold against platinum-iridium where high current and low induced voltage prevail. In these combinations, the material listed first is used for the positive contact.

Most regulator contacts fail through development of an open circuit because of oxides or other contaminants that come from the contact are, hydrocarbon vapors, or dust particles. Some failures for the same equipment at a different level of field current are caused by welding. Hundreds of different contact material combinations have been used in voltage regulators.

Switches. Two classes of snap-action switches must be considered. The manual type is found in the walls of homes and offices and on electric ranges, ovens, and other similar appliances. Lower-cost contact materials are used for manual switches because substantial slide or wipe of contact surfaces and high contact force can be tolerated.

The other type is a precision snap-action switch that may be operated electromagnetically or mechanically by precision rotating or sliding cams with little movement or low operating forces. This type of switch is used on equipment such as machine tools, precision controls, and thermostats.

Bronze is unsuitable for precision snap-action switches because it corrodes too readily. In circuits that are sensitive to resistance and in which the voltage is low (1 V or less), either silver, gold, or platinum alloys are used. In more than 80% of heat thermostats, mercury-molybdenum or mercury-platinum switches are used; the remainder are of materials such as fine silver, 90Ag-10CdO, 90Pt-10Ir, tungsten, 35Pd-30Ag-14Cu-10Pt-10Au-1Zn, 90Ag-10Fe, and 69Au-25Ag-6Pt.

Mercury switches are well suited for use in thermostats because they promise absolute reliability in making and breaking of contact. However, they must be kept in the desired position.

Fine silver is used extensively if the voltage is as high as 20 V and the current is 1 A or higher. Where a current of 10 to 30 A is controlled and the voltage is higher than 110 V, Ag-CdO is used, especially if the making and breaking of electrical contact is slow.

The precious metals, particularly gold alloys, are recommended where low voltage and so-called dry circuits are involved. It is good practice to have multiple contacts when there is a need for high reliability in making electrical contact.

It has been demonstrated experimentally that reliability can be increased as much as 2700% by using two contacts rather than one, and with the pressure force on each contact being only half of the force on the single contact.

Telecommunications Equipment. In electrical contacts for use in telecommunications equipment, the contact resistance must be low enough to ensure satisfactory circuit operation and to prevent excessive transmission losses. The contact resistance also must be constant to avoid noise modulation in the transmitted signal. Contact separation should not become unreliable because of welding, snagging, or excessive surface roughness due to arcing. The contacts should not become excessively worn due to mechanical action or eroded due to arcing.

The types of contacts most frequently used in telecommunications equipment are:

- Connector contacts that close with considerable slide and high force but are not required to be changed often--for example, a multiwire cable plug and its socket
- Sliding contacts that operate with considerable slide but with low force to make operation easier and to reduce mechanical wear from frequent operation. The contact in a rotary switch is an example
- Butting contacts that generally close with light force and without much slide. The low force and slide minimize power requirements and wear, thereby permitting operation at a high rate. Telephone relays feature this kind of contact

Table 14 lists materials recommended for telecommunications equipment. The most frequently used metals are platinum, palladium, iridium, ruthenium, gold, silver, copper, nickel, and tungsten. The precious metals, because of their tarnish resistance, provide greater reliability of closure and sometimes greater resistance to arc erosion. The base metals, where they can be used, are more economical and provide greater freedom from welding and snagging of pits and buildups arising from arcing.

Table 14 Recommended contact materials for telecommunication equipment

Voltage, V	Current, A	Closed force, g	Make and break with V and A	Expected life, max No. of operations	Materials used[(a)]	Advantages	Usual cause of failure
Connectors

(i) Wear resistance.

(j) Surface deterioration, resistance, and noise.

(k) Resistance and noise.

(l) Wear, resistance, and noise.

(m) Allows low contact force.

(n) Electrical conductivity.

(o) Dust, polymer, carbonaceous deposits, and erosion sticking.

(p) Reduced polymer formation.

(q) Material provides improved resistance to metal transfer and pitting.

Microcontacts are considered to be those contacts having a closure force of 50 mN (0.01 lbf) or less and carrying currents measured in milliamperes at voltages of 120 V or less. Materials recommended for microcontacts are given in Table 15.

Table 15 Recommended materials for microcontacts

Current, microamperes	Voltage, V	Closed force, g	Slide or wipe	Expected operations, millions	Materials used[a]	Advantages	Usual cause of failure
Meter-movement relays							
Magnetic contacts							
100 max	120 max, ac or dc	2-4	Small	2-5	Plated bright Au	[b], [c], [d], [e]	[g]
					Plated bright Ag	[b], [c], [e], [f]	[g]
Load-current-aiding type							
5-25	75-120, dc	$\frac{1}{2}$ -1	Small	2-5	Pt-Ir	[b], [c], [d], [e], [h]	[g]
Sensitive contacts							
200 max	6 max, dc	0.001-0.1	Small	2-20	Pt-Ir	[b], [c], [d], [e], [i]	[g]

Armature-type sensitive relays							
3000 max	120 max, ac or dc	1-5	Small	0.1-1.0	Pd	(b), (c), (d), (i)	(g)
					Au-plated Pd	(b), (c), (d), (e) (f)	
					Au	(b), (c), (d), (e), (f)	
Micropotentiometers							
Brushes							
100 max	120 max, ac or dc	0.1-5	Intermittent		71.5Au-14.5Cu-8.5Pt-4.5Ag-1Zn	(b), (c), (d), (e), (h)	(l)
					35Pd-30Ag-14Cu-10Au-10Pt-1Zn	(b), (c), (d), (h)	
					44Pd-38Ag-16Cu-1Pt-1Zn	(b), (c), (d), (h)	
					69Au-25Ag-6Pt	(b), (c), (d)	
					60Pd-40Ag	(h), (k)	
Miniature slip rings							
Wire							
1 max	120 max, ac or dc	1-5	Continuous		71.5Au-14.5Cu-8.5Pt-4.5Ag-1Zn	(b), (c), (d), (e), (h)	(m)
					35Pd-30Ag-14Cu-10Au-10Pt-1Zn	(b), (c), (d), (h)	
					44Pd-38Ag-16Cu-1Pt-1Zn	(b), (c), (d), (h)	
					90Pt-10Rh	(b), (c), (d)	
Brush rings							
1 max	120 max, ac or dc	1-5	Continuous		71.5Au-14.5Cu-8.5Pt-4.5Ag-1Zn	(h), (d)	(m)

					35Pd-30Ag-14Cu-10Au-10Pt-1Zn	(h)	
					69Au-25Ag-6Pt	(b), (c), (d)	
					Hard Au plate	(b), (c), (d), (e)	
					Rh plate	(h)	(l)

(a) Materials are listed in order of decreasing preference.

(b) Surface oxidation resistance.

(c) Lower contact resistance.

(d) Low contact force.

(e) Reduced polymer formation.

(f) Electrical conductivity.

(g) Frictional polymer and wear.

(h) Wear resistance.

(i) Less sticking and welding.

(j) (j)Arc erosion resistance.

(k) Low-cost material.

(l) Wear, noise, and polymer.

(m) Wear and noise

Silver metals are generally used as microcontacts that have more than 10 mN (0.002 lbf) force and preferably some wipe. Other metals plated with silver are also used, as in magnetically operated microcontacts. In such devices, the fixed contact is a magnet that must be capable of being plated with a metal that can carry the current. The moving contact is iron or a magnetically soft alloy, which also must be plated. These contacts are used in meter-movement relays that have an actuating current of as little as 2 mA. When the soft iron on the pointer is deflected so that it enters the field of the magnetic contact, magnetic attraction causes the contacts to close with a force of 18 to 40 mN (0.004 to 0.009 lbf), and with some impact and wipe. Silver is used in armature-type sensitive relays less frequently than palladium, which is better

than silver in such low-force low-current applications. Palladium is used, for example, for brushes in micropotentiometers.

Platinum-iridium (usually 80Pt-20Ir) is the material most commonly used where the contact force is less than 10 mN (0.002 lbf). Contacts made from 80Pt-20Ir are used in meter-movement relays, both load-current-contact-aiding (LCCA) and sensitive types. In both types, the contacts must close with extremely low force. With the LCCA type, the load current through the contact also passes through an extra winding on the moving coil and thereby increases the closure force. Initial contact often is made with less than 10 μN (2×10^{-6} lbf) of force. Although hardness in a contact material is an advantage, it can also be a disadvantage. For instance, 70Pt-30Ir and 65Pt-35Ir are too hard for most microcontact applications.

Gold has become more widely used in microcontacts since the development of sealed relays. It is a less potent catalyst than members of the platinum family and therefore does not collect as much polymer on contacting surfaces. Like silver, it is easily plated and is used in this form on magnetic contacts. Gold is also plated over palladium in sealed relays to decrease the polymer effect. In miniature slip rings and micropotentiometers, gold alloys are used as brushes, rings, and wire.

Slip ring-brush assemblies are the mechanical devices that transfer electrical information in applications such as gyroscopes, strain gages, and video tape heads by means of contact surfaces that move relative to one another. The smaller of the two moving parts is referred to as the brush, wiper, or contact. By nature these applications require low electrical noise, low friction, long life, and high reliability. Various combinations of metals are used to meet the above demands.

The alloys to be used in slip ring-brush assemblies are selected on an empirical basis, with consideration for environmental conditions, performance requirements, shelf life, and cost. The advantages of wrought precious metals are their low and predictable oxidation rates, long shelf life, and low electrical noise. When compromises are economically necessary, the ring material is changed because it represents a large volume of material compared with the brush.

In general the brush material should be harder than the ring material because the wear of the brush takes place over a relatively small area as compared to the ring. Although the brush should be harder than the ring, it should not be so hard as to act as a cutting tool against the ring material.

A lower-cost alternative to solid wrought precious metals is the electrodeposition of a noble metal, usually a hardened gold. Some use is made of rhodium-plated surfaces, but unless a thin overplate of gold is used, rhodium is not suitable for low noise requirements because of the formation of insulating polymers. Several potential problems with plated surfaces can significantly affect performance and reliability. Porosity, entrapped plating salts, and changes in chemistry through the plating thickness can cause inconsistent performance.

Availability

Silver, gold, platinum, palladium, and most of their ductile alloys are available as stamped contacts. Except for material from which contact disks are produced, a variety of stock sizes is not maintained because, in general, no two applications are identical. For disks, material in strip form, varying in thickness from 0.25 mm to 1 mm (0.010 to 0.040 in.) is available.

Except for tungsten and molybdenum, contact materials are ductile enough so that they can be produced in all contact forms. Tungsten and molybdenum and some of the P/M materials have lower ductility and are available in fewer forms. The commercially available forms of common electrical contact materials are listed in Table 16.

Table 16 Commercially available forms of electrical contact materials

Alloy	Product form										Mig method	
	Solid rivet	Wire	Strip	Tape	Disks	Attached[a]	Composite weld disks[b]	Clad[c]	Rings	Brushes	Melting	P/M

(a) Contact disks attached to screws, rivets, blades and bars.

(b) Composite welding-type buttons produced for resistance welding attachment. Backings of nickel, Monel, and steel.

(c) Clad materials including overlay, throughlay, edgelay, strip of precious metal on (or in) base metal

Silver, gold, platinum, palladium, and nearly all the alloys of these metals, as well as tungsten, molybdenum, and the various sintered products of silver and the refractory metals, can be used to produce steel-back contacts. Steel-back contacts have been made in the form of screws, rivets, or buttons for projection welding.

Powder metallurgy materials are available with final densities up to 99% of theoretical and with high-conductivity surfaces as inserts or overlays. Both P/M and wrought materials may be attached to appropriate carriers by brazing, welding, or diffusion bonding, even though they contain cadmium oxide. For percussion welding of Ag-CdO contacts, backing is not required. For resistance welding, a fine silver backing is needed.

P/M contacts are available with a silver matrix for air and oil applications, and with a copper matrix for oil applications only. The second phase may be tungsten, molybdenum, graphite, tungsten carbide, cadmium oxide, or zinc oxide.

Materials with a high content of refractory metal (50% or more) are usually made by infiltration. In this process, the refractory metal powder is pressed into the desired size and shape with a controlled porosity. The compact is sintered at high temperature in a reducing atmosphere, and then molten silver or copper is infiltrated into the porous sintered compact.

Compositions of a lower refractory content are made by blending powders, pressing them to a desired size and shape, sintering the pressed compact at a high temperature, and re-pressing to size the parts and to increase the density of the compact.

Although parts usually are molded to final shape, they are sometimes finished by machining or grinding to obtain special shapes or unusually close tolerances. When only a few parts are needed, they may be machined from bars to save the cost of expensive dies for pressing a P/M compact.

Sintered materials are available in sizes ranging from rectangles or disks about 0.8 mm ($\frac{1}{32}$ in.) thick by 3 mm ($\frac{1}{8}$ in.) square or 3 mm ($\frac{1}{8}$ in.) in diameter to bars 200 mm (8 in.) long. Most are available in widths up to 75 mm (3 in.) and thicknesses up to 12.5 mm ($\frac{1}{2}$ in.). For some materials, these dimensions may be exceeded.

In small sizes (up to about 12.5 mm, or $\frac{1}{2}$ in., square), the higher refractory compositions are frequently made with serrated surfaces coated with excess silver or silver-base brazing alloy so that they can be attached easily to a backing by welding or by resistance brazing in a welding machine. Larger sizes are generally attached to backing by silver-alloy brazing. The materials are often pre-tinned with silver-base brazing alloy in a controlled atmosphere for good wetting of the contact material.

Many of the low-refractory contact materials are fabricated as disks, rectangles, and special-contour facings that also are attached to backing by silver-alloy brazing. Most materials with 90% or more silver are ductile enough to allow

fabrication as rivets, and to allow assembly by staking or spinning. Among silver-graphite materials, those containing more than 0.5% graphite cannot be satisfactorily cold headed into rivets.

Ag-CdO mixtures are available as round, rectangular, or special-shape facings, and also as rivets.

Cost

Copper is the least expensive elemental material used as electrical contacts, followed by silver, palladium, gold, and platinum in that order. Copper is the most frequently used backing material to reduce cost. Sometimes nickel- or steel-backed contacts are used. Silver, gold, platinum, palladium, and their alloys all have been used to produce nickel-steel-back contacts in the form of screws, rivets, or buttons for projection welding. Nickel will not rust during fabrication or use.

Thermocouple Materials

T.P. Wang, Thermo Electric Company, Inc.

Introduction

ACCURATE MEASUREMENT of temperature is one of the most common and vital requirements in science, engineering, and industry. Measurement of temperature is generally thought to be one of the simplest and most accurate measurements that can be made. This is a misconception. Unless proper techniques are employed, highly inaccurate readings can occur, and either useless data can be generated or materials can be misprocessed. Also, under certain conditions, it may be difficult or impossible to obtain accurate temperature measurements regardless of whether proper techniques are employed.

Nine types of instruments, under appropriate conditions and within specific operating ranges, may be used for measurement of temperature: thermocouple thermometers, radiation thermometers, resistance thermometers, liquid-in-glass thermometers, filled-system thermometers, gas thermometers, optical fiber thermometers, Johnson noise thermometers, and bimetal thermometers. The success of any temperature-measuring system depends not only on the capacity of the system but also on how well the user understands the principles, advantages, and limitations of its application.

The thermocouple thermometer is by far the most widely used device for measurement of temperature. Its favorable characteristics include good accuracy, suitability over a wide temperature range, fast thermal response, ruggedness, high reliability, low cost, and great versatility of application.

Essentially, a thermocouple thermometer is a system consisting of a temperature-sensing element called a thermocouple, which produces an electromotive force (emf) that varies with temperature, a device for sensing emf, which may include a printed scale for converting emf to equivalent temperature units, and an electrical conductor (extension wires) for connecting the thermocouple to the sensing device. Although any combination of two dissimilar metals and/or alloys will generate a thermal emf, only seven thermocouples are in common industrial use today. These seven have been chosen on the basis of such factors as mechanical and chemical properties, stability of emf, reproducibility, and cost. They will be discussed individually after a review of the principles and practice of measuring temperature by use of thermocouples.

Principles of Thermocouple Thermometers

The principle on which thermocouples depend was discovered in 1821 by Seebeck, who found that when two dissimilar metals are joined in a closed circuit an electromotive force is generated if the two junctions are maintained at different temperatures. This *thermal emf* induces an electric current to flow continuously through the circuit and is termed *Seebeck emf* in honor of its discoverer.

Figure 1(a) is a schematic diagram of two electrical conductors, A and B, whose two junctions are exposed to different temperatures, T_1 and T_2. The thermal emf generated in this circuit, E_{AB}, is expressed:

$$E_{AB} = f[A, B, (T_2 - T_1)] \qquad \textbf{(Eq 1)}$$

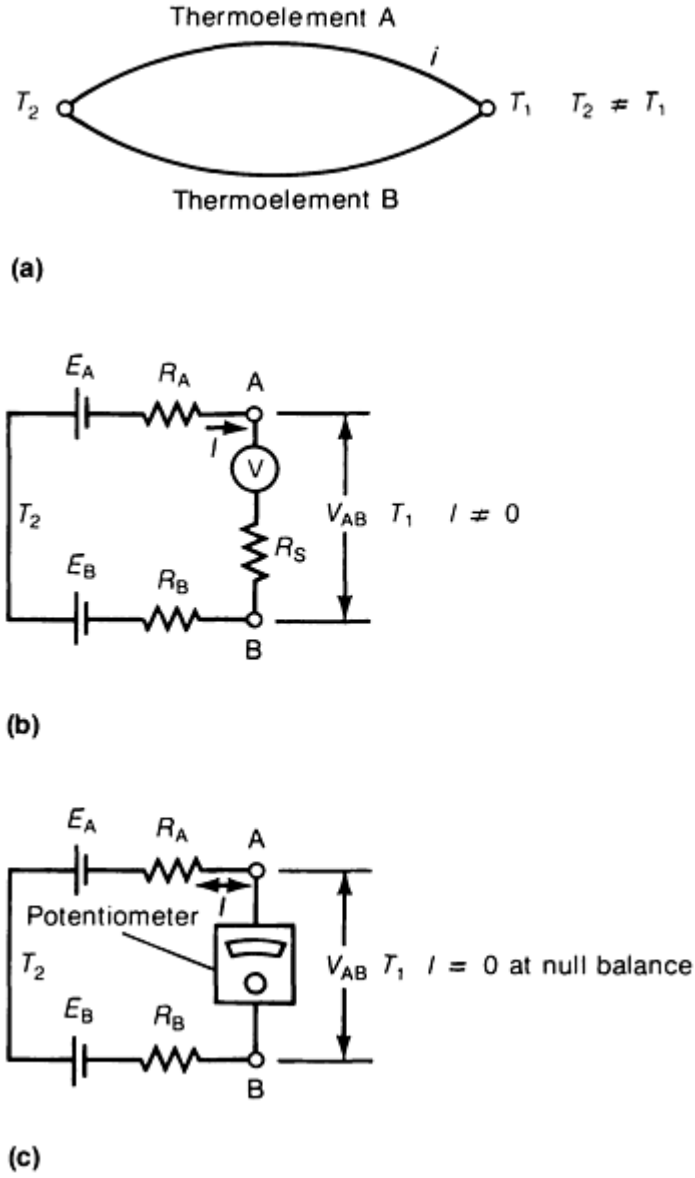

Fig. 1 Schematic (a) and equivalent circuit diagrams (b) and (c) of a typical thermocouple system. (b) Thermocouple in a voltmeter circuit. (c) Thermocouple in a potentiometer circuit. Adapted from Ref 1

The thermal emf E_{AB} is a vector quantity. Its magnitude and direction depend on the material characteristics of A and B as well as the temperature difference between the hot and cold junctions, T_2 - T_1, providing that A and B are homogenous is composition.

A circuit diagram describing a thermocouple in a voltmeter circuit is shown in Fig. 1(b). Thermoelement A is represented by a battery E_A and resistance R_A. E_A is the emf output of thermoelement A with reference to a certain standard, and R_A is the resistance of thermoelement A. Similarly, E_B is the emf output of thermoelement B with reference to the same standard and R_B is the resistance of thermoelement B.

The voltage drop between terminals A and B is given by the following equation:

$$V_{AB} = E_A - E_B - I(R_A + R_B + R_S) \qquad \textbf{(Eq 2)}$$

where R_S is the resistance of a large resistor in series with the thermoelements to minimize the effect of the resistance of the thermoelements. If E_A - (E_A + V_{AB}) is positive, the thermoelectric current I will flow continuously from A to B at the cold junction. In this case, A is termed the *positive thermoelement* and B the *negative thermoelement* of the thermocouple.

In Fig. 1(c), a potentiometer is connected across the terminals in place of the voltmeter. A bucking voltage is applied at the potentiometer until it is equal in magnitude and opposite in direction to the thermoelectric voltage E_{AB}. At null balance, there is no current flow. All the *IR* terms in Eq 2 become zero. Under this condition:

$$V_{AB} = E_{AB} = E_A - E_B \qquad \textbf{(Eq 3)}$$

Then, the measured emf at the potentiometer V_{AB} is the thermal emf of the thermocouple AB. It may be observed from Eq 3 that thermal emf is a bulk property. It is independent of the resistance, and hence of the diameter, of the wire.

The thermoelectric property of an electrical conductor is usually expressed in millivolts against a common reference. Platinum 67, because of its purity and excellent oxidation resistance at elevated temperatures, is the United States thermometric reference standard. This standard can be obtained from the National Institute of Standards and Technology (formerly NBS).

The change in emf with temperature for two electrical conductors A and B, which are, respectively, positive and negative with reference to platinum, is shown in Fig. 2(a). The emf values of both conductors change linearly with temperature. If A and B are joined as a couple and the two ends are exposed to temperatures T_1 and T_2, the emf of the couple AB at temperatures between T_1 and T_2 is equal to the algebraic difference in emf between the positive thermoelement A versus Pt and the negative thermoelement B versus Pt at temperatures in the same range. This is shown in Fig. 2(b) and expressed in the equation:

$$E_{AB}\begin{vmatrix} T_2 \\ T_1 \end{vmatrix} = E_A\begin{vmatrix} T_2 \\ T_1 \end{vmatrix} - E_B\begin{vmatrix} T_2 \\ T_1 \end{vmatrix} \qquad \textbf{(Eq 4)}$$

where $E_{AB}\begin{vmatrix} T_2 \\ T_1 \end{vmatrix}$ is the emf of thermocouple AB between T_1 and T_2, in millivolts,

$E_A\begin{vmatrix} T_2 \\ T_1 \end{vmatrix}$ is the emf of thermoelement A vs Pt between T_1 and T_2, in millivolts, and

$E_B\begin{vmatrix} T_2 \\ T_1 \end{vmatrix}$ is the emf of thermoelement B vs Pt between T_1 and T_2, in millivolts.

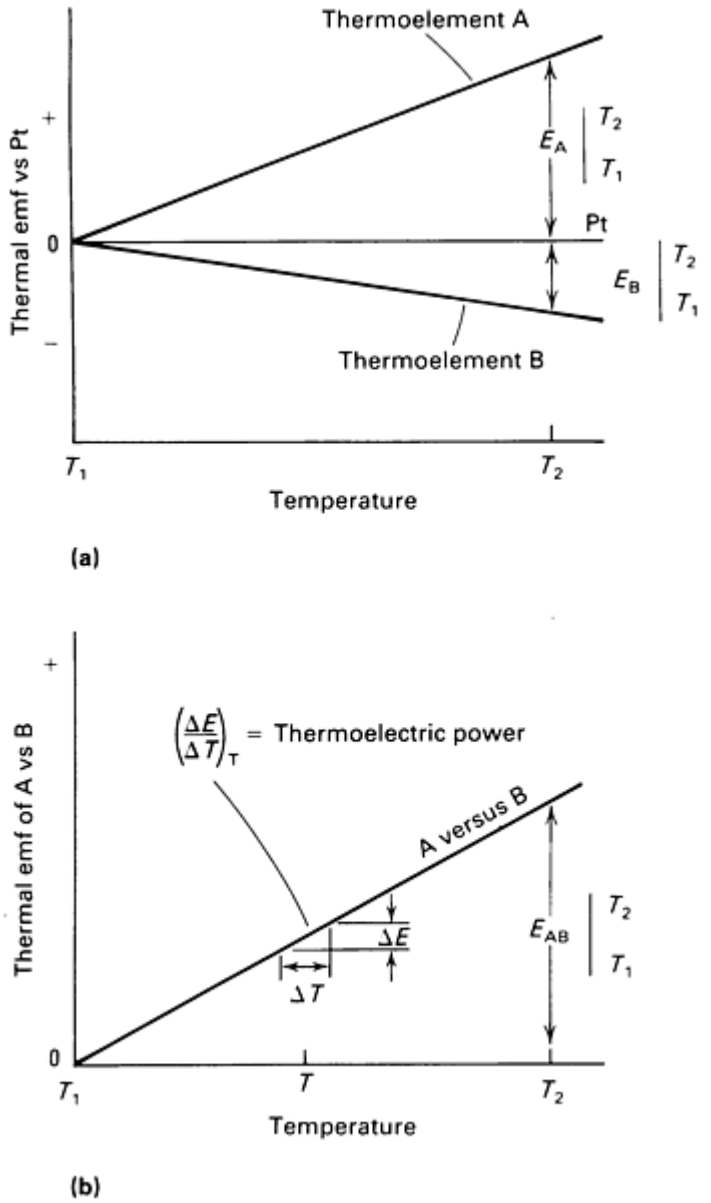

Fig. 2 Thermal emf of two thermoelements with respect to platinum and to each other. (a) Thermal emf of thermoelements A and B versus Pt. (b) Thermal emf of thermocouple A--B

Thermoelectric power at a given temperature T is defined as the rate of change of thermal emf with respect to temperature. The thermoelectric power of the thermocouple AB at temperature T is the slope of its emf/temperature curve,

$$\frac{\Delta E}{\Delta T}$$

as shown in Fig. 2(b). The thermoelectric power of a thermoelement at a given temperature T is the rate of change of its emf, referenced to Pt, with respect to temperature. In using a thermocouple for temperature measurement, it is essential that the thermoelectric power of the thermocouple be fairly large and uniform within the applicable temperature range.

In case the emf/temperature relationship of the thermocouple AB is well established we may determine the temperature difference between T_2 and T_1 by measuring with a potentiometer the generated thermal emf E_{AB}. Note that a thermocouple really does not measure the temperature of the hot junction T_2 but measures the temperature difference T_2 - T_1.

The ice point (0 °C, or 32 °F) is set universally as the reference cold junction (T_1) for all established emf tables. If we use the ice point as our reference cold junction T_1, then the measured emf does correspond to the temperature of the hot junction T_2.

Measurement of Temperature by a Thermocouple. A setup for measurement of temperature by use of a thermocouple is illustrated schematically in Fig. 3. The welded junction of thermocouple PN is inserted into an electric furnace, the temperature of which is to be measured. The ice-point cold junction is provided by two mercury U-tubes embedded in a Dewar flask packed with shaved ice. The legs of the thermocouple are inserted into the mercury U-tubes and connected to the positive and negative terminals of a potentiometer by insulated copper wires. The temperature of the furnace then can be obtained by measuring the emf generated by the thermocouple and referenced to the established emf table for that particular thermocouple. Commercially available automatic compensating cold junctions can be used in placed of the abovementioned mercury U-tubes to achieve a 0 °C reference junction. These may be built into an indicating or recording instrument used to measure the emf developed by the thermocouple or external of the measuring instrument.

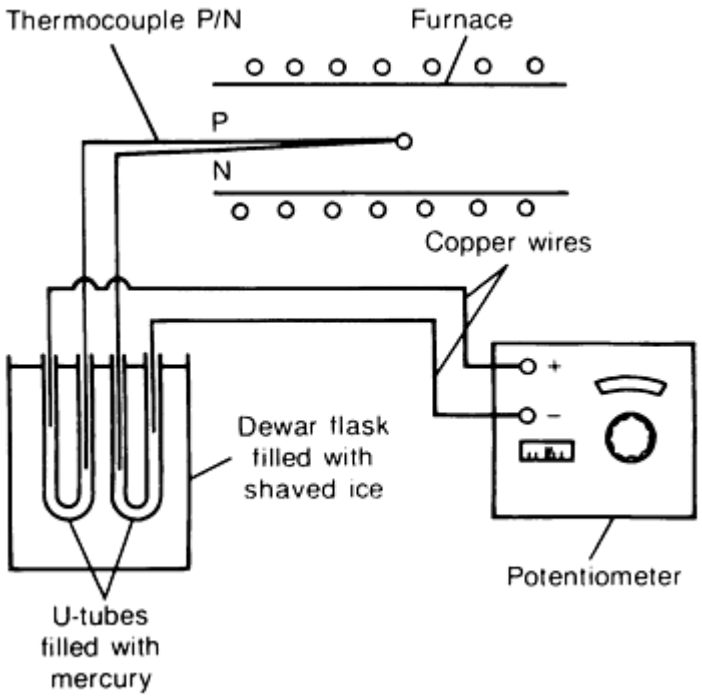

Fig. 3 Schematic diagram of the experimental setup for measuring temperature using a thermocouple and an ice-point reference junction. Adapted from Ref 2

In the absence of an ice junction, the thermocouple wires may be connected directly to the terminals of the potentiometer. The ambient temperature of the terminals is measured by a thermometer and converted to emf in millivolts from the emf table. The total emf generated by the thermocouple between the hot junction and the ice point is the sum of the emf thus measured by the potentiometer and this ambient-temperature correction factor. The temperature of the hot junction can be obtained by referring this total emf to the established table.

For additional information, see ASTM E 563, "Standard Recommended Practice for Preparation and Use of Freezing Point Reference Baths."

Preparation of the Measuring Junction. The two dissimilar thermoelements must be joined at the temperature-measuring junction to form the thermocouple. The joint must have good thermal and electrical conductivity without adversely affecting the mechanical and electrical properties of the thermocouple wires at this joint.

Prior to being joined, the thermoelements are straightened to facilitate insertion into hard-fired ceramic insulators. In this operation, care should be taken to avoid excessive cold working of the wires, which has a deleterious effect on the emf of the couple. After being cut to the desired length, the thermocouple wires are cleaned carefully (to remove lubricant

residue, fingerprints, and other contaminants) with a suitable solvent such as methyl ethyl ketone, Freon TF, or isopropyl alcohol, prior to joining.

For applications below about 500 °C (about 1000 °F), base-metal thermocouple wires may be silver brazed using borax as flux. Above this temperature, thermocouple junctions usually are prepared by welding. Noble-metal thermocouples should always be joined by welding. Thermocouples are usually welded using gas, electric-arc, resistance, tungsten-inert gas, and plasma-arc processes. In gas welding, a neutral flame is required (preferably oxidizing for noble metals). Prior to gas or arc welding, the ends of types E, J, K, and T thermocouple wires are first twisted one and a half turns.

Effecting a hot junction in a sheathed thermocouple requires a higher degree of skill, special equipment, and considerable care. After the sheath has been stripped away, joining usually is done by gas-tungsten-arc or plasma-arc welding. A clean, dry, and well-lighted work area is required to produce a finished element of good integrity. An oven capable of continuous operation at 90 °C (200 °F) should be available for storage of unsealed sheathed thermocouples during unavoidable delays in forming of junctions. Use of such an oven will minimize a pickup of airborne moisture and other contaminants.

Thermocouple Materials

Commercially available thermocouples are grouped according to material characteristics (base metal or noble metal) and standardization. At present, five base-metal thermocouples and three noble-metal thermocouples have been standardized and given letter designations by ANSI (American National Standards Institute), ASTM (American Society for Testing and Materials), and ISA (Instrument Society of America). Among the remaining thermocouples in use, some have not been assigned letter designations because of limited usage, and some are being considered for standardization.

Standard Thermocouples

The base compositions, melting points, and electrical resistivities of the individual thermoelements of the seven standard thermocouples are presented in Table 1. Maximum operating temperatures and limiting factors in environmental conditions are listed also.

Table 1 Properties of standard thermocouples

Type	Thermoelements	Base composition	Melting point, °C	Resistivity nΩ · m	Recommended service	Max temperature	
						°C	°F
J	JP	Fe	1450	100	Oxidizing or reducing	760	1400
	JN	44Ni-55Cu	1210	500

	BN	94Pt-6Rh	1826	175			

The relationships between emf and temperature for the individual thermoelements with reference to Platinum 67 and for the seven standard thermocouples are shown in Fig. 4 and 5, respectively. Tolerances for initial calibration of standard thermocouples (those meeting established tables within a specified tolerance) are listed in Table 2.

Table 2 Initial calibration tolerances for thermocouples when the reference junction is at 0 °C (32 °F)

Thermocouple type	**Temperature range, °C**	**Initial calibration tolerance**	
		Standard (whichever is greater)	**Special (whichever is greater)**
T	0 to 350	±1 °C or ±0.75%	±0.5 °C or 0.4%
J	0 to 750	±2.2 °C or ±0.75%	±1.1 °C or 0.4%
E	0 to 900	±1.7 °C or ±0.5%	±1 °C or ±0.4%
K	0 to 1250	±2.2 °C or ±0.75%	±1.1 °C or ±0.4%
N	0 to 1250	±2.2 °C or ±0.75%	±1.1 °C or ±0.4%

R or S	0 to 1450	±1.5 °C or ±0.25%	±0.6 °C or ±0.1%
B	800 to 1700	±0.5%	. . .
T[(a)]	-200 to 0 °C	±1 °C or ±1.5%	[(b)]
E[(a)]	-200 to 0 °C	±1.7 °C or ±1%	[(b)]
K[(a)]	-200 to 0 °C	±2.2 °C or ±2%	[(b)]

Source: Adapted from ANSI MC96.1

(a) Thermocouples and thermocouple materials are normally supplied to meet the limits of error specified in the table for temperatures above 0 °C. The same materials, however, may not fall within the subzero limits of error given in the second section of the table. If materials are required to meet the subzero limits, the purchase order must so state. Selection of materials usually will be required.

(b) Little information is available to justify establishment of special limits of error for subzero temperatures. Limited experience suggests the following limits for types E and T thermocouples: Type E, -200 to 0 °C ±1 °C or ±0.5%; Type T, 200 to 0 °C ±0.5 °C or ±0.8%. These limits are given only as a guide for discussion between purchaser and supplier. Due to the characteristics of the materials, subzero limits of error for type J thermocouples and special subzero limits for type K thermocouples are not listed.

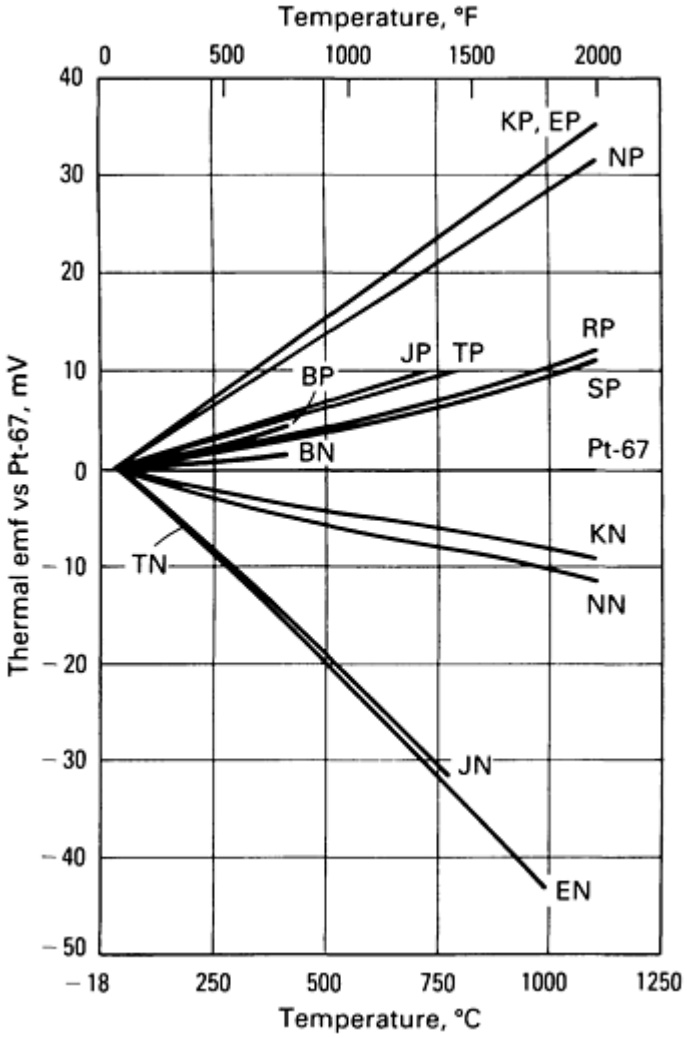

Fig. 4 Thermal emf of standard thermoelements. Adapted from Ref 1

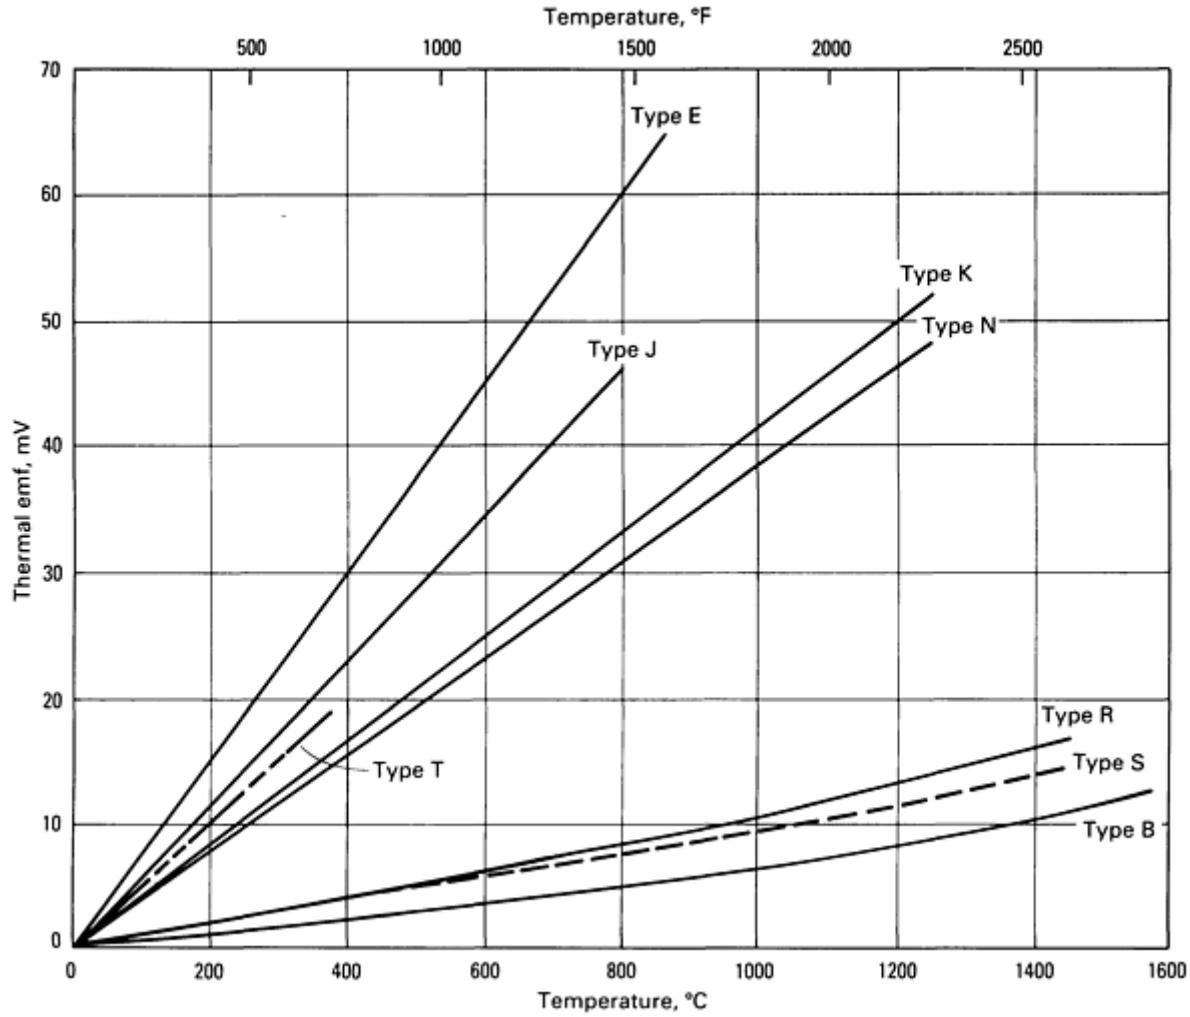

Fig. 5 Thermal emf curves for ISA standard thermocouples. Thermal emf plots are based on IPTS-68 (1974)

Type J. The type J thermocouple is widely used, primarily because of its versatility and low cost. In this couple, the positive thermoelement is iron and the negative thermoelement is constantan, a 44Ni-55Cu alloy. As shown in Fig. 4, the emf of iron is positive with reference to platinum, but the emf of constantan is the most negative with respect to platinum among all thermoelements. The thermoelectric power of the type J couple as a whole is about 55 μV/°C (30 μV/°F) over the temperature range from 0 to 750 °C (32 to 1380 °F), a value higher than that of any other standard couple except the type E couple.

The commercial grade of iron used as the positive leg of the type J thermocouple contains small amounts of carbon, cobalt, manganese, and silicon. Therefore, its emf can vary significantly from one heat to another. Accordingly, the emf of this iron is shown in Fig. 4 as a shaded band instead of a single line. However, constantan of a slightly different composition can be obtained commercially to match the iron wire on hand so that the thermocouple as a whole meets established emf/temperature requirements. As shown in Table 2, the initial calibration tolerance (to established table values) for standard-grade type J couples is ±2.2 °C (±4 °F) or ± $\frac{3}{4}$% of temperature, whichever is greater over the range from 0 to 750 °C (32 to 1380 °F).

Type J couples can be used in both oxidizing and reducing atmospheres at temperatures up to about 760 °C (1400 °F). They find extensive use in heat-treating applications in which they are exposed directly to the furnace atmosphere. The No. 8 gage (3.25 mm, or 0.128 in., diam) type J couple can have a useful service life of about 1000 h at 760 °C (1400 °F) in an oxidizing atmosphere. The same size couple can be used at higher temperatures in a reducing atmosphere. Smaller-gage type J couples are also available for laboratory use or applications where quicker heat-sensing response is desired. As thermocouple wire diameter decreases, the recommended upper temperature limit also decreases, as shown in Table 3.

Table 3 Recommended upper temperature limits for protected thermocouples of various wire sizes

Type of thermocouple	Upper temperature limit									
	No. 8 AWG, 3.25 mm (0.128 in.)		No. 14 AWG, 1.63 mm (0.064 in.)		No. 20 AWG, 0.81 mm (0.032 in.)		No. 24 AWG, 0.51 mm (0.020 in.)		No. 28 AWG, 0.33 mm (0.013 in.)	
	°C	°F	°C	°F	°C	°F	°C	°F	°C	°F
T	. . .	. . .	370	700	260	500	200	400	200	400
J	760	1400	590	1100	480	900	370	700	370	700
E	870	1600	650	1200	540	1000	430	800	430	800

N	1260	2300	1090	2000	980	1800	870	1600	870	1600
R, S	. . .	. . .	. . .	. . .	. . .	. . .	1480	2700	. . .	. . .
B	. . .	. . .	. . .	. . .	. . .	. . .	1700	3100	. . .	. . .

Type K thermocouples, like type J couples, are also widely used in industrial applications. The positive thermoelement is a 90Ni-9Cr alloy; its thermal emf versus platinum is the most positive. The negative thermoelement is a 94% Ni alloy containing silicon, manganese, aluminum, iron, and cobalt as alloying constituents; its emf is negative with respect to platinum. The thermoelectric power of the type K couple is close to 40 μV/°C (22 μV/°F) over the extended temperature range from 0 to 1100 °C (32 to 2000 °F); at temperatures up to 1250 °C (2300 °F), it is still close to 35 μV/°C (19 μV/°F). Commercial type K couples are Chromel-Alumel (trademark of Hoskins Manufacturing Company), T_1-T_2 (trademarks of Harrison Alloys, Inc.), and Tophel-Nial (trademark of Carpenter Technology Corporation).

Type K thermocouples can be used up to 1250 °C (2280 °F) in oxidizing atmospheres. As shown in Table 2, initial calibration of standard-grade type K couples should be within ±2.2 °C (±4 °F) or ± $\frac{3}{4}$% of table values (whichever is greater) up to 1260 °C (2300 °F). The maximum operating temperature of No. 8 gage wire (3.25 mm, or 0.128 in., diam) is 1260 °C) (2300 °F). For smaller-diameter wire, recommended upper temperature limits are lower, as shown in Table 3.

Type K couples should not be used in elevated-temperature service in reducing atmospheres or in environments containing sulfur, hydrogen, or carbon monoxide. At elevated temperatures in oxidizing atmospheres, uniform oxidation takes place, and the oxide formed on the surface of the positive (90Ni-10Cr) thermoelement is a spinel, NiO-Cr_2O_3. However, in reducing atmospheres, preferential oxidation of chromium takes place, forming only Cr_2O_3. The presence of this greenish oxide (commonly known as "green rot") depletes the chromium content, causing a very large negative shift of emf (up to -2 MV) and rapid deterioration of the thermoelement.

The type K positive thermoelement is susceptible to short-range ordering (changes from a random to an ordered atomic structure in localized regions) on aging at about 500 °C (930 °F). This causes a change in emf of about 0.2 MV, which is equivalent to a change of 5 °C (9 °F). This change can be essentially eliminated by preaging the thermoelement at 500 °C

(930 °F). However, the short-range ordering is a reversible process. The type K positive thermoelement will change back to its initial disordered condition if heated to 800 °C (1470 °F) or above, followed by rapid cooling.

Besides the above considerations, type K couples are quite versatile. They are the only standard base-metal thermocouples that can be used for sensing temperatures from 900 to 1260 °C (1650 to 2300 °F).

Type T thermocouples are used extensively for cryogenic measurements. The positive thermoelement is copper, the thermal emf of which is positive with respect to platinum. Commercial-grade oxygen-free high conductivity (OFHC) copper (C10100), unlike commercial grades of iron, is of high purity and is very homogeneous. Its emf is quite uniform from lot to lot. The constantan (44Ni-55Cu) used for the negative thermoelement of the type T couple has the same base composition as that of the constantan used in the type J couple, but is slightly different in minor alloying constituents. Because of this, the two types of constantan have different emf characteristics. As manufactured, the copper-constantan couple has an emf output that conforms to the emf table for type T thermocouples to within ±1 °C (±2 °F) at temperatures from 0 to 350 °C (32 to 660 °F. From -200 to 0 °C (-330 to 32 °F), the tolerance on the initial calibration is ±1% of temperature. Type T couples can be used in either oxidizing or reducing atmospheres. They should not be used above 370 °C (700 °F) because of the poor oxidation resistance of copper.

Type E. The positive thermoelement of the type E thermocouple is 90Ni-9Cr, the same as that of the type K thermocouple; the negative element is 44Ni-55Cu, the same as that of the type T couple. Among all standard thermoelements, these two are the most positive and most negative with respect to Platinum 67. Therefore, the thermoelectric power of the type E couple is the highest among all standard couples. Type E couples are used primarily for power-generation applications such as thermopiles.

The recommended maximum operating temperature for type E thermocouples is 870 °C (1600 °F). Like type K thermocouples, type E couples should be used only in oxidizing atmospheres, because their use in reducing atmospheres results in preferential oxidation of chromium (green rot).

Type N. The Nicrosil/Nisil thermocouple was developed for oxidation resistance and emf stability superior to those of type K thermocouples at elevated temperatures. The positive thermoelement is Nicrosil (nominal composition, 14 Cr, 1.4 Si, 0.1 Mg, bal Ni), and the negative thermoelement is Nisil (nominal composition, 4.4 Si, 0.1 Mg, bal Ni). Reference 3 presents emf values and various physical properties of Nicrosil/Nisil thermocouples. These couples have been shown (Ref 4, 5, 6) to have longer life and better emf stability than type K thermocouples at elevated temperatures in air, both in the laboratory and in several industrial applications (see Fig. 6). The Nicrosil/Nisil thermocouple was standardized as the type N thermocouple by ASTM. It was established as a standard thermocouple material by ISA and other technical societies in the late 1980s.

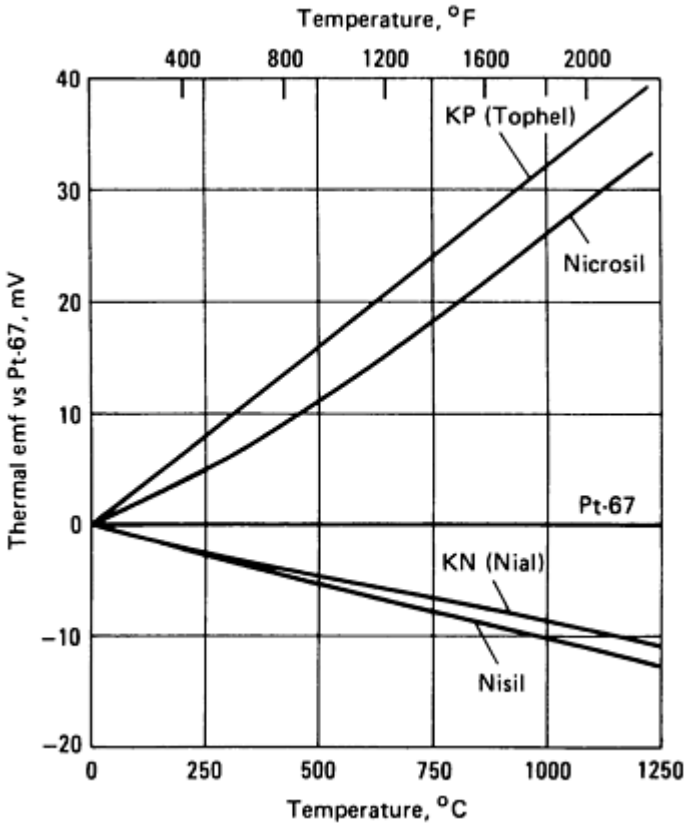

Fig. 6 Thermal emf of Nicrosil, Nisil, and type K thermoelements versus Pt-67. Adapted from Ref 7

Type S. The type S thermocouple served as the interpolating instrument for defining the International Practical Temperature Scale of 1968 (amended in 1975) from the freezing point of antimony (630.74 °C, or 1167.33 °F) to the freezing point of gold (1064.43 °C, or 1947.97 °F). It is characterized by a high degree of chemical inertness and stability at high temperatures in oxidizing atmospheres. The materials used in the legs of this thermocouple, Pt-10Rh and platinum, both are ductile and can be drawn into fine wire (as small as 0.025 mm, or 0.001 in., in diameter for special applications). For general-purpose use, wire 0.51 mm (0.020 in.) in diameter is commonly used.

The thermoelectric output of the type S thermocouple is about 6 μV/°C (3.3 μV/°F) at temperatures from 0 to 100 °C (32 to 212 °F) and about 11.5 μV/°C (6.4 μV/°F) at 1000 °C (1830 °F). Type S couples can be used in intermittent service up to 1750 °C (3180 °F) (the melting point of platinum is 1769 °C, or 3216 °F) and can be used continuously up to 1500 °C (2730 °F) if properly protected. Because of its low emf output, this thermocouple is not used for measuring subzero temperatures. Type S couples that match standard emf/temperature values within ±1.5 °C (±2.7 °F) or ±0.25% (whichever is greater), and under special conditions within ±0.6 °C (±1 °F) or ±0.1%, can be obtained from reliable sources.

The type S couple is widely used in industrial laboratories as a standard for calibration of base-metal thermocouples and other temperature-sensing instruments. It is commonly used for controlling processing of steel, glass, and many refractory materials. It should be used in air or in oxidizing or inert atmospheres. It should not be used unprotected in reducing atmospheres in the presence of easily reduced oxides, atmospheres containing metallic vapors such as lead or zinc, or atmospheres containing nonmetallic vapors such as arsenic, phosphorus, or sulfur. It should not be inserted directly into metallic protection tubes and is not recommended for service in vacuum at high temperatures except for short periods of time. Because the negative leg of this couple is fabricated from high-purity platinum (approximately 99.99% for commercial couples and 99.995%+ for special grades), special care should be taken to protect the couple from contamination by the insulators used as well as by the operating environment.

Type R. The type R thermocouple (Pt-13Rh/Pt) has characteristics similar to those of the type S couple. In 1922 it was found that the British Pt-10Rh alloy had a higher emf than the U.S. version but was unstable due to the presence of 0.34% Fe. In order to produce an alloy free from iron (and therefore stable) but with an emf that met the calibration of existing instruments (in other words, having an emf output equivalent to that of the couple using impure Pt-10Rh element), it was

necessary to increase the rhodium content to 13%. The emf output of the type R thermocouple is slightly higher than that of the type S couple. End-use applications for type S couples also apply to type R.

Type B thermocouples (Pt-30Rh/Pt-6Rh) may be used in still air or inert atmospheres for extended periods at temperatures up to 1700 °C (3100 °F) and intermittently up to 1760 °C (3200 °F) (Pt-6Rh leg melts at approximately 1826 °C, or 3319 °F). Because both of its legs are platinum-rhodium alloys, the type B couple is less sensitive than type R or type S to pickup of trace impurities from insulators or from the operating environment. Under corresponding conditions of temperature and environment, type B thermocouples exhibit less grain growth and less drift in calibration than type R or type S thermocouples.

The type B couple also is suitable for short-term use in vacuum at temperatures up to about 1700 °C (3100 °F); its emf stability varies with temperature, time at temperature, and degree of vacuum. It should not be used in reducing atmospheres, or in those containing metallic or nonmetallic vapors, unless suitably protected with ceramic protection tubes. It should never be inserted directly into a metallic primary protection tube.

This couple has a very small emf in the normal reference range from 0 to about 100 °C (32 to about 212 °F), and particularly from 0 to 50 °C (32 to 120 °F). Errors arising because of uncertainties in the temperature of the reference junction, or as a result of that temperature being ignored, are relatively small for measurements of high temperature (over 1000 °C, or 1830 °F). The thermoelectric power of the type B thermocouple is 9.1 μV/°C (5.1 μV/°F) at 1000 °C (1830 °F) and 11.3 μV/°C (6.3 μV/°F) at 1400 °C (2550 °F).

Nonstandard Thermocouples

19 Alloy/20 Alloy. The 19 alloy/20 alloy thermocouple was developed for temperature-sensing and control applications at elevated temperatures in hydrogen or in reducing atmospheres. The positive thermoelement is the 20 alloy, which has a nominal composition of 82Ni-18Mo. The negative thermoelement is the 19 alloy, the nominal composition of which is 99Ni-1Co. Values of emf versus platinum for 19 alloy and 20 alloy are given in Fig. 7. The emf of the 19 alloy/20 alloy thermocouple is somewhat larger than that of the type K couple. Physical, electrical, and mechanical properties of the 19 alloy/20 alloy thermocouple are listed in Table 4.

Table 4 Properties of two thermocouples: 19 alloy/20 alloy and Nicrosil-Nisil

Property	**19 alloy**	**20 alloy**	**Nicrosil**	**Nisil**
Nominal composition	Ni-1Co	Ni-18Mo	Ni-14Cr-1.4Si	Ni-4.4Si-0.1Mg
Melting point, °C (°F)	1450 (2640)	1425 (2600)	1410 (2570)	1400 (2550)
Specific gravity	8.9	9.1	8.52	8.70
Thermal conductivity, W/m · K at 20 °C	50	15	130	230
Coefficient of thermal expansion, μ/m · °C (20 to 100 °C)	13.6	11.9	13.3	12.1

Elongation, %	35	35	30	35

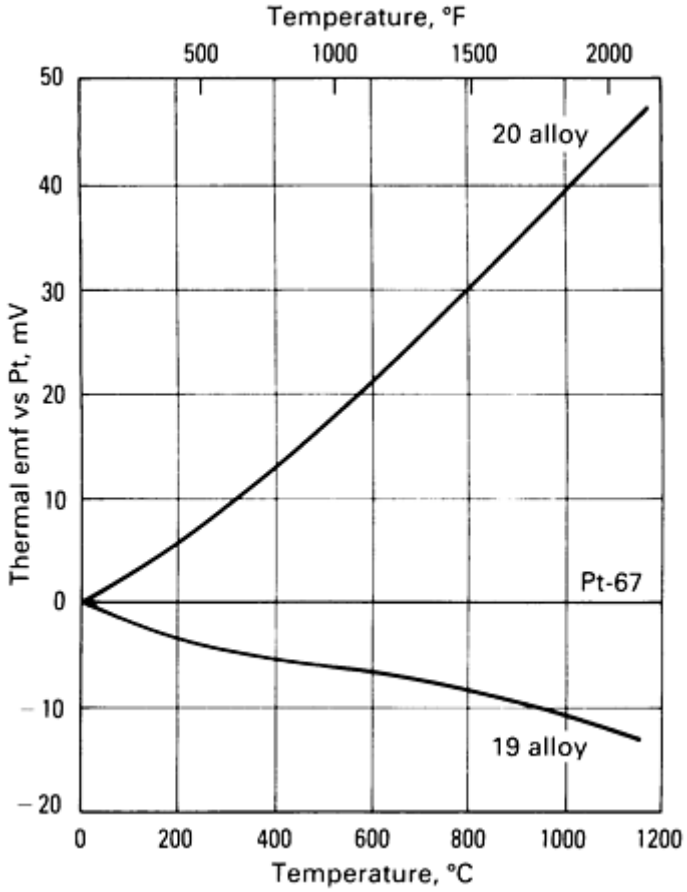

Fig. 7 Thermal emf of 19 alloy and 20 alloy versus Pt-67

19 alloy/20 alloy thermocouples can be used in hydrogen or in reducing atmospheres over the entire range from 0 to 1260 °C (32 to 2300 °F) with excellent performance. Hotchkiss (Ref 8) showed that, after exposure at about 950 °C (1750 °F), a type K couple was out of calibration by about 2mV (about 50 °C, or 90 °F) in the negative direction whereas a 19 alloy/20 alloy thermocouple remained essentially in calibration. The oxidation resistance of 19 alloy/20 alloy is not good when compared with that of the type K couple. 19 alloy/20 alloy thermocouples should not be used in oxidizing atmospheres above about 650 °C (1200 °F).

Iridium-Rhodium. Three iridium-rhodium thermocouples are commercially available: 60Ir-40Rh/Ir, 50Ir-50Rh/Ir, and 40Ir-60Rh/Ir. Of these three combinations, 60Ir-40Rh/Ir appears to be preferred at this time. Properties of iridium-rhodium couples are given in Table 5 and Fig. 8.

Table 5 Properties of iridium-rhodium thermocouples

(a) Not recommended.

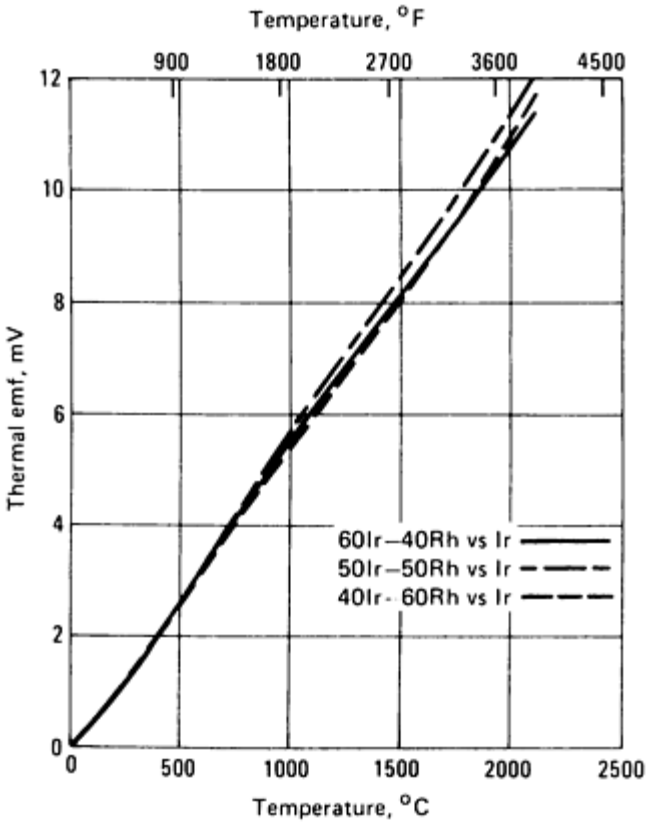

Fig. 8 Thermal emf of iridium-rhodium/iridium thermocouples. Adapted from Ref 9

Iridium-rhodium couples are suitable for use for limited periods of time in air or other oxygen-carrying atmospheres at temperatures up to about 2000 °C (3600 °F), and generally are used for such service at temperatures above the range in which types R, S, and B thermocouples are employed. They can be used in inert atmospheres and in vacuum, but not in reducing atmospheres (easily reduced oxides in contact with iridium or with Ir-Rh alloys are sources of contamination). These couples have been used for short periods of time at temperatures up to only 60 °C (110 °F) below the melting point of the alloy leg--that is, up to 2180 °C (3960 °F) for 60Ir-40Rh, up to 2140 °C (3880 °F) for 50Ir-50Rh, and up to 2090 °C (3790 °F) for 40Ir-60Rh.

After being hot worked, iridium thermoelements have a fibrous structure and are reasonably ductile. However, annealing causes the structure to become equiaxed, with resultant decreases in ductility and handleability. This should be considered if any preinstallation fabrication is anticipated.

Compensating extension wires are available for iridium-rhodium thermocouples--copper for the positive leg and stainless steel for the negative leg.

Platinum-Molybdenum. The Pt-5Mo/Pt-0.1Mo thermocouple is used for measuring temperatures from 1100 to about 1500 °C (2000 to about 2700 °F) under neutron radiation (type K couples are employed for temperatures up to 1100 °C). Basic characteristics of Pt-5Mo/Pt-0.1Mo couples are given in Table 6. Platinum alloys containing rhodium are not suitable for use under neutron radiation, because the rhodium is slowly transmuted to palladium.

Table 6 Properties of platinum molybdenum thermocouples

Property	**Pt-5Mo versus Pt-0.1Mo**

(a) Not recommended.

The output of the Pt-5Mo/Pt-0.1Mo couple is high and increases with temperature in a uniform manner (see Fig. 9). Detailed emf/temperature tables (at 1 °C intervals) are available from suppliers. Compensating lead wires, good from 0 to 70 °C (32 to 160 °F), are available for Pt-5Mo/Pt-0.1Mo thermocouples--copper for the positive leg and Cu-1.6Ni for the negative leg.

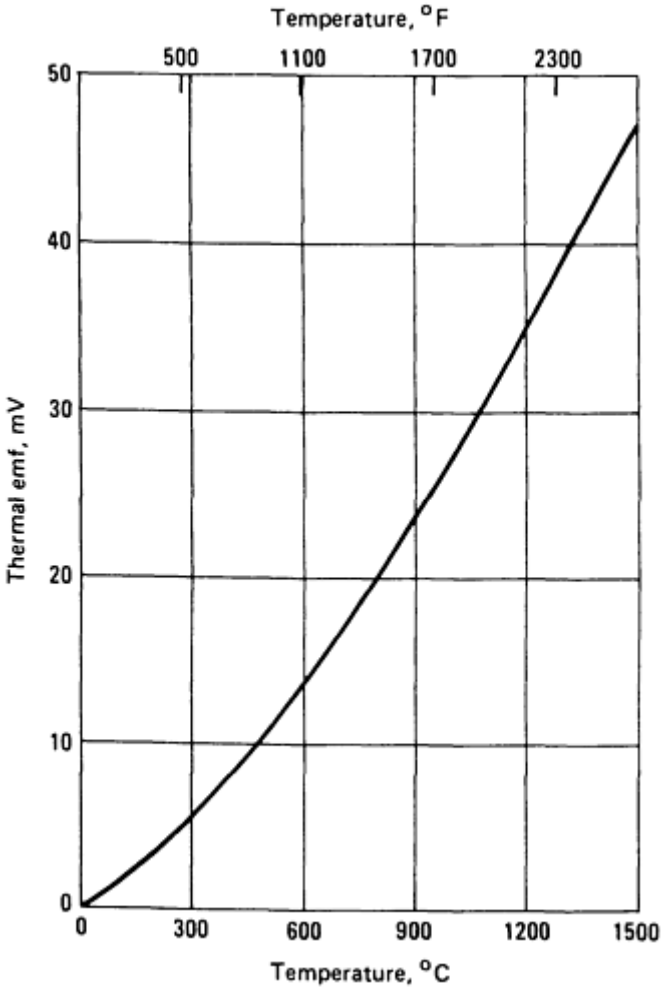

Fig. 9 Thermal emf of Pt-5Mo/Pt-0.1Mo thermocouples. Adapted from Ref 9

Platinel. The Platinel thermocouple (trademark of Englehard Corporation), an all-noble-metal combination, was metallurgically designed to approximate the emf/temperature characteristics of the type K couple. Actually, two combinations have been produced: Platinel I and Platinel II (see Table 7). Both have negative legs of 65Au-35Pd. The positive leg of the Platinel I couple is 83Pd-14Pt-3Au, and the positive leg of the Platinel II couple consists of 55Pd-31Pt-14Au. The Platinel II couple has superior high-temperature fatigue properties and appears to be preferred over Platinel I.

(a) Not recommended.

(b) High-purity alumina insulators are recommended.

Figure 10 compares thermal emf of Platinel thermocouples with that of the type K couple. The emf match with type K is good at elevated temperatures, but some departure occurs at lower temperatures. In an application involving measurement of turbine inlet temperatures in an aircraft engine, the connection between the thermocouple and type K extension wire is effected at 800 °C (1470 °F) where the emf match is excellent. In this application, only about 13 mm ($\frac{1}{2}$ in.) of Platinel II wire is used, and the remainder is type K. Other base-metal extension wires capable of matching the emf of the Platinels very closely over the range from 0 to 160 °C (32 to 320 °F) and also available.

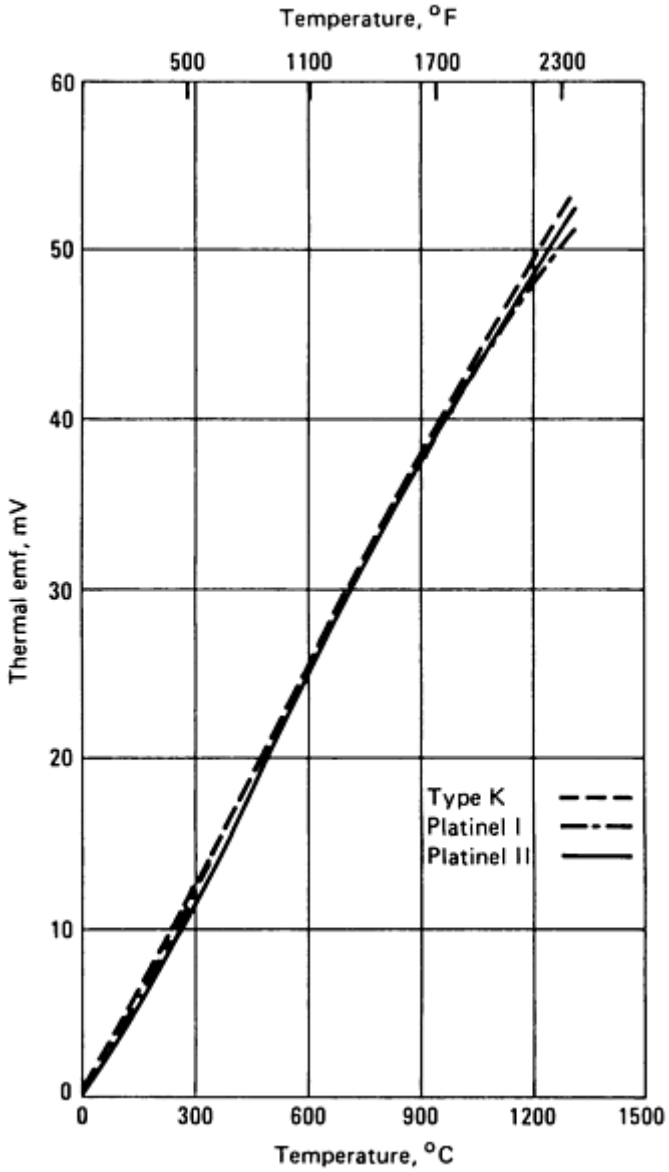

Fig. 10 Thermal emf of Platinel thermocouples compared with that of type K thermocouple. Adapted from Ref 9

Platinel couples can be used unprotected (insulators only) in air to 1200 °C (2190 °F) for extended periods of time and to 1300 °C (2370 °F) for shorter periods. Platinel II aged in commercial hydrogen for 1000 h at 1000 °C (1830 °F) showed

reasonably good stability. Drift did not exceed 0.75%. It is recommended that precautions usually followed with platinum-rhodium thermocouples also be observed with Platinels. In particular, it should be noted that phosphorus, sulfur, and silicon have deleterious effects on the life of Platinel thermocouples.

Tungsten-Rhenium. Three tungsten-rhenium thermocouples are commercially available: W/W-26Re, doped W-3Re/W-25Re, and W-5Re/W-26Re. All three couples have been used at temperatures up to 2760 °C (5000 °F), but they usually are employed only below 2315 °C (4200 °F) due to temperature limitations of ceramic insulators.

Early use of tungsten-rhenium thermocouples, particularly W/W-26Re couples, indicated that these couples might be capable of measuring high temperatures with reasonable accuracy; however, one serious drawback was immediately observed. The tungsten leg, when heated to its recrystallization temperature of 1200 °C (2200 °F), became embrittled, an effect that was not experienced with the opposite leg (W-25Re or W-26Re). Early research showed that addition of 10% rhenium to the tungsten element did much to retain ductility after recrystallization. However, although large additions of rhenium to tungsten solved this problem, they also lowered the emf of the thermocouple. Consequently, other techniques intended to retain room-temperature ductility were employed, including special processing and doping combined with addition of 5% or less rhenium to the tungsten element.

The "dope," in the form of potassium, silicon, and aluminum compounds, is added during preparation of the tungsten powder. With the exception of potassium, these additives are volatile and are almost eliminated during processing. Doping, however, assists in formation of a microstructure characterized by large, elongated grains whose boundaries make relatively small angles with the wire axis. This structure is similar to that found in the well-known "nonsag" tungsten filament wire. Within recent years, microvoids or "bubbles" containing potassium "plated" on the inside surface were found decorating the boundaries of these elongated grains. It is now accepted that these voids promote formation of the desired elongated grains.

The thermal emf values of the three W-Re combinations are compared in Fig. 11, and other pertinent properties are shown in Table 8. All three thermocouple combinations are supplied as matched pairs guaranteed to meet the emf outputs given in producer-developed tables within ±1% (see ASTM E 452 for calibration procedure). Compensating extension wires are available for each combination.

Table 8 Properties of tungsten-rhenium thermocouples

Property	**W versus W-26Re**	**W-3Re versus W-25Re**	**W-5Re versus W-26Re**
Nominal operating temperature range, °C (°F), in:			
Dry hydrogen	2760 (5000)	2760 (5000)	2760 (5000)
Inert atmosphere	2760 (5000)	2760 (5000)	2760 (5000)
Vacuum[(a)]	2760 (5000)	2760 (5000)	2760 (5000)
Maximum short-time temperature, °C (°F)	3000 (5430)	3000 (5430)	3000 (5430)
Approximate microvolts per °C (°F):			

Mean, over nominal operating range 0 to 2316 °C (32 to 4200 °F)	16.7 (9.3)	17.1 (9.5)	16.0 (8.9)
At top temperature of normal range 2316 °C (4200 °F)	12.1 (6.7)	9.9 (5.5)	8.8 (4.9)
Melting temperature, °C (°F), nominal:			
Positive thermoelement	3410 (6170)	3360 (6080)	3350 (6062)
Negative thermoelement	3120 (5648)	3120 (5648)	3120 (5648)
Stability with thermal cycling	Good	Good	Good
High-temperature tensile properties	Good	Good	Good
Stability under mechanical working	Fair	Fair	Fair
Ductility (of most brittle thermoelement) after use	Poor	Poor to good depending on atmosphere or degree of vacuum	Poor to good depending on atmosphere or degree of vacuum
Resistance to handling contamination	Good	Good	Good
Extension wire	Available	Available	Available

Source: Adapted from Ref 9

(a) Preferential vaporization of rhenium may occur when bare (unsheathed) couple is used at high temperatures and high vacuum. Check vapor pressure of rhenium at operating temperature and vacuum before using bare couple.

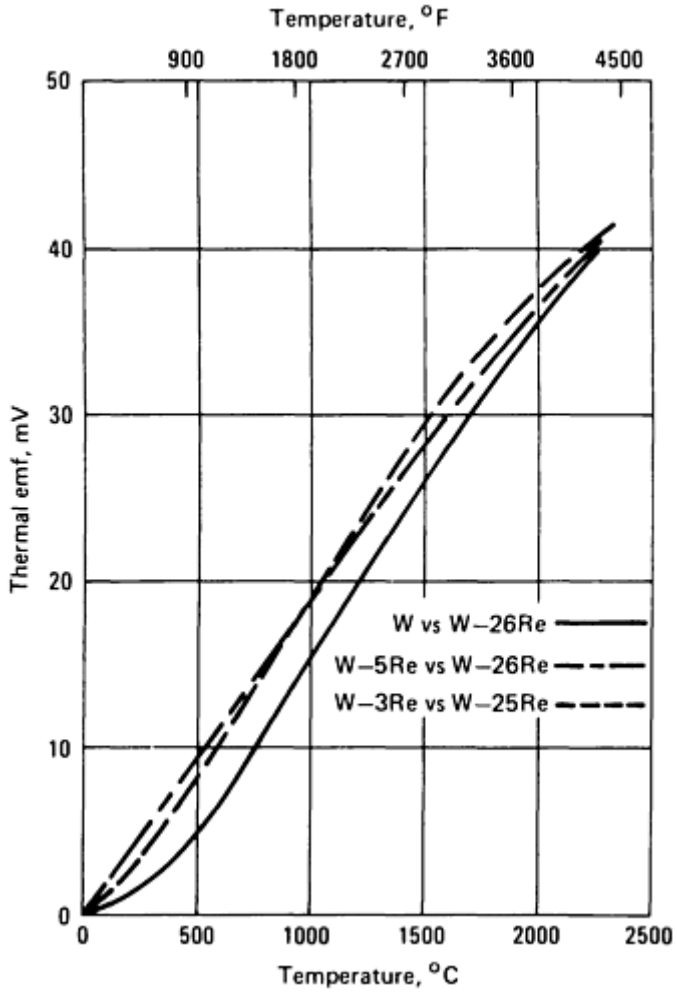

Fig. 11 Thermal emf of tungsten-rhenium thermocouples. Adapted from Ref 9

Important factors controlling the use of W-Re thermocouples at high temperatures include:

- Insulation, sheaths, and protection tubes (choice of insulation, sheaths, and protection tubes depends on operating temperature and environment)
- Diameter of thermoelements (larger diameters for higher temperatures)
- Atmosphere (vacuum, high-purity hydrogen, high-purity inert atmospheres required)

There is evidence that selective vaporization of rhenium occurs at temperatures of the order of 1900 °C (3450 °F) and higher when bare, unprotected W-Re couples are used in vacuum. This is not a problem, however, when these couples are protected with suitable refractory-metal sheaths.

For swaged-type thermocouples, maximum service temperature is affected by the diameter of the thermocouple wire as well as by the thickness of the ceramic insulating material (wire-to-wire and wire-to-sheath resistance). The problem here is mainly "shunt" error. At high temperatures, the resistivity of ceramic insulating materials decreases exponentially with temperature. Therefore, at a sufficiently high temperature, the insulation shunt resistance between thermocouple wires becomes comparable with wire resistance, and shunting results. The error in thermocouple reading may be positive or negative. Increasing the insulation thickness will also help to increase maximum allowable operating temperature.

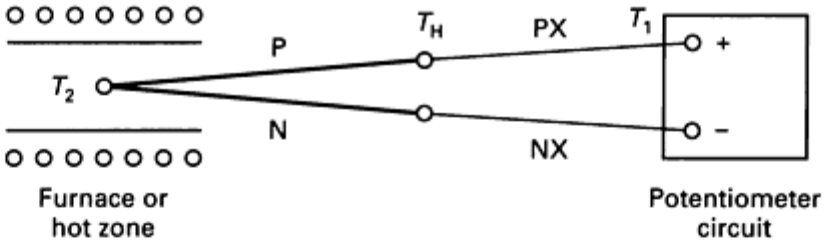
Thermocouple Extension Wires

Thermocouple extension wires, also known as extension wires or lead wires, are electrical conductors used for connecting the thermocouple wires to the temperature measuring and control instrument. Extension wires usually are supplied in cable form, with positive and negative wires electrically insulated from each other. The chief reasons for using extension wires are economy and mechanical flexibility.

- *Economy.* Base-metal thermoelements, which cost less than $10 per pound in 1980, are always used as extension wires for the noble-metal thermocouple wires, which in 1980 cost about $700 per troy ounce. For base-metal thermocouples, use of extension wires permits periodic replacement of the thermocouple, which is exposed to elevated temperatures, without replacing the insulated extension-wire cables
- *Mechanical Flexibility.* Insulated solid or stranded wires in sizes from 14 to 20 gage are used as extension wires. This lends mechanical sturdiness and flexibility to the thermocouple circuitry while permitting the use of larger-diameter (usually 3.2 mm, or $\frac{1}{8}$ in.) base-metal thermocouples for improved oxidation resistance and service life, or smaller-diameter (usually 0.5 mm, or 0.020 in.) noble-metal thermocouple wire to save cost

Circuitry of Thermocouple Wires and Extension Wires. A schematic diagram and circuitry of thermocouple and extension wires are shown in Fig. 12. One end of the positive extension wire PX and one end of the negative extension wire NX are joined to the positive thermoelement P and the negative thermoelement N, respectively, at the head junction. The temperature at the head junction is usually less than 205 °C (400 °F). The other ends of PX and NX are connected to the positive and the negative terminals, respectively, of the measuring or control instrument.



$$E_{assembly}\left|\begin{matrix}T_2\\ = E_{PX}\\ T_1\end{matrix}\right.\left|\begin{matrix}T_H\\ + E_P\\ T_1\end{matrix}\right.\left|\begin{matrix}T_2\\ + E_N\\ T_H\end{matrix}\right.\left|\begin{matrix}T_H\\ + E_{NX}\\ T_2\end{matrix}\right.\left|\begin{matrix}T_1\\ = (E_P - E_N)\\ T_H\end{matrix}\right.\left|\begin{matrix}T_2\\ + (E_{PX} - E_{NX})\\ T_H\end{matrix}\right.\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right. \quad \text{(Eq A)}$$

$$E_{PN}\left|\begin{matrix}T_2\\ = (E_P - E_N)\\ T_1\end{matrix}\right.\left|\begin{matrix}T_2\\ = (E_P - E_N)\\ T_1\end{matrix}\right.\left|\begin{matrix}T_2\\ + (E_P - E_N)\\ T_H\end{matrix}\right.\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right. \quad \cdots \text{(Eq B)}$$

$$(E_P - E_N)\left|\begin{matrix}T_H\\ = (E_{PX} - E_{NX})\\ T_1\end{matrix}\right.\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right. \quad \text{(Eq C)}$$

$$\text{For the extension wire: } E_P = E_{PX}\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right. \text{ and } E_N = E_{NX}\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right.$$

$$\text{For an alternative extension wire: } E_P \neq E_{PX}\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right. \text{ and } E_N \neq E_{NX}\left|\begin{matrix}T_H\\ \\ T_1\end{matrix}\right.$$

Fig. 12 Computation of thermal emf compensated to 0 °C (32 °F) for a normal industrial thermocouple setup. In this example, the emf of the assembly is calculated from Eq A; the remaining equations define terms used in Eq A. In the sketch and equations, P and N designate elements in the thermocouple wire, and PX and NX designate elements in the extension wire. T_2 = hot-junction temperature; T_1 = cold-junction temperature; and T_H = head-junction temperature (205 °C, or 400 °F). Adapted from Ref 3

By substituting in the equation for Kirchoff's law and rearranging terms, the emf of the thermocouple and extension wire assembly between hot- and cold-junction temperatures T_2 and T_1 can be shown to be equal to the sum of the emf of the thermocouple PN between T_2 and T_H (the head-junction temperature) and the emf of extension wire PX-NX between T_H and T_1 (see Eq A, in Fig. 12).

The emf of the thermocouple PN between T_2 and T_1, without the use of any extension wire, can be expressed as the sum of the emf of the couple PN between T_2 and T_H and the emf of the couple between T_H and T_1 (see Eq B, in Fig. 12).

In order that the thermocouple and extension wire assembly generates the same emf as that of the thermocouple PN between the hot-junction temperature T_2 and the cold-junction temperature T_1, the following condition must be met (Eq C, in Fig. 12):

$$(E_P - E_N)\Big|_{T_I}^{T_H} = (E_{PX} - E_{NX})\Big|_{T_I}^{T_H} \qquad \textbf{(Eq 5)}$$

where E_P is the emf of the positive thermoelement versus platinum, E_N is the emf of the negative thermoelement versus platinum, E_{PX} is the emf of the positive extension wire versus platinum, E_{NX} is the emf of the negative extension wire versus platinum, T_1, is the cold-junction temperature, and T_H is the head junction temperature. This expression means that the emf of the thermocouple PN within the temperature range T_1 to T_H must be the same as the emf of the extension-wire couple PX-NX within the same temperature range. It is not necessary, however, for the emf of the extension-wire couple to match that of the thermocouple over the entire range from T_1 to T_2. Extension wires of the same composition as that of the thermocouple wire are termed *extension wires.* Wires of different alloys used as extension wires to develop the same emf as that of the thermocouple wire from 0 to 200 °C (32 to 400 °F) are called *alternate* or *compensating extension wires*.

Extension wires are used for base-metal thermocouples. Alternate extension wires are used for noble-metal thermocouples. Base compositions, physical properties, ranges of application, and initial calibration tolerances of the extension wires for standardized thermocouples are listed in Table 9.

Table 9 Properties of thermocouple extension wires

Thermocouple type	Extension wire	Base composition	Resistivity, nΩ · m	Melting point		Temperature range, °C (°F)	Initial calibration tolerance
				°C	°F		
J	JPX	Fe	100	1450	2640	0 to 200 (32 to 390)	±2.2 °C (±4 °F)
	JNX	45Ni-55Cu	500	1210	2210		
K	KPX	90Ni-10Cr	700	1350	2460	0 to 200 (32 to 390)	±2.2 °C (±4 °F)
	KNX	95Ni-AlSiMg	320	1210	2210		
N	NPX	Ni-14Cr-1.4Si	930	1410	2570	0 to 200 (32 to 390)	±2.2 °C (±4 °F)
	NNX	Ni-4.4Si-0.1Mg	370	1400	2550		
T	TPX	Cu	17	1083	1981	-60 to 100 (-75 to 212)	±1.0 °C (±1.8 °F)
	TNX	45Ni-55Cu	500	1210	2210		
E	EPX	90Ni-10Cr	700	1450	2642	0 to 200 (32 to 390)	±1.7 °C (±3 °F)
	ENX	45Ni-55Cu	500	1450	2642		
R or S	SPX	Cu	17	1083	1981	0 to 200 (32 to 390)	±5 °C (±57 μV)

	SNX	Cu-1Ni-0.3Mn	45	1100	2010	(32 to 390)	(±57 μV)
B[(a)]	BPX[(b)]	Cu-2Mn	150	1100	2010	0 to 200 (32 to 390)	±33 μV
	BNX	Cu	17	1083	1981		

Source: Adapted from ANSI MC96.1

(a) Cu/Cu extension wire can be used if head-junction temperature is 100 °C or less.

(b) Proprietary alloy. Can be used up to 300 °C (570 °F) with initial calibration of +50 μV at this temperature.

Error Analysis. The error introduced by incorporation of extension wire in the thermocouple circuitry can be expressed:

$$\Delta E_{\text{assembly}} \left| \begin{matrix} T_2 \\ T_1 \end{matrix} \right. = \Delta E_{\text{PX-NX}} \left| \begin{matrix} T_H \\ T_1 \end{matrix} \right. - \Delta E_{\text{PN}} \left| \begin{matrix} T_H \\ T_1 \end{matrix} \right. + \Delta E_{\text{PN}} \left| \begin{matrix} T_2 \\ T_1 \end{matrix} \right. \quad \textbf{(Eq 6)}$$

where

$\Delta E_{\text{assembly}} \left| \begin{matrix} T_2 \text{ is the deviation (of initial calibration) of the thermocouple and extension wire assembly from established emf table} \\ T_1 \text{ between temperatures } T_1 \text{ and } T_2, \end{matrix} \right.$

$\Delta E_{\text{PX-NX}} \left| \begin{matrix} T_H \text{ is the deviation of the extension wire} \\ T_1 \text{ between } T_1 \text{ and } T_H, \end{matrix} \right.$

$\Delta E_{\text{PN}} \left| \begin{matrix} T_H \text{ is the deviation of the thermocouple} \\ T_1 \text{ between } T_1 \text{ and } T_H, \text{ and} \end{matrix} \right.$

$\Delta E_{\text{PN}} \left| \begin{matrix} T_2 \text{ is the deviation of the thermocouple} \\ T_1 \text{ between } T_1 \text{ and } T_2. \end{matrix} \right.$

Equation 6 shows that, besides the initial calibration error of the thermocouple over the temperature range T_1 to T_2, an additional term is introduced when extension is used. This term is equal to the difference of initial calibration of the extension-wire couple and the thermocouple between the cold-junction temperature T_1 and head-junction temperature T_H.

This additional term can be minimized by judiciously choosing a pair of extension wires or alternate extension wires, the initial emf calibration of which closely matches that of the thermocouple wire between T_1 and T_H.

Color Coding of Thermocouple Wires and Extension Wires

For many years ISA has coordinated an effort to standardize color coding of thermocouple and extension wires in the United States. The main objective has been to establish uniformity in designation of various types of thermocouples and extension wires to provide, by means of insulation color, identification of wires by type or composition as well as by polarity when used as part of a thermocouple system (Ref 9). The present U.S. color designations, as indicated in ANSI MC96.1 (1982), are given in Tables 10 and 11. Foreign and international color codes are given in Table 12. Color coding is not uniform throughout the world. United Kingdom, France, Germany, Japan, U.S.S.R., and China have their own color codes. At present, the International Electrotechnical Commission is adopting a new international color code in an attempt at world standardization.

(a) A tracer having the color corresponding to the positive wire code color may be used on the negative wire color code.

(b) *NOTE OF CAUTION:* In the procurement of random lengths of single conductor insulated extension wire, it must be recognized that such wire is commercially combined in matching pairs to conform to established calibration curves. Therefore, it is imperative that all single conductor insulated extension wire be procured in pairs, at the same time, and from the same source.

(c) The color identified as a trace may be applied as a tracer, braid, or by any other readily identifiable means.

Thermocouple Calibration

The temperature/emf relationship for a specific thermocouple combination is a definite physical property and thus does not depend on details of the apparatus or method used for determining this relationship. Consequently, thermocouples can be calibrated by any of several methods, the choice of which depends on type of thermocouple, temperature range, accuracy required, size of wires, apparatus available, and personal preference.

Calibration of a thermocouple is achieved through determination of its electromotive force (emf) at a series of known temperatures, which when coupled with a standardized means of interpolation will give values of emf over the entire temperature range in which it will be used. A standard thermometer that indicates temperatures on a universally

acceptable scale is required, as well as a means of measuring the emf of the thermocouple and a controlled heat source wherein the thermocouple and the standard can be brought to the same temperature.

Only the basic points of calibration techniques will be described in this review; the reader is directed to other, more detailed sources of information, such as Ref 9 and 10.

Temperature Scales (Ref 9 and 11). Meaningful measurement of temperature requires a scale with appropriate units, just as measurement of length requires a yardstick or meter stick with all of its subdivisions. The ideal temperature scale is known as the thermodynamic scale. However, measurement of temperature on this scale (using a gas thermometer) is extremely difficult even under laboratory conditions. For many years prior to 1927, the need for a more practical temperature scale had been apparent.

In 1927, such a scale, named the International Temperature Scale (ITS 27), was adopted by the Seventh General Conference on Weights and Measures. Among other advantages, this scale served to unify the existing national temperature scales (Germany, Britain, United States, and so forth). The scale was revised in 1948, and in a 1960 modification, the word "Practical" was inserted in the name of the scale, which now became the International Practical Temperature Scale. The scale was revised again in 1968, and was amended in 1975 (Ref 11).

The International Practical Temperature Scale of 1968 (amended in 1975), or IPTS 68 (amended 1975), was designed in such a way that the temperature measured on it closely approximates the thermodynamic temperature; the difference is within the limits of the present accuracy of measurement.

The IPTS 68 (amended 1975) is based on the assigned values of the temperatures of 13 reproducible equilibrium states (defining fixed points) and on standard instruments calibrated at these temperatures (Ref 11). Interpolation is provided by formulas used to establish the relations between indications on standard instruments and values of International Practical Temperature.

The IPTS 68 uses both International Practical Kelvin Temperature, symbol T_{68}, and International Practical Celsius Temperature, t_{68}. The relation between T_{68} and t_{68} is the same as that between T and t on the Thermodynamic Scale--that is, $t_{68} = T_{68} - 273.15$ K. The units of T_{68} and t_{68} are the kelvin symbol, K, and the degree Celsius symbol, °C, as in the case of thermodynamic temperature T and Celsius temperature t. The standard instruments used are:

- Platinum resistance thermometer 13.81 to 903.89 K (-434.81 to 1167.33 °F)
- Pt-10Rh/Pt thermocouple 630.74 °C to 1064.43 °C (gold point)
- Above 1064.43 °C (1947.97 °F), defined in terms of the Planck radiation law using 1064.43 as a reference temperature (Optical Pyrometer)

The International Temperature Scale of 1990 (ITS-90) is a new temperature scale, which became effective worldwide on 1 Jan 1990. The ITS-90 was developed to replace current temperature scale IPTS-68. This was done to overcome the deficiencies in accuracy and reproducibility of the existing scale and to incorporate the advances made in the last 20 years in thermometry. A new set of defining fixed points, such as the triple point of water (0.01 °C, or 273.16 K) and freeze points of high-purity metals was established. Platinum thermocouples are no longer used as the interpolating instrument for ITS-90. Resistance thermometers (primarily platinum resistance thermometers) are used instead. Above the gold point (1064.43 °C, or 1947.97 °F), radiation thermometers are used. As a result, temperatures on the ITS-90 scales are in much better agreement with thermodynamic values than are those on IPTS-68 and its subsequent revision in 1975.

The magnitude of the change in temperature from IPTS-68 to ITS-90 is within ±0.4 °C (±0.7 °F) from 0 to 1000 °C (32 to 1830 °F). Therefore, the existing tables for thermocouples and resistance temperature detectors (RTDs) need to be corrected to reflect these changes. The National Institute of Science and Technology (NIST) is preparing new tables of thermocouples and RTDs for ITS-90. For further details, see Ref 12.

Changes have also occurred in voltage and electrical resistance scales. The change in the Volt scale will be 9.3 ppm in the United States. (The changes in other parts of the world are slightly different.) The change in the Ohm scale will be 1.69 ppm. Instruments having this sensitivity range should be corrected to reflect the changes in volt and ohm scales.

Methods of Thermocouple Calibration. Initial calibration of a thermocouple can be done by any of the following methods:

- Freezing-point calibration
- Direct thermoelement emf measurement versus platinum
- Thermoelement comparison method
- Calibration of thermocouples by comparison methods

In the freezing-point method of calibration, the emf output of the thermocouple as a whole is measured during the cooling cycle of molten pure metals. In the second and third methods, the emf of both the positive and negative thermoelements are individually measured versus platinum or another calibrated standard.

Freezing-Point Calibration. In the calibration of a thermocouple at freezing points, the thermocouple (properly protected) is slowly immersed in the molten metal. The metal is brought essentially to a uniform temperature at the beginning of freezing by holding its temperature constant at about 10 °C (18 °F) above the freezing point for several minutes and then cooling slowly, or by agitating the metal with the thermocouple protection tube just before freezing begins. The emf of the thermocouple is observed at regular intervals of time. These values are plotted, and the emf corresponding to the flat portion of the cooling curve is the emf at the freezing point of the metal.

Metals of sufficient purity that may be used in freezing-point calibration are:

- Tin with a freezing point of 231.928 °C (449.470 °F)
- Indium with a freezing point of 156.5985 °C (313.8773 °F)
- Zinc with a freezing point of 419.527 °C (787.149 °F)
- Aluminum with a freezing point of 660.323 °C (1220.581 °F)
- Silver with a freezing point of 961.78 °C (1763.20 °F)
- Gold with a freezing point of 1064.18 °C (1947.52 °F)
- Copper with a freezing point of 1084.62 °C (1984.32 °F)
- Nickel with a freezing point of 1455 °C (2651 °F)
- Palladium with a freezing point of 1554 °C (2829 °F)
- Platinum with a freezing point of 1769 °C (3216 °F)

The triple point of water and the first seven freeze points of the above metals are the primary reference points in ITS-90 up to 1064.18 °C (1947.52 °F). The freezing points of the other metals listed above are secondary reference points. Of all these metals, antimony and tin have marked tendencies to undercool before freezing, but such undercooling will not be excessive if the liquid metal is stirred.

A Pt-10Rh/Pt thermocouple may be calibrated using values obtained at the freezing point of aluminum (660.323 °C), the freezing point of silver (961.78 °C), and the freezing point of gold (1064.18 °C).

The emf developed by a homogeneous thermocouple at the freezing point of a metal is constant and reproducible if all of the following conditions are fulfilled:

- The thermocouple is protected from contamination
- The thermocouple is immersed in the freezing-point sample sufficiently far to eliminate heating or cooling of the junction by heat flow along the wires and protection tube
- The reference junctions are maintained at a constant and reproducible temperature
- The freezing-point sample is of sufficient purity
- The metal is maintained at an essentially uniform temperature during freezing

Freezing points can be reproduced under industrial conditions within 0.1 to 5 °C (0.2 to 9 °F) for calibrations between the ice point and the melting point of platinum. Because of difficulty in testing, fixed points at temperatures above the freezing point of copper (1084.62 °C) usually are expressed as melting points rather than freezing points. Complete units including freezing-point sample, crucible, and heating source are available commercially.

See Ref 10 and 13, 14, 15 for additional information on the freezing-point method of calibrating thermocouples.

Direct emf Measurement Versus Platinum. The method used for direct measurement of thermoelement emf versus platinum at a fixed temperature is illustrated in Fig. 13. The thermocouple wire specimens, a primary platinum standard and a calibrated reference-grade type R couple (Pt-13Rh/Pt) are welded together at one end. The multiple couple is in turn welded into a heat sink, and the whole assembly is inserted halfway into a 2 m (6 ft) horizontal electric furnace to a depth of approximately 1 m (3 ft).

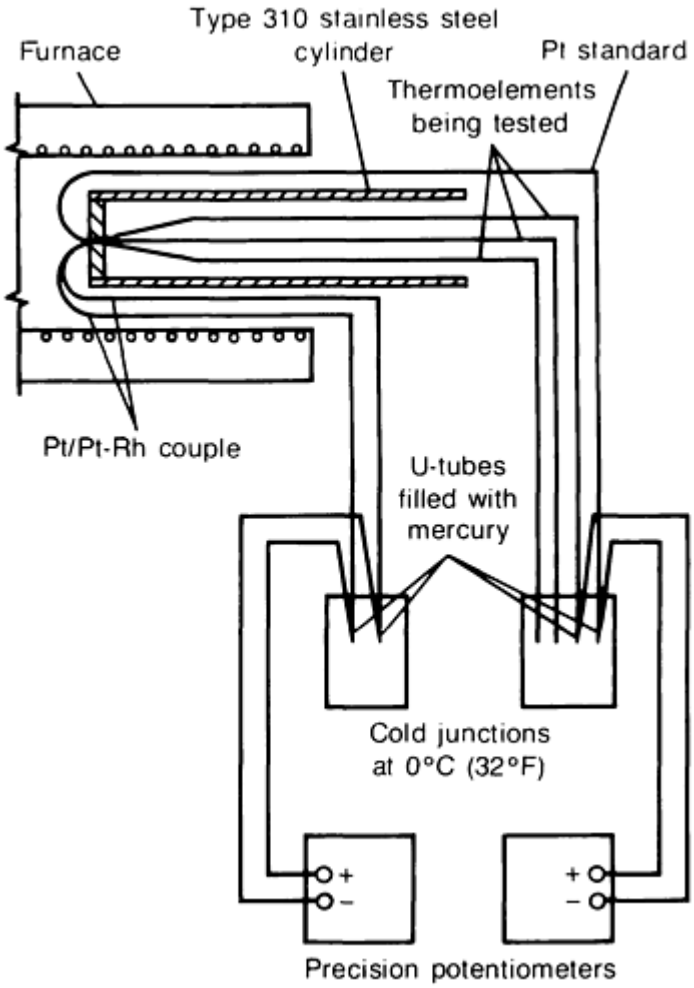

Fig. 13 Experimental setup for direct measurement of the emf of thermoelements versus platinum. Adapted from Ref 16

Precision potentiometers are used so that measurement of emf versus platinum for a test specimen, and measurement of temperature by the calibrated platinum thermocouple, can be made simultaneously. The test specimens, the calibrated platinum couple, and the platinum standard are inserted into mercury U-tubes embedded in Dewar flasks packed with shaved ice and are electrically connected to two precision potentiometers as shown in Fig. 13. Simultaneous measurements can be made as soon as the furnace temperature and the cold-junction temperature reach equilibrium.

Consider the case of emf measurements of Tophel, a type K positive thermoelement, at 980 °C (1800 °F). It is not necessary that the furnace temperature as measured by the calibrated Pt/Rh couple be exactly 980 °C (1796 °F). In actual practice, all that is needed is that the furnace temperature be within ±2.8 °C (±5 °F) of the desired temperature. The emf of the thermoelement at the desired test temperature can be computed with the following equation:

$$E_D = E_M - (T_M - T_D)\ z \qquad \textbf{(Eq 7)}$$

where E_D is the corrected specimen emf versus Pt at the desired temperature T_D, E_M is the measured emf at the measuring temperature T_M, and z is the thermoelectric power of the thermoelement versus Pt at T_D. As an example of the use of Eq 7, the following data were generated for a sample of Tophel:

Emf of Pt/Rh couple, mV	10.247
	10.248
	10.248
Corresponding temperature, T_M, °C (°F)	983 (1801.4)
Measured emf, E_M, mV	31.999
	32.000
	32.000
Thermoelectric power, mV/°C (mV/°F)	0.0306 (0.017)
Note: E_D = Corrected emf of sample vs Pt at 1800 °F = 32.000 mV - (1801.4 - 1800) × 0.017 mV/°F = 32.000 mV - 0.024 mV	

This value is in excellent agreement with National Bureau of Standards (NBS) calibrations on both ends of a single coil of Tophel: 31.970 mV and 31.980 mV. (The example shown above is in IPTS-68 scale.)

Comparison Method. In industrial practice, a thermoelement is calibrated at several fixed temperatures against a thermocouple standard of the same alloy calibrated by NIST. The procedure in ASTM E 207 describes the preferred standard method. The emf of the test specimen can be obtained by the following general equation:

$$\text{emf vs Pt} = \Delta\text{emf}_{\text{specimen vs std}} + \text{emf}_{\text{std vs Pt}} \qquad \textbf{(Eq 8)}$$

Figure 14(a) shows the emf versus Pt curve for a Tophel standard, a type K positive thermoelement. The type K positive thermoelement has a large thermoelectric power versus Pt. For example, its thermoeletric power versus Pt at 980 °C (1800 °F) is 31 μV/°C (17 μV/°F). An error of 34 μV would have been introduced by the temperature measurement error of only 1.1 °C (2 °F) in the case of direct measurement of emf versus Pt. However, this is not so in the comparison method, as can be readily observed from Fig. 14(b).

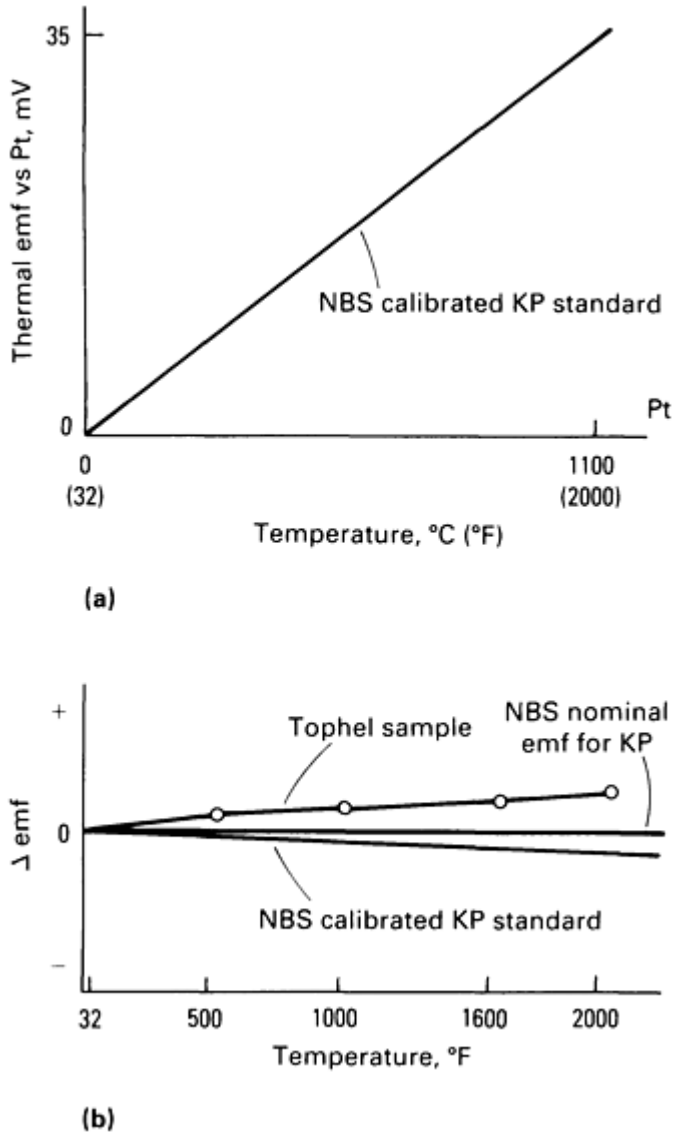

Fig. 14 Thermal emf plots for KP thermoelements illustrating the comparison method of emf measurement. (a) emf of KP standard versus platinum. (b) Δemf of Tophel sample and KP standard thermoelements versus NBS nominal emf for type KP. Adapted from Ref 2

Figure 14(b) shows values of Δemf versus NBS nominal emf as ordinates against temperature as abscissa. The emf deviations of the NIST-calibrated Tophel standard from NIST nominal emf values for the type K positive thermoelement are plotted with a heavy line. The deviation of the test specimen from NIST nominal emf at any test temperature can be obtained graphically by plotting measured Δemf on the chart or by use of the following equation:

$$\Delta\text{emf}_{\text{specimen vs NBS nominal emf}} = \Delta\text{emf}_{\text{specimen vs std}} + (\text{emf}_{\text{std vs Pt}} - \text{NIST nominal emf vs Pt}) \quad \textbf{(Eq 9)}$$

Equation 9 is a general equation applicable to both the positive and negative thermoelements. If we calculate Δemf for both thermoelements and substitute these values in Eq 4, then:

$$\Delta\text{emf}_{\text{couple}} = \Delta E_{\text{P}} - \Delta E_{\text{N}} \quad \textbf{(Eq 10)}$$

Calibration of Thermocouples by Comparison Methods. Calibration of a thermocouple by comparing it to a working standard is sufficiently accurate for most purposes and can be done conveniently in most industrial and technical laboratories. The emf of the thermocouple being calibrated is measured at selected calibration points, the temperature of each point being

measured by a standard thermocouple (usually one calibrated by NIST) or other standard thermometer, Test points are selected on the basis of thermocouple type, temperature range to be covered, accuracy required, and end use.

The accuracy obtained with this technique depends on the ability of the observer to bring the junction of the thermocouple to the same temperature as that of the sensing portion of the standard used, such as the measuring junction of a standard thermocouple or the sensitive portion of a resistance or liquid-in-glass thermometer. The accuracy obtained is further limited by the accuracy of the standard. The method of bringing both measuring junctions to the same temperature depends on type of thermocouple, type of standard, and method of heating.

Potentiometric instruments or high-impedance electronic instruments are used to measure emf, thus eliminating instrument loading as a contributor of significant error.

Additional information relative to this calibration method and attainable accuracies may by found in ASTM E 220, "Standard Method of Calibration of Thermocouples By Comparison Techniques," and in ANSI MC96.1.

Reference Tables for Thermocouples

Practical use of thermocouples requires that the selected thermocouple meet an established or standardized temperature/emf relationship within acceptable tolerance limits. Because the thermocouple in a thermoelectric thermometer system is replaced periodically due to drift, failure, or other reasons, conformance to an established temperature/emf relationship is necessary in order to permit interchangeability when commercially available readout equipment is used. Such widely acceptable reference tables have S and T thermocouples and are available in NBS Monographs 124 (Cryogenic) and 125 (Standard Couples), ANSI MC96.1 and ASTM E 230. Less detailed versions of these tables (at intervals of 10 °C, or 18 °F) usually may be obtained from producers or distributors of these thermocouples.

For other nonstandard thermocouples, including those that do not have letter designations, tables usually are developed by producers and are available from either producers or suppliers. Additionally, temperature/emf values for three W/Re combinations have been published "for information" by ASTM in the standards book containing standards related to thermocouples, and one combination (W-3Re/W-25Re) has values published in ASTM E 696.

All tables, in order to gain wide acceptance, must conform to an internationally recognized temperature scale. At this time, the scale is IPTS 68, and the latest published tables should conform to it. However, a large quantity of control or measurement instruments still in use are in compliance with IPTS 48, and replacement thermocouples for these

instruments are purchased on this scale. The difference in the two scales may or may not be significant depending on the application. In this regard, particular attention should be paid to types S, R, and B thermocouples for use above 1000 °C (1830 °F). See Ref 11 for differences arising from use of either scale.

Initial Calibration Tolerances. Table 2 lists manufacturers' tolerances for initial calibration of all standardized thermocouples. For example, a brand new type K couple could be in error by as much as ±4.2 °C (±7.5 °F) when used for temperature measurement at 540 °C (1000 °F). The deviation in emf of a thermocouple from the standard table value is equal to the algebraic difference of the individual emf deviations of the thermoelements, as shown in the following equation:

$$\Delta E_{\text{couple}} = \Delta E_{\text{P}} - \Delta E_{\text{N}} \qquad \textbf{(Eq 11)}$$

where ΔE_{couple} is the emf deviation of the couple from the table value, in millivolts; ΔE_{P} is the emf deviation of the positive thermoelement from NBS nominal value, in millivolts; and ΔE_{N} is the emf deviation of the negative thermoelement from NBS nominal value, in millivolts.

The deviations in initial calibration of a typical type K couple from NBS table values are illustrated in Fig. 15. The corresponding deviation of initial calibration expressed in temperature is obtained as follows:

$$\Delta T = \frac{\Delta E_{couple}}{Th.p.} \qquad \textbf{(Eq 12)}$$

where ΔE is the emf deviation of the couple at a certain temperature and Th.p. is the thermoelectric power of the couple at the same temperature.

Change of Calibration During Service

Any thermocouple can be subject to failure (of a type that creates an open circuit) during service. Failure can be caused by localized melting of the thermoelements as a result of overheating, by vibration resulting in fatigue failure, or by gradual reduction of wire diameter through high-temperature oxidation. Prior to failure, the emf calibration of a thermocouple will change, primarily as a result of the individual or combined changes in chemical composition, homogeneity, and structure that take place in the thermoelements. The magnitudes and directions of these changes are dependent on temperature, time, wire diameter, and environmental conditions.

Effect of Environment on Base-Metal Thermocouples. The change in emf, as a function of test temperature, of a 3.25 mm diam (0.128 in. diam) type K thermocouple on exposure to air up to 1100 °C (2000 °F) is shown in Fig. 16. After 10 h of exposure, the emf of the coupled had changed about 3 °C (5 °F) at 1100 °C (2000 °F) in the positive direction. The change had increased to + 10 °C (+ 18 °F) after exposure for 1000 h. At lower test temperatures, the magnitude of the change is smaller. A decrease in silicon and chromium contents of the positive thermoelement through preferential oxidation causes a net change in emf. Similarly, the change in emf of the negative thermoelement is attributed to preferential oxidation of its alloy constituents Si, Mn, Al, and Fe (Ref 16 and 17).

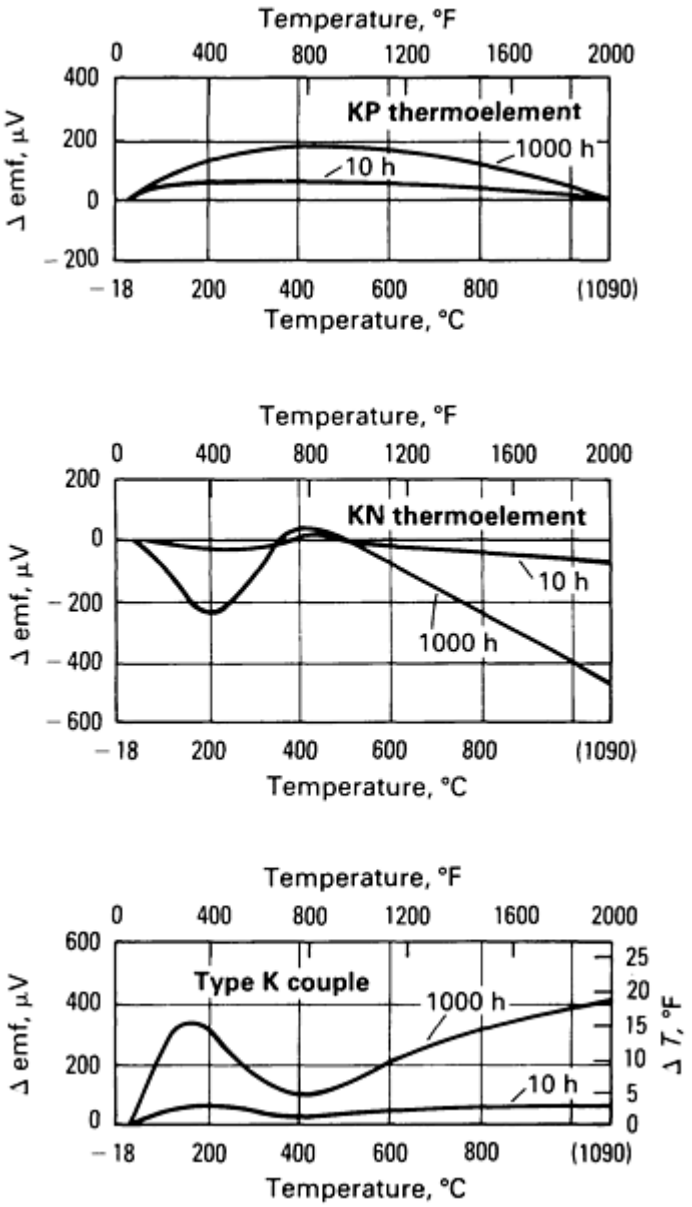

Fig. 16 Changes in thermal emf of a type K thermocouple resulting from long-time exposure in air at temperatures up to 1100 °C (2000 °F)

The oxidation resistance and emf stability of type J couples are inferior to those of type K couples, and type J couples should not be used above 760 °C (1400 °F).

Type K couples are recommended for use in inert atmospheres at elevated temperatures only for short intervals. Type J couples, on the other hand, are stable and can perform better in inert environments than in air.

Type K thermocouples are not recommended for use in reducing or hydrogen-bearing atmospheres. Type J couples are stable and can be expected to perform well at temperatures up to 760 °C (1400 °F).

Effect of Environment on Bare Pt-Rh Thermocouples. Pt-10Rh/Pt, Pt-13Rh/Pt, and Pt-30Rh/Pt-6Rh thermocouples can be used with very good results continuously in air or in oxidizing atmospheres to 1500 °C, or 2730 °F, for types S and R; to 1700 °C, or 3090 °F, for type B) and intermittently to temperatures approaching the melting point of platinum (1769 °C, or 3216 °F) for types S and R and to 1780 °C (3235 °F) for type B. For these couples in these atmospheres, life is governed by the temperature of operation, partial pressure of oxygen, rate of change of the atmosphere in the vicinity of the hot junction, and method of mounting of the thermocouple.

It is generally agreed that volatile oxides of platinum and rhodium are formed when these metals are heated at high temperatures and are the principal cause of the loss of metal. Experience indicates slightly more rhodium than platinum volatilizes in air, which results in a negative drift of the couple after long periods of operation. A negative drift of 6 to 9 °C (11 to 16 °F) has been reported for a thermocouple that was in continuous use in air at 1290 °C (2350 °F) for over three years.

Bare Pt-Rh thermocouples can be used in inert atmospheres such as argon, helium, or nitrogen with very good results.

As far as can be ascertained, reducing gases such as carbon monoxide and hydrogen do not have adverse effects on types S, R, and B couples directly, but it is suspected that these gases reduce impurity oxides such as silica, which is usually present in alumina. The silicon reduced from the silica is known to unite with platinum to form a low-melting eutectic (830 °C, or 1530 °F). Close contact of these couples by easily reduced oxides of any metal should not be permitted.

Type S, type R, and type B thermocouples have been used for short periods of time in vacuum. Long-time exposure to vacuum is not recommended.

It has been reported that unstable hydrocarbons crack in contact with hot platinum-group metals, causing damage to these metals in the form of a fine intergranular precipitate of carbon.

Halogen gases have harmful effects on platinum-group metals at high temperatures.

Direct contact between bare couples and compounds of easily reduced metals such as lead, bismuth, and antimony should be avoided at high temperatures, because such contact results in formation of low-fusing platinum alloys.

Unprotected platinum thermocouples are attacked by phosphorus, arsenic, sulfur, and vapors of metals such as zinc and lead. This attack generally results in brittleness and hot shortness.

All contact between bare couples and caustic alkalis, nitrates, cyanides, alkaline earths, and the hydroxides of barium and lithium should be avoided, because these substances attack platinum at red heat.

Judicious use of insulators and protection tubes will eliminate problems with many of the contaminants listed above. A variety of ceramics, some of which are gastight, are available, but it should be kept in mind that no single ceramic will suit all applications.

Certain precautions should be followed when platinum-group metals are in contact with ceramics in reducing atmospheres. It is generally known that when platinum or platinum alloys in contact with silica are heated in reducing atmospheres above 1200 °C (2200 °F), platinum silicides with low melting points (as low as 830 °C, or 1530 °F) are formed at the grain boundaries, which results in embrittlement of the wire. It has been shown that this attack also occurs at and above 1100 °C (2000 °F) when platinum and platinum alloys are adjacent to but not in contact with silica-bearing materials.

In experiments conducted at about 1100 °C (2000 °F), in which silica was present in the alumina insulation, and carbon and sulfur were also present (residue of drawing compound on wire), thermocouple wires failed due to melting. Based on failure analysis, it was hypothesized that a volatile compound of SiS_2 is first formed, which serves to transport silicon present in the insulator or protection tube to the platinum or platinum alloy. This compound decomposes in contact with the hot platinum, and the liberated sulfur recombines with additional silicon in the refractory.

It is quite obvious that all traces of lubricating oils, drawing compounds, or other sulfur-bearing compounds should be removed from the thermocouple assembly, because silica is present in varying amounts in all commercial refractories (particularly mullite and sillimanite). Fractures in wires, caused by platinum silicide, generally present a melted appearance, and the fracture surface contains a number of glazed areas.

Insulation and Protection

To operate properly, thermocouple wires must be electrically insulated from one another at all points other than the measuring junction and must be protected from the operating environment.

Thermocouple Wire Insulation. For cryogenic applications (below 0 °C and as low as about 4 K) varnish-type coatings are used to insulate thermoelements from one another. The coating usually is selected on the basis of good electrical resistance, ease of application, and ability to withstand flexing at the very low temperatures. Form-var, polyurethane, teflon, Pyre-ML-Polymide (E. I. Du Pont de Nemours and Company, Inc.), and GE 7031 (General Electric Company) have been used for this purpose. In particular, the polyimide coating has not only good electrical resistance but also excellent flexing strength at very low temperatures.

A variety of material, polyvinyl chloride, thermoplastic elastomer, fluoroethylene, synthetic polyimide fiber, polyimide film, fiberglass fibers, high-temperature fiberglass fibers, vitrified silica fibers, and ceramic fibers are available for insulating thermocouple from ambient to 1370 °C (2500 °F). The maximum service temperatures on these thermocouple insulation materials are listed in Table 13. The material is listed essentially in the order of dielectric strength at increasing operating temperatures. Besides dielectric strength, which dictates the maximum operating temperature of the insulation, the resistance to chemicals, moisture, flame, and abrasion are also listed for comparison.

Table 13 Maximum service temperatures, advantages and limitations of thermocouple wire insulation

Code	Material	Maximum temperature		Advantages and limitations
		°C	°F	
P	Polyvinyl chloride	105	221	Resistance to chemicals and moisture
R[(a)]	Thermoplastic elastomer	125	257	Application to -55 °C (-65 °F). Flame resistant
N	Nylon[(b)]	150	300	Resistant to chemicals. Flammable
TZ	Tefzel[(b)]	150	300	Resistant to chemicals. Nonflammable
TEX	Teflon[(b)]	200	400	Resistant to chemicals. Nonflammable
PFA, TF	Teflon[(b)]	260	500	Resistant to chemicals. Nonflammable
B[(a)]	Polyamide fiber	260	500	Replacement for asbestos. Nonflammable. Good abrasion resistance
K	Kapton[(b)]	260	500	Resistance to chemicals and abrasion
G	Fiberglass	500	932	Nonflammable, resists oils
Q	High-temperature fiberglass	700	1300	Nonflammable, resists oils

HG	Refrasil[c], vitrified silica	1000	1832	Excellent dielectric at high temperature. Poor abrasion resistance
Cefir[a]	Nextel 312(c), ceramic fiber	1200	2200	Excellent dielectric at high temperature. Good abrasion resistance, moisture resistant
. . .	Nextel 440[d], ceramic fiber	1370	2500	Excellent dielectric at high temperature. Good abrasion resistance, moisture resistance

Each type has its own advantages and limitations, and a knowledge of these advantages and limitations is essential if accurate and reliable measurements are to be made. It is important that these types of insulation be selected only after consideration of exposure temperatures, heating rates, number of temperature cycles, mechanical handling, moisture, routing of wires, and chemical deterioration.

Ceramic Insulation. At temperatures above approximately 300 °C (570 °F), hard-fired ceramic insulators are used on most bare thermocouple elements. Such insulators are available with single, double, or multiple bores, and in a variety of shapes, diameters, and lengths. The thermocouple supplier should be consulted on the type or types of insulation available for each specific application. The hard-fired ceramic insulators that are used with base-metal thermocouples are mullite, aluminum oxide, and steatite. Steatite is the most commonly used material for fish-spline insulators.

Platinum-rhodium thermocouples (types R, S, and B) for use below 1000 °C (1830 °F) may be insulated with quartz, mullite, sillimanite, or porcelain. Mullite and sillimanite have been used in industrial applications involving oxidizing atmospheres and temperatures from 1000 to 1400 °C (1830 to 2550 °F), but 99% Al_2O_3 is preferable for such service. Because both of these materials contain silica in various proportions, care should be taken to prevent promotion of a reducing atmosphere via carbonaceous impurities (such as residual lubricant on thermoelements). For all laboratory uses, for industrial uses in slightly reducing atmospheres (above 1000 °C, or 1830 °F), for critical applications, and for all uses of type B couples to around 1750 °C (3180 °F), pure, sintered, dense alumina (99.5% min Al_2O_3) is recommended. This insulation should be of one-piece, full-length construction to provide maximum protection from contamination.

For iridium-rhodium and tungsten-rhenium thermocouples, choice of insulation depends on temperature of use as well as environment. Hard-fired insulators of high-purity alumina may be used to approximately 1800 °C (3270 °F). From 1800 °C (3270 °F) to approximately 2300 °C (4170 °F), beryllium oxide (melting point: 2565 °C, or 4650 °F) should be considered. However, when beryllium oxide is used, certain safety precautions are necessary.

When hard-fired, dense, beryllia insulators are used, dimensional changes should be considered in design of the temperature-measuring system if it is to be used at or above approximately 2150 °C (3900 °F). At this temperature, beryllia undergoes a phase change. The problem is not serious in swaged thermocouples when crushable beryllia is used.

Thoria, which has a melting point higher than that of beryllia, has been used at temperatures up to about 2500 °C (4500 °F). However, the lower electrical resistivity of this ceramic material limits its applications at very high temperatures. Hafnia has been used on an experimental basis with some success.

In addition to conventional thermocouple assemblies with hard-fired ceramic insulators, sheathed, compacted, ceramic-insulated thermocouples are in common use. Magnesium oxide generally is used as the insulating material. A more detailed discussion of this type of construction is presented in a later section on metal-sheathed thermocouples.

Protection. Closed-end tubes made of metal, porcelain, mullite, sillimanite, quartz, or pyrex-glass may be used to prevent contamination of thermocouple sensing elements by the environment and to provide mechanical protection and support. Such tubes are called protection tubes. In some instances, two concentric tubes are employed. A protection tube must be large enough in inside diameter to accommodate an insulated matched couple (positive and negative thermoelements joined at the hot end). However, larger-diameter tubes may be used for strength, to permit insertion of a checking thermocouple alongside the service thermocouple, and to provide an adequate diameter-to-length ratio. Metallic protection tubes are generally available in pipe sizes of $\frac{1}{2}$ in. , $\frac{3}{4}$ in., and 1 in.

Bare, insulated base-metal thermocouples may be inserted directly into base-metal protection tubes. For noble-metal protection tubes. For noble-metal thermocouples, however, a ceramic protection tube generally is employed between the couple and the base-metal protection tube. For severe operating environments at elevated temperatures, platinum or platinum-rhodium protection tubes may be used. Bare but insulated noble-metal thermocouples may be inserted directly into these tubes. In any event, protection tubes must be internally clean and free of sulfur-bearing compounds, oils, and easily reduced oxides.

A wide range of metal and ceramic protection tubes is available commercially (see for example Table 14). This allows for the selection of a particular protection tube for a specific application.

Table 14 Maximum service temperatures for protection tubes

Materials	**Maximum service temperature**	
	°C	**°F**
Carbon steel	540	1000
Wrought iron	700	1300
Cast iron	700	1300
304 stainless steel	870	1600
316 stainless steel	870	1600
Chrome iron (446)	980	1800
Nickel	980	1800
Inconel	1150	2100
Porcelain	1650[(a)]	3000[(a)]

Silicon carbide	1650	3000
Sillimanite	1650[(a)]	3000[(a)]
Aluminum oxide	1760[(a)]	3200[(a)]

Source: Adapted from ANSI MC96.1

(a) Horizontal tubes should receive additional support above 1480 °C (2700 °F).

Steel protection tubes may be used at temperatures up to about 500 °C (930 °F). Stainless steels of the 18-8 variety may be used at up to 800 °C (1470 °F), and stainless steels of higher alloy content at up to about 1000 °C (1830 °F). The 80Ni-20Cr alloys and certain Ni-Cr-Fe alloys may be used to around 1100 °C (2000 °F), with the latter having better resistance to sulfur. It should be remembered that high-nickel alloys should not be used in sulfur-containing atmospheres at temperatures above 400 °C (750 °F).

Protection tubes for platinum-rhodium thermocouples (types R, S, and B) have been made of quartz for service at temperatures up to about 1000 °C (1830 °F), and of mullite for service up to around 1650 °C (3000 °F). Both materials have good resistance to thermal shock. However, in order to ensure long life and emf stability, fused alumina tubes or insulators are preferable for such couples at temperatures above 1200 °C (2200 °F). Fused alumina tubes are more expensive than mullite tubes and have lower resistance to thermal shock. Double ceramic tubes, comprising fused-alumina primary tubes and mullite secondary tubes, are used in certain applications.

Metal protection tubes made of iridium, tantalum, tungsten, and molybdenum, and of Ir-Rh, Nb-1Zr, W-26Re, and Mo-50Re alloys, have been used to protect tungsten-rhenium thermocouples at high temperature. The noble metal iridium is the only known metal that may be used in air unprotected for short periods of time at temperatures up to approximately 2100 °C (3800 °F) without undergoing catastrophic failure. Iridium-rhodium alloys may be used under similar circumstances up to 2000 °C (3600 °F). Experience has shown that, within their recommended temperature ranges, Ir-Rh alloys have better oxidation resistance than that of iridium.

The refractory metal tubes noted above must always be used in inert atmospheres or in a good vacuum. Of these, the tantalum and Nb-1Zr tubes, because of their excellent cold workability, have found extensive use in swaged-type W-Re thermocouples. They are presently being used at temperatures up to approximately 2100 °C (3800 °F).

The Mo-50Re alloy has some interesting possibilities as a material for protective sheaths. This alloy has some cold workability and, more important, is still ductile at room temperature after exposure to temperatures above its recrystallization temperature. At these high temperatures, cleanness of both wire and tubing (thermowell or swaged sheath) is very important. It has been found that carbon present in the tubing (possibly lubricant residue) can react with beryllium oxide insulators at temperatures below 2000 °C (3600 °F).

Protecting wells are employed for thermocouples used in liquids and gasses at high pressure. These wells are made of metal, and they may be turned and drilled from bar stock or built up by welding. Materials such as stainless steels (18-8), carbon steel, and 14% chromium iron are used to fabricate these wells depending on end use.

The foregoing paragraphs describe the procedures used to insulate and protect conventional thermocouples ("bare-wire" thermocouples). Sheathed thermocouple elements ("swaged-type" thermocouples) are fabricated from commercially available sheathed thermocouple wires. Fabricating such thermocouples successfully requires special equipment, special precautions, and more skill than is usually required for fabricating conventional bare-wire thermocouple assemblies. This type of thermocouple assembly is described briefly in the following section.

Thermocouple Assemblies

Conventional Thermocouples. Some typical thermocouple assemblies employed in industrial applications are shown in Fig. 17. In the assembly shown at the top of this figure, a closed-end pipe protection tube may be substituted for the nipple and ceramic protection tube in the base-metal thermocouple applications. For additional details, see also ANSI MC96.1 "Temperature Measurement Thermocouples," and suppliers' literature.

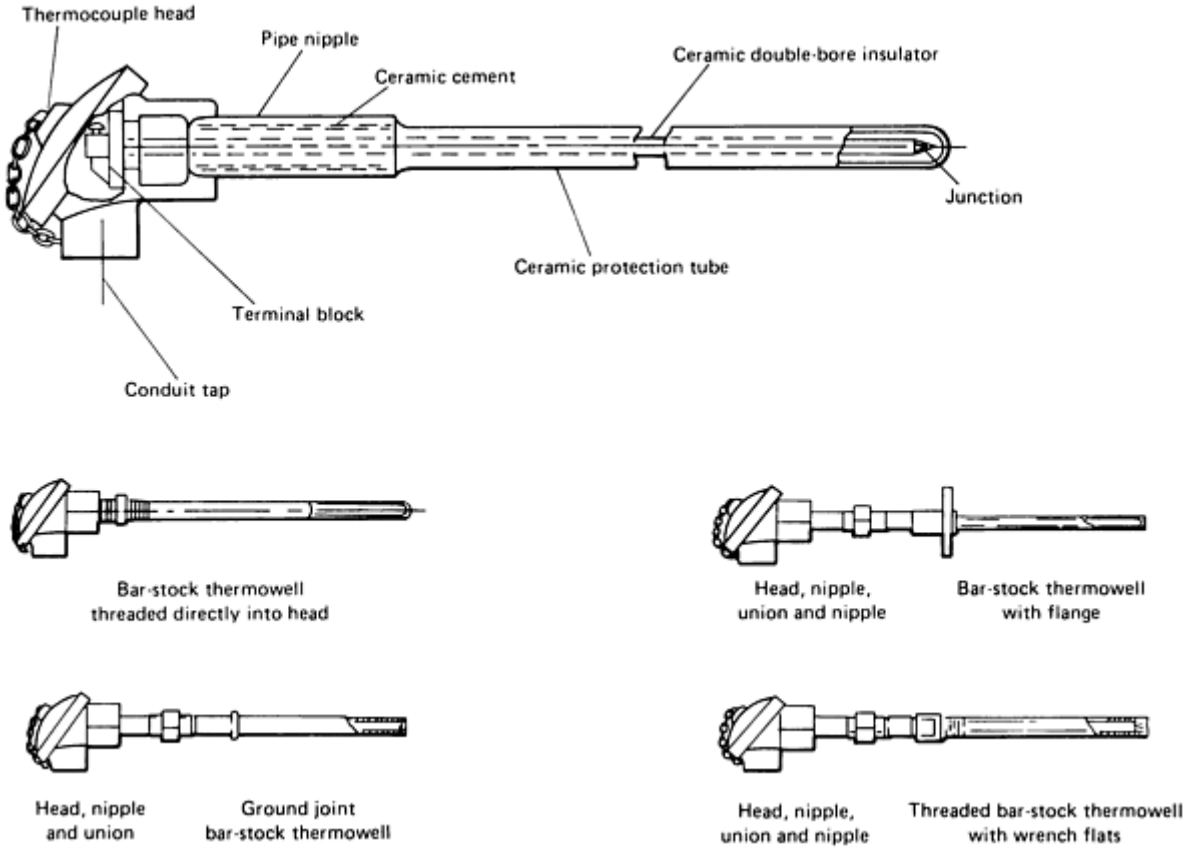

Fig. 17 Typical industrial thermocouples insulated with hard-fired ceramics. Adapted from Ref 9

Metal-Sheathed Thermocouples. In metal-sheathed couples, the wires are insulated from each other and from the sheath by means of compressed pure refractory oxide powder. The resulting assembly (thermocouple wires, oxide powder, and integral sheath) is flexible enough to be formed around a diameter equal to four times that of the assembly, without damage.Fabrication of a metal-sheathed thermocouple is simple and begins with matched thermocouple wires surrounded by a partly sintered ceramic material held within a metal tube. By swaging, drawing, or any other mechanical-reduction process, the assembly is reduced in diameter. As a result of this working, the insulation is first broken into powder and then is compacted around the wires while the assembly is elongated. An assembly produced in this fashion should have a minimum insulation resistance of 100 MΩ at 500 V dc for sizes larger than 1.6 mm ($\frac{1}{16}$ in.) in outside diameter. This requires some care during fabrication and use of dry, uncontaminated compacted ceramic. Because of the hygroscopic nature of powdered ceramics--especially MgO--moisture can be absorbed through the exposed ends of the sheath by capillary action. For this reason, the metal-sheathed couple or cable should be purchased with the ends closed by welding or suitably sealed in some other manner. Under certain circumstances, organic seals may not be suitable for this purpose. It has been reported that cable sealed with an organic material leaked when shipped by air freight, with a resulting decalibration of the thermocouple. The following precautions should be exercised when handling compacted ceramic-insulated thermocouples, in order to preserve the integrity of the insulation:

- Never leave an end of a sheathed couple exposed for more than 2 or 3 min; seal ends immediately. Use appropriate seal, depending on method of shipping
- Expose ends only in areas of low relative humidity
- Store sheathed assemblies in an area that is warm (above 38 °C, or 100 °F) and dry (relative humidity

less than 25%)

Sheaths are selected to suit specific end-use requirements. The materials that have been used for this purpose include: types 304, 310, 316, 321, 347, and 440 stainless steels; platinum alloys; Hastelloy X; copper; aluminum; Inconel 600; Inconel 702; and tantalum and niobium alloys.

Depending on temperature and application, magnesia, alumina, beryllia, or thoria may be used for the insulation. Grounded (to sheath) or ungrounded junctions may be supplied as required, the former having faster response time in temperature sensing.

Among the advantages of compacted sheathed thermocouple construction are small dimensions (as small as 0.5 mm, or 0.020 in., OD) and flexibility. In addition, the assembly is completely resistant to thermal shock, to which more conventional assemblies comprising hard-fired insulators and outer refractory ceramic sheaths are prone.

Criteria for Selection of Thermocouples for Industrial Applications

No thermocouple meets all requirements of temperature measurements over the entire range from cryogenic through 2700 °C (4900 °F). However, each of the previously discussed standard or nonstandard thermocouples possesses characteristics most desirable for a particular application. The following criteria should be given careful consideration during selection and design of thermocouple systems:

Performance requirements

- Accuracy in temperature measurement
- EMF stability
- Service life

Operating environment

- Temperature range
- Time at temperature
- Temperature gradient
- Thermal cycling
- Effect of pressure or vacuum
- Nuclear radiation
- Chemical composition

Cost and availability

- Initial and replacement cost of thermocouple (parts and labor)
- Initial and replacement cost of thermocouple extension wire (parts and labor)
- Initial and replacement cost of thermocouple accessories (parts and labor)
- Downtime
- Delivery time (immediate or extended)

Design selection

- Thermocouple and extension wires (types)
- Temperature/emf relationship and temperature range
- Sensitivity of couple
- Available wire diameter
- Insulation and protection (types)
- Bare-wire versus sheathed construction, with proper end sealing for sheathed construction
- Assembly configuration and type of measuring junction
- Chemical, physical, and mechanical properties (electrical resistance, temperature coefficient of resistivity, coefficient of expansion, thermal conductivity, density, specific heat)

Cryogenic Applications. With the exception of types J, E, T, N, and K, standard thermocouples developed for use at moderate or high temperatures are too low in sensitivity at cryogenic temperatures to be of any practical value in cryogenic applications. Of these five, type E, and to a lesser extent type T, are suitable for general low-temperature service down to -200 °C (-330 °F).

Advocated for applications at still lower temperatures (below 50 K, and possibly as low as 4 K) is a thermocouple consisting of gold plus a trace amount of iron versus either the KP or the EP thermoelement (90Ni-9Cr; see Table 1). Actually, three different Au-Fe thermoelements have been used: Au-0.02 at.% Fe, Au-0.03 at.% Fe, and Au-0.07 at.% Fe. Of these three, the latter may have wider application.

To ensure a high emf in the cryogenic range as well as reproducibility from lot to lot, the Au-Fe alloys must be carefully prepared. High-purity (99.999%) gold is used, and trace amounts of iron are added. For example, only 57 ppm (by weight) of iron are added to the gold in making Au-0.02 at.% Fe, 85 ppm in making Au-0.03 at.% Fe, and 200 ppm in producing Au-0.07 at.% Fe.

If standard thermocouples (types E and T) are intended for cryogenic use (to -200 °C, or -325 °F), the supplier should be notified of this intention in order to facilitate selection of materials. If a Au-Fe-KP or Au-Fe/EP couple is being considered, it should be kept in mind that the gold-bearing thermoelement must be made to special order because it is not a stocked item. Wires used in cryogenic applications generally are fine-gage wires (0.10 to 0.15 mm, or 0.004 to 0.006 in., in diameter).

Good Thermocouple Practice

After the proper thermocouple and extension wire have been selected, care must be taken in installation of the thermocouple system to ensure that errors are not introduced that can affect service. Following are some precautions that should be observed:

- Avoid cold working of thermocouple and extension wire. Excessive deformation can adversely affect accuracy of the thermocouple. Severe bending, flexing, or hammering of the thermocouple wire should be avoided. If cold working does occur, heat treatment should be considered to remove its effects. The degree of cold work that may be tolerated without annealing will depend on the end use and accuracy required
- Extraneous junctions should be monitored--as when connecting lead wires in a thermocouple circuit and when connecting the circuit to a recorder. The solution is to maintain a uniform ambient temperature in the vicinity of these junctions and at the measuring device
- Provide adequate protection. Generally, thermocouples must be equipped with suitable protection in the form of wells or protection tubes to guard the immersed portion against physical damage or contamination

A protecting tube is a tube designed to enclose a temperature-sensing device and to protect it from the deleterious effects of the environment. It may provide for attachment to a connection head, but it is not primarily designed for pressure-tight attachment. A thermowell is a pressure-tight receptacle adapted to receive a temperature-sensing element and is provided with external threads or other means for pressure-tight attachment to a vessel. There are many varieties of these tubes and

wells, in various metals, alloys, and refractory materials, available on the market today to meet special requirements. Adequate protection may also be obtained through the use of metal sheathed, mineral insulated thermocouples. In the latter case, the sheath is an integral part of the thermocouple assembly. On the debit side, it should be stated that the protecting tube interferes with ideal temperature measurement and control. It decreases the sensitivity of measurement (speed of response) and increases installation space and cost.

- Select largest practical wire size for a particular end use. The largest practical wire size should be used, consistent with end use requirements such as rapid response, flexibility, and available space. Heavy gage thermocouples have greater long-term stability at high temperatures than thermocouples of a lighter gage but also have a slower response. Speed of response, or rate at which the thermocouple detects temperature changes, may be of vital concern in many applications; particularly where these changes occur rapidly. However, many factors of heat transfer affect the speed of response of a thermocouple, and the mass of the couple is only one of them
- Thermocouples should be located properly to achieve maximum benefits. The thermocouple should be placed so that the measured temperature is representative of the equipment or medium that is being studied. For example, stagnant areas (not at representative temperature) or exposure to direct flame impingement (unless desired) could result in erroneous readings. If the thermocouple is immersed in a fluid (liquid or gas), the depth of immersion should be sufficient to minimize heat transfer away from the measuring junction. For many applications, a minimum immersion depth of ten times the outside diameter of the protection tube is considered adequate to prevent serious temperature errors (readings on low side). Also to be considered is the probability of radiation heat transfer to a bare thermocouple junction from the environment. In this case, radiation shields should be used
- When measuring high temperatures, install the thermocouple vertically whenever possible to prevent sagging of the protection tube. However, care should be taken to properly support the thermocouple within the tube. This is particularly true for the noble metal thermocouples when used at elevated temperatures greater than 600 °C (1100 °F). In this case, the thermocouple assembly may be supported by resting the bead of the thermocouple and the insulator on the bottom of the tube (on high purity alumina powder when a metal tube is used)
- Make sure that the protecting tube or well extends far enough beyond the outer surface of the vessel or heat source to bring the connecting head to approximately ambient temperature (particularly with type K using alternate extension wire and types R or S)
- When making thermocouples, clean the free ends of the wire well before fastening them to the connecting head, and be sure that they are inserted with proper polarity as identified on the terminal block

Maintenance of Thermocouples

Scheduled maintenance can be beneficial. The life and reliability of a thermocouple measuring system can be improved, and the likelihood of catastrophic failure is reduced if recommended calibration and maintenance procedures are followed. In addition, any gradual aging or drift can be determined by periodic observation and recording of thermocouple behavior. Based on information obtained in the maintenance program, scheduled replacement of the thermocouple probe can be made before it has deteriorated beyond acceptable limits or before failure. The portion of the Metal Treating Institute specification MT12000, "Quality Assurance Specifications for Performance of Heat Treating Processes," relating to temperature measurement is one example of a planned maintenance approach.

The personnel employed in the maintenance program should be familiar with the operating procedures upon which the system is based. Of primary importance, the equipment used for maintenance should be in good working order.

The following items are generally considered a good basis for planned maintenance:

- Thermocouples should be checked regularly at intervals determined by experience. For example, checking base metal thermocouples once a month may be sufficient for some applications but not for others. Exceptions could vary greatly
- If a thermocouple must be removed for examination, carefully reinsert it so as not to change the depth of immersion. Most important of all, do not decrease immersion

- It is preferable to check thermocouples in place. However, rather than checking thermocouples, it may be preferable to replace thermocouples after a predetermined average life has been achieved. This would ensure nearly perfect operation without the periodic problem of checking thermocouples
- A type K thermocouple should not be exposed to temperatures greater than 760 °C (1400 °F) if it is to be used for accurate temperature measurement below 540 °C (1000 °F)
- "Burned out" protection tubes should not be used, otherwise the thermocouple may be damaged or ruined. In particular, old, previously utilized, protection tubes and insulators should not be used with new noble metal thermocouples because of possible contamination (especially true for types R and S thermocouples)
- Contacts must be kept clean if switches are used in the thermocouple circuit
- When recording or indicating potentiometers are connected in parallel for operation from a single thermocouple, the circuit should be analyzed carefully to determine possible effects of one instrument on the other

Troubleshooting. The prime requisite in troubleshooting is a good knowledge and understanding of how the temperature-measuring system operates and why it fails to operate. Familiarity with the previous history of operation of a particular system can be important in quickly determining and correcting a problem.

In general, troubleshooting entails systematic checking of the system one section at a time. Readings should be taken with independent instruments, or one can substitute components that were previously found to be in good working order. This is continued until the problem has been isolated. If an independent source of heat is used to stimulate the system, it may not be possible to produce the same temperature gradients found in normal operation, and the emf results obtained with aged wire will not correspond with those obtained in actual operation.

Because it would be difficult, if not impossible, to discuss all potential operating problems, several common ones have been selected to get an idea of what may be expected in actual practice:

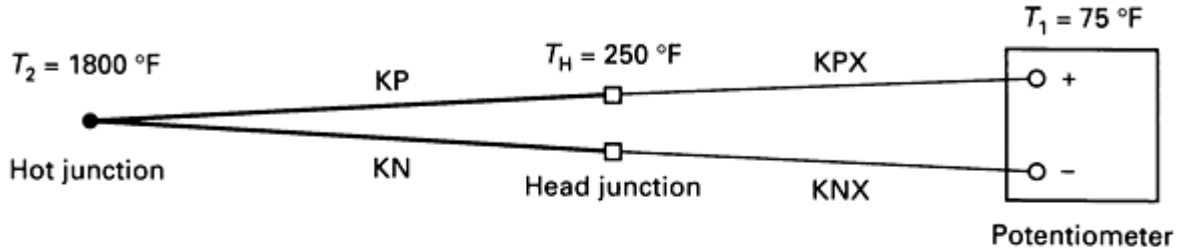
- First make sure that the correct extension or compensating extension wire has been used. This is particularly true for installations that may have a number of different types of thermocouples. In this case, it is not unusual to find extension wire designed for one type of thermocouple to be used with another. Also, it is not unusual to find that the initially purchased extension wire or thermocouples were wrong. A common mistake is to use compensating extension wire intended for the type R or type S thermocouple with the type B couple
- The positive extension wire must be connected to the positive thermoelement and the negative extension wire must be connected to the negative thermoelement. A very large temperature error will be introduced if the polarity is reversed. Figure 18 shows that a temperature error of about 180 °C (355 °F) is observed when a type K couple is used in measuring a temperature of 980 °C (1800 °F) with its extension wire in a reversed position
- Check the polarity of spliced extension wire and make certain that the splice will not be subject to intermittent or high-resistance contact. The system may be installed by electricians or mechanics who may not appreciate the seriousness of polarity reversal
- Make sure that the thermocouple is suitable for the instrument used and that the connections at the terminal block are tight
- If the extension wire color coding differs from the standard U.S. color coding shown in Tables 10, 11, and 12 (see also ANSI Standard MC96.1, Temperature Measurement Thermocouples), particularly in new installations, check to see that this particular extension wire is correct for this thermocouple
- When there is doubt about the type of a thermocouple used, there are several ways by which this can be determined quickly. This can be done visually, as for example distinguishing the noble metal thermocouples (types R, S, and B) from the base metal ones (types J, K, E, and T); copper leg of the type T thermocouple. With the use of a magnet, the positive legs of the types E, J, and K couples can be distinguished (magnetic). Other checks consist of making up a thermocouple of the lead wire and checking the output at a fixed temperature; this is also true for distinguishing whether the couple is type R or S. Checks on lead wire may not be necessary where standard color coding is clearly distinguishable

but may be useful in old installations where the color coding has become faded

- Checking the resistance of a thermocouple circuit will indicate immediately whether it is in good condition. Low resistance may be equated to the probability of good performance. High resistance may be an indication that the thermocouple is nearing the end of its useful life or that there is a loose connection. In particular, this is a good test in installations where a large number of couples are connected to a readout device through switches

$$E_t = E_{PN}\Big|_{T_H}^{T_2} + E_{PXNX}\Big|_{T_1}^{T_H}$$

Case 1: correct polarity

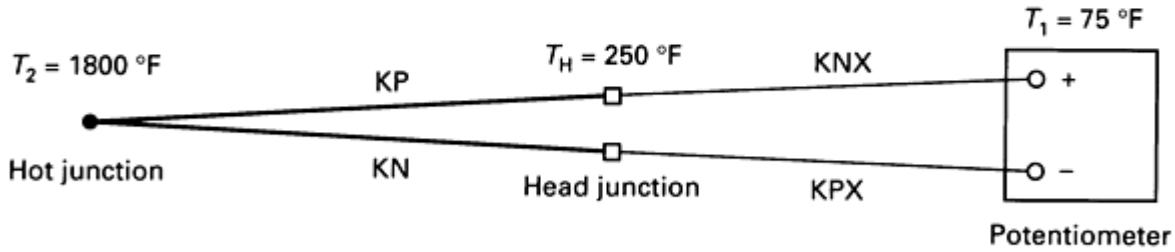


$$E_t = E_{KPKN}\Big|_{250\,°F}^{1800\,°F} + E_{KPXKNX}\Big|_{75\,°F}^{250\,°F} + E_{KPXKNX}\Big|_{32\,°F}^{75\,°F}$$

E_t = (40.62 – 4.97) + (4.97 – 1.00) + 1.00 mV

E_t = 40.62 mV; equivalent to 1800 °F

Case 2: reversed polarity



$$E_t = E_{KPKN}\Big|_{250\,°F}^{1800\,°F} - E_{KPXKNX}\Big|_{75\,°F}^{250\,°F} + E_{KPXKNX}\Big|_{32\,°F}^{75\,°F}$$

E_t = (40.62 – 4.97) – (4.97 – 1.00) + 1.00 mV

E_t = 32.68 mV; equivalent to 1445 °F

Fig. 18 Effect of reversed polarity at the head junction on emf output of a type K thermocouple assembly. Adapted from Ref 2

Low-Expansion Alloys

Revised by Earl L. Frantz, Carpenter Technology Corporation

Introduction

LOW-EXPANSION ALLOYS include various binary iron-nickel alloys and several ternary alloys of iron combined with nickel-chromium, nickel-cobalt, or cobalt-chromium alloying. Many of the low-expansion alloys are identified by trade names:

- *Invar,* which is a 64%Fe-36%Ni alloy with the lowest thermal expansion coefficient of iron-nickel alloys
- *Kovar,* which is a 54%Fe-29%Ni-17%Co alloy with coefficients of expansion closely matching those of standard types of hard (borosilicate) glass
- *Elinvar,* which is a 52%Fe-36%Ni-12%Cr alloy with a zero thermoelastic coefficient (that is, an invariable modulus of elasticity over a wide temperature range)
- *Super Invar,* which is a 63%Fe-32%Ni-5%Co alloy with an expansion coefficient smaller than Invar but over a narrower temperature range

Besides these common trade names, alloy compositions are also selected to have appropriate expansion characteristics for a particular application. Low-expansion alloys are used in applications such as:

- Rods and tapes for geodetic surveying
- Compensating pendulums and balance wheels for clocks and watches
- Moving parts that require control of expansion, such as pistons for some internal-combustion engines
- Bimetal strip
- Glass-to-metal seals
- Thermostatic strip
- Vessels and piping for storage and transportation of liquefied natural gas
- Superconducting systems in power transmissions
- Integrated-circuit lead frames
- Components for radios and other electronic devices
- Structural components in optical and laser measuring systems

Low-expansion alloys are also used with high-expansion alloys (65%Fe-27%Ni-5%Mo, or 53%Fe-42%Ni-5%Mo) to produce movements in thermoswitches and other temperature-regulating devices.

Iron-Nickel Alloys

Alloys of iron and nickel have coefficients of linear expansion ranging from a small negative value (-0.5 ppm/°C) to a large positive (20 ppm/°C) value. Figure 1 shows the effect of nickel content on the linear expansion of iron-nickel alloys at room temperature. In the range of 30 to 60% Ni, it is possible to select alloys with appropriate expansion characteristics. The alloy containing 36% nickel (with small quantities of manganese, silicon, and carbon amounting to a

total of less than 1%) has a coefficient of expansion so low that its length is almost invariable for ordinary changes in temperature. This alloy is known as Invar, which is a trade name (of Imphy, S.A.) meaning invariable.

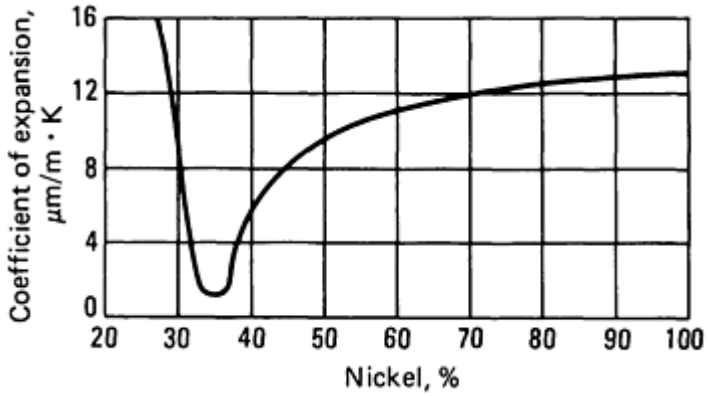

Fig. 1 Coefficient of linear expansion at 20 °C versus Ni content for Fe-Ni alloys containing 0.4% Mn and 0.1% C

After the discovery of Invar, an intensive study was made of the thermal and elastic properties of several similar alloys. Iron-nickel alloys that have nickel contents higher than that of Invar retain to some extent the expansion characteristics of Invar. Alloys that contain less than 36% nickel have much higher coefficients of expansion than alloys containing 36% or more nickel. Further information on iron-nickel alloys besides Invar is given in the section "Iron-Nickel Alloys Other Than Invar" in this article.

Invar

Invar (UNS number K93601) and related alloys have low coefficients of expansion over only a rather narrow range of temperature (see Fig. 2). At low temperatures in the region from A to B, the coefficient of expansion is high. In the interval between B and C, the coefficient decreases, reaching a minimum in the region from C to D. With increasing temperature, the coefficient begins again to increase from D to E, and thereafter (from E to F), the expansion curve follows a trend similar to that of the nickel or iron of which the alloy is composed. The minimum expansivity prevails only in the range from C to D.

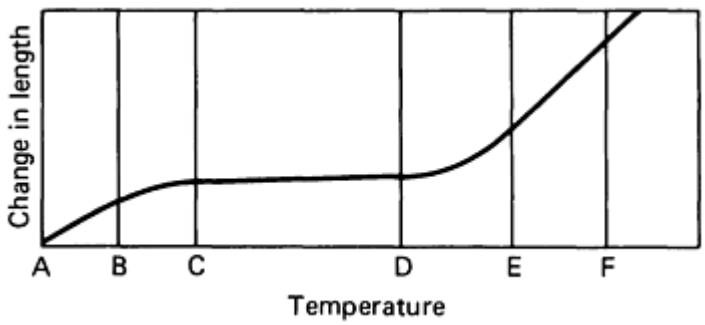

Fig. 2 Change in length of a typical Invar over different ranges of temperature

In the region between D and E in Fig. 2, the coefficient is changing rapidly to a higher value. The temperature limits for a well-annealed 36% Ni iron are 162 and 271 °C (324 and 520 °F). These temperatures correspond to the initial and final losses of magnetism in the material (that is, the Curie temperature). The slope of the curve between C and D is then a measure of the coefficient of expansion over a limited range of temperature.

Table 1 gives coefficients of linear expansion of iron-nickel alloys between 0 and 38 °C (32 and 100 °F). The expansion behavior of several iron-nickel alloys over wider ranges of temperature is represented by curves 1 to 5 in Fig. 3. For comparison, Fig. 3 also includes the similar expansion obtained for ordinary steel.

Table 1 Thermal expansion of Fe-Ni alloys between 0 and 38 °C

Ni, %	Mean coefficient, µm/m · K
31.4	3.395 + 0.00885 *t*
34.6	1.373 + 0.00237 *t*
35.6	0.877 + 0.00127 *t*
37.3	3.457 - 0.00647 *t*
39.4	5.357 - 0.00448 *t*
43.6	7.992 - 0.00273 *t*
44.4	8.508 - 0.00251 *t*
48.7	9.901 - 0.00067 *t*
50.7	9.984 + 0.00243 *t*
53.2	10.045 + 0.00031 *t*

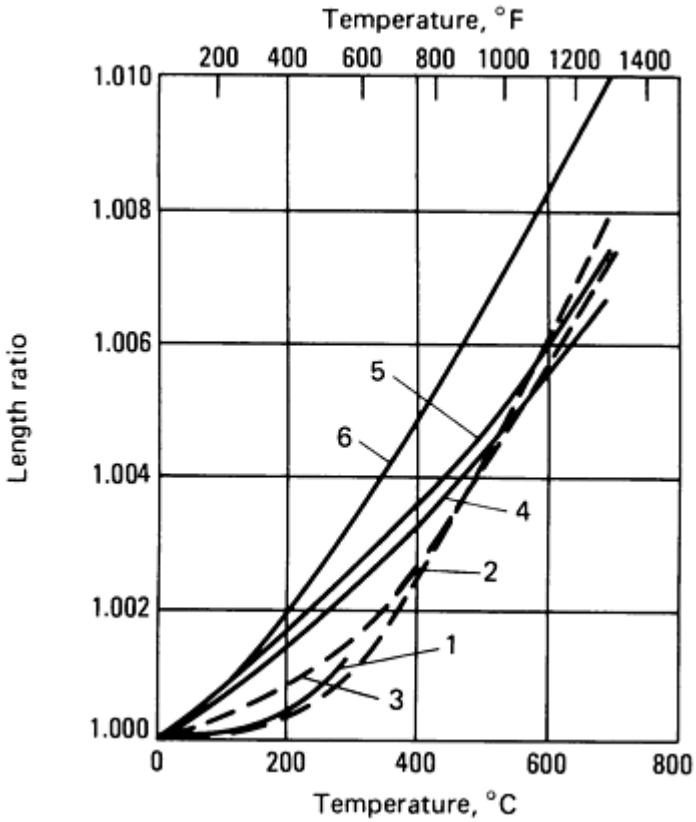

Fig. 3 Thermal expansion of Fe-Ni alloys. Curve 1, 64Fe-31Ni-5Co; curve 2, 64Fe-36Ni (Invar); curve 3, 58Fe-42Ni; curve 4, 53Fe-47Ni; curve 5, 48Fe-52Ni; curve 6, carbon steel (0.25% C)

Effects of Composition on Expansion Coefficient. The effect of variation in nickel content on linear expansivity is shown in Fig. 1. Minimum expansivity occurs at about 36% Ni, and small additions of other metals have considerable influences on the position of this minimum. Because further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve (Fig. 2) also rises with increasing nickel content.

The addition of third and fourth elements to Fe-Ni provides useful changes of desired properties (mechanical and physical), but significantly changes thermal expansion characteristics. Minimum expansivity shifts toward higher nickel contents when manganese or chromium is added, and toward lower nickel contents when copper, cobalt, or carbon is added. Except for the ternary alloys with nickel-iron-cobalt compositions (Super-Invars), the value of the minimum expansivity for any of these ternary alloys is, in general, greater than that of a typical Invar alloy.

The effects of additions of manganese, chromium, copper, and carbon are shown in Fig. 4. Additions of silicon, tungsten, and molybdenum produce effects similar to those caused by additions of manganese and chromium; the composition of minimum expansivity shifts towards higher contents of nickel. Addition of carbon is said to produce instability in Invar, which is attributed to the changing solubility of carbon in the austenitic matrix during heat treatment.

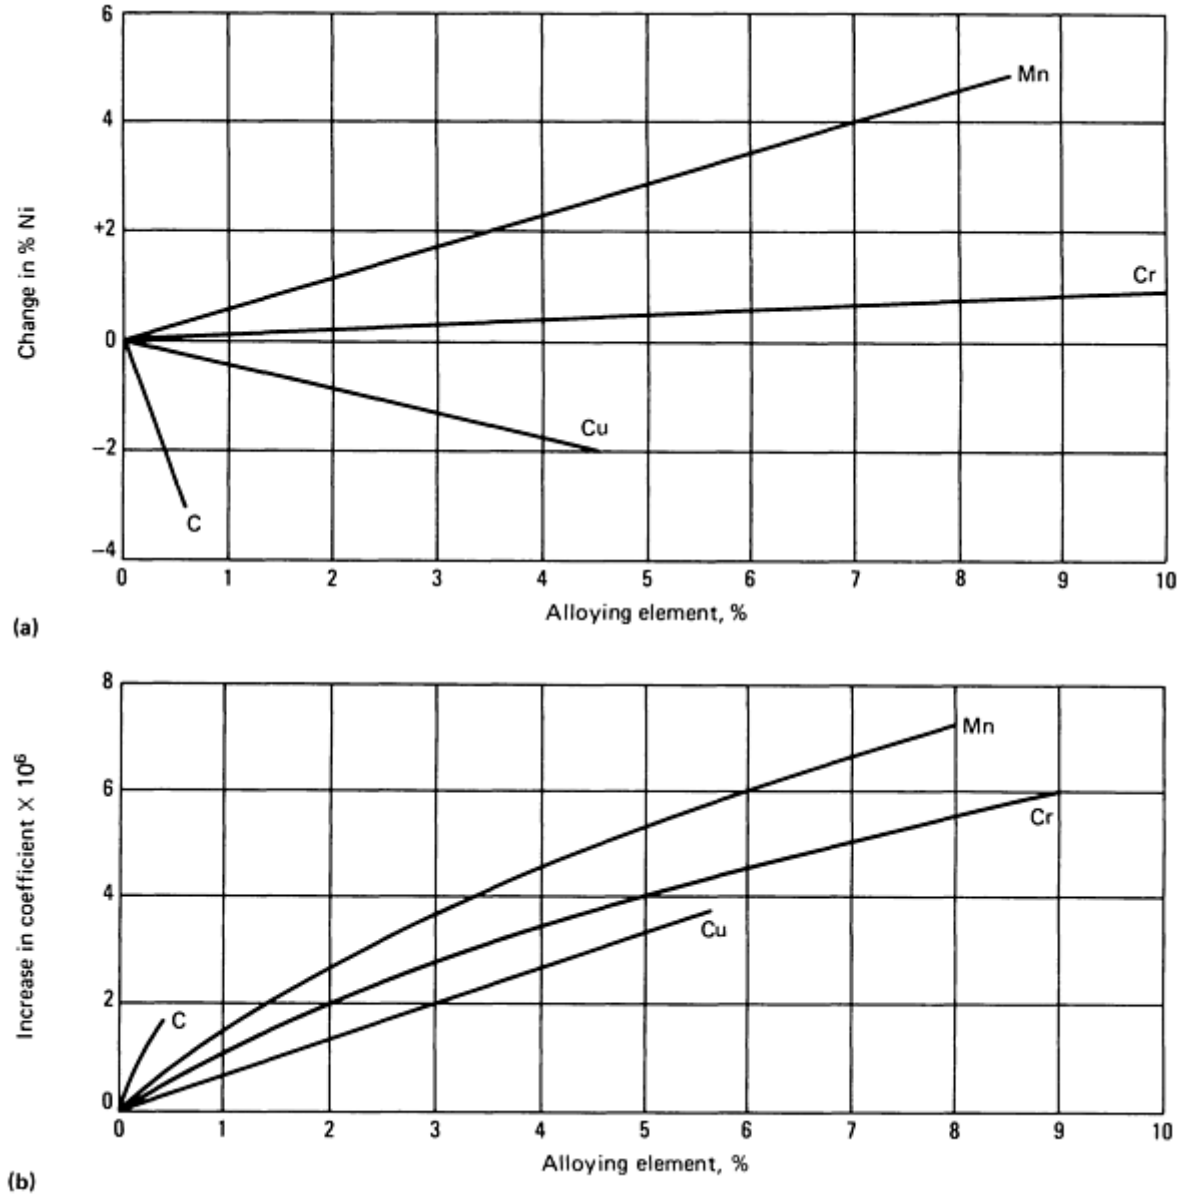

Fig. 4 Effect of alloying elements on expansion characteristics of Fe-Ni alloys. (a) Displacement of nickel content caused by additions of manganese, chromium, copper, and carbon to alloy of minimum expansivity. (b) Change in value of minimum coefficient of expansion caused by additions of manganese, chromium, copper, and carbon

Effects of Processing. Heat treatment and cold work change the expansivity of Invar alloys considerably. The effect of heat treatment for a 36% Ni Invar alloy is shown in Table 2. The expansivity is greatest in well-annealed material and least in quenched material.

Table 2 Effect of heat treatment on coefficient of thermal expansion of Invar

Condition	**Mean coefficient, µm/m · K**
As forged	
At 17-100 °C (63-212 °F)	1.66

At 17-250 °C (63-480 °F)	3.11
Quenched from 830 °C (1530 °F)	
At 18-100 °C (65-212 °F)	0.64
At 18-250 °C (65-480 °F)	2.53
Quenched from 830 °C and tempered	
At 16-100 °C (60-212 °F)	1.02
At 16-250 °C (60-480 °F)	2.43
Cooled from 830 °C to room temperature in 19 h	
At 16-100 °C (60-212 °F)	2.01
At 16-250 °C (60-480 °F)	2.89

Hot workability is enhanced by very close control of deoxidation and degassing during the melt process. Considerable care must be used in hot working of iron-nickel alloys because at hot-working temperature they have a tendency to check and break up when carelessly handled. Invar and related alloys should be annealed in a reducing atmosphere. Because they are susceptible to intercrystalline oxidation during annealing, they should be processed in an atmosphere that contains a large percentage of a neutral gas (such as nitrogen) and a small percentage of a reducing gas. Cold rolling and drawing of iron-nickel alloys are quite similar to corresponding processing procedures for nickel.

Heat Treatment. The iron-nickel binary alloys are not hardenable by heat treatment. Annealing practice should be adjusted to be consistent with requirements of the intended application. Exposure to temperatures and times that promote excessive grain growth will limit further fabricating steps that require extreme bending, forming, deep drawing, chemical etching, and so forth.

Annealing is done at 750 to 850 °C (1380 to 1560 °F). When the alloy is quenched in water from these temperatures, expansivity is decreased, but instability is induced both in actual length and in coefficient of expansion. To overcome these deficiencies and to stabilize the material, it is common practice to stress relieve approximately at 315 to 425 °C (600 to 800 °F) and to age at a low temperature 90 °C (200 °F) for 24 to 48 hours.

Cold drawing also decreases the thermal expansion coefficient of Invar alloys. The values for the coefficients in the following table are from experiments on two heats of Invar:

Material condition	**Expansivity, ppm/°C**
Direct from hot mill	1.4 (heat 1)

	1.4 (heat 2)
Annealed and quenched	0.5 (heat 1)
	0.8 (heat 2)
Quenched and cold drawn (>70% reduction with a diameter of 3.2 to 6.4 mm, or 0.125 to 0.250 in.)	0.14 (heat 1)
	0.3 (heat 2)

By cold working after quenching, it is possible to produce material with a zero, or even a negative, coefficient of expansion. A negative coefficient may be increased to zero by careful annealing at a low temperature. However, these artificial methods of securing an exceptionally low coefficient may produce instability in the material. With lapse of time and variation in temperature, exceptionally low coefficients usually revert to normal values. For special applications (geodetic tapes, for example), it is essential to stabilize the material by cooling it slowly from 100 to 20 °C (212 to 68 °F) over a period of many months, followed by prolonged aging at room temperature. However, unless the material is to be used within the limits of normal atmospheric variation in temperature, such stabilization is of no value. Although these variations in heat-treating practice are important in special applications, they are of little significance for ordinary uses.

Magnetic Properties. Invar and all similar iron-nickel alloys are ferromagnetic at room temperature and become paramagnetic at higher temperatures. Because additions in nickel contents raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve rises with increasing nickel content. The loss of magnetism in a well-annealed sample of a true Invar begins at 162 °C (324 °F) and ends at 271 °C (520 °F). In a quenched sample, the loss begins at 205 °C (400 °F) and ends at 271 °C (520 °F). Figure 5 shows how the Curie temperature changes with nickel content in iron.

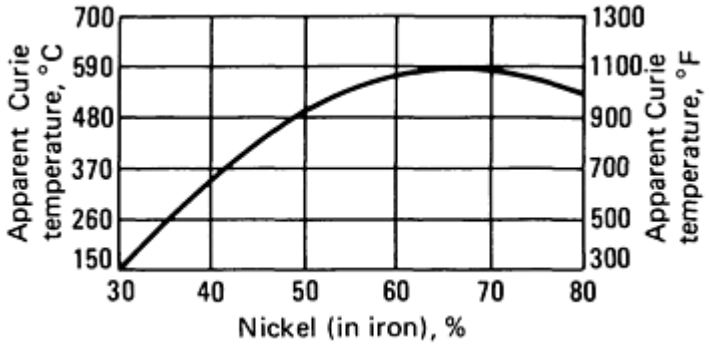

Fig. 5 Effect of nickel content on the Curie temperature of iron-nickel alloys

The thermoelastic coefficient, which describes the changes in the modulus of elasticity as a function of temperature, varies according to the nickel content of iron-nickel low-expansion alloys. Invar has the highest thermoelastic coefficient of all low-expansion iron-nickel alloys, while two alloys with 29 and 45% nickel have a zero thermoelastic coefficient (that is, the modulus of elasticity does not change with temperature). However, because small variations in nickel content produce large variations in the thermoelastic coefficient, commercial application of these two iron-nickel alloys with a zero thermoelastic coefficient is not practical. Instead, the iron-nickel-chromium Elinvar alloy provides a practical way of achieving a zero thermoelastic coefficient.

Electrical Properties. The electrical resistivity of 36Ni-Fe Invar is between 750 and 850 nΩ · m at ordinary temperatures. The temperature coefficient of electrical resistivity is about 1.2 mΩ/Ω · K over the range of low expansivity. As nickel

content increases above 36%, the electrical resistivity decreases to ~165 nΩ · M at ~80% NiFe. This is illustrated in Fig. 6.

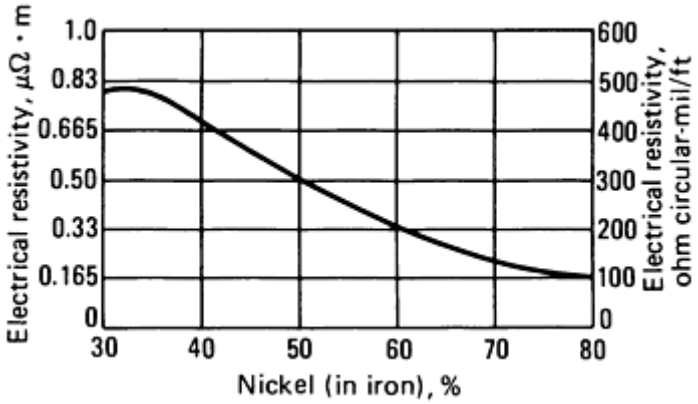

Fig. 6 Effect of nickel content on electrical resistivityof nickel-iron alloys

Other Physical and Mechanical Properties. Table 3 presents data on miscellaneous properties of Invar in the hot-rolled and forged conditions. The effects of temperature on mechanical properties of forged 66Fe-34Ni are illustrated in Fig. 7.

Table 3 Physical and mechanical properties of Invar

Solidus temperature, °C (°F)	1425 (2600)
Density, g/cm^3	8.1
Tensile strength, MPa (ksi)	450-585 (65-85)
Yield strength, MPa (ksi)	275-415 (40-60)
Elastic limit, MPa (ksi)	140-205 (20-30)
Elongation, %	30-45
Reduction in area, %	55-70
Seleroscope hardness	19
Brinell hardness	160
Modulus of elasticity, GPa (10^6 psi)	150 (21.4)
Thermoelastic coefficient, μm/m · K	500

Specific heat, at 25-100 °C (78-212 °F), J/kg · °C (Btu/lb · °F)	515 (0.123)
Thermal conductivity, at 20-100 °C (68-212 °F), W/m · K (Btu/ft · h · °F)	11 (6.4)
Thermoelectric potential (against copper), at -96 °C (-140 °F), μV/K	9.8

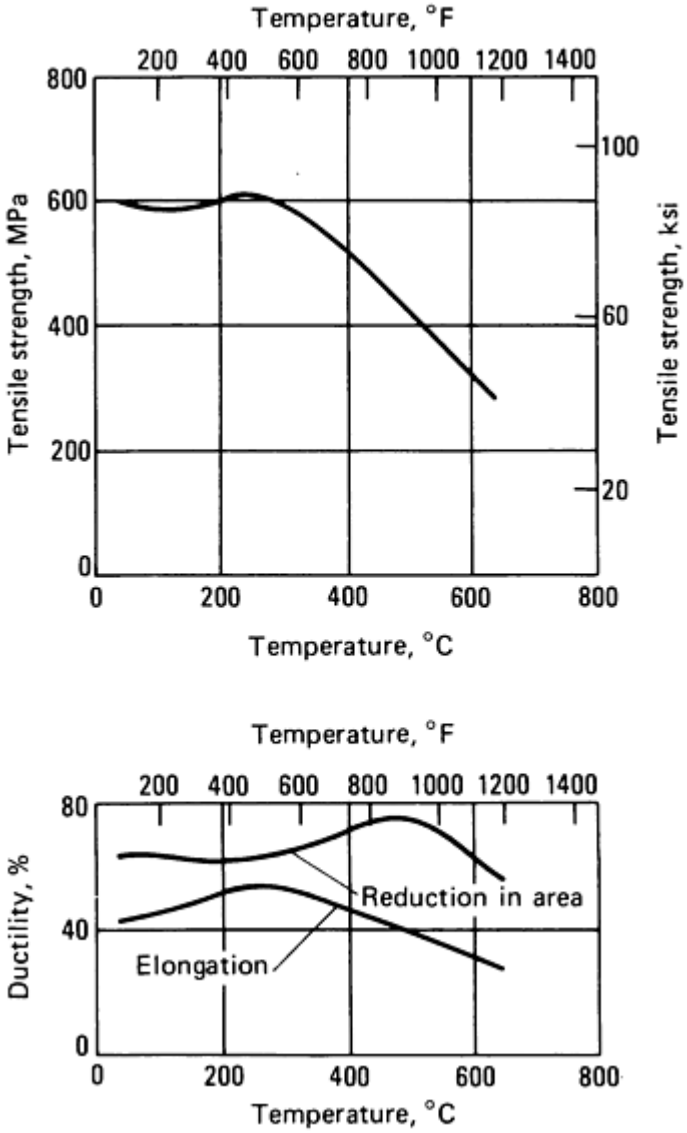

Fig. 7 Mechanical properties of a forged 34% Ni alloy. Alloy composition: 0.25 C, 0.55 Mn, 0.27 Si, 33.9 Ni, balance Fe. Heat treatment: annealed at 800 °C (1475 °F) and furnace cooled

The binary iron-nickel alloys are not hardenable by heat treatment. Significant increases in strength can be obtained by cold working some product forms such as wire, strip, and small-diameter bar. Table 4 shows tensile and hardness data for both 36% and 50% nickel-iron alloys after cold working various percent cross-section reduction.

Table 4 Mechanical properties of Invar and a 52% Ni-48% Fe glass-sealing alloy

UNS number (alloy name)	0.2% yield strength	Ultimate tensile strength	Elongation, %	Approximate equivalent hardness, HRB

	MPa	ksi	MPa	ksi		hardness, HRB
K93601 (Invar 36% Ni)						
As annealed	260	38	470	68	37	75
10% cold worked	370	54	565	82	23	86
30% cold worked	550	80	675	98	10	95
50% cold worked	640	93	725	105	5	96
70% cold worked	703	102	730	106	3	97
K14052 (glass-sealing alloy 52% Ni)						
As annealed	235	34	538	78	32	83
10% cold worked	525	76	640	93	19	92
30% cold worked	715	104	750	109	6	99
50% cold worked	770	112	814	118	3	100
70% cold worked	800	116	834	121	2	26 HRC

Mechanical properties such as tensile strength and hardness decrease rapidly with increasing service temperatures. Selected elevated-temperature data for iron-nickel alloys are shown in Table 5.

Table 5 Typical tensile properties at elevated temperatures for some low-expansion nickel-iron alloys

UNS number (alloy name)	Test temperature		0.2% yield strength		Ultimate tensile strength		Elongation, %	Reduction of area, %
	°C	°F	MPa	ksi	MPa	ksi		
Invar 36% Ni (K9360l)	24	75	265	38.5	483	70	44	81.5
	150	300	139	20.2	405	59	44.5	77.5

	480	900	217	31.5	385	55.8	35.5	51.9

Corrosion Resistance. The iron-nickel low-expansion alloys are not corrosion resistant, and applications in even relatively mild corrosive environments must consider their propensity to corrode. A comparison to corrosion of iron, in both high humidity and salt spray environments, is shown in Fig. 8 and Table 6. Rust initiation occurs in approximately 24 hours for nickel contents less than ~40% in high-humidity tests. Severe corrosion occurs after 200 hours exposure to a neutral salt spray at 35 °C (95 °F).

Table 6 Effects of relative humidity on selected nickel-iron low-expansion alloys

Specimens exposed to 95% relative humidity for 200 h at 35 °C (95 °F)

Alloy type (UNS number)	**Condition**	**Portion of surface rusted (average), %[(a)]**	**First rust (three specimens), h**

Machinability. The iron-nickel alloys can be machined using speeds or feeds that are modified to accommodate their gummy and stringy characteristics. As a general comparison to other austenitic alloys, they are similar to 316 stainless steel. Using single point turning as a measure of machinability, the iron-nickel low-expansion alloys exhibit a 25% machinability rating compared to resulfurized carbon steel (such as B 1112). Some general machining parameters for

iron-nickel alloys are shown in Table 7. There are "free-cut" varieties of Invar-type alloys available. These require minor additions of other elements (such as selenium) which when combined with moderate adjustments to other residual elements (such as manganese) will produce a twofold improvement in the machinability characteristic of these alloys. Some increase in thermal expansion characteristics results from the modified compositions.

Table 7 Examples of various machining parameters for iron-nickel low-expansion alloys

Turning (single-point and box tools)

Feed, mm/tooth (in./tooth), with 25-50 mm (1-2 in.) cutter diam	0.125 (0.005)

Welding. Invar can be successfully welded using most standard arc-welding processes. In general, preparation for welding should be similar to stainless steels and should include proper cleaning and handling. Joint designs should allow easy access to the weld because of poor weld pool fluidity but also should limit total weld volume to reduce shrinkage problems. Preheating and postheating are not required and should be avoided. A low interpass temperature (150 °C, or 300 °F max) should be maintained.

Welding is most commonly performed using the gas-tungsten-arc or gas-metal-arc processes. Gas-tungsten-arc welding can be accomplished with argon and/or helium shielding gases. Welding is best performed with a freshly ground thoriated tungsten electrode. Gas-metal-arc welding can be successfully performed in all metal transfer modes, depending primarily on base metal thickness. Shielding gases should be argon or argon-helium mixtures. Other nonarc welding processes (such as resistance welding) may also be used.

When a filler metal is needed, a matching composition will provide the best match in thermal expansion properties. Invarod weld filler metal (a 36Ni-Fe alloy containing ~1% Ti and 2.5% Mn) has been successfully used for matching expansion characteristics. If a matching composition is not available, a high-nickel filler metal conforming to AWS A5.14 ERNi-1 or ER-NiCrFe-5 can be used. These materials will result in a weld with different thermal expansion properties.

Iron-Nickel Alloys Other Than Invar

Although iron-nickel alloys other than Invar have higher coefficients of thermal expansion, there are applications where it is advantageous to have nickel contents above or below the 36% level of Invar. The alloy containing 39% Ni, for example, has a coefficient of expansion corresponding to that of low-expansion glasses.

Alloys that contain less than 36% Ni have much higher coefficients of expansion than alloys with a higher percentage. Alloys containing less than 36% Ni include temperature-compensator alloys (30 to 34% Ni). These exhibit linear changes in magnetic characteristics with temperature change. They are used as compensating shunts in metering devices and speedometers.

Iron-nickel alloys that have nickel contents higher than that of Invar retain to some extent the expansion characteristics of Invar. Because further additions of nickel raise the temperature at which the inherent magnetism of the alloy disappears, the inflection temperature in the expansion curve (Fig. 2) rises with increasing nickel content. Although this increase in range is an advantage in some circumstances, it is accompanied by an increase in coefficient of expansion. Table 8 and Fig. 9 present additional information on the coefficients of expansion of nickel-iron alloys at temperatures up to the inflection temperature. They also give data on alloys with up to 68% Ni.

Table 8 Expansion characteristics of Fe-Ni alloys

Composition, %			Inflection temperature		Mean coefficient of expansion, from 20 °C to inflection temperature, µm/m · K

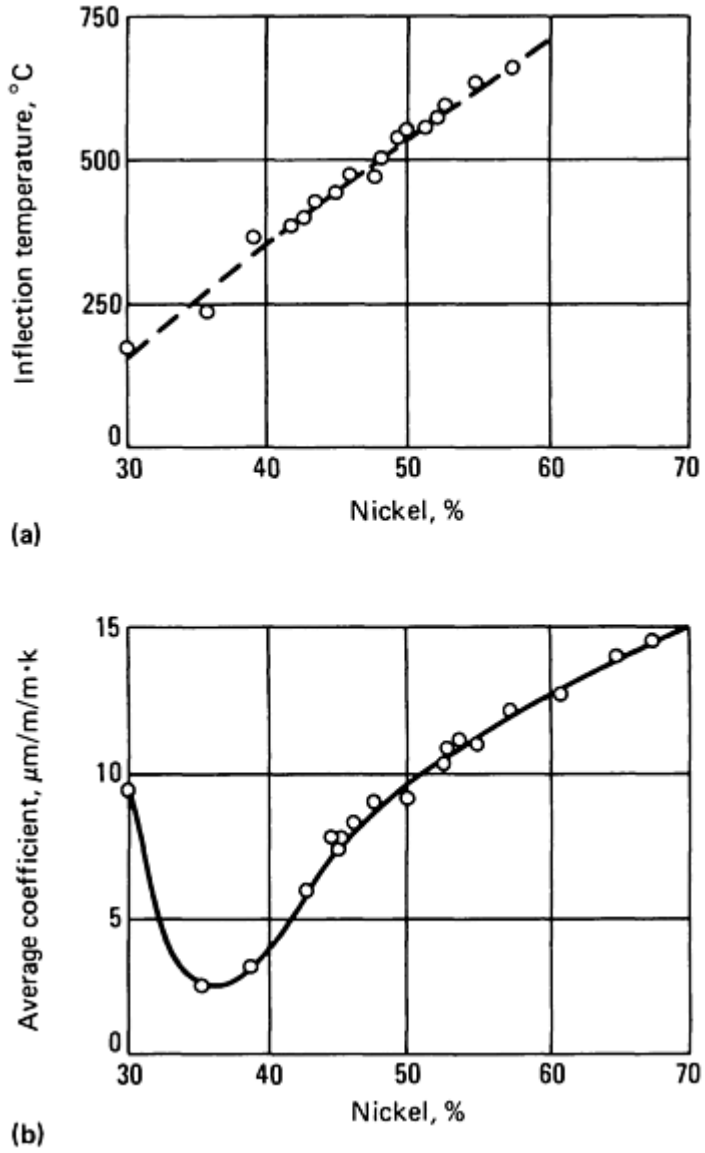

Fig. 9 Effect of nickel content on expansion of Fe-Ni alloys. (a) Variation of inflection temperature. (b) Variation of average coefficient of expansion between room temperature and inflection temperature

Of significant commercial interest are those alloys containing approximately 40% to 50% nickel-iron alloys. Typical compositions and thermal expansions for some of these alloys are given in Table 9.

Table 9 Composition and typical thermal expansion coefficients for common iron-nickel low-expansion alloys

Alloy	ASTM specification	Composition(a), %			
		C(max)	Mn(max)	Si(max)	Ni(nom)
42 Ni-Iron	F 30	0.02	0.5	0.25	41
46 Ni-Iron	F 30	0.02	0.5	0.25	46
48 Ni-Iron	F 30	0.02	0.5	0.25	48
52 Ni-Iron	F 30	0.02	0.5	0.25	51
42 Ni-Iron (Dumet)	F 29	0.05	1.0	0.25	42

42 Ni-Iron (Dumet)	. . .	. . .	6.6	3.7	. . .	. . .

(a) Balance of iron with residual impurity limits of 0.25% max Si, 0.015% max P, 0.01% max S, 0.25% max Cr, and 0.5% max Co.

(b) From room temperature to 90 °C (200 °F).

(c) From room temperature to 150 °C (300 °F).

(d) From room temperature to 370 °C (700 °F).

The 42% Ni-irons are widely used in applications for their low-expansion characteristics. These include semiconductor packaging components, thermostat bimetals, incandescent light bulb glass seal leads (copper clad), and seal beam lamps.

Dumet wire is an alloy containing 42% Ni. It is clad with copper to provide improved electrical conductivity and to prevent gassing at the seal. It can replace platinum as the seal-in wire in incandescent lamps and vacuum tubes.

The 43 to 47% Ni-iron alloys are commonly used for glass seal leads, grommets, and filament supports. This group of alloys includes Platinate (36% Ni to 64% Fe), which has a coefficient of thermal expansion equivalent to that of platinum (9.0 ppm/°C).

Iron-Nickel-Chromium Alloys

Elinvar is a low-expansion iron-nickel-chromium alloy with a thermoelastic coefficient of zero over a wide temperature range. It is more practical than the straight iron-nickel alloys with a zero thermoelastic coefficient, because its thermoelastics coefficient is less susceptible to variations in nickel content expected in commercial melting.

Elinvar is used for such articles as hair-springs and balance wheels for clocks and watches and for tuning forks used in radio synchronization. Particularly beneficial where an invariable modulus of elasticity is required, it has the further advantage of being comparatively rustproof.

The composition of Elinvar has been modified somewhat from its original specification of 36% Ni and 12% Cr. The limits now used are 33 to 35 Ni, 61 to 53 Fe, 4 to 5 Cr, 1 to 3 W, 0.5 to 2 Mn, 0.5 to 2 Si, and 0.5 to 2 C. Elinvar, as created by Guillaume and Chevenard, contains 32% Ni, 10% Cr, 3.5% W, and 0.7% C.

Other iron-nickel-chromium alloys with 40 to 48% Ni and 2 to 8% Cr are useful as glass-sealing alloys because the chromium promotes improved glass-to-metal bonding as a result of its oxide-forming characteristics. The most common of these contain approximately 42 to 48% nickel with chromium of 4 to 6%. Although chromium additions increase the minimum thermal expansion and lower inflection points (Curie temperature), they have a beneficial effect on the glass-sealing behavior of these alloys. The chromium promotes formation of a surface chromium oxide that improves wetting at the metal/glass interface. Some of this metal oxide is absorbed by the glass during the actual glass seal and promotes a higher-strength metal/glass bond (graded seals). Compositions and thermal expansions for some Fe-Ni-Cr alloys are shown in Table 10.

Table 10 Type, composition, and typical thermal expansion for some iron-nickel-chromium glass-seal alloys

Alloy type	ASTM specifications	Composition[(a)], %			
		Mn(max)	Si(max)	Cr(nom)	Ni(nom)

Iron-Nickel-Cobalt Alloys

Replacement of some of the nickel by cobalt in an alloy of the Invar composition lowers the thermal expansion coefficient and makes the alloy's expansion characteristics less susceptible to variations in heat treatment. These iron-nickel-cobalt alloys (known as Super-Invars), however, have a more restrictive temperature range of useful application. In its restricted temperature range, the expansion coefficient of a Super-Invar alloy is lower than that of Invar (unless the Invar is in the cold-worked condition).

Super-Invar. Substitution of ~5% Co for some of the nickel content in the 36% Ni (Invar) alloy provides an alloy with an expansion coefficient even lower than that Invar. A Super-Invar alloy with a nominal 32% Ni and 4 to 5% Co will exhibit a thermal expansion coefficient close to zero, over a relatively narrow temperature range. Figure 10 compares thermal expansion for 32% Ni-5% Co Super-Invar with that of an Invar alloy.

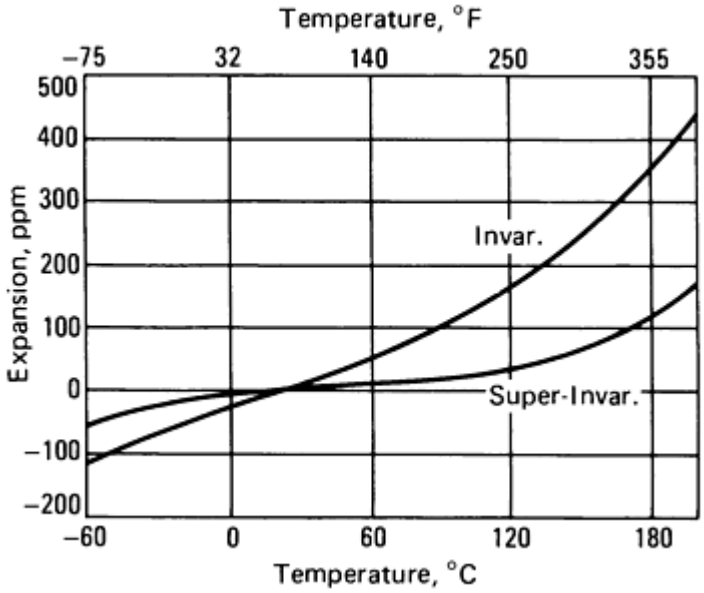

Fig. 10 Comparison of thermal expansion for Super-Invar (63% Fe, 32% Ni, 5% Co) and Invar (64% Fe, 36% Ni) alloys

Cobalt has been added to other Fe-Ni alloys in amounts as high as 40%. Such additions increase the coefficient of expansion at room temperature. However, because they also raise the inflection temperature, they produce an alloy with a moderately low coefficient of expansion over a wider range of temperature. If Θ is inflection temperature in °C, X is

nickel content, *Y* is cobalt content, and *Z* is manganese content. The inflection temperature of any low-expansion Fe-Ni-Co alloy is approximated by $\theta = 19.5 (X + Y) - 22Z - 465$. Carbon content does not significantly affect the inflection temperature.

For practical applications, these Fe-Ni-Co alloys require that Ni+Co content be sufficient to lower the martensite start temperature (M_s) to well below room temperature. Nickel-cobalt contents for M_s temperatures of about -100 °C (-150 °F) can be approximated by:

$$Y = 0.0795\,\theta + 4.82 + 19W - 18.1$$

$$X = 41.9 - 0.0282\,\theta - 37Z - 19W$$

where *W* is carbon content.

Kovar is a nominal 29%Ni-17%Co-54%Fe alloy that is a well-known glass-sealing alloy suitable for sealing to hard (borosilicate) glasses. Kovar has a nominal expansion coefficient of approximately 5 ppm/°C and inflection temperature of ~450 °C (840 °F) with an M_s temperature less than -80 °C (-110 °F). The Dilver-P alloy produced by Imphy, S.A., is a competitive grade with the Kovar alloy of Carpenter Steel.

Special Alloys

Iron-Cobalt-Chromium Low-Expansion Alloys. An alloy containing 36.5 to 37%Fe, 53 to 54.5% Co, and 9 to 10% Cr has an exceedingly low, and at times, negative (over the range from 0 to 100 °C, or 32 to 212 °F) coefficient of expansion. This alloy has good corrosion resistance compared to low-expansion alloys without chromium. Consequently, it has been referred to as "Stainless Invar." Fernichrome, a similar alloy containing 37% Fe, 30% Ni, 25% Co, and 8% Cr, has been used for seal-in wires for electronic components sealed in special glasses.

Hardenable Low-Expansion Alloys. Alloys that have low coefficients of expansion, and alloys with constant modulus of elasticity, can be made age hardenable by adding titanium. In low-expansion alloys, nickel content must be increased when titanium is added. The higher nickel content is required because any titanium that has not combined with the carbon in the alloy will neutralize more than twice its own weight in nickel by forming an intermetallic compound during the hardening operation.

As shown in Table 11, addition of titanium raises the lowest attainable rate of expansion and raises the nickel content at which the minimum expansion occurs. Titanium also lowers the inflection temperature. Mechanical properties of alloys containing 2.4% titanium and 0.06% carbon are given in Table 12.

Table 11 Minimum coefficient of expansion in low-expansion Fe-Ni alloys containing titanium

Ti, %	Optimum Ni, %	Minimum coefficient of expansion, µm/m · K
0	36.5	1.4
2	40.0	2.9
3	42.5	3.6

Table 12 Mechanical properties of low-expansion Fe-Ni alloys containing 2.4 Ti and 0.06 C

Condition	Tensile strength		Yield strength		Elongation[(a)], %	Hardness, HB
	MPa	ksi	MPa	ksi

52Ni-45.5Fe-2.4Ti-0.06C[(c)]						
Solution treated	585	85	240	35	27	125
Solution treated and age hardened	825	120	655	95	17	305

(a) In 50 mm (2 in.).

(b) Inflection temperature, 220 °C (430 °F); minimum coefficient of expansion, 3.2 μm/m · K.

(c) Inflection temperature, 440 °C (824 °F); minimum coefficient of expansion, 9.5 μm/m · K

In alloys of the constant-modulus type containing chromium, addition of titanium allows the thermoelastic coefficients to be varied by adjustment of heat-training schedules. The alloys in Table 13 are the three most widely used compositions. The recommended solution treatment for the alloys that contain 2.4% Ti is 950 to 1000 °C (1740 to 1830 °F) for 20 to 90 min., depending on section size. Recommended duration of aging varies from 48 h at 600 °C (1110 °F) to 3 h at 730 °C (1345 °F) for solution-treated material.

Table 13 Thermoelastic coefficients of constant modulus Fe-Ni-Cr-Ti alloys

Composition, %				**Thermoelastic coefficient, annealed condition, μm/m · K**	**Range of possible coefficients[(a)], μm/m · K**
Ni	**Cr**	**C**	**Ti**		
42	5.4	0.06	2.4	0	18 to -23
42	6.0	0.06	2.4	36	54 to 13

(a) Any value in this range can be obtained by varying the heat treatment.

For material that has been solution treated and subsequently cold worked 50% aging time varies from 4 h at 600 °C (1100 °F) to 1 h at 730 °C (1350 °F). Table 14 gives mechanical properties of a constant-modulus alloy containing 42% Ni, 5.4% Cr, and 2.4% Ti. Heat treatment and cold work markedly affect these properties.

Table 14 Mechanical properties of constant-modulus alloy 50Fe-42Ni-5.4Cr-2.4Ti

Condition	Tensile strength		Yield strength		Elongation[(a)], %	Hardness, HB	Modulus of elasticity	
	MPa	ksi	MPa	ksi			GPa	10^6 psi
Solution treated	620	90	240	35	40	145	165	24
Solution treated and aged 3 h at 730 °C (1345 °F)	1240	180	795	115	18	345	185	26.5
Solution treated and cold worked 50%	930	135	895	130	6	275	175	25.5

High-Strength, Controlled-Expansion Alloys. There is a family of Fe-Ni-Co alloys strengthened by the addition of niobium and titanium that show the strength of precipitation-hardened superalloys while maintaining low coefficients of thermal expansion typical of certain alloys from the Fe-Ni-Co system. Compositions of the alloys are shown in Table 15; typical mechanical properties are presented in Table 16. The combination of exceptional strength and low coefficient of expansion makes this family useful for applications requiring close operating tolerances over a range of temperatures. Several components for gas turbine engines are produced from these alloys. Further information on low-expansion superalloys is contained in the article "Nickel and Nickel Alloys" in this Volume.

Table 15 Composition and thermal expansion coefficients of high-strength controlled-expansion alloys

Alloy designation	Composition, %	Coefficient of thermal expansion, from room temperature to:						Inflection temperature

Engineering Applications

Use of alloys with low coefficients of expansion has been confined mainly to such applications as geodetic tape, bimetal strip, glass-to-metal seals, and electronic and radio components. Almost all variable condensers are made of Invar. Struts on jet engines are made of Invar to ensure rigidity with temperature changes. Close control of residuals (such as sulfur, phosphorus, aluminum, and nitrogen) has resulted in a readily weldable alloy (Invar M63 in Table 17) which has been extensively used for making tanks of liquid natural gas ships.

Table 17 Tradenames of various low-expansion alloys

Nominal composition, %	UNS number	Tradename and producing company
Iron-nickel alloys		
36% Ni, bal Fe	K93601	Invar (INCO and Imphy, S.A.) Invar M63 (Imphy, S.A.) AL-36 (Allegheny Ludlum) Invar "36" (Carpenter Steel)
39% Ni, bal Fe	. . .	Low expansion "39" (Carpenter Steel)
42% Ni, bal Fe	K94100	Low expansion "42" (Carpenter Steel) AL-42 (Allegheny Ludlum) N42 (Imphy, S.A.)
46% Ni, bal Fe	. . .	Platinate (same expansion coefficient as platinum) Glass Sealing "46" (Carpenter Steel)

47-48% Ni, bal Fe	. . .	N47, N48 (Imphy, S.A.)
49% Ni, bal Fe	. . .	AL-4750 (Allegheny Ludlum) Low expansion "49" (Carpenter Steel)
52% Ni, bal Fe	K14042	Glass Sealing "52" (Carpenter Steel) AL-52 (Allegheny Ludlum) N52 (Imphy, S.A.)
Iron-nickel-cobalt alloys		
32% Ni, 5% Co, bal Fe	. . .	Super Invar (INCO)
		Super Invar 32-5 (Carpenter Steel)
Iron-nickel-chromium alloys		
42% Ni, 6% Cr, bal Fe	K94760	Sealmet 4 (Allegheny Ludlum) Glass Sealing "42-6" (Carpenter Steel) N426 (Imphy, S.A.) SNC-K (Toshiba)

More recent applications of the iron-nickel "low" expansion alloys include structural components for optical and laser measurement systems, and lay-up tooling for graphite/epoxy composite components. Significant quantities of these alloys find application in substrates and housings for hermetic packaging of semiconductors where ceramic components require some matching of thermal expansion.

There is increasing use of Invar-type alloys for shadow masks in color television picture tubes. The low thermal expansion of Invar prevents excessive distortion of this shadow mask as internal temperatures increase during operation of the picture tube.

Shape Memory Alloys

Darel E. Hodgson, Shape Memory Applications, Inc.; Ming H. Wu, Memry Corporation; and Robert J. Biermann, Harrison Alloys, Inc.

Introduction

THE TERM SHAPE MEMORY ALLOYS (SMA) is applied to that group of metallic materials that demonstrate the ability to return to some previously defined shape or size when subjected to the appropriate thermal procedure. Generally, these materials can be plastically deformed at some relatively low temperature, and upon exposure to some higher temperature will return to their shape prior to the deformation. Materials that exhibit shape memory only upon heating are referred to as having a one-way shape memory. Some materials also undergo a change in shape upon recooling. These materials have a two-way shape memory.

Although a relatively wide variety of alloys are known to exhibit the shape memory effect, only those that can recover substantial amounts of strain or that generate significant force upon changing shape are of commercial interest. To date, this has been the nickel-titanium alloys and copper-base alloys such as Cu-Zn-Al and Cu-Al-Ni.

A shape memory alloy may be further defined as one that yields a thermoelastic martensite. In this case, the alloy undergoes a martensitic transformation of a type that allows the alloy to be deformed by a twinning mechanism below the transformation temperature. The deformation is then reversed when the twinned structure reverts upon heating to the parent phase.

History

The first recorded observation of the shape memory transformation was by Chang and Read in 1932 (Ref 1). They noted the reversibility of the transformation in AuCd by metallographic observations and resistivity changes, and in 1951 the shape memory effect (SME) was observed in a bent bar of AuCd. In 1938, the transformation was seen in brass (copper-zinc). However, it was not until 1962, when Buehler and co-workers (Ref 2) discovered the effect in equiatomic nickel-titanium (Ni-Ti), that research into both the metallurgy and potential practical uses began in earnest. Within 10 years, a number of commercial products were on the market, and understanding of the effect was much advanced. Study of shape memory alloys has continued at an increasing pace since then, and more products using these materials are coming to the market each year (Ref 3, 4).

As the shape memory effect became better understood, a number of other alloy systems that exhibited shape memory were investigated. Table 1 lists a number of these systems (Ref 5) with some details of each system. Of all these systems, the Ni-Ti alloys and a few of the copper-base alloys have received the most development effort and commercial exploitation. These will be the focus of the balance of this article.

Table 1 Alloys having a shape memory effect

Alloys	**Composition**	**Transformation-temperature range**		**Transformation hysteresis**	
		°C	**°F**	**Δ°C**	**Δ°F**
Ag-Cd	44/49 at.% Cd	-190 to -50	-310 to -60	≈15	≈25
Au-Cd	46.5/50 at.%Cd	30 to 100	85 to 212	≈15	≈25
Cu-Al-Ni	12/14.5 wt% Al 3/4.5 wt% Ni	-140 to 100	-220 to 212	≈35	≈65
	3/4.5 wt% Ni				
Cu-Sn	≈15 at.% Sn	-120 to 30	-185 to 85

General Characteristics

The martensitic transformation that occurs in the shape memory alloys yields a thermoelastic martensite and develops from a high-temperature austenite phase with long-range order. The martensite typically occurs as alternately sheared platelets, which are seen as a herringbone structure when viewed metallographically. The transformation, although a first-order phase change, does not occur at a single temperature but over a range of temperatures that varies with each alloy system. The usual way of characterizing the transformation and naming each point in the cycle is shown in Fig. 1. Most of the transformation occurs over a relatively narrow temperature range, although the beginning and end of the transformation during heating or cooling actually extends over a much larger temperature range. The transformation also exhibits hysteresis in that the transformation on heating and on cooling does not overlap (Fig. 1). This transformation hysteresis (shown as *T* in Fig. 1) varies with the alloy system (Table 1).

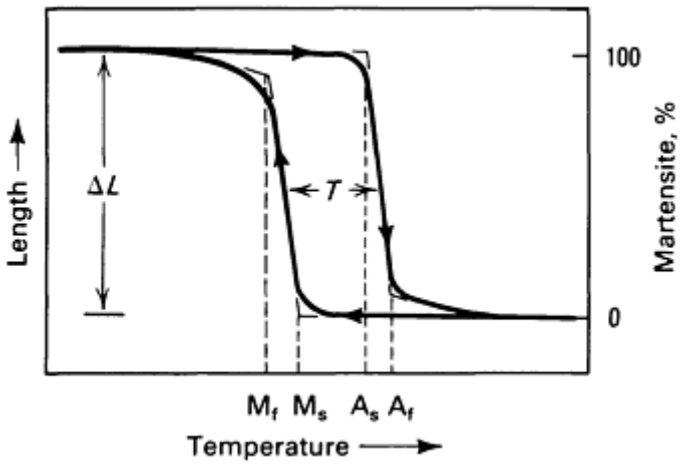

Fig. 1 Typical transformation versus temperature curve for a specimen under constant load (stress) as it is cooled and heated. *T*, transformation hysteresis. M_s, martensite start; M_f, martensite finish; A_s, austenite start; A_f, austenite finish

Crystallography of Shape Memory Alloys

Thermoelastic martensites are characterized by their low energy and glissile interfaces, which can be driven by small temperature or stress changes. As a consequence of this, and of the constraint due to the loss of symmetry during transformation, thermoelastic martensites are crystallographically reversible.

The herringbone structure of athermal martensites essentially consists of twin-related, self-accommodating variants (Fig. 2b). The shape change among the variants tends to cause them to eliminate each other. As a result, little macroscopic strain is generated. In the case of stress-induced martensites, or when stressing a self-accommodating structure, the variant that can transform and yield the greatest shape change in the direction of the applied stress is stabilized and becomes dominant in the configuration (Fig. 2c). This process creates a macroscopic strain, which is recoverable as the crystal structure reverts to austenite during reverse transformation.

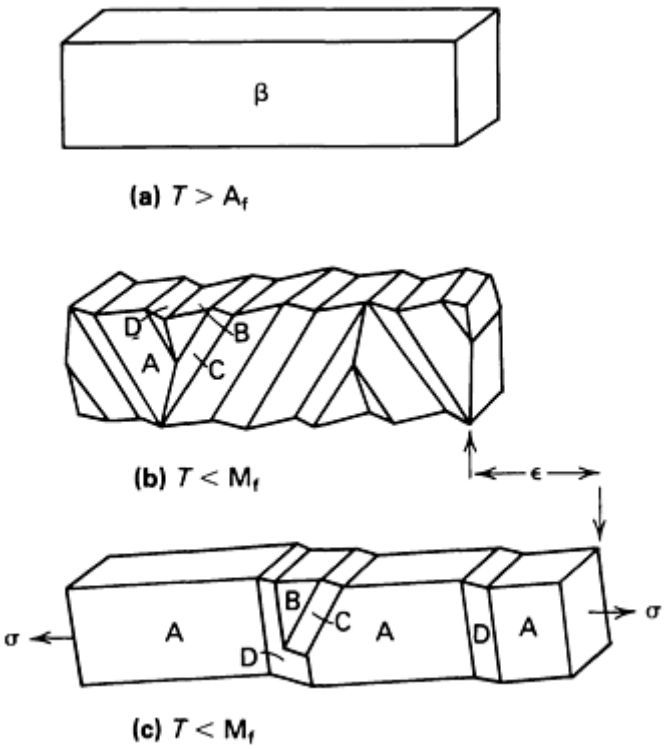

Fig. 2 (a) A β phase crystal. (b) Self-accommodating, twin-related variants A, B, C, and D, after cooling and transformation to martensite. (c) Variant A becomes dominant when stress is applied.

Thermomechanical Behavior

The mechanical properties of shape memory alloys vary greatly over the temperature range spanning their transformation. This is seen in Fig. 3, where simple stress-strain curves are shown for a nickel-titanium alloy that was tested in tension below, in the middle of, and above its transformation-temperature range. The martensite is easily deformed to several percent strain at quite a low stress, whereas the austenite (high-temperature phase) has much higher yield and flow stresses. The dashed line on the martensite curve indicates that upon heating after removing the stress, the sample "remembered" its unstrained shape and reverted to it as the material transformed to austenite. No such shape recovery is found in the austenite phase upon straining and heating, because no phase change occurs.

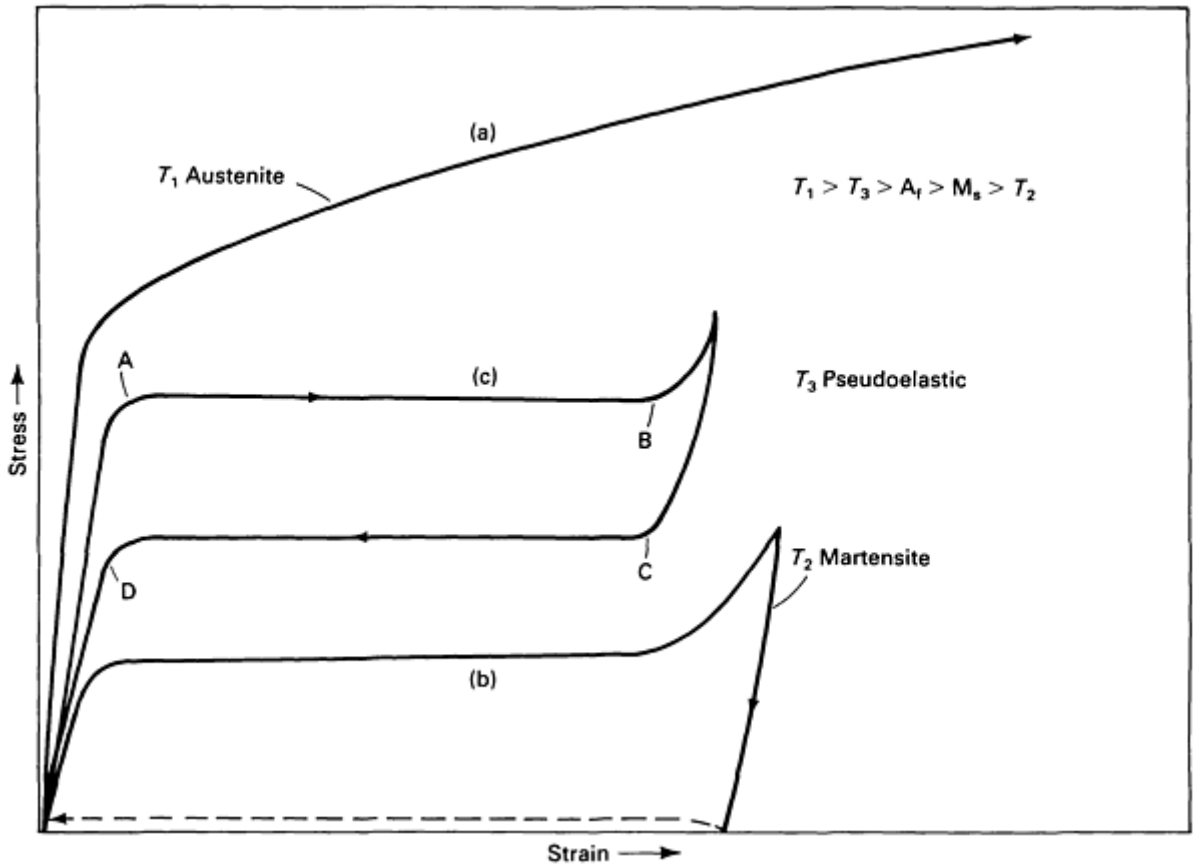

Fig. 3 Typical stress-strain curves at different temperatures relative to the transformation, showing (a) Austenite. (b) Martensite. (c) Pseudoelastic behavior

An interesting feature of the stress-strain behavior is seen in Fig. 3(c), where the material is tested slightly above its transformation temperature. At this temperature, martensite can be stress induced. It then immediately strains and exhibits the increasing strain at constant stress behavior, seen in AB. Upon unloading, though, the material reverts to austenite at a lower stress, as seen in line CD, and shape recovery occurs, not upon the application of heat but upon a reduction of stress. This effect, which causes the material to be extremely elastic, is known as pseudoelasticity. Pseudoelasticity is nonlinear. The Young's modulus is therefore difficult to define in this temperature range as it exhibits both temperature and strain dependence.

In most cases, the memory effect is one way. That is, upon cooling, a shape memory alloy does not undergo any shape change, even though the structure changes to martensite. When the martensite is strained up to several percent, however, that strain is retained until the material is heated, at which time shape recovery occurs. Upon recooling, the material does not spontaneously change shape, but must be deliberately strained if shape recovery is again desired.

It is possible in some of the shape memory alloys to cause two-way shape memory. That is, shape change occurs upon both heating and cooling. The amount of this shape change is always significantly less than obtained with one-way memory, and very little stress can be exerted by the alloy as it tries to assume its low-temperature shape. The heating shape change can still exert very high forces, as with the one-way memory.

A number of heat-treatment and mechanical training methods have been proposed to create the two-way shape memory effect (Ref 6, 7). All rely on the introduction of microstructural stress concentrations, which cause the martensite plates to initiate in particular directions when they form upon cooling, resulting in an overall net-shape change in the desired direction.

Characterization Methods

There are four major methods of characterizing the transformation in SMAs and a large number of minor methods that are only rarely used and will not be discussed.

The most direct method is by differential scanning calorimeter (DSC). This technique measures the heat absorbed or given off by a small sample of the material as it is heated and cooled through the transformation-temperature range. The sample can be very small, such as a few milligrams, and because the sample is unstressed this is not a factor in the measurement. The endotherm and exotherm peaks, as the sample absorbs or gives off energy due to the transformation, are easily measured for the beginning, peak, and end of the phase change in each direction.

The second method often used is to measure the resistivity of the sample as it is heated and cooled. The alloys exhibit interesting changes and peaks in the resistivity (by up to 20%) over the transformation-temperature range; however, correlating these changes with measured phase changes or mechanical properties has not always been very successful. Also, there are often large changes in the resistivity curves after cycling samples through the transformation a number to times. Thus, resistivity is often measured as a phenomenon in its own right, but is rarely used to definitely characterize one alloy versus another.

The most direct method of characterizing an alloy mechanically is to prepare an appropriate sample, then apply a constant stress to the sample and cycle it through the transformation while measuring the strain that occurs during the transformation in both directions. The curve shown in Fig. 1 is the direct information one obtains from this test. The values obtained for the transformation points, such as M_s and A_f, from this method are offset to slightly higher temperatures from the values obtained from DSC testing. This happens because the DSC test occurs at no applied stress, and the transformation is not stress induced; therefore, increasing test stress will lead to increasing transformation-temperature results. This test is directly indicative of the property one can expect in a mechanical device used to perform some function using shape memory. Its disadvantages are that specimens are often difficult to make, and results are quite susceptible to the way the test is conducted.

Finally, the stress-strain properties can be measured in a standard tensile test at a number of temperatures across the transformation-temperature range, and from the change in properties the approximate transformation-temperature values can be interpolated. This is very imprecise, through, and is much better applied as a measure of the change in properties of each phase, due to such things as work hardening or different heat treatments.

Commercial SME Alloys

The only two alloy systems that have achieved any level of commercial exploitation are the Ni-Ti alloys and the copper-base alloys. Properties of the two systems are quite different. The Ni-Ti alloys have greater shape memory strain (up to 8% versus 4 to 5% for the copper-base alloys), tend to be much more thermally stable, have excellent corrosion resistance compared to the copper-base alloys' medium corrosion resistance and susceptibility to stress-corrosion cracking, and have much higher ductility. On the other hand, the copper-base alloys are much less expensive, can be melted and extruded in air with ease, and have a wider range of potential transformation temperatures. The two alloy systems thus have advantages and disadvantages that must be considered in a particular application.

Nickel-Titanium Alloys. The basis of the nickel-titanium system of alloys is the binary, equiatomic intermetallic compound of Ni-Ti. This intermetallic compound is extraordinary because it has a moderate solubility range for excess nickel or titanium, as well as most other metallic elements, and it also exhibits a ductility comparable to most ordinary alloys. This solubility allows alloying with many of the elements to modify both the mechanical properties and the transformation properties of the system. Excess nickel, in amounts up to about 1%, is the most common alloying addition. Excess nickel strongly depresses the transformation temperature and increases the yield strength of the austenite. Other frequently used elements are iron and chromium (to lower the transformation temperature), and copper (to decrease the hysteresis and lower the deformation stress of the martensite). Because common contaminants such as oxygen and carbon can also shift the transformation temperature and degrade the mechanical properties, it is also desirable to minimize the amount of these elements.

The major physical properties of the basic binary Ni-Ti system and some of the mechanical properties of the alloy in the annealed condition are shown in Table 2. Note that this is for the equiatomic alloy with an A_f value of about 110 °C (230 °F). Selective work hardening, which can exceed 50% reduction in some cases, and proper heat treatment can greatly improve the ease with which the martensite is deformed, give an austenite with much greater strength, and create material that spontaneously moves itself both in heating and on cooling (two-way shape memory). One of the biggest challenges in using this family of alloys is in developing the proper processing procedures to yield the properties desired.

Table 2 Properties of binary Ni-Ti shape memory alloys.

Properties	**Property value**
Melting temperatures, °C (°F)	1300 (2370)
Density, g/cm^3 ($lb/in.^3$)	6.45 (0.233)
Resistivity, μΩ· cm	
Austenite	≈100

Transformation temperatures, °C (°F)	-200 to 110 (-325 to 230)

Latent heat of transformation, kJ/kg · atom (cal/g · atom)	167 (40)
Shape memory strain	8.5% maximum

Because of the reactivity of the titanium in these alloys, all melting of them must be done in a vacuum or an inert atmosphere. Methods such as plasma-arc melting, electron-beam melting, and vacuum-induction melting are all used commercially. After ingots are melted, standard hot-forming processes such as forging, bar rolling, and extrusion can be used for initial breakdown. The alloys react slowly with air, so hot working in air is quite successful. Most cold-working processes can also be applied to these alloys, but they work harden extremely rapidly, and frequent annealing is required. Wire drawing is probably the most widely used of the techniques, and excellent surface properties and sizes as small as 0.05 mm (0.002 in.) are made routinely.

Fabrication of articles from the Ni-Ti alloys can usually be done with care, but some of the normal processes are difficult. Machining by turning or milling is very difficult except with special tools and practices. Welding, brazing, or soldering the alloys is generally difficult. The materials do respond well to abrasive removal, such as grinding, and shearing or punching can be done if thicknesses are kept small.

Heat treating to impart the desired memory shape is often done at 500 to 800 °C (950 to 1450 °F), but it can be done as low as 300 to 350 °C (600 to 650 °F) if sufficient time is allowed. The SMA component may need to be restrained in the desired memory shape during the heat treatment, otherwise, it may not remain there.

Commercial copper-base shape memory alloys are available in ternary Cu-Zn-Al and Cu-Al-Ni alloys, or in their quaternary modifications containing manganese. Elements such as boron, cerium, cobalt, iron, titanium, vanadium, and zirconium are also added for grain refinement.

The major alloy properties are listed in Table 3. The martensite-start (M_s) temperatures and the compositions of Cu-Zn-Al alloys are plotted in Fig. 4. Compositions of Cu-Al-Ni alloys usually fall in the range of 11 to 14.5 wt% Al and 3 to 5 wt% Ni. The martensitic transformation temperatures can be adjusted by varying chemical composition. Figure 4 and the following empirical relationships are useful in obtaining a first estimate:

- Cu-Zn-Al: M_s(°C) = 2212 - 66.9 (at.% Zn) - 90.65 (at.% Al) (Ref 8)
- Cu-Al-Ni: M_s(°C) = 2020 - 134 (wt% Al) - 45 (wt% Ni) (Ref 9)

Table 3 Properties of copper-base shape memory alloys

Property	**Property value**	
	Cu-Zn-Al	**Cu-Al-Ni**

(a) The Young's modulus of shape memory alloys becomes difficult to define between the M_s and the A_s transformation temperatures. At these temperatures, the alloys exhibit nonlinear elasticity, and the modulus is both temperature- and strain-dependent.

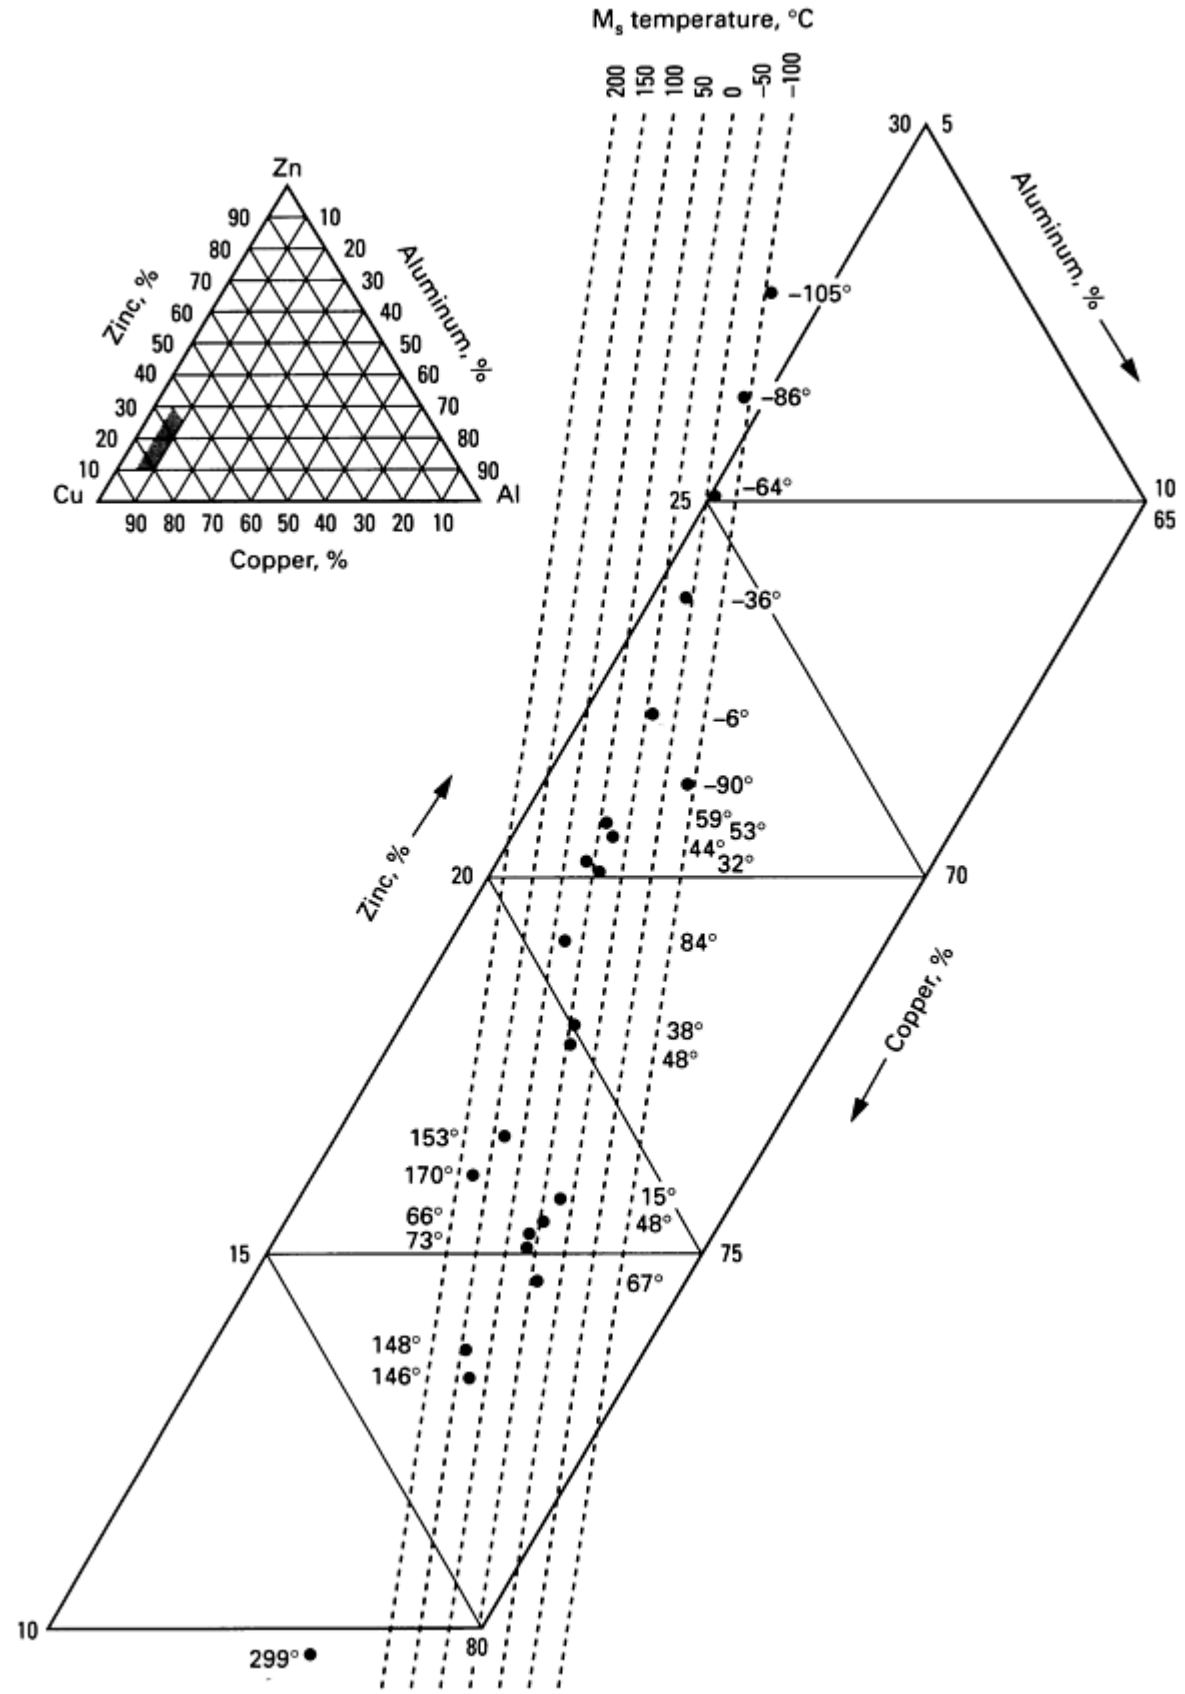

Fig. 4 M_s temperatures and compositions of Cu-Zn-Al shape memory alloys

The melting of Cu-base shape memory alloys in similar to that of aluminum bronzes. Most commercial alloys are induction melted. Protective flux on the melt and the use of nitrogen or inert-gas shielding during pouring are necessary to

prevent zinc evaporation and aluminum oxidation. Powder metallurgy and rapid solidification processing are also used to produce fine-grain alloys without grain-refining additives.

Copper-base alloys can be readily hot worked in air. With low aluminum content (<6 wt%), Cu-Zn-Al alloys can be cold finished with interpass annealing. Alloys with higher aluminum content are not as easily cold workable. Cu-Al-Ni alloys, on the other hand, are quite brittle at low temperatures and can only be hot finished.

Manganese depresses transformation temperatures of both Cu-Zn-Al and Cu-Al-Ni alloys and shifts the eutectoid to higher aluminum content (Ref 10). It often replaces aluminum for better ductility.

Because copper-base shape memory alloys are metastable in nature, solution heat treatment in the parent β-phase region and subsequent controlled cooling are necessary to retain β-phase for shape memory effects. Prolonged solution heat treatment causes zinc evaporation and grain growth and should be avoided. Water quench is widely used as a quenching process, but air cooling may be sufficient for some high-aluminum content Cu-Zn-Al alloys and Cu-Al-Ni alloys. The as-quenched transformation temperature is usually unstable. Postquench aging at temperatures above the nominal A_f temperature is generally needed to establish stable information temperatures.

Cu-Zn-Al alloys, when quenched rapidly and directly into the martensitic phase, are susceptible to the martensite stabilization effect (Ref 11). This effect causes the reverse transformation to shift toward higher temperatures. It therefore delays and may completely inhibit the shape recovery. For alloys with M_s temperatures above the ambient, slow cooling or step quenching with intermediate aging in the parent β-phase state should be adopted.

The thermal stability of copper-base alloys is ultimately limited by the decomposition kinetics. For this reason, prolonged exposure of Cu-Zn-Al and Cu-Al-Ni alloys at temperatures above 150 °C (300 °F) and 200 °C (390 °F) respectively, should be avoided. Aging at lower temperatures may also shift the transformation temperatures. In case of aging in the β phase, this results from the change in long-range order (Ref 12). When aged in the martensitic state, the alloys exhibit an aging-induced martensite stabilization effect (Ref 11). For high-temperature stability, Cu-Al-Ni is generally a better alloy system than Cu-Zn-Al. However, even for moderate temperature applications, which demand tight control of transformation temperatures, these effects need to be evaluated.

Applications

There is a wide variety of uses for the shape memory alloys. The following will illustrate one or two products in several categories of application.

Free recovery is illustrated when an SMA component is deformed while martensitic, and the only function required of the shape memory is that the component return to its previous shape (while doing minimal work) upon heating. A prime application of this is the blood-clot filter developed by M. Simon (Ref 13). The Ni-Ti wire is shaped to anchor itself in a vein and catch passing clots. The part is chilled so it can be collapsed and inserted into the vein, then body heat is sufficient to turn the part to its functional shape.

Constrained Recovery. The most successful example of this type of product is undoubtedly the Cryofit hydraulic couplings made by Raychem Corporation (Ref 14). These fittings are manufactured as cylindrical sleeves slightly smaller than the metal tubing they are to join. Their diameters are then expanded while martensitic, and, upon warming to austenite, they shrink in diameter and strongly hold the tube ends. The tubes prevent the coupling from fully recovering its manufactured

shape, and the stresses created as the coupling attempts to do so are great enough to create a joint that, in many ways, is superior to a weld.

Similar to the Cryofit coupling, the Betalloy coupling (Ref 15) is a Cu-Zn-Al coupling also designed and marketed by Raychem Corporation for copper and aluminum tubing. In this application, the Cu-Zn-Al shape memory cylinder shrinks on heating and acts as a driver to squeeze a tubular liner onto the tubes being joined. The joint strength is enhanced by a sealant coating on the liner.

Force Actuators. In some applications the shape memory component is designed to exert force over a considerable range of motion, often for many cycles. Such an application is the circuit-board edge connector made by Beta Phase Inc. (Ref 16). In this electrical connector system, the SMA component is used to force open a spring when the connector is heated. This allows force-free insertion or withdrawal of a circuit board in the connector. Upon cooling, the Ni-Ti actuator becomes weaker and the spring easily deforms the actuator while it closes tightly on the circuit board and forms the connections.

Based on the same principle, Cu-Zn-Al shape memory alloys have found several applications in this area. One such example is a fire safety valve, which incorporates a Cu-Zn-Al actuator designed to shut off toxic or flammable gas flow when fire occurs (Ref 17).

Proportional Control. It is possible to use only a part of the shape recovery to accurately position a mechanism by using only a selected portion of the recovery because the transformation occurs over a range of temperatures rather than at a single temperature. A device has been developed by Beta Phase Inc. (Ref 18) in which a valve controls the rate of fluid flow by carefully heating a shape0-memory-alloy component just enough to close the valve the desired amount. Repeatable positioning within 0.25 μm (10^{-5} in.) is possible with this technique.

Superelastic Applications. A number of products have been brought to market that use the pseudoelastic (or superelastic) property of these alloys. Eyeglass frames that use superelastic Ni-Ti to absorb large deformations without damaging the frames are now marketed, and guide wires for steering catheters into vessels in the body have been developed using Ni-Ti wire, which resists permanent deformation if bent severely. Arch wires for orthodontic correction using Ni-Ti have been used for many years to give large rapid movement of teeth.

The properties of the Ni-Ti alloys, particularly, indicate their probable greater use in biomedical applications. The materials is extremely corrosion resistant, demonstrates excellent biocompatibility, can be fabricated into the very small sizes often required, and has properties of elasticity and force delivery that allow uses not possible any other way.

Future Prospects

Although specific products that might use the Ni-Ti alloys in the future cannot be foretold, some directions are obvious. The cost of these alloys has slowly decreased as use has increased, so uses that require lower-cost alloys to be viable are being explored. Alloy development has yielded several ternary compositions with properties improved over those obtained with binary material, and alloys tailored to specific product needs are likely to multiply. The medical industry has developed a number of products using Ni-Ti alloys because of their excellent biocompatibility and large pseudoelasticity, and many more of these applications are likely. Finally, the availability of small wire that is stable, is easily heated by a small electrical current, and gives a large repeatable stroke should lead to a new family of actuator devices (Ref 19). These devices can be inexpensive, are reliable for thousands of cycles, and are expected to move Ni-Ti into the high-volume consumer marketplace.

Recent interest in the development of iron-base shape memory alloys has challenged the concept that long-range order and thermoelastic martensitic transformation are necessary conditions for shape memory effect. Among the alloys, Fe-Pt (Ref 20), Fe-Pd (Ref 21), and Fe-Ni-Co-Ti (Ref 22) can be heat treated to exhibit thermoelastic martensitic transformation, and, therefore, shape memory effect. However, alloys such as Fe-Ni-C (Ref 23), Fe-Mn-Si (Ref 24), and Fe-Mn-Si-Cr-Ni (Ref 25) are not ordered and undergo nonthermoelastic transformation, and yet exhibit good shape memory effect. These alloys are characteristically different from conventional shape memory alloys in that they rely on stress-induced martensite for shape memory effect, exhibit fairly large transformation hysteresis, and, in general, have less than 4% recoverable strain. The commercial potential of these alloys has yet to be determined, but the effort has opened up new classes of alloys for exploration as shape memory alloys. These new classes included β-Ti alloys and iron-base alloys.

Metal-Matrix Composites

John V. Foltz, Metallic Materials Branch, Naval Surface Warfare Center, White Oak Laboratory; Charles M. Blackmon, Applied Materials Technology Branch, Naval Surface Warfare Center, Dahlgren Laboratory

Introduction

METAL-MATRIX COMPOSITES (MMCs) are a class of materials with potential for a wide variety of structural and thermal management applications. Metal-matrix composites are capable of providing higher-temperature operating limits than their base metal counterparts, and they can be tailored to give improved strength, stiffness, thermal conductivity, abrasion resistance, creep resistance, or dimensional stability. Unlike resin-matrix composites, they are nonflammable, do not outgas in a vacuum, and suffer minimal attack by organic fluids such as fuels and solvents.

The principle of incorporating a high-performance second phase into a conventional engineering material to produce a combination with features not obtainable from the individual constituents is well known. In a MMC, the continuous, or matrix, phase is a monolithic alloy, and the reinforcement consists of high-performance carbon, metallic, or ceramic additions. Reinforced intermetallic compounds such as the aluminides of titanium, nickel, and iron are also discussed in this article (for more information on intermetallic compounds, see the article "Ordered Intermetallics" in this Volume).

Reinforcements, characterized as either continuous or discontinuous, may constitute from 10 to 60 vol% of the composite. Continuous fiber or filament reinforcements include graphite (Gr), silicon carbide (SiC), boron, aluminum oxide (Al_2O_3), and refractory metals. Discontinuous reinforcements consist mainly of SiC in whisker (w) form, particulate (p) types of SiC, Al_2O_3, or titanium diboride (TiB_2), and short or chopped fibers of Al_2O_3 or graphite. Figure 1 shows cross sections of typical continuous and discontinuous reinforcement MMCs.

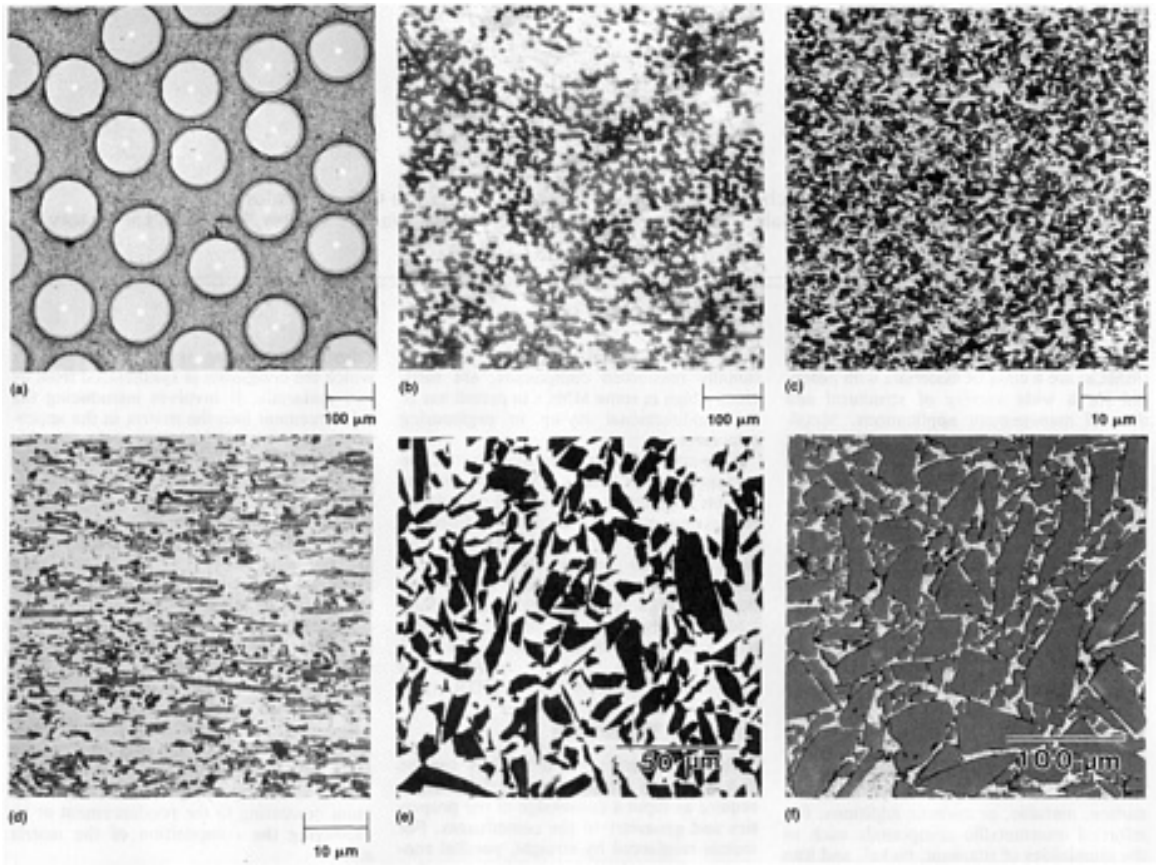

Fig. 1 Cross sections of typical fiber-reinforced MMCs. (a) Continuous-fiber-reinforced boron/aluminum composite. Shown here are 142 μm diam boron filaments coated with B_4C in a 6061 aluminum alloy matrix. (b) Discontinuous graphite/aluminum composite. Cross section shows 10 μm diam chopped graphite fibers (40 vol%) in a 2014 aluminum alloy matrix. (c) A 6061 aluminum alloy matrix reinforced with 40 vol% SiC particles. The salient characteristics of metals as matrices are manifested in a variety of ways; in particular, a metal matrix imparts a metallic nature to the composite in terms of thermal and electrical conductivity, manufacturing operations, and interaction with the environment. Matrix-dominated mechanical properties, such as the transverse elastic modulus and strength of unidirectionally reinforced composites, are sufficiently high in some MMCs to permit use of the unidirectional lay-up in engineering structures.

This article will give an overview of the current status of MMCs, including information on physical and mechanical properties, processing methods, distinctive features, and the various types of continuously and discontinuously reinforced MMCs. More information on the processing and properties of MMCs is available in the Section "Metal, Carbon/Graphite, and Ceramic Matrix Composites" in *Composites*, Volume 1 of the *Engineered Materials Handbook* published by ASTM INTERNATIONAL.

Property Prediction

Property predictions of MMCs can be obtained from mathematical models, which require as input a knowledge of the properties and geometry of the constituents. For metals reinforced by straight, parallel continuous fibers, three properties that are frequently of interest are the elastic modulus, the coefficient of thermal expansion, and the thermal conductivity in the fiber direction. Reasonable values can be obtained from rule-of-mixture expressions for Young's modulus (Ref 1):

$$E_c = E_f v_f + E_m v_m \qquad \textbf{(Eq 1)}$$

coefficient of thermal expansion (Ref 2):

$$a_c = \frac{a_f v_f E_f + a_m v_m E_m}{E_f v_f + E_m v_m} \qquad \textbf{(Eq 2)}$$

and thermal conductivity (Ref 3):

$$k_c = k_f v_f + k_m v_m \qquad \textbf{(Eq 3)}$$

where v is volume fraction, and E, α, and k are the modulus, coefficient of thermal expansion, and thermal conductivity in the fiber direction, respectively. The subscripts c, f, and m refer to composite, fiber, and matrix, respectively.

Processing Methods

Processing methods for MMCs are divided into primary and secondary categories. Primary processing is the operation by which the composite is synthesized from its raw materials. It involves introducing the reinforcement into the matrix in the appropriate amount and location, and achieving proper bonding of the constituents. Secondary processing consists of all the additional steps needed to make the primary composite into a finished hardware component.

Many reinforcement and matrix materials are not inherently compatible, and such materials cannot be processed into a composite without tailoring the properties of an interface between them. In some composites the coupling between the reinforcing agent and the metal is poor and must be enhanced. For MMCs made from reactive constituents, the challenge is to avoid excessive chemical activity at the interface, which would degrade the properties of the material. These problems are usually resolved either by applying a surface treatment or coating to the reinforcement or by modifying the composition of the matrix alloy.

Solidification processing (Ref 4, 5), solid-state bonding, and matrix deposition techniques have been used to fabricate MMCs. Solidification processing offers a near-net-shape manufacturing capability, which is economically attractive. Developers have explored various liquid metal techniques that use multifilament yarns, chopped fibers, or particulates as the reinforcement. A castable ceramic/aluminum MMC is now commercially available (Ref 6); cast components of this composite are shown in Fig. 2. Solid-state methods use lower fabrication temperatures with potentially better control of the interface thermodynamics and kinetics. The two principal categories of solid-state fabrication are diffusion bonding of materials in thin sheet form (Ref 7) and powder metallurgy techniques (Ref 8). Matrix deposition processes, in which the matrix is deposited on the fiber, include electrochemical plating, plasma spraying, and physical vapor decomposition (Ref 7). A new method, metal spray deposition, is currently being investigated (Ref 9). After deposition processing, a secondary consolidation step such as diffusion bonding often is needed to produce a component.

Pictured are a sand cast automotive disk brake rotor and upper control arm, a permanent mold cast piston, a high-pressure die cast bicycle sprocket, an investment cast aircraft hydraulic manifold, and three investment cast engine cylinder inserts. Courtesy of Dural Aluminum Composites Corporation

Which secondary processes are appropriate for a given MMC depends largely on whether the reinforcement is continuous or discontinuous. Discontinuously reinforced MMCs are amenable to many common metal forming operations, including extrusion, forging, and rolling. Because a high percentage of the materials used to reinforce discontinuous MMCs are hard oxides or carbides, machining can be difficult, and methods such as diamond sawing, electrical discharge machining (Ref 10), and abrasive waterjet cutting (Ref 11) are sometimes utilized (see *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook* for more information about these machining methods).

Aluminum-Matrix Composites

Most of the commercial work on MMCs has focused on aluminum as the matrix metal. The combination of light weight, environmental resistance, and useful mechanical properties has made aluminum alloys very popular; these properties also make aluminum well suited for use as a matrix metal. The melting point of aluminum is high enough to satisfy many application requirements, yet low enough to render composite processing reasonably convenient. Also, aluminum can

accommodate a variety of reinforcing agents, including continuous boron, Al_2O_3, SiC, and graphite fibers, and various particles, short fibers, and whiskers (Ref 12). The microstructures of various aluminum matrix MMCs are shown in Fig. 1.

Continuous Fiber Aluminum MMC. Boron/aluminum is a technologically mature continuous fiber MMC (Fig. 1a). Applications for this composite include tubular truss members in the midfuselage structure of the Space Shuttle orbiter and cold plates in electronic microchip carrier multilayer boards. Fabrication processes for B/Al composites are based on hot-press diffusion bonding or plasma spraying methods (Ref 13). Selected properties of a B/Al composite are given in Table 1.

Table 1 Room-temperature properties of unidirectional continuous fiber aluminum-matrix composites

Property	B/6061 Al	SCS-2/6061 Al	P100 Gr/6061 Al	FP/Al-2Li[(a)]
Fiber content, vol%	48	47	43.5	55
Longitudinal modulus, GPa (10^6 psi)	214 (31)	204 (29.6)	301 (43.6)	207 (30)
Transverse modulus, GPa (10^6 psi)	. . .	118 (17.1)	48 (7.0)	144 (20.9)
Longitudinal strength, MPa (ksi)	1520 (220)	1462 (212)	543 (79)	552 (80)
Transverse strength, MPa (ksi)	. . .	86 (12.5)	13 (2)	172 (25)

Source: Ref 14, 15, 16

(a) FP is the proprietary designation for an alpha alumina (α-Al_2O_3) fiber developed by E.I. Du Pont de Nemours & Company, Inc.

Continuous SiC fibers (SiC_c) are now commercially available; these fibers are candidate replacements for boron fibers because they have similar properties and offer a potential cost advantage. One such SiC fiber is SCS, which can be manufactured with any of several surface chemistries to enhance bonding with a particular matrix, such as aluminum or titanium (Ref 14). The SCS-2 fiber, tailored for aluminum, has a 1 μm (0.04 mil) thick carbon rich coating that increases in silicon content toward its outer surface.

Silicon carbide/aluminum MMCs exhibit increased strength and stiffness as compared with unreinforced aluminum, and with no weight penalty. Selected properties of SCS-2/Al are given in Table 1. In contrast to the base metal, the composite retains its room-temperature tensile strength at temperatures up to 260 °C (500 °F) (Fig. 3). This material is the focus of development programs for a variety of applications; an example of an advanced aerospace application for an SCS/Al MMC is shown in Fig. 4.

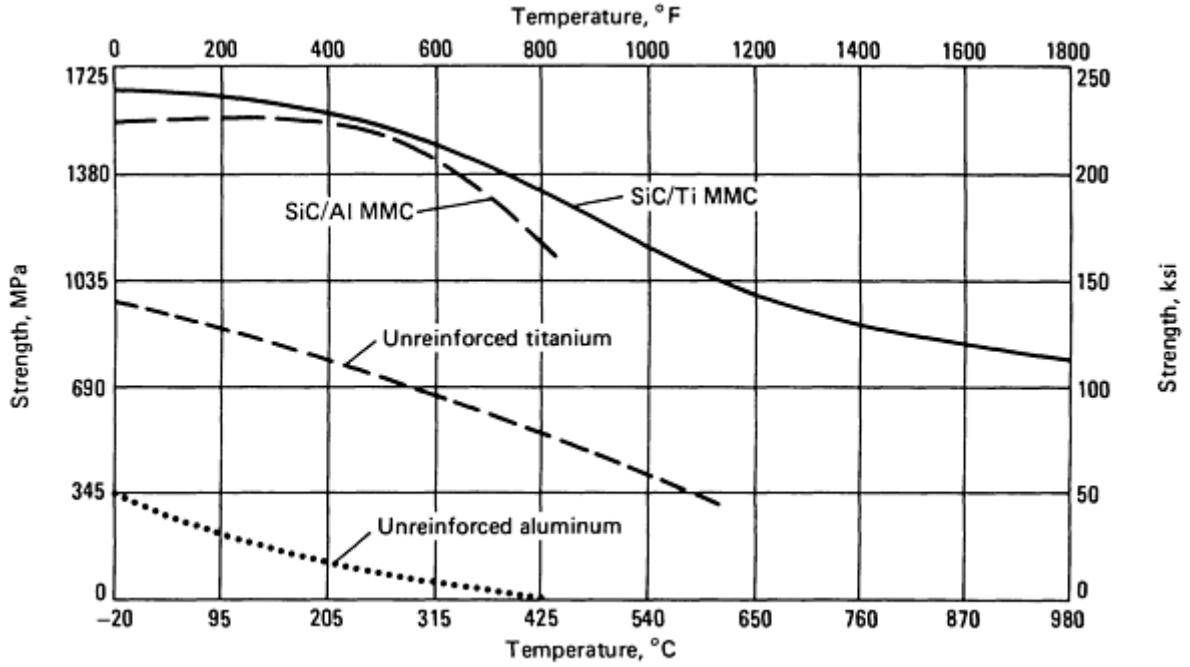

Fig. 3 Effect of temperature on tensile strength for two continuous fiber MMCs and two unreinforced metals. Source: Ref 17

Fig. 4 Advanced aircraft stabilator spar made from an SCS/Al MMC. Courtesy of Textron Specialty Materials

Graphite/aluminum (Gr/Al) MMC development was initially prompted by the commercial appearance of strong and stiff carbon fibers in the 1960s. As shown in Fig. 5, carbon fibers offer a range of properties, including an elastic modulus up to 966 GPa (140 psi × 10^6) and a negative coefficient of thermal expansion down to -1.62 × 10^{-6}/°C (-0.9 × 10^{-6}/°F). However, carbon and aluminum in combination are difficult materials to process into a composite. A deleterious reaction between carbon and aluminum, poor wetting of carbon by molten aluminum, and oxidation of the carbon are significant technical barriers to the production of these composites (Ref 19). Three processes are currently used for making commercial Gr/Al MMCs: liquid metal infiltration of fiber tows (Ref 20), vacuum vapor deposition of the matrix on spread tows (Ref 21, 22), and hot press bonding of spread tows sandwiched between sheets of aluminum (Ref 19). With both precursor wires and metal-coated fibers, secondary processing such as diffusion bonding or pultrusion is needed to make structural elements. Squeeze casting also is feasible for the fabrication of this composite (Ref 23).

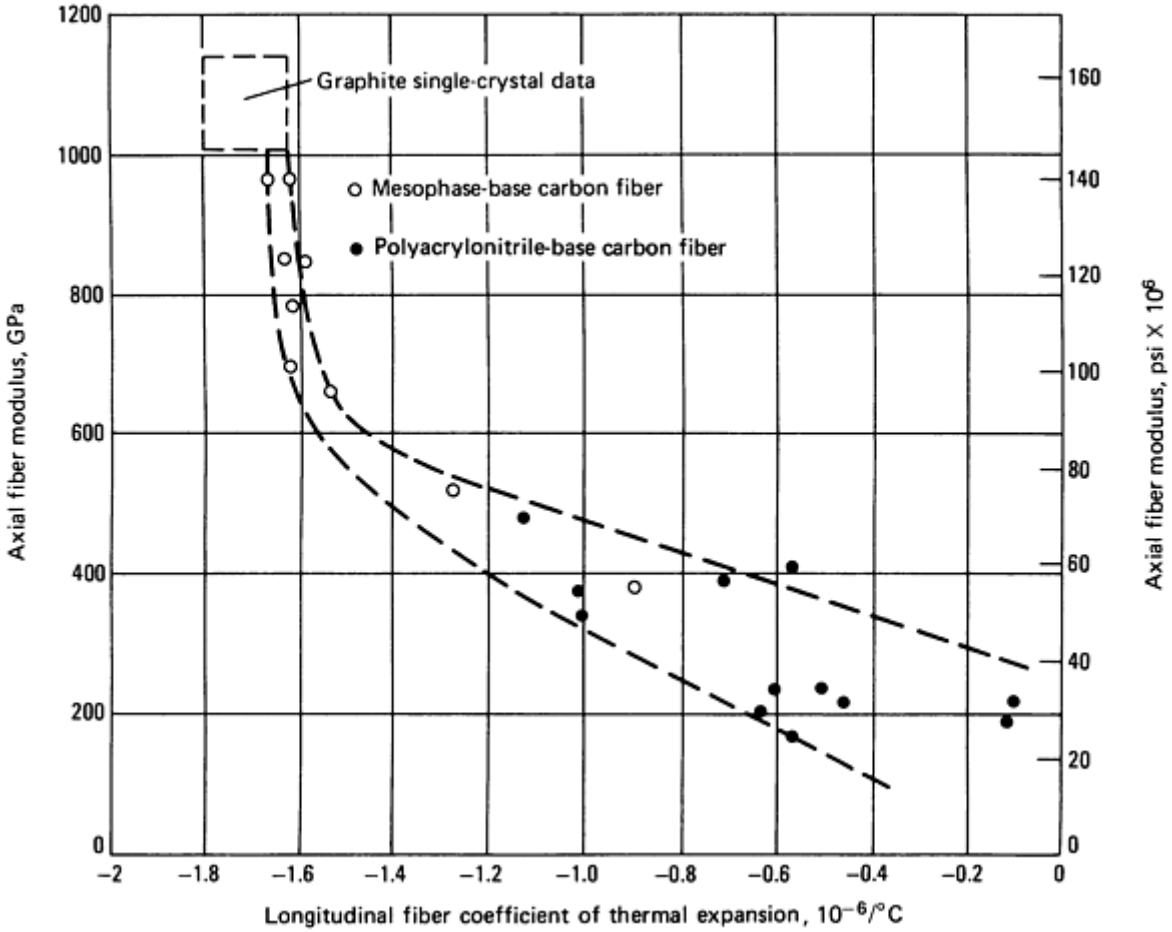

Fig. 5 Carbon fiber axial modulus versus axial coefficient of thermal expansion for mesophase (pitch-base) and polyacrylonitride-base (pan-base) graphite fibers. Source: Ref 18

Precision aerospace structures with strict tolerances on dimensional stability need stiff, lightweight materials that exhibit low thermal distortion. Graphite/aluminum MMCs have the potential to meet these requirements. Unidirectional P100 Gr/6061 Al pultruded tube (Ref 15) exhibits an elastic modulus in the fiber direction significantly greater than that of steel, and it has a density approximately one-third that of steel (Table 1). Reference 24 contains additional data for P100 Gr/Al.

In theory, Gr/Al angle-plied laminates can be designed to provide a coefficient of thermal expansion (CTE) of exactly zero by selecting the appropriate ply-stacking arrangement and fiber content. In practice, a near-zero CTE has been realized, but expansion behavior is complicated by hysteresis attributed to plastic deformation occurring in the matrix during thermal excursions (Fig. 6). Full-scale segments of a Gr/Al space truss (Fig. 7) have been fabricated and successfully tested. The advent of pitch-based graphite fibers with three times the thermal conductivity of copper (Ref 26) suggests that a high-conductivity low-CTE version of Gr/Al can be developed for electronic heat sinks and space thermal radiators.

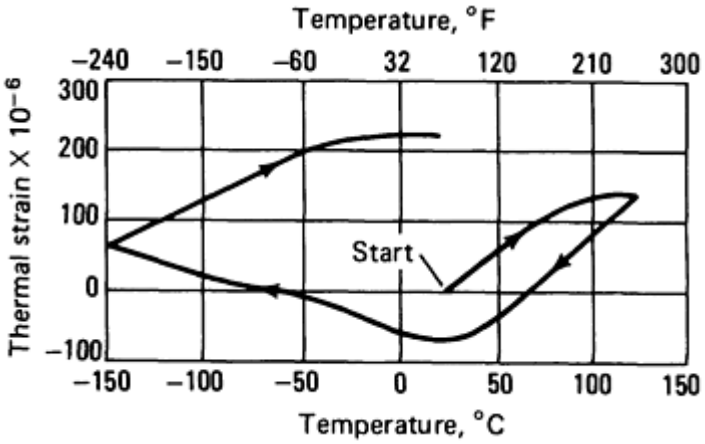

Fig. 6 Thermal expansion in the fiber direction of a P100 Gr/6061 Al single-ply unidirectional composite laminate. Source: Ref 25

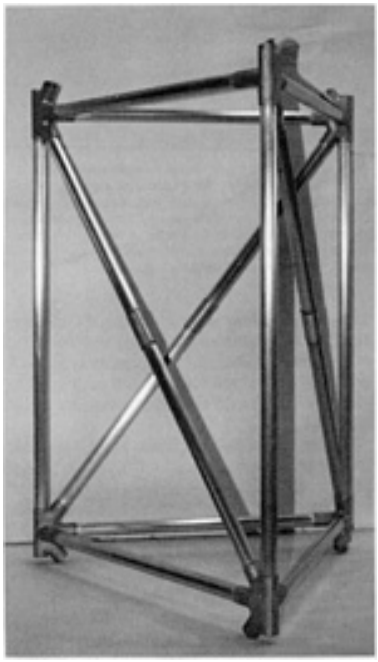

Fig. 7 Space truss made of ±12° lay-up graphite/aluminum tubes. Axial coefficient of thermal expansion is -0.072 × 10^{-6}/°C per bay. Courtesy of DWA Composite Specialties, Inc.

Aluminum oxide/aluminum (Al_2O_3/Al) MMCs can be fabricated by a number of methods, but liquid or semisolid-state processing techniques are commonly used. Certain of the oxide ceramic fibers used as reinforcements are inexpensive and provide the composite with improved properties as compared with those of unreinforced aluminum alloys. For example, the composite has an improved resistance to wear and thermal fatigue deformation and a reduced coefficient of thermal expansion. Continuous fiber Al_2O_3/Al MMCs are fabricated by arranging Al_2O_3 tapes in a desired orientation to make a preform, inserting the preform into a mold, and infiltrating the preform with molten aluminum via a vacuum assist (Ref 27). Reinforcement-to-matrix bonding is achieved by small additions of lithium to the melt. The room-temperature properties of a unidirectional Al_2O_3/Al (FP/Al-2Li) are given in Table 1; additional mechanical properties of continuous Al_2O_3/Al are given in Ref 28.

Discontinuous Aluminum MMCs. Discontinuous silicon carbide/aluminum (SiC_d/Al) is a designation that encompasses materials with SiC particles, whiskers, nodules, flakes, platelets, or short fibers in an aluminum matrix (see Fig. 1). Several companies are currently involved in the development of powder metallurgy SiC_d/Al, using either particles or whiskers as the reinforcement phase (Ref 8). A casting technology exists for this type of MMC, and melt-produced ingots

can be produced in whatever form is needed--extrusion billets, ingots, or rolling blanks--for further processing (Ref 29). Arsenault and Wu (Ref 30) compared powder metallurgy and melt-produced discontinuous SiC/Al composites to determine if a correlation exists between strength and processing type. They found that if the size, volume fraction, distribution of the reinforcement, and bonding with the matrix are the same, then the strengths of the powder metallurgy and melt-produced MMCs are the same.

Whiskers in discontinuously reinforced MMCs can be oriented in processing to provide directional properties. McDanels (Ref 31) evaluated the effect of reinforcement type, matrix alloy, reinforcement content, and orientation on the tensile behavior of SiC_d/Al composites made by powder metallurgy techniques. He concluded that these composites offer a 50 to 100% increase in elastic modulus as compared with unreinforced aluminum (Fig. 8). He also found that these materials have a stiffness approximately equivalent to that of itanium but with one-third less density. Tensile and yield strengths of SiC_d/Al composites are up to 60% greater than those of the unreinforced matrix alloy. Selected properties of SiC_d/Al MMCs are given in Table 2. Studies of the elevated-temperature mechanical properties of SiC_d/Al with either 20% whisker or 25% particulate reinforcement indicate that SiC_d/Al can be used effectively for long-time exposures to temperatures of at least 200 °C (400 °F) and for short exposures at 260 °C (500 °F) (Ref 31, 33).

Table 2 Properties of discontinuous silicon carbide/aluminum composites

Property	**SiC_p/Al-4Cu-1.5Mg[(a)]**	**SiC_w/Al-4Cu-1.5Mg[(b)]**
Reinforcement content, vol%	20	15
Longitudinal modulus, GPa (10^6 psi)	110 (16)	108 (15.7)
Transverse modulus, GPa (10^6 psi)	105 (15)	90 (13)

Discontinuous silicon carbide/aluminum MMCs are being developed by the aerospace industry for use as airplane skins, intercostal ribs, and electrical equipment racks (Fig. 9). These composites can be tailored to exhibit dimensional stability, that is, resistance to microcreep, which is important for precision mirror optics and inertial measurement units (Fig. 10). In the electronics industry, metals such as iron-nickel alloys that are now used for packaging materials and heat sinks are candidates for replacement by SiC_d/Al. The composite has lower density, better thermal conductivity (≥ 160 W/m · K), and can be made to have a low coefficient of thermal expansion (Fig. 11). Hybrid electronic packages made from SiC_d/Al are shown in Fig. 12.

Most Gr/Al MMC development work has focused on using continuous fibers as reinforcement. However, various solidification processing techniques have been investigated for use in the production of cast particle Gr/Al for applications needing an inexpensive antifriction material (Ref 35).

Discontinuous Al_2O_3/Al MMCs are made using short fibers, particles, or compacted staple fiber preforms as reinforcements. The addition of chopped Al_2O_3 fibers to an agitated, partially solid aluminum alloy slurry has been used to produce a castable discontinuous MMC (Ref 36). Squeeze casting has attracted much attention because the process minimizes material and energy use, produces net shape components, and offers a selective reinforcement capability (Ref 37, 38).

A recent development in MMC fabrication technology is the proprietary Lanxide PRIMEX™ process, which involves pressureless metal infiltration into a ceramic preform. This process has been used to produce an Al_2O_3/Al composite by

the infiltration of a bed of alumina particles with a molten alloy that was exposed to an oxidizing atmosphere. The matrix material of the resultant composite is composed of a mixture of the oxidation reaction product and unreacted aluminum alloy (Ref 39). The Lanxide process offers net shape capability (Fig. 13), and the properties of composites produced by this method can be tailored to fit specific applications.

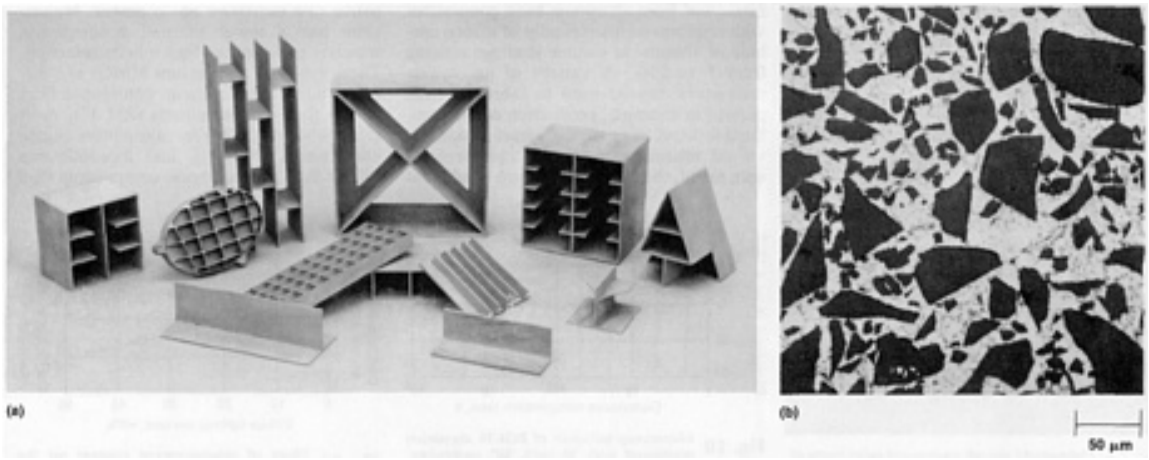

Fig. 13 Discontinuous silicon carbide/aluminum MMC (60 vol% SiC) produced by the PRIMEX^{TM} process. (a) Near-net-shape components fabricated from the composite. (b) Composite microstructure. Courtesy of Lanxide Corporation

Aluminum oxide/aluminum MMCs are candidate materials for moving parts of automotive engines, such as pistons (Ref 40), connecting rods (Ref 16), piston pins, and various components in the cylinder head and valve train (Ref 41). Examples of automotive parts fabricated from MMCs are shown in Fig. 14. These components were fabricated from aluminum-base composites with reinforcements typically of silicon carbide or alumina in volume loadings ranging from 5 to 25%. A variety of processing techniques can be used to fabricate such parts. For example, production of the combustion bowl area of the diesel piston involved squeeze casting a ceramic preform with metal; the cylinder liner was sand mold cast; and the connecting rod was made using novel forming processes specifically adapted for composites. Other possible automotive applications for this class of materials include brake rotors, brake calipers, and drive shafts.

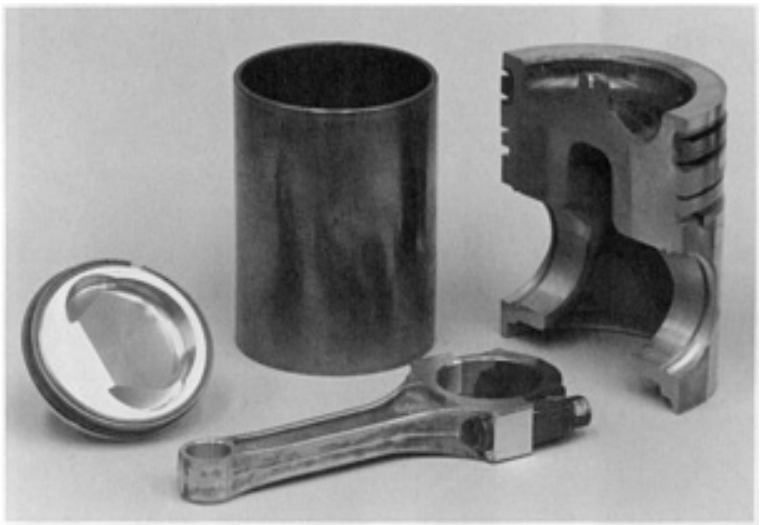

Fig. 14 Automotive components fabricated from MMCs. Clockwise from left: experimental piston for a gasoline engine, experimental cylinder liner, production piston for a heavy-duty diesel truck engine, and experimental connecting rod. Courtesy of Ford Motor Company

A Toyota diesel engine piston selectively reinforced with an aluminosilicate ceramic compact is currently in production (Ref 42). Selective reinforcement of the all-aluminum piston with a ceramic fiber preform provides wear resistance equal

to that of a piston with an iron insert, and the thermal transport is only marginally lower than that of unreinforced aluminum. With the elimination of the iron insert, piston weight is reduced, and high-temperature strength and thermal stability are enhanced.

Magnesium-Matrix Composites

Magnesium composites are being developed to exploit essentially the same properties as those provided by aluminum MMCs: high stiffness, light weight, and low CTE. In practice, the choice between aluminum and magnesium as a matrix is usually made on the basis of weight versus corrosion resistance. Magnesium is approximately two-thirds as dense as aluminum, but it is more active in a corrosive environment. Magnesium has a lower thermal conductivity, which is sometimes a factor in its selection. Three types of magnesium MMCs are currently under development: continuous fiber Gr/Mg for space structures (Ref 43), short staple fiber Al_2O_3/Mg for automotive engine components (Ref 44), and discontinuous SiC or B_4C/Mg for engine components (Ref 45) and low-expansion electronic packaging materials (Ref 46). Processing methods for all three types parallel those used for their aluminum MMC counterparts.

The production of the continuous-fiber Gr/Mg composite involves the titanium-boron coating method of making composite wires, physical vapor deposition of the matrix on fibers, or diffusion bonding of fiber-thin sheet sandwiches to make panels. A casting technology exists for Gr/Mg that involves the deposition of an air-stable silicon dioxide coating on the fibers from an organometallic precursor solution (Ref 47). Magnesium wets the coating, permitting incorporation of the matrix by near-net-shape casting procedures (Ref 48). Testing of a unidirectionally reinforced Gr/Mg MMC in the fiber direction recorded modulus values in agreement with Eq 1 and a tensile strength of 572 MPa (83 ksi) (Ref 43). A P100 Gr/AZ91C Mg unidirectional laminate was shown to have a lower CTE and smaller residual strain than those of a P100 Gr/6061 Al MMC after both composites had undergone thermal cycling between -155 °C and 120 °C (-250 and 250 °F) (Ref 25).

Titanium-Matrix Composites

Titanium was selected for use as a matrix metal because of its good specific strength at both room and moderately elevated Temperatures and its excellent corrosion resistance. In comparison with aluminum, titanium, retains its strength at higher Temperatures; it has increasingly been used as a replacement for aluminum in aircraft and missile structures as the operating speeds of these items have increased from subsonic to supersonic. Efforts to develop titanium MMCs were hampered for years by processing problems stemming from the high reactivity of titanium with many reinforcing materials. Reference 49 is a review of titanium MMC technology. Silicon carbide is now the accepted reinforcement; the SCS-6 fiber is an example of one commercially available type. The SCS-6 fiber has a 140 μm (5.6 mil) diameter, a 33 μm (1.3 mil) carbon core, and a carbon-rich surface (Fig. 15).

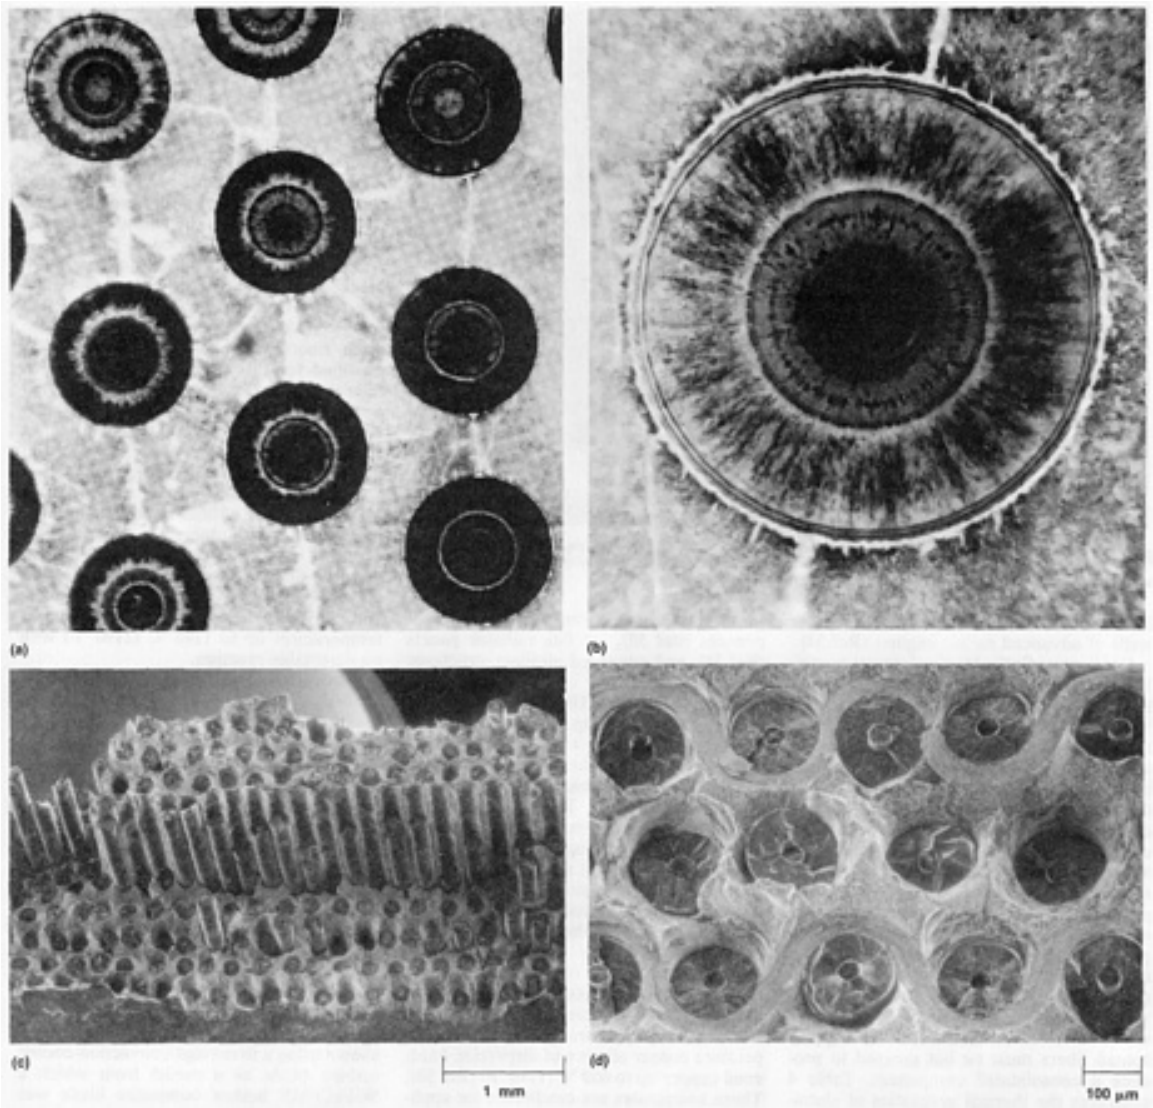

Fig. 15 Continuous-fiber-reinforced titanium-matrix MMCs. (a) Hot-pressed SiC fibers (SCS-6, 35 vol%) in a Ti-6Al-4V matrix. Fiber thickness, 140 μm; density, 3.86 g/cm^3. (b) Chemical vapor deposited SiC fiber (SCS-6) showing the central carbon monofilament substrate and the carbon-rich surface. Fiber properties; thickness, 140 μm; tensile strength, 3450 MPa (500 ksi); modulus of elasticity, 400 GPa (58 × 10^6 psi); density, 3.0 g/cm^3. (c) Fracture surface of a hot-pressed SCS-6 SiC/titanium MMC plate. (d) Close-up view of fractured SCS-6 fibers. Courtesy of Textron Specialty Materials, a subsidiary of Textron, Inc.

Although a number of processing techniques have been evaluated for titanium MMCs, only high-Temperature/short-time rol bonding, hot isostatic pressing, and vacuum hot pressing have been used to any substantial degree. Plasma spraying also is employed to deposit a titanium matrix onto the fibers (Ref 50). Properties for a representative unidirectional SiC/Ti laminate are given in Table 3. The elevated-Temperature strength of the SiC/Ti composite is significantly greater than that of unreinforced titanium (Fig. 3). Potential applications for continuous titanium MMCs lie primarily in the aerospace industry and include major aircraft structural components (Ref 51) and fan and compressor blades for advanced turbine engines.

Table 3 Room-temperature properties of a unidirectional SiC$_c$/Ti MMC

Longitudinal strength, MPa (ksi)	1447 (210)
Transverse strength, MPa (ksi)	413 (60)

Source: Ref 14

Titanium MMCs with discontinuous reinforcements are in the early stages of development (Ref 52). This type of composite has a moderate stiffness and elevated-Temperature strength advantage over monolithic titanium alloys. It also offers a near-net-shape manufacturing capability with the use of powder metallurgy techniques; therefore, it may be more economical to fabricate than continuous fiber titanium MMCs.

Copper-Matrix Composites

Copper appears to have potential as a matrix metal for composites that require thermal conductivity and high-Temperature strength properties superior to those of aluminum MMCs. Copper MMCs with continuous and discontinuous reinforcements are being evaluated.

Continuous tungsten fiber reinforced copper composites were first fabricated in the late 1950s as research models for studying stress-strain behavior, stress-rupture and creep phenomena, and impact strength and conductivity in MMCs (Ref 53). The composites were made by liquid-phase infiltration. On the basis of their high strength at temperatures up to 925 °C (1700 °F), W/Cu MMCs are now being considered for use as liner materials for the combustion chamber walls of advanced rocket engines (Ref 54).

Continuous Gr/Cu MMCs. Interest in continuous Gr/Cu MMCs gained impetus from the development of advanced graphite fibers. Copper has good thermal conductivity, but it is heavy and has poor elevated-temperature mechanical properties. Pitch-base graphite fibers have been developed that have room-temperature axial thermal conductivity properties better than those of copper (Ref 26). The addition of these fibers to copper reduces density, increases stiffness, raises the service temperature, and provides a mechanism for tailoring the coefficient of thermal expansion. One approach to the fabrication of Gr/Cu MMCs uses a plating process to envelop each graphite fiber with a pure copper coating, yielding MMC fibers flexible enough to be woven into fabric (Ref 55). The copper-coated fibers must be hot pressed to produce a consolidated component. Table 4 compares the thermal properties of aluminum and copper MMCs with those of unreinforced aluminum and copper. Graphite/copper MMCs have the potential to be used for thermal management of electric components (Ref 55), satellite radiator panels (Ref 56), and advanced airplane structures (Ref 57).

Table 4 Thermal properties of unreinforced and reinforced aluminum and copper

Material	Reinforcement content, vol %	Density		Axial thermal conductivity		Axial coefficient of thermal expansion	
		g/cm^3	lb/ft^3	W/m · °C	Btu/ft · h · °F	10^{-6}/°C	10^{-6}/°F

***In situ* Composites.** Discontinuous MMCs formed by the working of mixtures of individual metal phases exhibit strengths as much as 50% higher than those predicted in theory from the strength of the individual constituents (Ref 8). These materials are called *in situ* composites because the elongated ribbon morphology of the reinforcing phase is developed in place by heavy mechanical working, which can consist of extrusion, drawing, or rolling. This approach has been applied to the fabrication of discontinuous refractory metal/copper composites, with niobium/copper serving as the prototype. Niobium/copper maintains high strength at temperatures up to 400 °C (750 °F), and it remains stronger than high-temperature copper alloys and dispersion-hardened copper up to 600 °C (1110 °F) (Ref 58). These composites are candidates for applications such as electrical contacts that require good strength plus conductivity at moderate temperatures.

Superalloy-Matrix Composites

Superalloys are commonly used for turbine engine hardware and, therefore, superalloy-matrix composites were among the first candidate materials considered for upgrading turbine performance by raising component operating temperatures. Superalloy MMCs were developed to their present state over a period of years, starting from the early 1960s. The following summary is drawn from the review in Ref 59.

High-temperature strength is superalloy MMCs has been achieved only through the use of refractory metal reinforcements (tungsten, molybdenum, tantalum, and niobium fibers with compositions specially modified for this purpose). The strongest fiber developed, a tungsten alloy, exhibited a strength of more than 2070 MPa (300 ksi) at 1095 °C (2000 °F), or more than six times the strength of the superalloy now used in the Space Shuttle main engine.

Much of the early work on superalloy MMCs consisted of fiber-matrix compatibility studies, which ultimately led to the use of matrix alloys that exhibit limited reaction with the fibers. Tungsten fibers, for example, are least reactive in iron-base matrices, and they can endure short exposures at temperatures up to 1195 °C (2190 °F) with no detectable reaction.

Fabrication of superalloy MMCs is accomplished via solid-phase, liquid-phase, or deposition processing. The methods include investment casting, the use of matrix metals in thin sheet form, the use of matrix metals in powder sheet form made by rolling powders with an organic binder, powder metallurgy techniques, slip casting of metal alloy powders, and arc spraying. Iron-, nickel-, and cobalt-base MMCs have been made, and a wide range of properties have been achieved with these MMCs, including elevated-temperature tensile strength, stress-rupture strength, creep resistance, low- and high-cycle fatigue strength, impact strength, oxidation resistance, and thermal conductivity (Ref 59). The feasibility of making a component with a complex shape was shown using a first-stage convection-cooled turbine blade as a model from which a W/FeCrAlY hollow composite blade was designed and fabricated. Additional information on superalloy MMCs reinforced with refractory metals can be found in the article "Refractory Metals and Alloys" in this Volume.

Intermetallic-Matrix Composites

One disadvantage of superalloy MMCs is their high density, which limits the potential minimum weight of parts made from these materials. High melting points and relatively low densities make intermetallic-matrix composites (IMCs) viable candidates for lighter turbine engine materials (Ref 60). An intermetallic compound differs from an alloy in that the former has a fixed compositional range, a long-range order to the arrangement of atoms within the lattice, and a limited number of slip systems available for plastic deformation. At present, the IMC technology is in its infancy, and many critical issues remain to be addressed.

Aluminides of nickel, titanium, and iron have received most of the early attention as potential matrices for IMCs. Work on aluminide IMCs is concerned with developing methods to fabricate reproducible specimens with useful properties; work is also being done on characterizing the interface chemical reactions of fiber/matrix combinations. Candidate reinforcements for commercially available intermetallic materials are SiC and Al_2O_3 fibers, refractory metal fibers, and particulates such as titanium carbide (TiC) and titanium diboride (TiB_2). Research is being done to find methods for growing advanced single-crystal fibers and using refractory metal aluminides and silicides as matrices (Ref 61). Key factors in selecting a reinforcement/matrix combination are chemical compatibility at the processing temperature and an approximate match of thermal expansion coefficients between the material pair to minimize residual fabrication stresses.

Reference 62 is an overview of the development of nickel aluminide IMCs, and it describes the various processing techniques used to make this composite. These techniques include hot pressing, diffusion bonding, hot extrusion, reactive sintering, and liquid infiltration. Reference 63 presents evidence that silicon carbide cannot serve as a reinforcement for nickel aluminide IMCs without the use of a diffusion barrier coating. A gas pressure liquid infiltration technique has been

used to produce continuous fiber Al_2O_3/NiAl (Ref 64). Reference 65 describes a powder cloth method for the fabrication of a 40 vol% continuous fiber SiC/Ti_3Al + Nb IMC. Data on IMC properties are very limited.

The XD composites are a proprietary class of discontinuous reinforcement *in situ* composites. The XD technology uses a casting process to produce a fine, closely spaced, and uniform distribution of second-phase particles (Ref 66). The dispersoids are formed and grown *in situ* instead of being mechanically mixed as a separate additive. This approach to making ceramic-stiffened composites has been demonstrated for a number of metals as well as for titanium and nickel aluminides (Ref 67). Strength levels of greater than 690 MPa (100 ksi) were measured at 20 °C (70 °F) and at 800 °C (1470 °F) for a two-phase lamellar Ti-45 at.% Al alloy reinforced with equiaxed TiB_2 ceramic particulates (Ref 66).

Ordered Intermetallics

C.T. Liu and J.O. Stiegler, Metals and Ceramics Division, Oak Ridge National Laboratory; F.H. (Sam) Froes, Institute for Materials and Advanced Processes, Colleges of Mines, University of Idaho

Introduction

ORDERED INTERMETALLIC compounds constitute a unique class of metallic materials that form long-range ordered crystal structures (Fig. 1) below a critical temperature, generally referred to as the critical ordering temperature (T_c). These ordered intermetallics usually exist in relatively narrow compositional ranges around simple stoichiometric ratios.

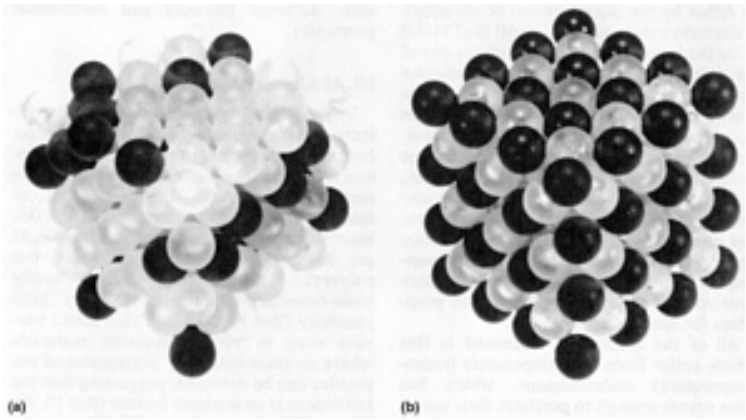

Fig. 1 Atomic arrangements of conventional alloys and ordered intermetallic compounds. (a) Disordered crystal structure of a conventional alloy. (b) Long-range ordered crystal structure of an ordered intermetallic compound

Ordered intermetallic alloys with relatively low critical ordering temperatures (<700 °C, or 1290 °F) were studied quite extensively in the 1950s and 1960s, following the discovery of unusual dislocation structures and mechanical behavior associated with ordered lattices (Ref 1, 2, 3, 4). Deformation in ordered alloys is controlled by the glide of superlattice or paired dislocations, as illustrated in Fig. 2 for a two-dimensional ordered lattice having an AB composition. The first, or leading, dislocation creates a layer of antiphase domain (which can be thought of simply as a layer of wrong bonding), and the second, or following, dislocation restores the order. The relatively low mobility of superlattice dislocations at higher temperatures gives rise to anomalous yield behavior; that is, yield strength increases rather than decreases with increasing test temperature (Ref 5, 6, 7, 8, 9, 10, 11, 12). The anomalous yielding has been observed in many ordered intermetallics, such as Ni_3Al (Ref 5, 6, 7) and Cu_3Au (Ref 8) alloys. The results obtained by these studies are summarized in Ref 1.

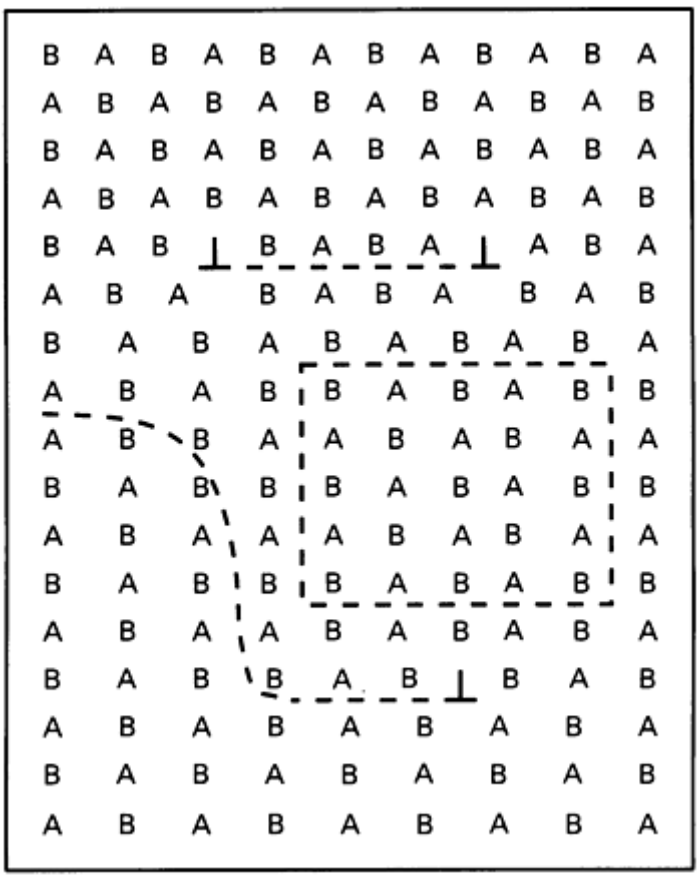

Fig. 2 Schematic representation of a superlattice dislocation in a two-dimensional simple cubic lattice, along with two thermally produced antiphase boundaries, one of which terminated on an ordinary dislocation. Source: Ref 1

The interest in ordered intermetallics subsided in the latter part of the 1960s because of severe embrittlement problems encountered with the compounds. Most strongly ordered intermetallics are so brittle that they simply cannot be fabricated into useful structural components (Ref 1, 2, 3, 4). Even when fabricated, these compounds have a low fracture toughness that severely limits their use as engineering materials. However, in the latter part of the 1970s, some prominent results were reported that showed that the ductility and fabricability of ordered intermetallics could be dramatically improved by alloy design efforts using physical metallurgy principles. The ductility of Co_3V was substantially improved by macroalloying with iron additions that reduced the average electron concentration and changed the ordered crystal structure from hexagonal to cubic (Ref 13, 14, 15, 16, 17). The alloys $(Fe, Co, Ni)_3V$ with the cubic $L1_2$ ordered structure exhibited more than 40% ductility at room temperature (Ref 14). The ductility of polycrystalline Ni_3Al was dramatically increased by microalloying with boron additions (Ref 18), which segregated to grain boundaries and suppressed brittle intergranular fracture (Ref 19, 20, 21). Both cases have demonstrated the feasibility of achieving high tensile ductility in strongly ordered intermetallic alloys.

The recent search for new high-temperature structural materials has stimulated further interest in ordered intermetallics (Ref 22, 23, 24). These compounds generally exhibit promising high-temperature properties because cause the long-range ordered superlattice lowers dislocation mobility and diffusion processes at elevated temperatures (Ref 1, 2, 3, 4, 22, 23, 24). However, because of the brittleness problem, the intermetallics have been used mainly as strengthening constituents in structural materials. For example, high-temperature nickel-base superalloys owe their oustanding strength properties to a fine dispersion of precipitated particles of the ordered γ' phase (Ni_3Al) embedded in a ductile disordered matrix.

Recent research has focused on understanding the brittle fracture and low ductility in ordered intermetallics (Ref 1, 2, 3, 4, 22, 23, 24, 25, 26, 27, 28, 29). Possible causes for brittleness include:

- Insufficient number of deformation modes
- High yield strength or hardness caused by difficulty in the generation and glide of dislocations
- Poor cleavage strength or low surface energy
- Planar slip and localized deformation
- High strain rate sensitivity (which promotes brittle crack propagation at crack tips)
- Grain boundary weakness
- Environmental embrittlement

In some cases, the brittleness results from strong resistance to the motion of dislocations, to the point that cleavage or intergranular fracture may be favored. In many cases, however, the dislocations are relatively mobile. Brittleness results either from low-symmetry crystal structures that do not possess enough independent slip systems to permit arbitrary deformation or from the presence of grain boundaries that are too weak to resist the propagation of cracks. Recently, it has been found that quite a number of ordered intermetallics, such as iron aluminides (Ref 28, 29), exhibit environmental embrittlement at ambient temperatures. The embrittlement involves the reaction of water vapor in air with reactive elements (aluminum, for example) in intermetallics to form atomic hydrogen, which drives into the metal and causes premature fracture.

In recent years, alloying and processing have been employed to control the ordered crystal structure, microstructural features, ang grain-boundary structure and composition to overcome the brittleness problem of ordered intermetallics (Ref 22, 23, 24). Success in this work has inspired parallel efforts aimed at improving strength properties. The results have led to the development of a number of attractive intermetallic alloys having useful ductility and strength.

Alloy design work has been centered primarily on aluminides of nickel, iron, and titanium (Ref 22, 23, 24). These materials possess a number of attributes that make them attractive for high-temperature applications. They contain sufficient amounts of aluminum to form, in oxidizing environments, thin films of alumina (Al_2O_3) that often are compact and protective (Ref 30). These materials have low densities, relatively high melting points, (Table 1) and good high-temperature strength properties.

Table 1 Properties of nickel, iron, and titanium aluminides

Alloy	Crystal structure[(a)]	Critical ordering temperature (T_c)		Melting point (T_m)		Material density g/cm^3	Young's modulus	
		°C	°F	°C	°F		GPa	10^6 psi
Ni_3Al	$L1_2$ (ordered fcc)	1390	2535	1390	2535	7.50	179	25.9
NiAl	$B2$ (ordered bcc)	1640	2985	1640	2985	5.86	294	42.7
Fe_3Al	$D0_3$ (ordered bcc)	540	1000	1540	2805	6.72	141	20.4
	$B2$ (ordered bcc)	760	1400	1540	2805	. . .	. . .	. . .
FeAl	$B2$ (ordered bcc)	1250	2280	1250	2280	5.56	261	37.8
Ti_3Al	$D0_{19}$ (ordered hcp)	1100	2010	1600	2910	4.2	145	21.0

(a) fcc, face-centered cubic; bcc, body-centered cubic; hcp, hexagonal close packed

Crystal structures showing the ordered arrangements of atoms in several of these aluminides are illustrated in Fig. 3. For most of the aluminides listed in Table 1, the critical ordering temperature is equal to the melting temperature. Others disorder at somewhat lower temperatures, and Fe_3Al passes through two ordered structures ($D0_3$ and $B2$) before becoming disordered. Deviations from stoichiometry are accommodated either by the incorporation of vacancies in the lattice (for example, NiAl) (Ref 31, 32, 33, 34) or by the location of antisite atoms in one of the sublattices. Many of the aluminides exist over a range of compositions, but the degree of order decreases as the deviation from stoichiometry increases. Additional elements can also be incorporated without losing the ordered structure. For example, in Ni_3Al, silicon atoms are located on aluminum sites, cobalt atoms on nickel sites, and iron atoms on either (Ref 35). In many instances, the so-called intermetallic compounds can be used as bases for alloy development to improve or optimize properties for specific applications.

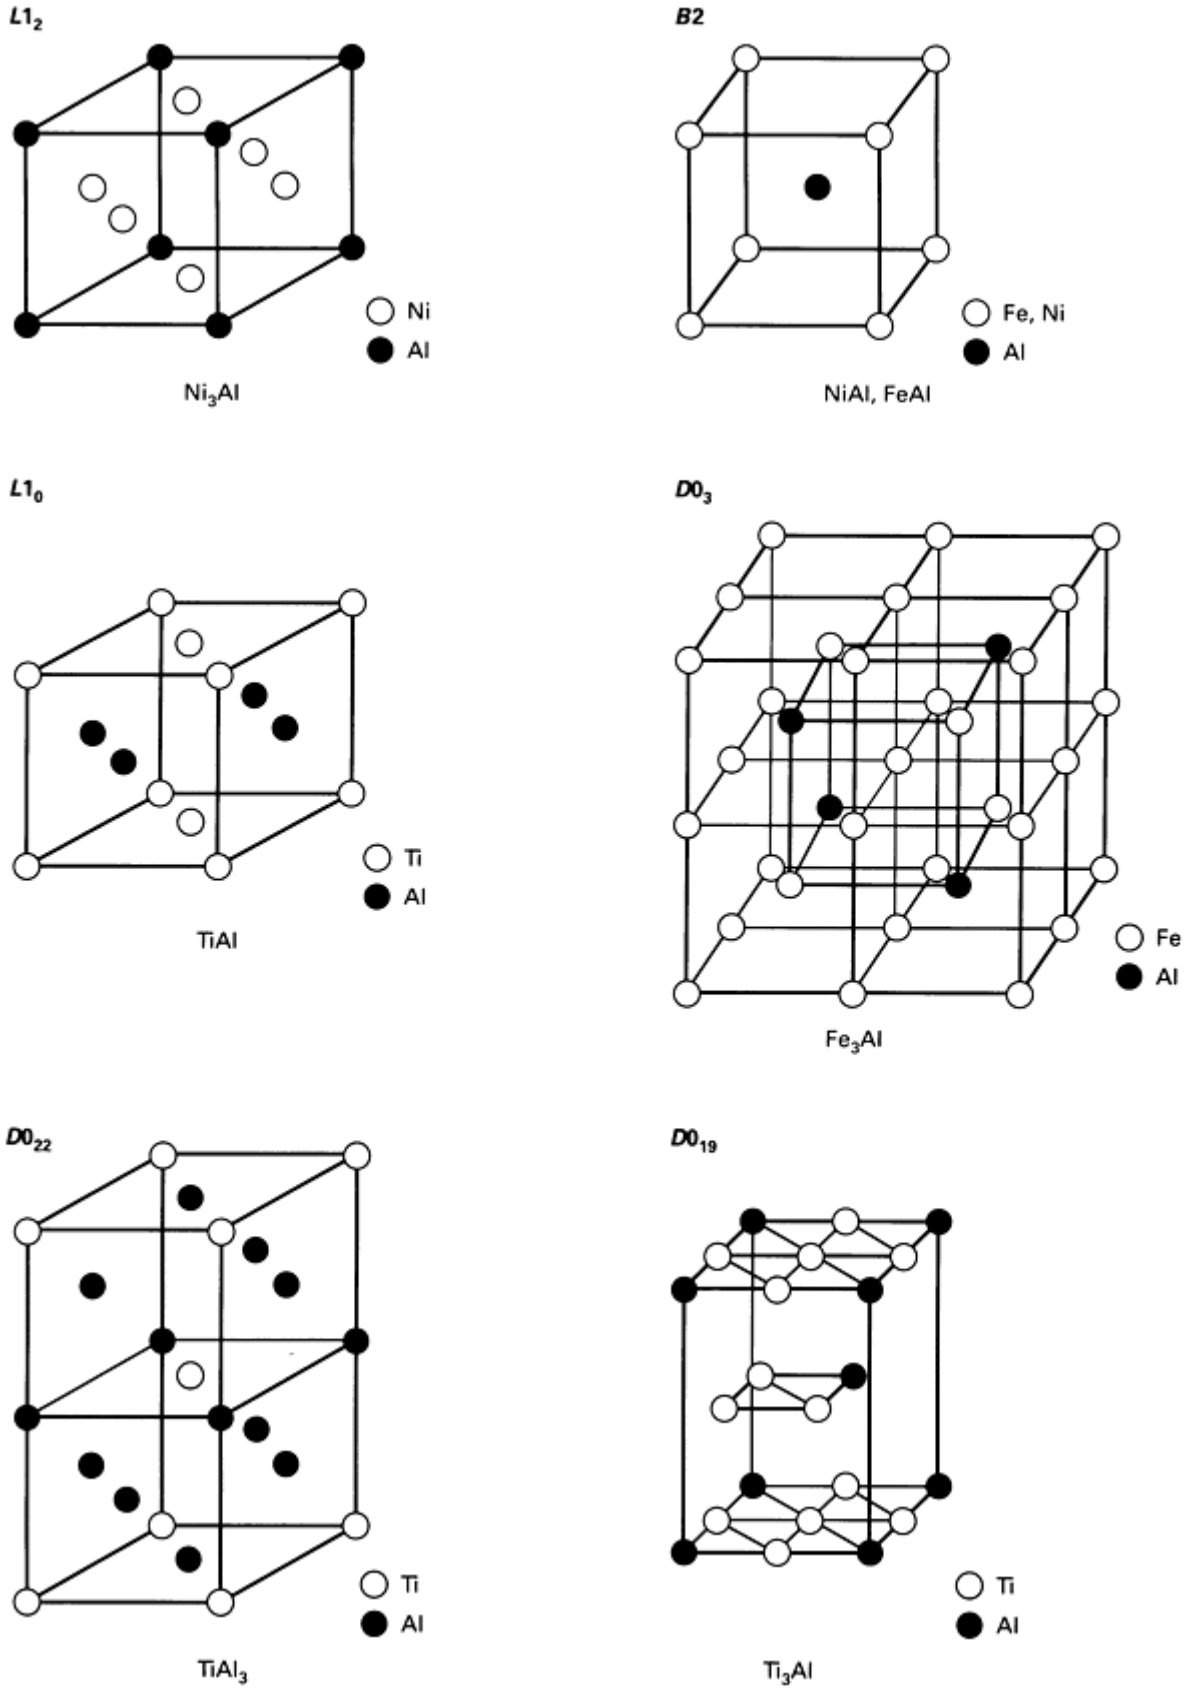

Fig. 3 Crystal structures of nickel, iron, and titanium aluminides

All of the aluminides discussed in this article suffer from low-temperature (room-temperature) embrittlement, which has been severe enough to preclude their use as structural materials. In several cases, however, metallurgical solutions have

been discovered that offer the possibility of engineering applications (Ref 22, 23, 24). This article summarizes research and development of nickel aluminides based on Ni_3Al and NiAl, iron aluminides based on Fe_3Al and FeAl, titanium aluminides based on Ti_3Al and TiAl, and other aluminides and intermetallics such as silicides; this article also provides a brief summary on applications of intermetallics.

This article focuses almost exclusively on compounds under development as structural materials. Information on other intermetallics, such as samarium-cobalt materials for permanent magnets and niobium-base superconductive materials, is available in the articles "Rare Earth Metals," "Permanent Magnet Materials," and "A15 Superconductors" in this Volume.

Nickel Aluminides

The nickel-aluminum phase diagram shows two stable intermetallic compounds, Ni_3Al and NiAl, formed on the nickel-rich end (Ref 36). The compound Ni_3Al has an $L1_2$ crystal structure, a derivative of the face-centered cubic (fcc) crystal structure; NiAl has a *B*2 structure, a derivative of the body-centered cubic (bcc) crystal structure (see Fig. 3). Because of the different crystal structures, the two nickel aluminides have quite different physical and mechanical properties.

Ni_3Al Aluminides

Intergranular Fracture and Alloying Effects. The aluminide Ni_3Al is of interest because of its excellent strength and oxidation resistance at elevated temperatures. As mentioned earlier, Ni_3Al is the most important strengthening constituent in nickel-base superalloys. Single crystals of Ni_3Al are ductile at ambient temperatures, but polycrystalline materials fail by brittle grain-boundary fracture with very little plasticity (Ref 19, 37, 38). This effect persists even in very high-purity materials where no grain-boundary segregation of impurities can be detected, suggesting that the brittleness is an intrinsic feature (Ref 19, 20, 39, 40). The observation of this characteristic turned attention toward a search for segregants that might act in a beneficial way.

Studies of segregants led to the startling discovery (Ref 18, 19, 20, 21) that small (~0.1 wt%) boron additions not only eliminated the brittle behavior of Ni_3Al but converted the material to a highly malleable form exhibiting tensile ductility as high as 50% at room temperature (Fig. 4) (Ref 19, 20). The beneficial effect of boron is, however, dependent on stoichiometry, and boron is effective in increasing the ductility of Ni_3Al only in alloys containing less than 25 at.% aluminum (Ref 20, 41). Both Auger spectroscopy (Ref 20) and imaging atom probe (Ref 42, 43, 44, 45) studies have demonstrated the strong segregation of boron to grain boundaries, although the extent of segregation varies along boundaries and even at different points along the same boundary. Segregation is less strong in aluminum-rich alloys (Ref 20). The beneficial effect of boron has been attributed to an increase in the intrinsic strength or cohesion of the grain boundary (Ref 20, 46, 47, 48, 49, 50) and enhancement of dislocation generation and facilitation of slip transmission across grain boundaries (Ref 51, 52, 53, 54). Both suggested mechanisms can be rationalized from boron-induced atomic disordering in the grain-boundary region (Ref 54, 55, 56, 57, 58).

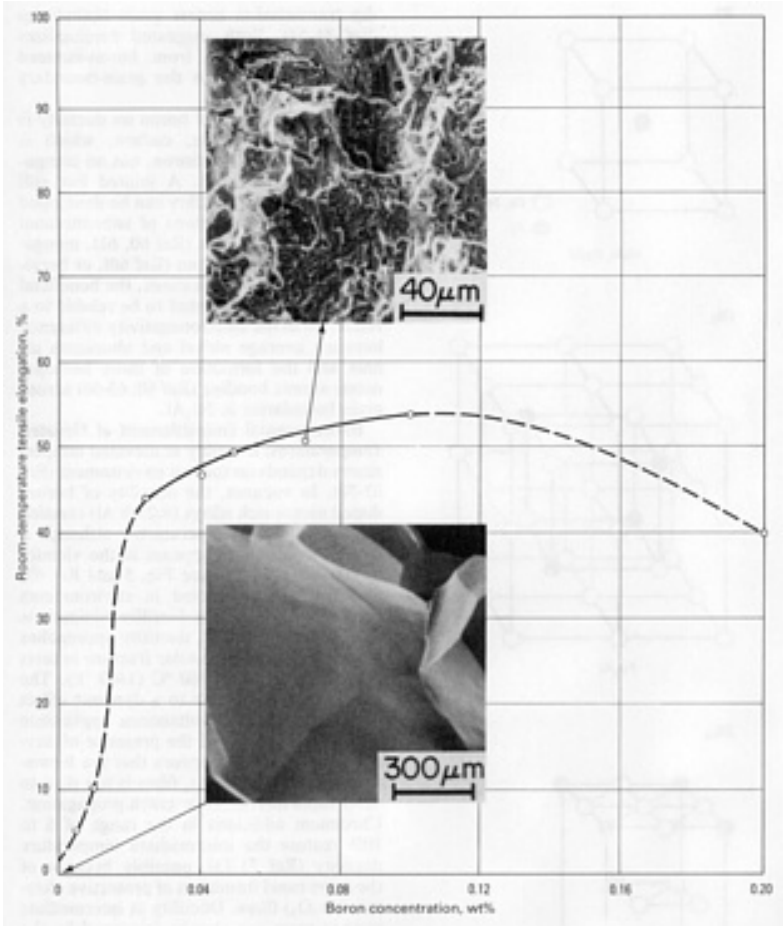

Fig. 4 Effect of boron additions on the room-temperature tensile elongation and fracture behavior of Ni_3Al (24 at.% Al)

The strong effect of boron on ductility is unique. For example, carbon, which is chemically similar to boron, has no comparable effect (Ref 59). A limited but still useful amount of ductility can be developed by much larger additions of substitutional elements such as iron (Ref 60, 61), manganese (Ref 60), chromium (Ref 60), or beryllium (Ref 62). In these cases, the beneficial effect has been suggested to be related to a reduction in the electronegativity difference between average nickel and aluminum atoms and the formation of more homogeneous atomic bonding (Ref 60, 63, 64, 65, 66) across grain boundaries in Ni_3Al.

Environmental Embrittlement at Elevated Temperatures. Ductility at elevated temperatures depends on the test environment (Ref 67, 68, 69, 70). In vacuum, the ductility of boron-doped nickel-rich alloys (<23% Al) remains high at all test temperatures, although a moderate minimum appears in the vicinity of 800 °C (1470 °F) (see Fig. 5 and Ref 67, 68). In tests conducted in environments containing oxygen, the ductility minimum is much deeper. In fact, ductility approaches zero with full intergranular fracture in tests conducted in air at 760 °C (1400 °F). The loss in ductility is due to a dynamic effect that requires the simultaneous application of a tensile stress and the presence of oxygen (Ref 67, 68, 69, 70). It appears that the formation of protective Al_2O_3 films is too slow to deter rapid intergranular crack propagation. Chromium additions in the range of 6 to 10% restore the intermediate temperature ductility (Ref 71, 72, 73), possibly because of the more rapid formation of protective chromia (Cr_2O_3) films. Ductility at intermediate temperatures can also be improved by the production of an elongated grain structure in Ni_3Al (Ref 74).

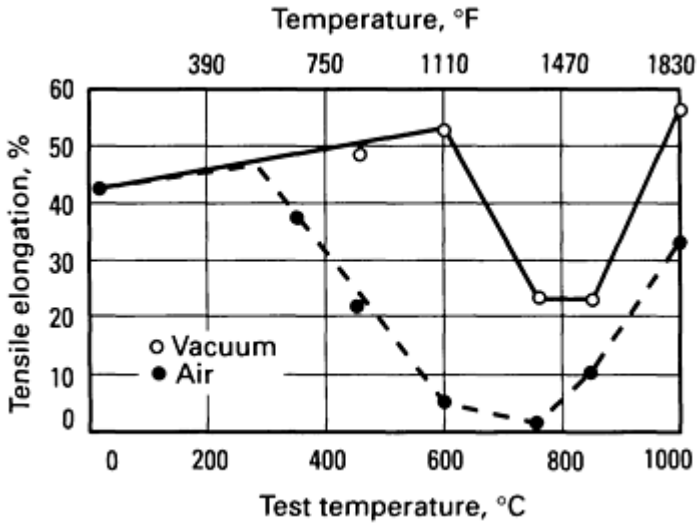

Fig. 5 Tensile elongation of alloy IC-145 (Ni-21.5Al-0.5Hf-0.1B at.%) in vacuum and in air

Anomalous Dependence of Yield Strength on Temperature. Ni_3Al is one of a number of intermetallic alloys that exhibit an engineering yield strength (0.2% offset) that increases with increasing temperature (Ref 6, 7, 9). This is shown in Fig. 6, which is a plot of yield stress as a function of test temperature. The anomalous yielding effect, which is lower at lower strains, occurs because of extremely rapid work hardening. The work hardening in caused by the cross slip of screw dislocation segments from the primary {111} slip planes to {100} planes, where they become pinned and much less mobile (Fig. 7). Driving forces for cross slip include anisotropy of the energy of antiphase boundaries formed between the superdislocation pairs required for deformation in the ordered lattice (Ref 9, 10, 76, 77) and the torque exerted between the screw dislocation pairs arising from elastic anisotropy (Ref 11, 12). In either case, the cross slip pinning process is thermally activated, which leads to the positive temperature dependence of the yield strength shown in Fig. 6. The reduction of yield strength at high temperatures occurs because of enhanced dislocation mobility on {100} planes, which reduces the effectiveness of the pinning centers formed by the cross slip process. The anomalous yielding behavior makes Ni_3Al stronger than many commercial solid-solution alloys (such as type 316 stainless steel and Hastelloy alloy X) at elevated temperatures (Fig. 6).

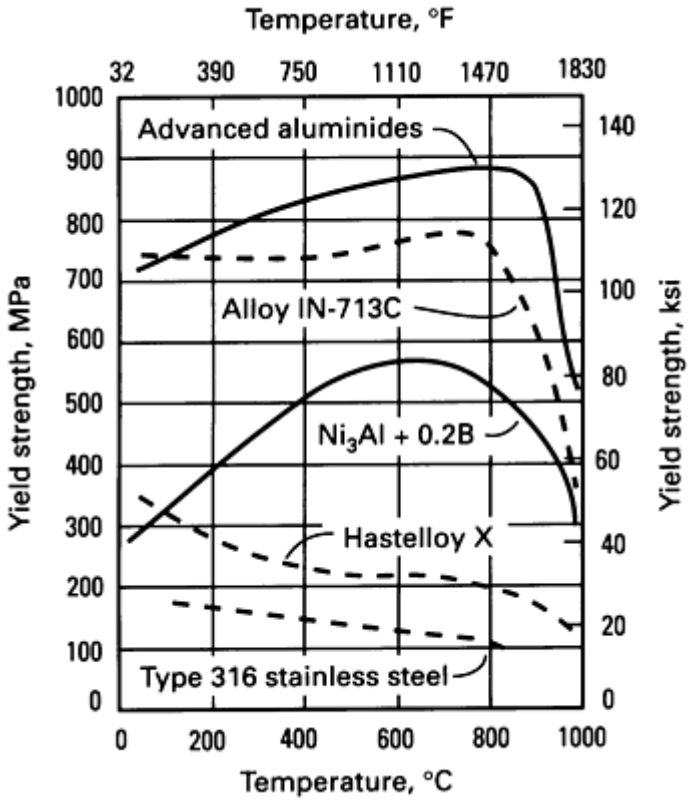

Fig. 6 Yield strength versus test temperature for Ni_3Al alloys, two superalloys, and type 316 stainless steel. Source: Ref 75

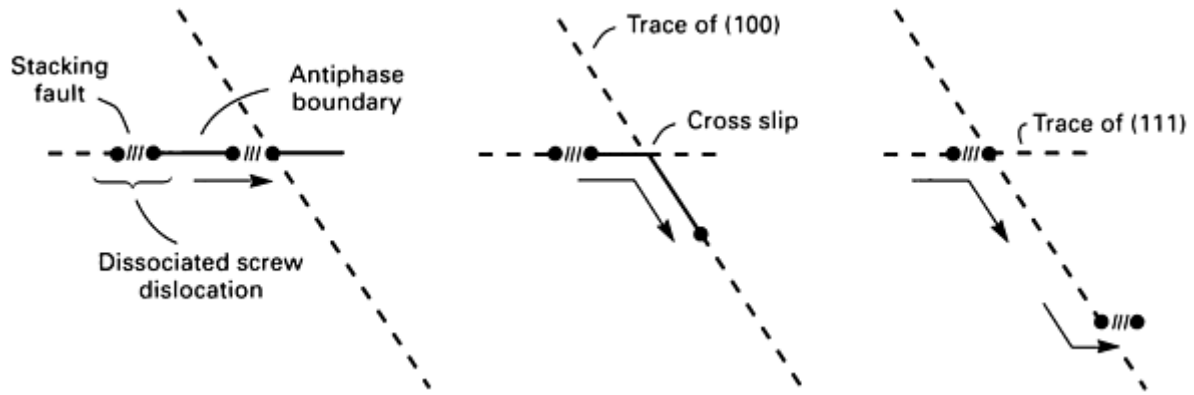

Fig. 7 Mechanism of cross-slip pinning as proposed in Ref 76 (after Ref 77)

Solid-Solution Hardening. Ni_3Al doped with boron serves as a design base for ductile and strong materials for structural uses. The aluminide is capable of being hardened by solid-solution effects because it can dissolve substantial alloying additions without losing the advantage of long-range order. One study constructed the solubility lobes of ternary Ni_3Al phase ($L1_2$) at 1000 °C (1830 °F) for various alloying elements (Ref 35). The elements that dissolve substantially in Ni_3Al can be divided into three groups (Fig. 8). The first group of elements, including silicon, germanium, titanium, vanadium, and hafnium, substitutes almost exclusively on aluminum sublattice sites. The second group, consisting of copper, cobalt, and platinum, substitutes on nickel sublattice sites. The third group, which includes elements such as iron, manganese, and chromium, substitutes on both sublattice sites. Guard and Westbrook (Ref 5) first suggested that the electronic structure (that is, the position of elements in the periodic table) rather than the atom size factor plays a dominant role on the substitution behavior. The extent of solid solution in Ni_3Al, however, is controlled by the atomic size misfit and the difference in the heats of formation between Ni_3Al and Ni_3X.

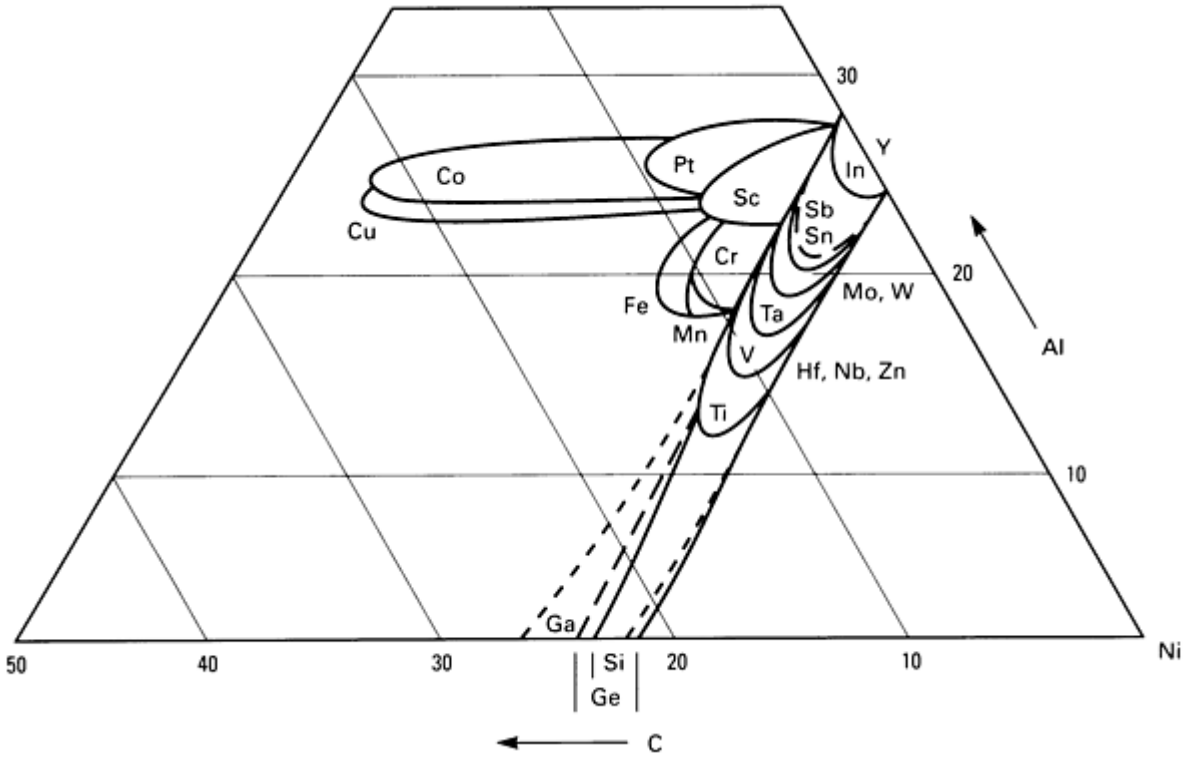

Fig. 8 Semischematic depiction of the solubility lobes of ternary Ni_3Al phase around 1000 °C (1830 °F). Source: Ref 35

The room-temperature solid-solution hardening of Ni_3Al depends on the substitutional behavior of alloying elements, atomic size misfit, and the degree of nonstoichiometry of the alloy. A review of the mechanical properties of Ni_3Al indicated that it could be hardened more effectively by the elements substituting on aluminum sites and, to a lesser degree, by the elements substituting on nickel or on both nickel and aluminum sites (Ref 78). In addition, the strengthening is most pronounced for stoichiometric alloys and aluminum-rich alloys; it is much less pronounced for nickel-rich alloys. The solid-solution hardening is quite complex at elevated temperatures (Ref 79, 80). The hardening effects depend strongly on crystal orientation and test temperature, which cannot be explained by the classic solid-solution models developed based on the elastic interaction between dislocations and symmetric defects (Ref 81). For example, hafnium is found to be more effective in hardening at 850 °C (1560 °F) than at room temperature (Ref 75). These observations suggest that the unusual hardening is related to how solutes affect the cross slip pinning processes occurring at elevated temperatures. Hafnium and zirconium are most effective in strengthening Ni_3Al at elevated temperatures (Ref 75, 82). Solid-solution hardening is the subject of current studies (Ref 83).

Mechanical Properties. The study of ductility and strength of Ni_3Al has led to the development of ductile nickel aluminide alloys for structural applications (Ref 17, 84, 85). The alloys generally contain hafnium, zirconium, tantalum, and molybdenum at levels up to 5 at.% for improving strength at elevated temperatures; they contain up to 10 at.% Cr for enhancing ductility at intermediate temperatures (400 to 900 °C, or 750 to 1650 °F). Boron at levels less than 500 ppm is added for strengthening grain boundaries and increasing ductility at ambient temperature. Figure 6 shows the yield strength of a cast Ni_3Al alloy, which is stronger than nickel-base alloy IN-713C at elevated temperatures. The Ni_3Al alloys generally possess ductilities of 25 to 40% at temperatures up to 700 °C (1290 °F), and 15 to 30% at up to 1000 °C (1830 °F) in air. The chromium-containing Ni_3Al alloys generally contain 5 to 15% of disordered (γ) phase, the amount of which depends on the aluminum concentration.

Creep properties of Ni_3Al alloys have been characterized as functions of stress, temperature, and composition. Hafnium and zirconium additions are most effective in improving the creep resistance of Ni_3Al (Ref 71). Figure 9 shows creep data for the polycrystalline nickel aluminide alloy IC-221 (Ni-16.1Al-8.0Cr-1.0Zr-0.8B, at.%). The creep properties of Ni_3Al alloys, like those of nickel-base superalloys, are sensitive to grain size, but the Ni_3Al alloys have better creep resistance for coarse-grain materials (for example, cast materials). For applications where creep resistance is important, coarse-grain material is more desirable at temperatures greater than 700 °C (1290 °F). Creep properties of single-crystal Ni_3Al alloys containing refractory elements such as tantalum have been studied at temperatures up to 1000 °C (1830 °F) (Ref 85). In

general, the creep resistance of Ni_3Al is comparable to that of most of the nickel-base superalloys, but it is not as good as that of some advanced single-crystal nickel-base superalloys used for jet engine turbine blades.

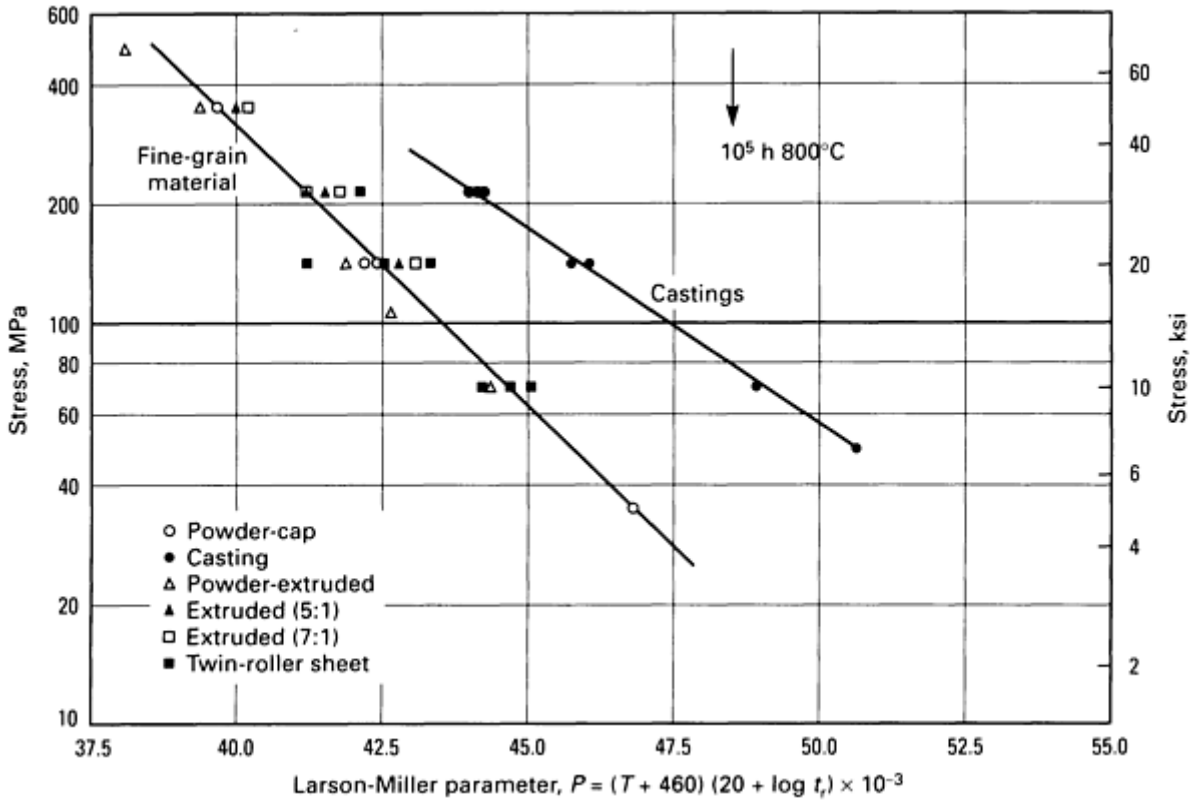

Fig. 9 Larson-Miller parameter (*P*) plot showing the effect of processing on the creep-rupture properties of lC-221 (Ni-16.1Al-8Cr-1Zr-0.8B, at.%). Tests were conducted in the temperature range of 650 to 870 °C (1200 to 1600 °F) for times ranging from 10 to 12 464 h. Source: Ref 84

Fatigue and fatigue crack growth are substantially better in Ni_3Al alloys than in nickel-base superalloys in tests below the range of the ductility minium (Ref 86, 87, 88); see Fig. 10 for room-temperature fatigue crack growth. The good fatigue resistance of Ni_3Al and other ordered intermetallic alloys has been attributed to fine planar slip and superlattice dislocation structure. Dynamic embrittlement in oxidizing environments severely reduces the fatigue resistance of Ni_3Al at temperatures above 500 °C (930 °F) (Ref 86); however, this problem has been alleviated by adding moderate amounts (for example, 8 at.%) of chromium to Ni_3Al (Ref 86, 87, 88). Fatigue/creep interactions in single crystals and directionally solidified Ni_3Al alloys have been characterized for temperatures up to 800 °C (1470 °F) (Ref 89, 90). Limited results indicate that the performance of single-crystal Ni_3Al alloyed with hafnium and boron is superior to that of Udimet 115 at 760 °C (1400 °F).

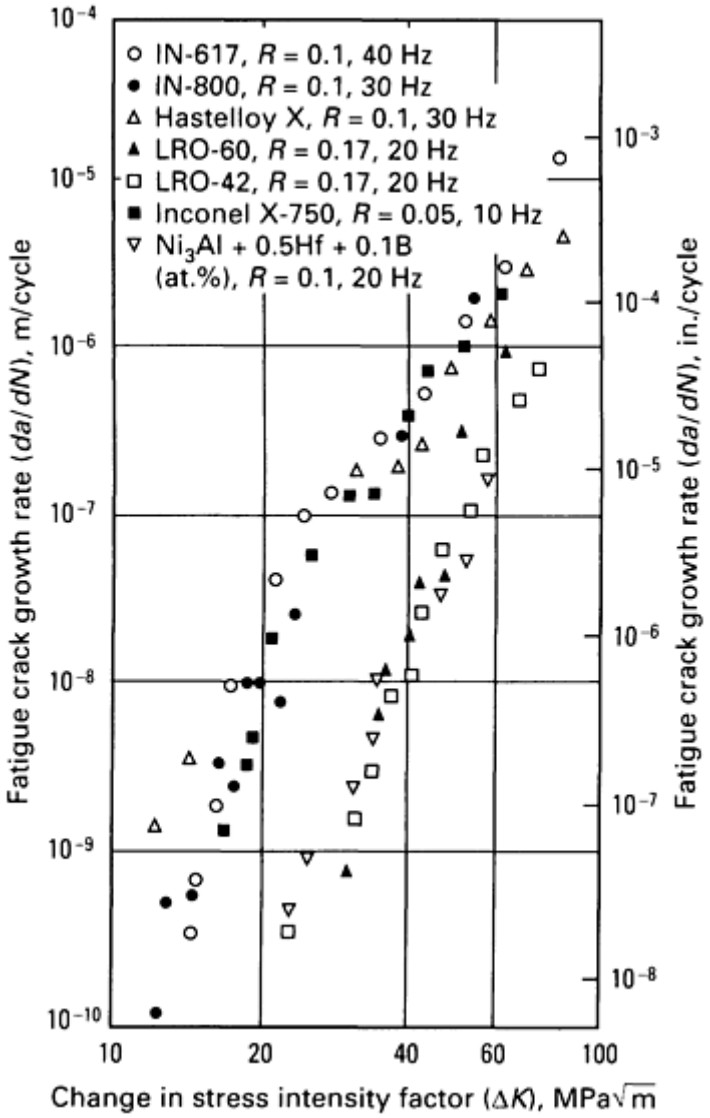

Fig. 10 Crack growth rates of nickel aluminide (Ni-23.5Al-0.5Hf-0.1B, at.%), LRO alloys [$(Fe, Ni)_3(V,Ti)$], and several high-temperature alloys tested in air at 25 °C (80 °F). Source: Ref 87

Processing and Fabrication. Alloys based on Ni_3Al are susceptible to weld cracking; however, if welding is done with care, sound welds can be made in most of the alloys (Ref 91, 92, 93). Welding speed should be reduced, and the boron level has to be limited to about 0.1 at.% to avoid hot cracking. Oxygen is particularly detrimental: Oxide scale on alloy surfaces should be removed prior to welding, and the atmosphere must be controlled to reduce oxygen during welding. Certain alloying additions (iron, for example) have been found to promote weldability.

The unique strength and ductility characteristics of Ni_3Al present correspondingly unique challenges and opportunities in the processing of the aluminide alloys (Ref 71, 84, 94). The alloys generally show excellent ductility at ambient temperatures; however, their hot ductility is sensitive to test temperature, grain size, and alloy composition. Conventional fabrication techniques (such as hot rolling for large ingots) are ineffective because regions near the surface cool to the range of the ductility minimum, which leads to the formation of large intergranular surface cracks. Isothermal forging offers excellent possibilities for fabrication because the alloys exhibit superplastic behavior above about 1000 °C (1830 °F). Conventional hot forging is feasible for fine-grain alloys containing less than 0.3 at.% Zr or Hf. Cold fabrication is effective if the materials can be cast into sheet or rod forms that can be cold formed further without the need for repeated recrystallization treatments. Figure 11 is a photograph of direct cast sheets of alloy IC-218 (Ni-16.7Al-8.0Cr-0.4Zr-0.08B, at.%). The as-cast sheet has excellent ductility and is ready to be fabricated into wrought material by cold rolling. Hot extrusion of powder metallurgy materials is another effective fabrication method for Ni_3Al alloys.

Fig. 11 Direct cast sheets of IC-50 (Ni-23.5Al-0.5Zr-0.08B, at.%) and IC-218 (Ni-16.7Al-8.0Cr-0.4Zr-0.08B, at.%) Ni_3Al alloys. Source: Ref 84

Structural Applications. Although the properties of alloys based on alloys on Ni_3Al approach those of established superalloys, the Ni_3Al alloys are unlikely to displace superalloys in aircraft engine applications. The opportunity exists, however, for enhancing the properties of Ni_3Al alloys further through the incorporation of second phases. In addition, alloys based on Ni_3Al could provide an attractive matrix for composite development (Ref 95, 96, 97, 98, 99). Monolithic aluminide alloys are likely to find near-term use in applications that take advantage of some of their unique or unusual properties (Ref 84). The potential applications (and the properties they would exploit) include:

- Gas, water, and steam turbines (the excellent cavitation, erosion, and oxidation resistance of the alloys)
- Aircraft fasteners (low density and ease of achieving the desired strength)
- Automotive turbochargers (high fatigue resistance and low density)
- Pistons and valves (wear resistance and capability of developing a thermal barrier by high-temperature oxidation treatment)
- Bellows for expansion joints to be used in corrosive environments (good aqueous corrosion resistance)
- Tooling (high-temperature strength and wear resistance developed through preoxidation)
- Permanent molds (the ability to develop a thermal barrier coating by high-temperature oxidation)

NiAl Aluminides

Nickel-aluminum containing more than about 40 at.% Ni starts to form a single-phase B2-type ordered crystal structure based on the bcc lattice (Ref 36). In terms of physical properties, *B*2 NiAl offers more potential for high-temperature applications than $L1_2$ Ni_3Al. It has a higher melting point (1638 °C, or 2980 °F), a substantially lower density (5.86 g/cm^3 for NiAl versus 7.50 g/cm^3 for Ni_3Al), and a higher Young's modulus (294 GPa, or 42.7×10^6 psi, versus 179 GPa, or 25.9×10^6 psi). In addition, NiAl offers excellent oxidation resistance at high temperatures (Ref 30, 100). In the 1950s and 1960s, NiAl alloys were employed as coating materials for hot components in corrosive environments. The oxidation resistance of NiAl can be further improved by alloying with yttrium and other refractory elements such as hafnium and zirconium (Ref 101, 102).

Structure and Property Relationships. The use of NiAl in structural members suffers two major drawbacks: poor ductility at ambient temperatures and low strength and creep resistance at elevated temperatures. Single crystals of NiAl are quite ductile in compression, but both single and polycrystalline NiAl appear to be brittle in tension at room temperature. The nickel aluminide exhibits mainly {100} slip, rather than {111} slip as commonly observed for bcc materials (Ref 103, 104, 105). The lack of sufficient slip systems has been regarded as the major cause of low ductility in NiAl. The aluminide shows a sharp increase in ductility above 400 °C (750 °F) and becomes very ductile above 600 °C (1110 °C) (Ref 38, 106); therefore, fabrication of NiAl at high temperatures presents no major problems.

The ordered *B*2 structure exists in NiAl over a solubility range of about 15 at.%. Deviations from stoichiometry are accommodated by the incorporation of vacancies in aluminum-rich alloys and by the formation of antisite defects in nickel-rich alloys (Ref 31, 32, 33, 34). The presence of lattice defects has a strong effect on low-temperature strength, with minimum strength occurring at the stoichiometric composition (Fig. 12). The minimum becomes less pronounced with increasing temperature and is essentially eliminated at 600 °C (1110 °F). At all compositions, the yield strength decreases with increasing temperature (Ref 38, 106). Abrupt drops in strength in the range of 400 to 600 °C (750 to 1110 °F) are accompanied by a sharp increase in ductility. The alloys are highly ductile but extremely weak at higher temperatures. For example, Ni-50Al (at.%) showed a yield strength of 35 MPa (5 ksi) and a tensile ductility of greater than 50% at 1000 °C (1830 °F) (Ref 38, 108).

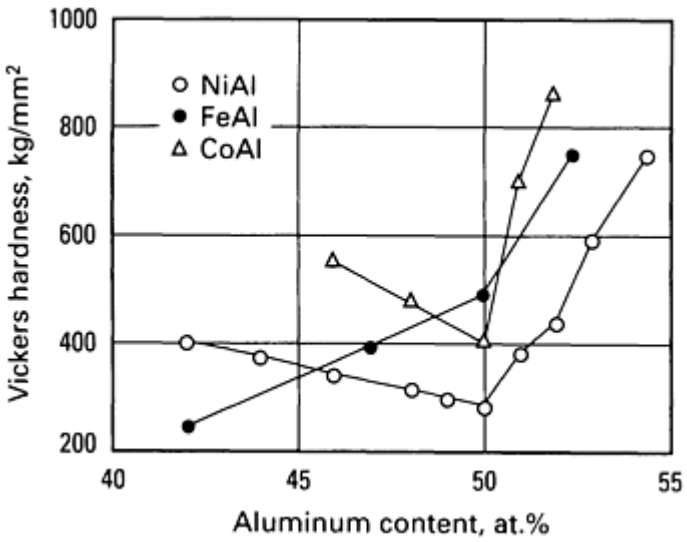

Fig. 12 Vickers hardness of CoAl, FeAl, and NiAl as a function of aluminum content. Source: Ref 107

NiAl is quite weak in creep at elevated temperatures (Ref 108, 109, 110, 111). However, its creep properties can be substantially improved by alloy additions (Ref 109). Figure 13 shows the compressive creep rate of NiAl alloyed with up to 5 at.% ternary additions. The strength at 1300 K of alloys containing tantalum, niobium, and hafnium is comparable to or even greater than that of the superalloy IN-100. These alloying elements showed very low solubility in NiAl, and the improvement apparently comes from the precipitation of fine second-phase particles that impede the motion of dislocations. It has recently been reported that alloying with 15 at.% Fe to replace nickel lowers diffusion rates and thus reduces the creep rate of NiAl (Ref 110).

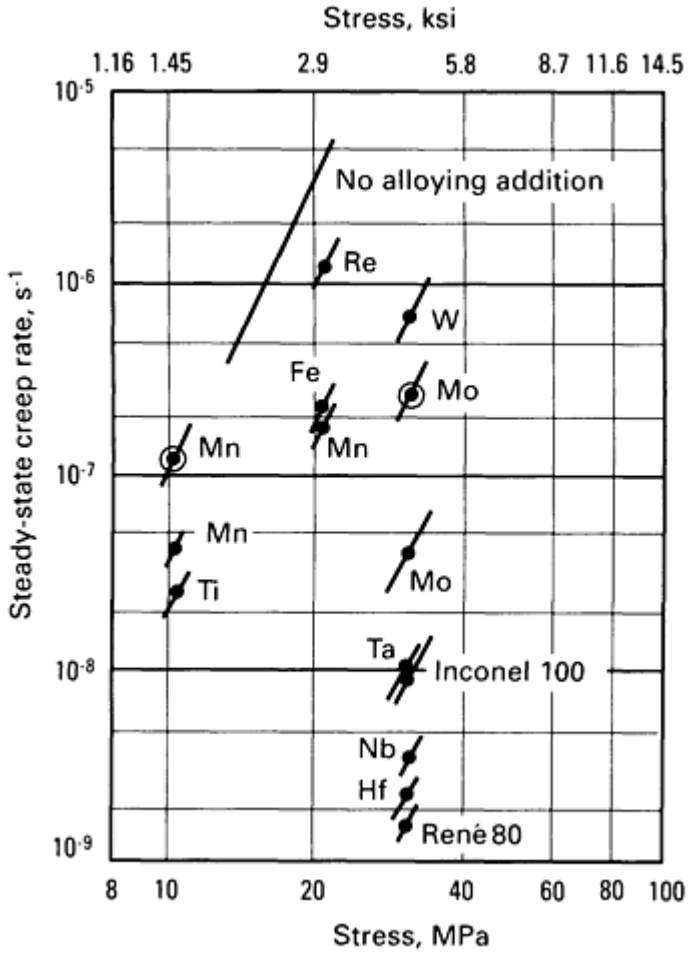

Fig. 13 Compressive creep data for NiAl alloys containing various alloying elements tested at 1300 K. Data for selected conventional superalloys are provided for comparison. Lines drawn through data points are expected slopes. Source: Ref 109

Effect of Grain Size and Alloy Stoichiometry on Ductility. Considerable efforts have been devoted to improving the ductility of NiAl at ambient temperatures by controlling microstructure and alloy additions. Schulson and Bakrer (Ref 112) studied ductile-to-brittle transition as a function of grain size and temperature for NiAl and other aluminides and silicides. NiAl specimens produced by hot extrusion of powder metallurgy (P/M) material, even those with extremely fine grain sizes, were brittle at ambient temperatures. They found that grain refinement alone did not improve the room-temperature ductility of NiAl. On the other hand, NiAl (49 at.% Al) showed a sharp brittle-to-ductile transition at a critical grain size at elevated temperatures. For example, NiAl exhibited a sharp increase in ductility at 400 °C (750 °F) for grain sizes less than 20 μm (Fig. 14). A tensile elongation of 40% was achieved at 400 °C (750 °F) for NiAl with a grain size of 3 μm.

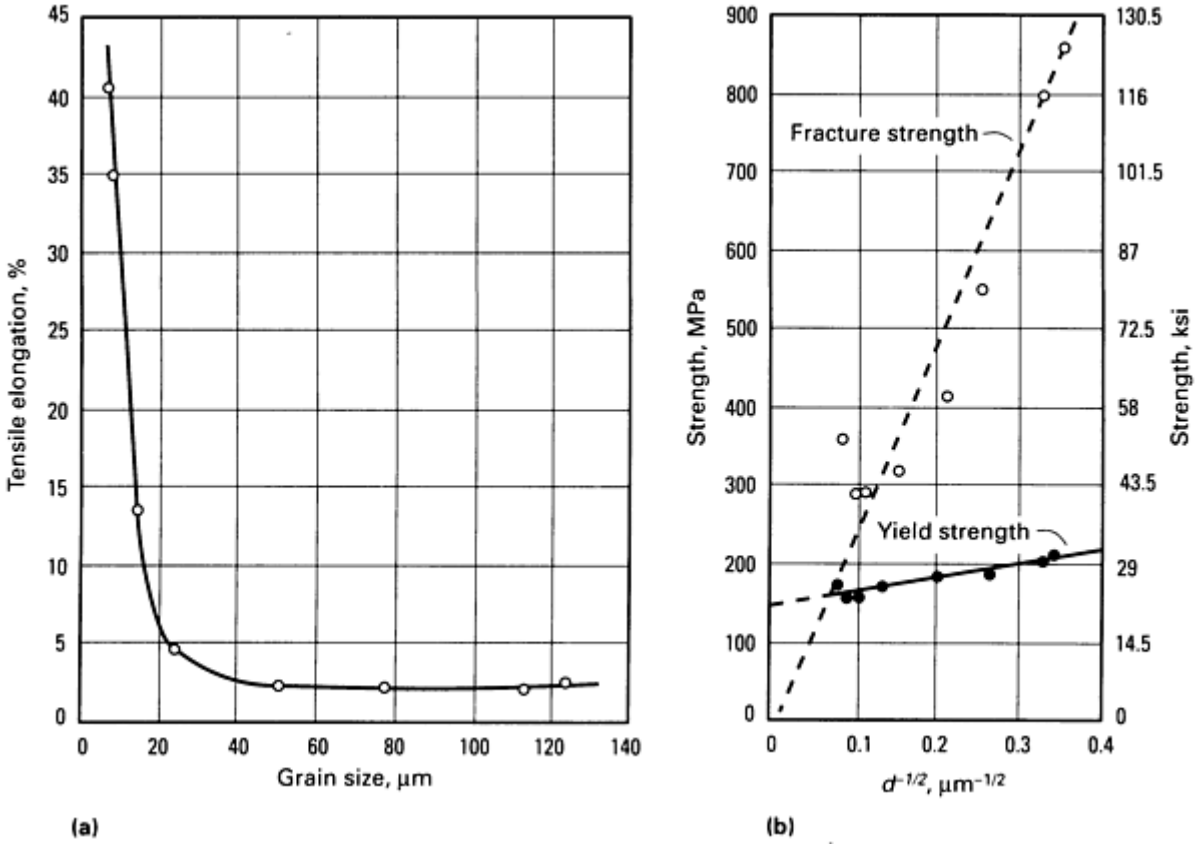

Fig. 14 Effect of grain side (*d*) on properties of NiAl at 673 K. (a) Tensile elongation. (b) Yield strength and fracture strength. Source: Ref 112)

Hahn and Vedula (Ref 106) recently investigated tensile elongation and fracture behavior as functions of aluminum concentration in NiAl prepared by hot extrusion of cast ingots. They found that NiAl alloys with off-stoichiometric compositions fractured with no appreciable plastic deformation, whereas an alloy with a near-stoichiometric composition exhibited significant tensile elongation (~2%) at both room temperature and 200 °C (390 °F) (Fig. 15). Their findings essentially confirm previous results reported in Ref 113. Although the stoichiometric effect is not well understood at the present time, it is believed that yield strength plays a dominant role in the ductility observed for near-stoichiometric NiAl. As indicated in Fig. 15, the yield strength for the near-stoichiometric composition (Ni-50.3Al) is distinctly lower than that for off-stoichiometric compositions. The low yield strength apparently prevents the initiation and propagation of brittle fracture until a high stress level is reached by strain hardening through plastic deformation.

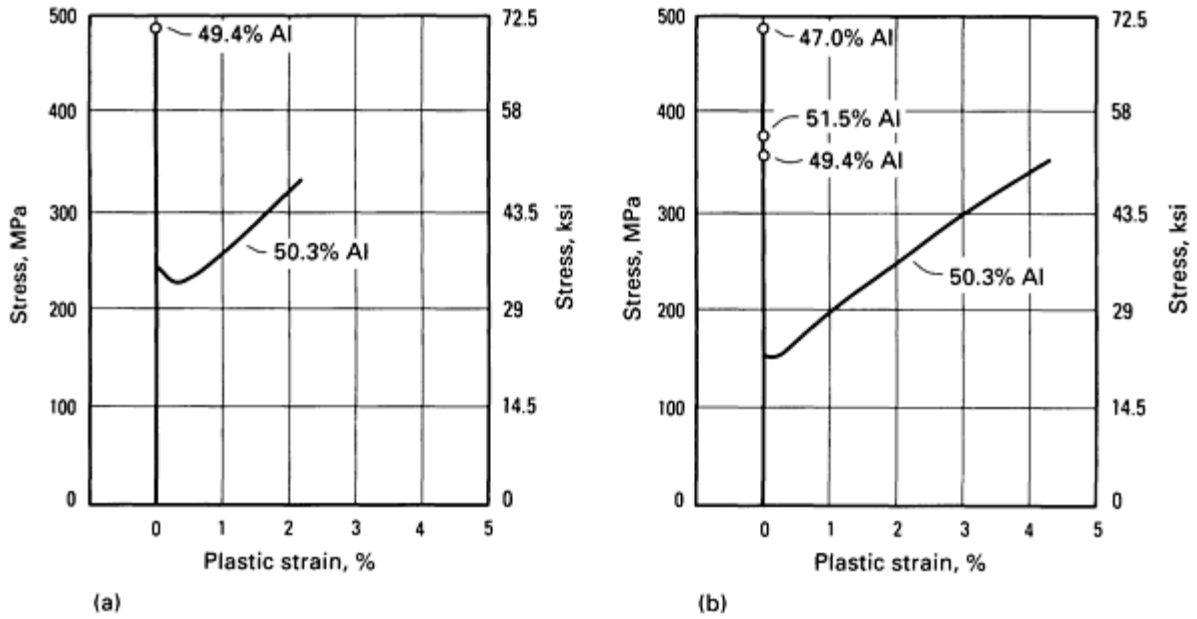

Fig. 15 Effect of stoichiometry on tensile properties of cast and extruded binary NiAl alloys. Nominal strain rate, 1.41×10^{-3}/s. (a) Tested at room temperature. (b) Tested at 473 K. Source: Ref 106

Alloying Effect and Ductility Improvement. Because NiAl with on- and off-stoichiometric compositions shows mainly brittle intergranular fracture (Ref 106), it is possible to improve its ductility by the control of grain-boundary composition through microalloying. Auger analyses have revealed that grain boundaries in NiAl (50% Al) are clean and free of any segregated impurities (Fig. 16), indicating that they are intrinsically brittle (Ref 114). Boron added to NiAl has a strong tendency to segregate to the grain boundaries and suppress intergranular fracture (Fig. 16). However, there is no attendant improvement in tensile ductility because boron is an extremely potent solid-solution strengthener in NiAl. Unlike boron, both carbon and beryllium are ineffective in suppressing intergranular fracture in NiAl. Beryllium slightly improves the room-temperature tensile ductility of NiAl. In these microalloyed alloys, the nickel and aluminum contents of the grain boundaries are not significantly different from the bulk levels, and no evidence of strong boron-nickel cosegregation has been found (Ref 114).

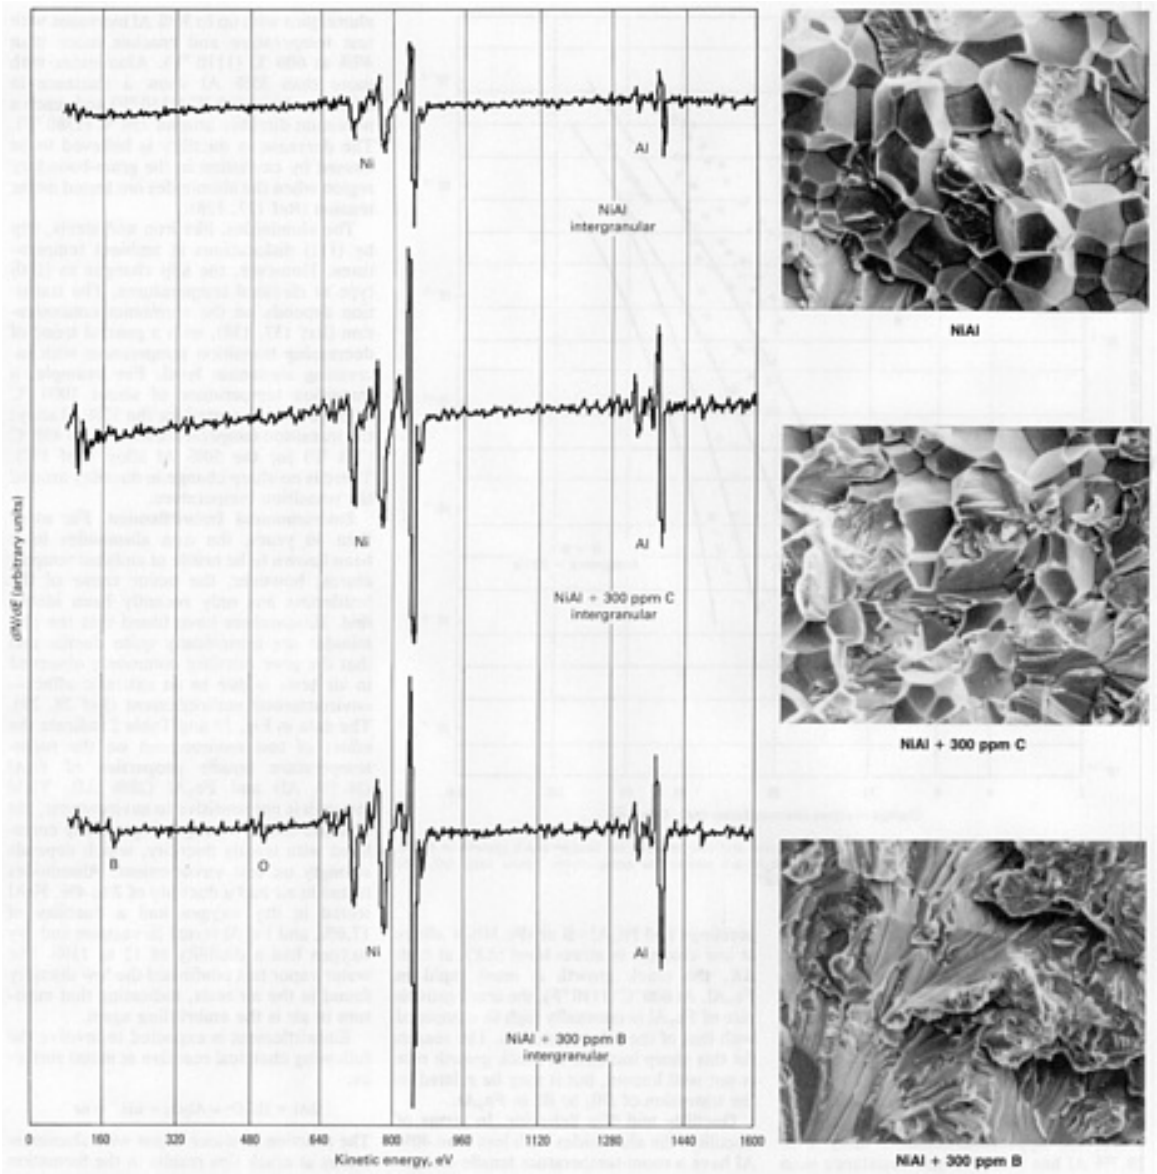

Fig. 16 Results of Auger electron analysis showing the effect of microalloying on the grain-boundary composition and the room-temperature fracture mode of NiAl. Top to bottom: unalloyed NiAl (mainly grain-boundary fracture), NiAl doped with 300 ppm C, and NiAl doped with 300 ppm B. All photomicrographs 400×. Source: Ref 114

Attempts have also been made to improve room-temperature ductility by macroalloying NiAl with alloy additions that might change its deformation behavior in bulk material. Additions of chromium, manganese, and vanadium were reported to promote <111> slip vectors in NiAl; however, no improvement in ductility was observed (Ref 115, 116). On the other hand, limited tensile ductility was obtained in NiAl alloyed with cobalt (Ref 117), which promotes additional deformation modes through possibly martensitic transformation. Sufficient iron additions to nickel-rich NiAl, such as Ni-30Al-20Fe (at.%) with a B2 structure, also result in approximately 2% plastic elongation (Ref 118). The same alloy with a fine-grain structure shows 5% elongation when produced by a rapid solidification technique (Ref 119). The alloy Ni-20Al-30Fe, which has a two-phase structure (NiAl + Ni_3Al), exhibited a tensile ductility of 22% when produced by hot extrusion (Ref 120) and a lower ductility (10 to 17%) when produced by rapid solidification (Ref 119, 121).

Potential and Future Work. Although significant progress has been made, NiAl has not yet developed into an engineering material for structural use. Further efforts must be devoted to improving both low-temperature ductility and high-temperature strength. The design options offered by NiAl are certainly attractive enough to motivate additional research into the development of NiAl alloys. At present, major NiAl development efforts are going on in a number of laboratories. NiAl and its alloys are also attractive as matrix materials for intermetallic composites, and a great deal of work has been conducted in this area (Ref 122).

Iron Aluminides

Phase Stability and Potential for Structural Use. Iron aluminides form bcc ordered crystal structures over the composition range of 25 to 50 at.% (Ref 36). The aluminide Fe_3Al exists in the ordered $D0_3$ structure up to 540 °C (1000 °F) and in the $B2$ structure between 540 and 760 °C (1000 and 1400 °F); it has a disordered structure above 760 °C (1400 °F). The $D0_3 \rightarrow B2$ transition temperature decreases and the $B2$ ordered temperature increases with an increase in aluminum concentration above 25%. Only the $B2$ structure is stable at aluminum levels above 36%, and the single-phase field extends to approximately 50 at.% Al (FeAl).

The iron aluminides based on Fe_3Al and FeAl possess unique properties and have development potential as new materials for structural use. This potential is based on the capability of the aluminides to form protective aluminum oxide scales in oxidizing and sulfidizing environments at elevated temperatures (Ref 123, 124, 125, 126). In addition to excellent corrosion resistance, the aluminides offer low material cost, low density, and conservation of strategic elements. However, the major drawbacks of the aluminides are their low ductility and fracture toughness at ambient temperature and their poor strength at temperatures above 600 °C (1110 °F). Recently, considerable efforts have been devoted to understanding and improving their mechanical properties through control of grain structure, alloy additions, and material processing.

Mechanical Behavior of Fe_3Al and FeAl. The aluminides show low ductility and brittle fracture at room temperature and their fracture mode depends on aluminum concentration. The aluminides containing less than 40 at.% Al exhibit mainly transgranular cleavage fracture, whereas those with more than 40% Al show essentially brittle intergranular fracture (Ref 127, 128, 129, 130, 131). The fracture mode is also sensitive to other parameters such as grain size and impurities. Fe_3Al (25 at.% Al) has been reported to fracture intergranularly when it contains excess carbon (Ref 132). Also, some FeAl alloys with less than 40% Al show grain-boundary fracture when prepared by P/M techniques and contaminated with oxygen (Ref 128).

Mechanical properties of the iron aluminides have been characterized as functions of test temperature and alloy composition in a number of studies (Ref 127, 128, 129, 130, 131). In general, yield strength is not sensitive to temperature below 600 to 650 °C (1110 to 1200 °F); above that temperature range, strength shows a sharp drop with temperature. For intermediate and coarse-grain materials, the aluminides with less than about 40% Al generally show a small increase in yield strength with temperature, with strength reaching a peak at temperatures of about 550 to 650 °C (1020 to 1200 °F). For the aluminides with higher levels of aluminum, the increase in yield strength is suppressed, possibly because of grain-boundary sliding at elevated temperatures (Ref 127, 128, 131).

The room-temperature yield strength of Fe_3Al that contains approximately 25 at.% Al is quite high (550 to 700 MPa, or 80 to 100 ksi) because of the low mobility of single dislocations and particle strengthening due to the presence of a disordered bcc phase (Ref 131, 133). Strength decreases with increasing aluminum concentration and reaches a minimum at an aluminum content of about 30%. With further increase in aluminum concentration, strength shows a moderate increase. Unlike NiAl, the FeAl aluminide shows a substantial increase in strength and hardness when it approaches a stoichiometric composition (Fig. 12). The cause for this different behavior is not well understood at the present time.

The fatigue and crack growth behavior of Fe_3Al alloys have been studied as functions of aluminum concentration (23.7 to 28.7 at.% Al) and test temperature (20 to 600 °C, or 70 to 1110 °F) (Ref 87). At room temperature, the hyperstoichiometric alloy with 28.7% Al has better fatigue resistance than the hypostoichiometric alloy with 23.7% Al. The better fatigue properties of the higher-aluminum alloys have been attributed to the presence of superdislocations, which cause crack initiation to be more difficult than in the hypostoichiometric alloy. However, the trend is reversed at 500 °C (930 °F). Figure 17 compares the crack growth behavior of Fe_3Al with that of other materials. At room temperature and 500 °C (930 °F), Fe_3Al aluminides are generally intermediate in crack growth rates between nickel-base superalloys and Ni_3Al + B or $(Fe,Ni)_3V$ alloys at low changes in stress level (ΔK); at high ΔK, the crack growth is most rapid in Fe_3Al. At 600 °C (1110 °F), the crack growth rate of Fe_3Al is unusually high as compared with that of the other materials. The reason for this sharp increase in crack growth rate is not well known, but it may be related to the transition of $D0_3$ to $B2$ in Fe_3Al.

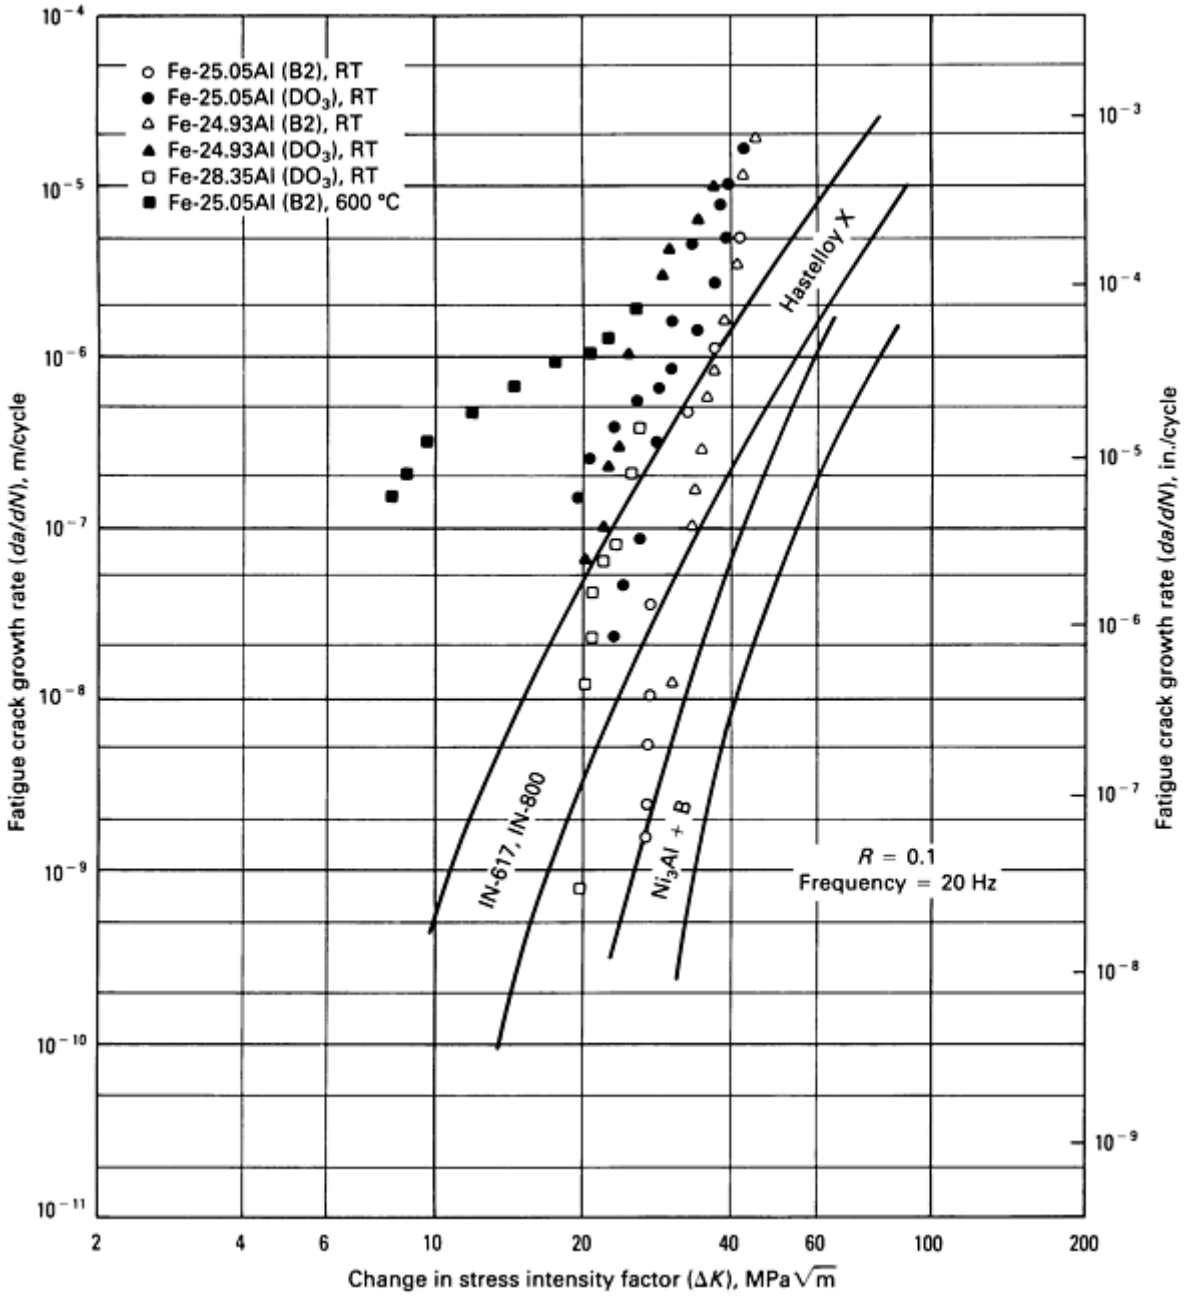

Fig. 17 Effects of aluminum content, crystal structure, and temperature on fatigue crack growth in Fe_3Al. Curves for nickel-base superalloys and Ni_3Al are shown for comparison. Stress ratio (R), 0.1; frequency, 20 Hz. RT, room temperature. Source: Ref 87

Ductility and Slip Behavior. In terms of ductility, the aluminides with less than 40% Al have a room-temperature tensile elongation of about 2 to 4% for coarse-grain materials (that is, materials with grain sizes of 150 to 200 μm) (Ref 28). Elongation increases to 6 to 8% when the grain structure is refined (Ref 134, 135), indicating the effect of grain size on the ductility. A recent study found that the ductility of FeAl with 40% Al was substantially improved by mechanical alloying (Ref 136); the mechanical alloying probably reduced the grain size, thereby reducing the tendency toward brittle intergranular fracture. The ductility of aluminides with up to 30% Al increases with test temperature and reaches more than 40% at 600 °C (1110 °F). Aluminides with more than 35% Al show a decrease in ductility above 600 °C (1110 °F) and reach a minimum ductility around 750 °C (1380 °F). The decrease in ductility is believed to be caused by cavitation in the grain-boundary region when the aluminides are tested under tension (Ref 127, 128).

The aluminides, like iron and steels, slip by {111} dislocations at ambient temperatures. However, the slip changes to {100} type at elevated temperatures. The transition depends on the aluminum concentration (Ref 137, 138), with a general trend of decreasing transition temperature with increasing aluminum level. For example, a transition temperature of about 1000 °C (1830 °F) was reported for the 35% Al alloy; the transition temperature was below 400 °C (750 °F) for the 50% Al alloy (Ref 137). There is no sharp change in ductility around the transition temperature.

Environmental Embrittlement. For more than 40 years, the iron aluminides have been known to be brittle at ambient temperatures; however, the major cause of the brittleness has only recently been identified. Researchers have found that the aluminides are intrinsically quite ductile and that the poor ductility commonly observed in air tests is due to an extrinsic effect--environmental embrittlement (Ref 28, 29). The data in Fig. 18 and Table 2 indicate the effect of test environment on the room-temperature tensile properties of FeAl (36.5% Al) and Fe_3Al (28% Al). Yield strength is not sensitive to environment, but ultimate tensile strength is generally correlated with tensile ductility, which depends strongly on test environment. Aluminides tested in air had a ductility of 2 to 4%. FeAl tested in dry oxygen had a ductility of 17.6%, and Fe_3Al tested in vacuum and dry oxygen had a ductility of 12 to 13%. The water vapor test confirmed the low ductility found in the air tests, indicating that moisture in air is the embrittling agent.

Table 2 Effect of selected test environments on room-temperature tensile properties of iron aluminides

Test environment (gas pressure)	Elongation, %	Yield strength		Ultimate tensile strength	
		MPa	ksi	MPa	ksi
Fe_3Al (28% Al)[(a)]					
Air	4.1	387	56	559	81
Vacuum (~1×10^{-4} Pa)	12.8	387	56	851	123
Argon + 4% H_2 (6.7×10^4 Pa)	8.4	385	55.8	731	106
Oxygen (6.7×10^4 Pa)	12.0	392	56.8	867	126
Water vapor (1.3×10^3 Pa)	2.1	387	56	475	69
FeAl (36.5% Al)[(a)]					
Air	2.2	360	52.2	412	60

Vacuum (<1 × 10^{-4} Pa)	5.4	352	51	501	73
Argon + 4% H_2 (6.7 × 10^4 Pa)	6.2	379	55	579	84
Oxygen (6.7 × 10^4 Pa)	17.6	360	52.2	805	117
Water vapor (67 Pa)	2.4	368	53.4	430	62

(a) All specimens were annealed 1 h at 900 °C (1650 °F) + 2 h at 700 °C (1290 °F).

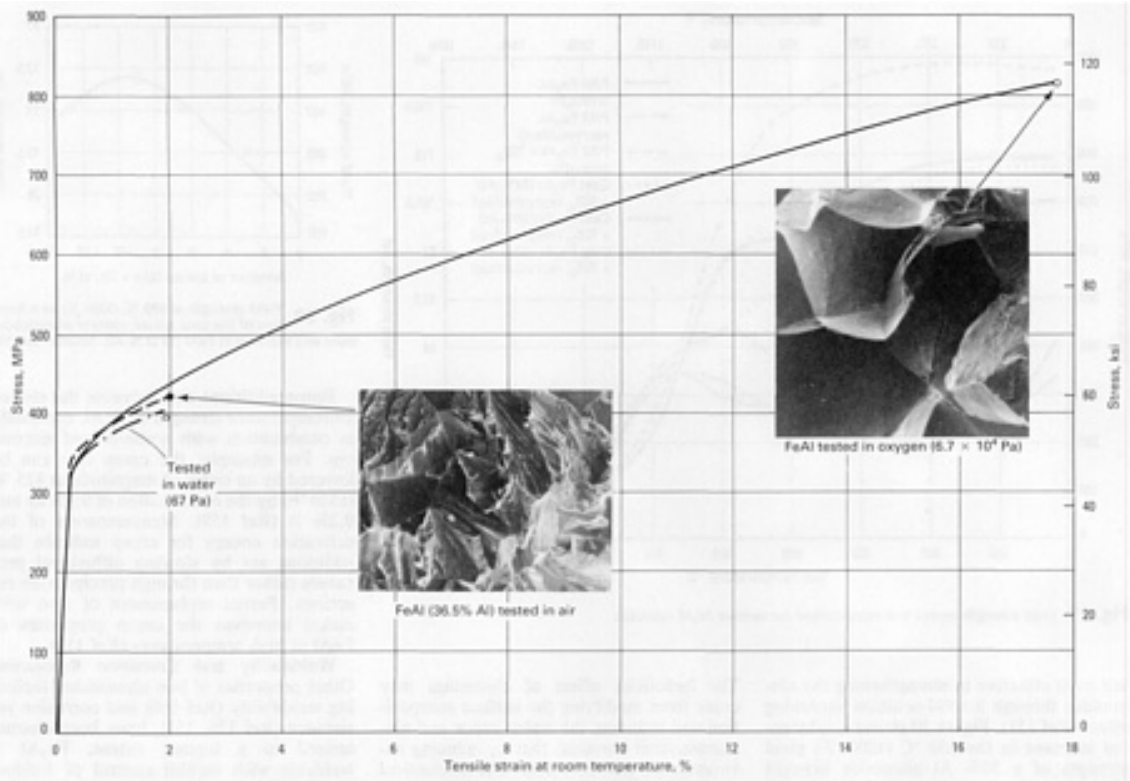

Fig. 18 Effect of test environment on the room-temperature ductility and fracture behavior of FeAl (36.5% Al)

Embrittlement is expected to involve the following chemical reaction at metal surfaces:

$$2Al + 3H_2O \rightarrow Al_2O_3 + 6H^+ + 6e^-$$

The reaction of water vapor with aluminum atoms at crack tips results in the formation of atomic hydrogen that drives into the metal and causes crack propagation. The fact that yield strength (Table 2) is insensitive to ductility and test environment is consistent with the mechanisms of hydrogen embrittlement observed in other ordered intermetallic alloys (Ref 139, 140, 141, 142, 143, 144, 145, 146, 147). Molecular hydrogen causes much less embrittlement in the aluminides, possibly because of its lower activity as compared with that of the atomic hydrogen produced from the water vapor reaction.

Alloying Effects in Fe_3Al Aluminides. Grain structure refinement by material processing and alloy additions has been shown to be useful in increasing ductility in Fe_3Al aluminides (Ref 148, 149). Additions of titanium diboride (TiB_2) to Fe_3Al powders are very effective in reducing grain size, and they increase the tensile ductility of recrystallized materials from

2% to 5 to 7%. Stress relief following hot working of the same materials results in ductilities as high as 18%. The presence of TiB_2 particles increases the recrystallization temperature from 650 to 1100 °C (1200 to 2010 °F), which means that wrought materials will retain room-temperature ductility even after exposure to temperatures as high as 1000 °C (1830 °F). For these materials, ductility is very high at temperatures above 600 °C (1110 °F), and conventional hot fabrication techniques can be employed without difficulty.

Strength properties of these aluminides are also sensitive to microstructure and the level of aluminum (Ref 125, 148, 149, 150) (Fig. 19). Room-temperature yield strength drops sharply with an increase of aluminum above 25%. This drop is, as mentioned before, a result of both the increase in mobility of paired dislocations and the elimination of particle strengthening from the disordered bcc phase. Additions of TiB_2, which reduce the grain size of recrystallized material and stabilize the wrought structure, increase the strength significantly and cause it to be retained to higher temperatures.

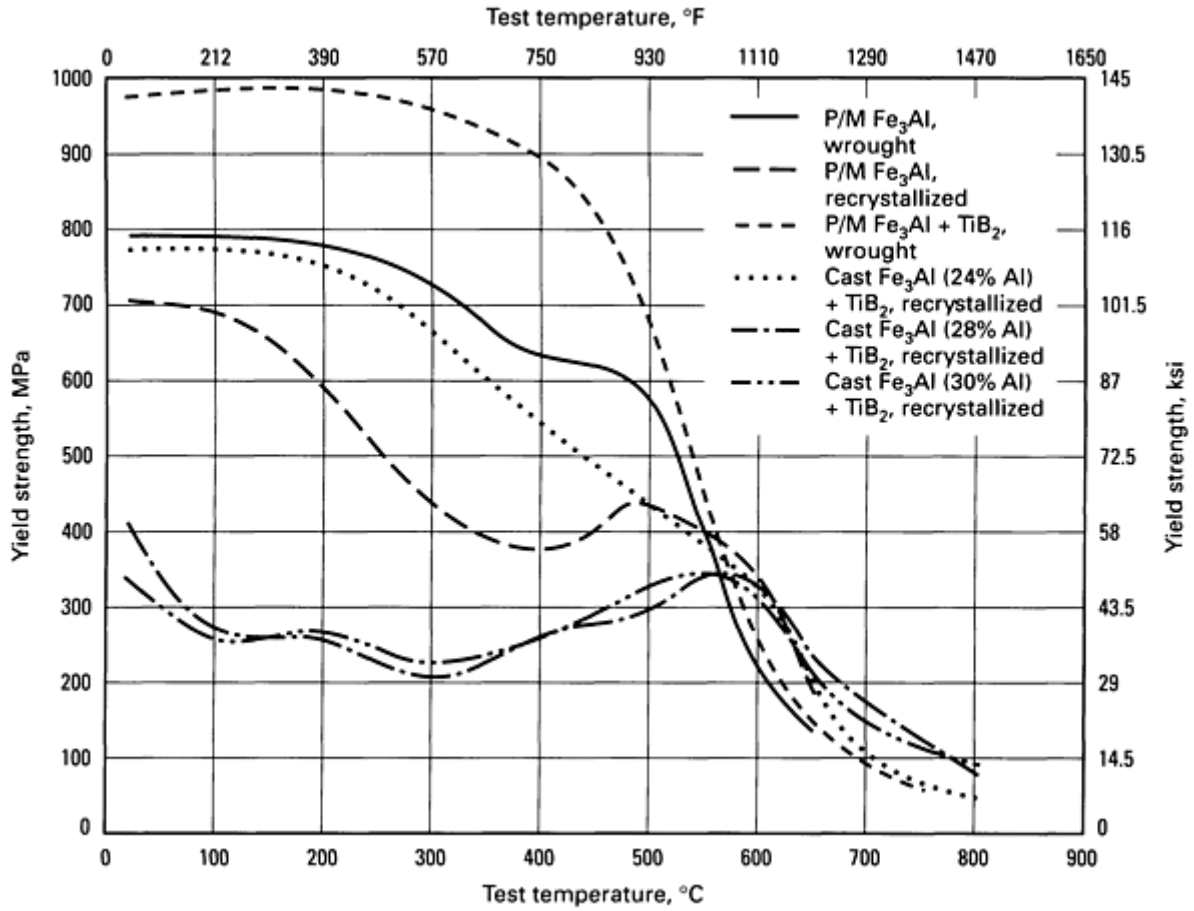

Fig. 19 Yield strength versus test temperature for various Fe_3Al materials

Substantial efforts have been made toward improving the elevated-temperature properties of Fe_3Al aluminides by alloy additions of such elements as titanium, molybdenum, silicon, chromium, nickel, manganese, niobium, and tantalum (Ref 148, 149, 151, 152, 153, 154, 155, 156). Among these alloying elements, titanium, molybdenum, and silicon are most effective in strengthening the aluminides through a solid-solution hardening effect (Ref 151). Figure 20 shows a substantial increase in the 650 °C (1200 °F) yield strength of a 30% Al aluminide brought about by alloying with molybdenum and titanium. In fact, the yield strength is tripled when the combined molybdenum and titanium content reaches 9%. The increase in strength has been related to an increase in the $D0_3 \rightarrow B2$ transition temperature and associated changes in the nature of the dislocations involved in the deformation processes. In terms of creep properties, alloying with molybdenum and additions of TiB_2 particles increases the stress for 100-h rupture life of a P/M aluminide from 28 to 193 MPa (4 to 28 ksi) at 650 °C (1200 °F) (Ref 148, 149). The solubility of niobium, tantalum, zirconium, and hafnium is low (<1%) in iron aluminides, and alloying with 1 or 2% of these elements substantially improves the room- and elevated-temperature strengths of iron aluminides through a precipitation-hardening effect (for example, precipitation of $L2_1$ particles in Fe_3Al containing 2% Nb) (Ref 153, 156).

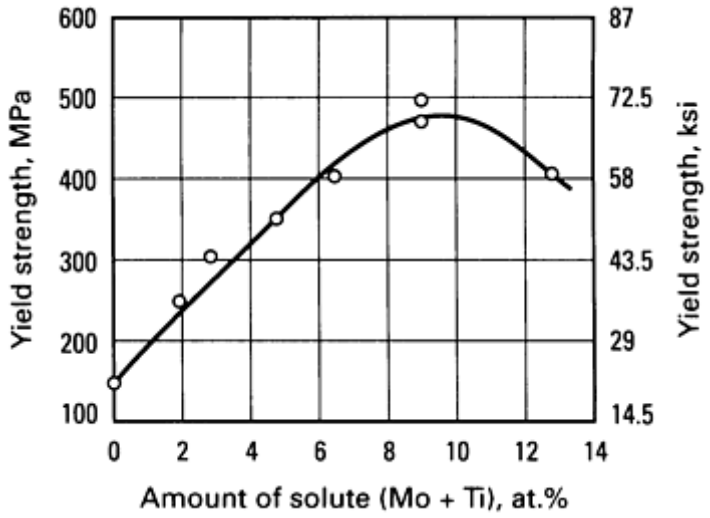

Fig. 20 Yield strength at 650 °C (1200 °F) as a function of the total solute content of molybdenum and titanium in FeAl (30 at.% Al). Source: Ref 151

A recent alloy design of Fe_3Al showed that the ductility of the aluminide prepared by melting and casting and fabricated by hot rolling can be substantially improved by increasing the aluminum content from 25 to 28 or 30 at.% and by adding chromium at a level of 2 to 6% (Ref 154, 155). The increase in the aluminum concentration sharply decreases the yield strength of the aluminide. The beneficial effect of chromium may come from modifying the surface composition and reducing the water vapor and aluminum atom reaction, that is, reducing environmental embrittlement. The mechanical properties of the chromium-modified Fe_3Al alloys can be further improved by thermo-mechanical treatment and alloy additions of molybdenum and niobium (Ref 157). Some of these alloys show a tensile ductility of more than 15% at room temperature and a yield strength of close to 500 MPa (72.5 ksi) at 600 °C (1110 °F). These ductile Fe_3Al alloys are much stronger than austenitic and ferritic steels such as type 314 stainless steel and Fe-9Cr-1Mo steel. The refractory elements also substantially enhance the creep properties of the Fe_3Al alloys.

Alloying Effect in FeAl Aluminides. FeAl aluminides containing 40% or more aluminum fail at room temperature by intergranular fracture with little tensile ductility (Ref 127, 128). Small additions of boron (0.05 to 0.2%) suppress grain-boundary fracture and allow a small increase in ductility (~3%) of Fe-40Al, but not of Fe-50Al (Ref 158). The beneficial effect of boron is not nearly as dramatic in FeAl as it is in Ni_3Al, but it is nevertheless significant. The ductility of boron-doped FeAl aluminides remains low because the alloys are still embrittled by the test environment (air). It has been found recently that boron-doped FeAl (40% Al) exhibits a high ductility (18%) when tested in dry oxygen to avoid environmental embrittlement (Ref 108).

Boron additions also increase the elevated-temperature strength of FeAl, especially in combination with niobium and zirconium. For example, the creep rate can be lowered by an order of magnitude at 825 °C (1520 °F) by the combination of 0.1% Zr and 0.2% B (Ref 159). Measurements of the activation energy for creep indicate that additions act by slowing diffusional processes rather than through precipitation reactions. Partial replacement of iron with nickel improves the creep properties of FeAl at high temperatures (Ref 110).

Weldability and Corrosion Resistance. Other properties of iron aluminides, including weldability (Ref 160) and corrosion resistance (Ref 126, 157), have been characterized to a limited extent. Fe_3Al is weldable with careful control of welding parameters and minor alloy additions. Additions of TiB_2 promote hot cracking and are detrimental to the weldability of Fe_3Al aluminides. Sound weldments have been achieved in Fe_3Al alloys using both electron beam and gas tungsten are welding processes.

The iron aluminides are highly resistant to oxidation and sulfidation at elevated temperatures (Ref 123, 124, 125, 126). This resistance stems from the ability of the aluminides to form highly protective Al_2O_3 scales. The oxidation resistance generally increases with increasing aluminum content; the major products are α-Al_2O_3 and trace amounts of iron oxides when the aluminides are oxidized at temperatures above 900 °C (1650 °F) (Ref 123). Cyclic oxidation of Fe-40Al alloyed with up to 1 at.% Hf, Zr, and B produced little degradation at temperatures up to 1000 °C (1830 °F) (Ref 124). Aluminide

specimens tested at 700 and 870 °C (1290 and 1600 °F) showed no indication of attack in sulfidizing environments, except for the formation of a thin layer of oxides with a thickness in an interference color range (Ref 157). As shown in Fig. 21, the iron aluminide alloys exhibited corrosion rates lower than those of the best existing iron-base alloys (including coating material) by a couple of orders of magnitude when tested in a severe sulfidizing environment at 800 °C (1470 °F). In addition, the aluminides with more than 30% Al are very resistant to corrosion in molten nitrate salt environments at 650 °C (1200 °F).

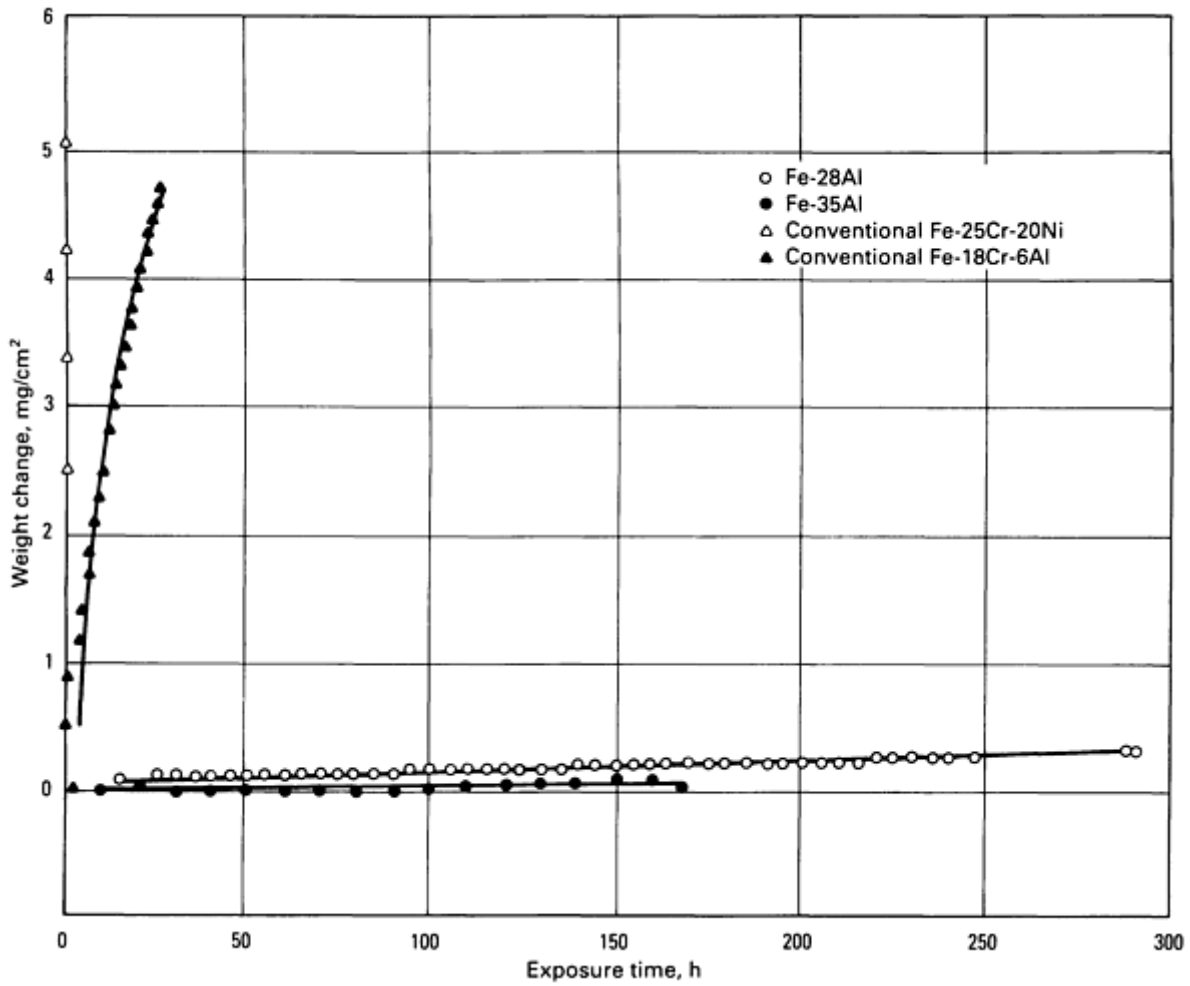

Fig. 21 Comparison of corrosion behavior of iron aluminides with that of conventional iron-base alloys Fe-18Cr-6Al (coating material) and Fe-25Cr-20Ni. All materials were exposed to a severe sulfidizing environment at 800 °C (1470 °F). Source: Ref 126

Potential Applications. Iron aluminides were previously excluded from the realm of structural materials because of their brittleness at ambient temperatures and poor strength at elevated temperatures. Recent research and development activities have demonstrated that adequate engineering ductility (10 to 15%) can be achieved in the aluminides through the control of microstructure and alloy additions. Both tensile and creep strengths of the aluminides are substantially improved by alloying with refractory elements, which results in solution hardening and particle strengthening. The recently developed aluminide alloys are stronger than austenitic steels and ferritic low-alloy steels at ambient and elevated temperatures (Ref 157). Adequate ductility and strength combined with low cost, excellent oxidation and corrosion resistance, low density, and good fabricability make the aluminide alloys promising for structural use at temperatures up to 700 to 800 °C (1290 to 1470 °F). Potential applications include molten salt systems for chemical air separation, automotive exhaust systems, immersion heaters, heat exchangers, catalytic conversion vessels, chemical production systems, coal conversion systems, and so on. Several industrial companies have started to prepare large heats as a first step in the commercialization of iron aluminide alloys. Further research is required to develop a data base (including information on tensile and creep properties, fracture toughness, low- and high-cycle fatigue, crack growth, and elastic modulus) on some promising aluminides for specific engineering applications.

Titanium Aluminides

Because of their low density, titanium aluminides based on Ti_3Al and TiAl are attractive candidates for applications in advanced aerospace engine and airframe components (Ref 161, 162, 163, 164, 165, 166). The characteristics of titanium aluminides are presented along-side those of other aluminides in Table 1; the creep behavior of titanium aluminides is compared with that of conventional titanium alloys in Fig. 22. The present materials mix in an advanced jet engine is shown in Fig. 23, and a possible future engine material mix is given in Table 3. Despite a lack of fracture resistance (low ductility, fracture toughness, and fatigue crack growth rate), the titanium aluminides Ti_3Al (α-2) and TiAl (γ) have great potential for enhanced performance. Properties of these aluminides are compared with those of conventional titanium alloys and superalloys in Table 4. Because they have slower diffusion rates than conventional titanium alloys, the titanium aluminides feature enhanced high-temperature properties such as strength retention, creep and stress rupture, and fatigue resistance (Ref 170).

Table 3 Possible material mix in a 2010 jet turbine engine

Material	Engine use, %

Another negative feature of titanium aluminides, in addition to their low ductility at ambient temperatures, is their oxidation resistance, which is lower than desirable at elevated temperatures (Ref 171, 172, 173). The titanium aluminides are characterized by a strong tendency to form TiO_2, rather than the protective Al_2O_3, at high temperatures. Because of this tendency, a key factor in increasing the maximum-use temperatures of these aluminides is enhancing their oxidation resistance while maintaining adequate levels of creep and strength retention at elevated temperatures.

Composite concepts using the titanium aluminides as a matrix are also being actively pursued (Ref 174), specifically to increase "forgiveness," modulus, and elevated-temperature performance; however, these materials will not be considered in this article. A recent detailed review of monolithic titanium aluminides is contained in Ref 166, which expands on many of the points made in this article.

Alpha-2 Alloys

Crystal Structure and Deformation Behavior. Ti_3Al, which has an ordered $D0_{19}$ structure, contains three linearly independent slip systems that account for dislocation motion on the basal {0001}, prism {1010}, and pyramidal {0221} planes (Fig. 24) (Ref 175, 176). Prism slip requires only a single dislocation without creating a near-neighbor antiphase boundary, and additional slip requires movement of two dislocations (Ref 26). In addition, two independent slip systems involving <*c* + *a*> slip occur to satisfy the Von Mises criterion for uniform deformation.

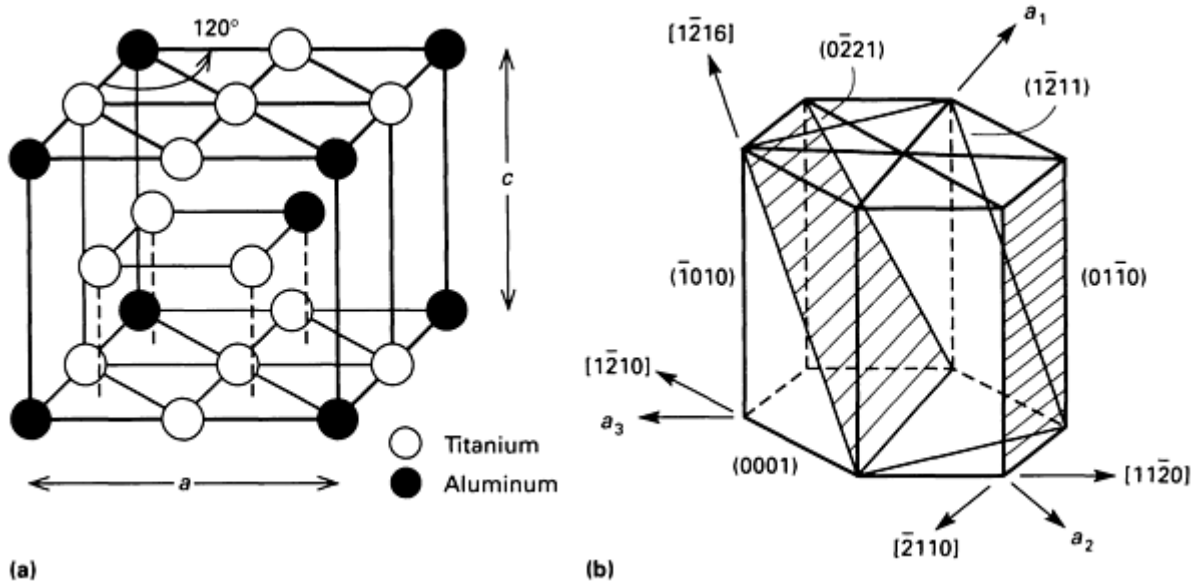

Fig. 24 Crystal structure of Ti_3Al. (a) $D0_{19}$ hexagonal superlattice structure of Ti_3Al with lattice constants of c = 0.420 nm and a = 0.577 nm. (b) Possible slip planes and slip vectors in the structure

The semicommercial and experimental α-2 alloys developed up to the present time are two phase (α-2 + β/*B*2), with contents of 23 to 25 at.% Al and 11 to 18 at.% Nb. Alloy compositions with current engineering significance are Ti-24Al-11Nb (Ref 177, 178), Ti-25Al-10Nb-3V-1Mo (Ref 165), Ti-25-Al-17Nb-1Mo (Ref 179) and modified alloy compositions such as Ti-24.5Al-6Nb-6(Ta,Mo,Cr,V). Increasing the niobium content generally enhances most material properties, although excessive niobium can degrade creep performance. Niobium can be replaced by specific elements for improved strength (molybdenum, tantalum, or chromium), creep resistance (molybdenum), and oxidation resistance (tantalum, molybdenum). However, for full optimization of mechanical properties, control of the microstructure must be maintained, particularly for tensile, fatigue, and creep performance.

The α-2 (Ti_3Al) alloy has a wide range of compositional stability, with aluminum contents of 22 to 39 at.%. The compound is congruently disordered at a temperature of 1180 °C (2155 °F) and an aluminum content of 32 at.%. The stoichiometric composition, Ti-25Al, is stable up to about 1090 °C (1995 °F) (Ref 36). Ternary phase diagrams centered around the α-2 phase are not yet well developed (Ref 180, 181), and even specifics of the Ti_3Al-Nb pseudobinary system are still being debated (Ref 182, 183). At niobium contents of less than 5 at.%, a martensitic transformation to the αphase occurs during rapid cooling from the high-temperature βphase (Ref 182, 184, 185). Increased niobium contents suppress the martensitic transformation, and βor *B*2 can be retained at room temperature (Ref 182, 184, 186). This quenched-in *B*2 phase is metastable, and it contains transitional microstructures and phases such as antiphase boundaries (Ref 184, 185), "tweed" microstructures (Ref 182, 184, 187, 188), the 0 phase, and fine ω-phase particles (Ref 187); the ω transforms to α-2 upon heat treatment in a similar manner to the $\omega \rightarrow \alpha$ transformation that occurs in conventional terminal titanium alloys (Ref 161).

Material Processing. Microstructural features that can be varied by thermomechanical processing include primary α-2 grain size and volume fraction, secondary α-2 plate morphology and thickness, and the presence of secondary β grains (Ref 166). Beta processing generally results in elongated Widmanstätten α-2 in large primary β grains in a manner similar to that in conventional titanium alloys (Ref 161).

Up to 4 wt% H can be dissolved in titanium alloys at elevated temperatures. This hydrogen can then be used to improve processibility, and final mechanical properties are enhanced after its removal; removal of the hydrogen can be easily achieved by vacuum annealing (Ref 189, 190). This thermochemical processing technique allows titanium aluminides to be processed at reduced temperatures (Ref 189, 190, 191, 192) and results in a finer microstructures (Ref 175, 189, 190, 192).

Mechanical and Metallurgical Properties. Typical mechanical properties for a number of α-2 alloys are listed in Table 5. Production of two-phase alloys by alloying Ti_3Al with β-stabilizing elements results in up to a doubling of strength. Interface strengthening of the two-phase mixture appears to be predominantly responsible for the increased strength, but other strengthening factors, such as long-range order, solid solution, and texture effects, also contribute (Ref 166, 193).

Table 5 Properties of α-2 Ti_3Al alloys with various microstructures

Alloy	Microstructure[a]	Yield strength		Ultimate tensile strength		Elongation, %	Plane-strain fracture toughness		Creep rupture[b]

(a) E, equiaxed α-2; W, Widmanstätten; FW, fine Widmanstätten; C, colony structure; P, primary α-2 grains.

(b) Time to rupture, h, at 650 °C (1200 °F) and 380 MPa (55 ksi).

A fine Widmanstätten microstructure with a small amount of primary α-2 grains exhibits better ductility than microstructures with a coarse Widmanstätten microstructure or an aligned acicular α-2 morphology (Ref 166). The fatigue properties of titanium alloys are strongly influenced by microstructure and work on conventional titanium alloys (Ref 161) suggests that high-ductility alloys perform best under low-cycle fatigue (LCF) conditions (Ref 194). The low ductility exhibited in material with Widmanstätten αplates in α+ β alloys is responsible for low high-temperature LCF strength. Early data (Ref 195) suggest that fatigue crack growth rate is relatively insensitive to microstructure, although the coarse Widmanstätten microstructure exhibits the slowest fatigue crack growth rate at low stress intensities. Fracture toughness appears to depend on microstructures as well as alloys composition, but the precise relationship is yet to be defined (Ref 166). A recent detailed investigation into the effect of microstructure on creep behavior in Ti-25Al-10Nb-3V-1Mo has shown that the colony-type microstructure shows better creep resistance than other microstructures (Ref 196). Creep resistance of Ti-25-10-3-1 is raised by a factor of ten in the steady-state regime over that of conventional alloy Ti-1100 (Ti-6Al-3Sn-4Zr-0.4Mo-0.45Si) and two orders of magnitude over that of Ti-6Al-2Sn-4Zr-2Mo-0.1Si (Ref 196). However, 0.4% creep strain in Ti-25-10-3-1 is reached within 2 h.

Additions of silicon and zirconium appear to improve creep resistance (Ref 197), but the most significant improvement is attained by increasing the aluminum content to 25 at.% and limiting β-stabilizing elements to about 12 at.% (Ref 178, 198). However, the Ti-24.5Al-17Nb-1Mo alloy exhibits a rupture life superior to that of other α-2 alloys (Ref 166).

Gamma Alloys

Crystal Structure and Deformation Behavior. The γ-TiAl phase has an $L1_0$ ordered face-centered tetragonal structure (Ref 199, 200, 201), which has a wide range (49 to 66 at.% Al) of temperature-dependent stability (Ref 36, 199). At the equiatomic TiAl composition, the c/a ratio is 1.02; tetragonality increases up to c/a = 1.03 with increasing aluminum concentration (Ref 202, 203, 204). Within the compositional range specified at off-stoichiometric compositions, excess titanium or aluminum atoms occupy antisites without creating constitutional vacancies (Ref 205). The γ-TiAl phase apparently remains ordered up to its melting point of approximately 1450 °C (2640 °F) (Ref 36).

The layered arrangement of titanium and aluminum atoms on successive (002) planes and the slight tetragonality of c/a = 1.02 (Fig. 25) gives rise to two types of dislocations with $\frac{1}{2}$<110>-type Burgers vectors on {111} in γ-TiAl: ordinary dislocations $\frac{1}{2}$<110> and superdislocations <011> = $\frac{1}{2}$<011> + $\frac{1}{2}$<011> that will leave the superlattice undisturbed (Fig. 25). Another superdislocation, with a Burgers vector of $\frac{1}{2}$<112>, has also been suggested (Ref 206, 207). The superdislocation core can dissociate further into other complex partial dislocations, which are energetically more favorable, involving planar defects such as stacking faults and antiphase boundaries (Ref 206, 207, 208). The slip systems and partial dislocations are shown in Fig. 25. The $\frac{1}{6}<\bar{1}12>$ on $\{1\bar{1}1\}$ partials form twin dislocations, but $\frac{1}{6}<2\bar{1}1>$ partials are forbidden as twinning dislocations in the $L1_0$ structure (Ref 166, 209, 210).

(b) Slip dislocations on (111) plane, ordinary dislocations $\frac{1}{2}$<110>, superdislocations <011> and $\frac{1}{2}$<112>, and twin dislocations $\frac{1}{6}$<112> with possible dissociations. Source: Ref 202

In single-phase γalloys containing 52 to 54 at.% Al, deformation at room temperature occurs by motion of both ordinary and superdislocations; however, the superdislocations [011] and [101] are largely immobile because segments of the trailing $\frac{1}{6}$ [112]-type superpartials form faulted dipoles that must be extended as deformation progresses (Ref 206, 207, 208, 210, 211). Increasing temperature and decreasing aluminum content increase the $\frac{1}{2}$<110> slip activity as the faulted dipoles disappear and twinning dominates (Ref 166, 211, 212). In two-phase Ti-48-Al, the deformation modes of primary γgrains are twinning with <112> twin dislocations and slip by $\frac{1}{2}$ [110]-type dislocations.

The extremely low ductility values at ambient temperature and the increased ductility with increasing temperatures strongly influence the observed fracture mode. Tensile and fatigue specimens indicate that the predominant fracture modes are cleavage at low temperatures due to dislocation pileups and intergranular fracture at temperatures above the brittle-ductile transition (Ref 211, 212, 213, 214, 215).

The γ alloys introduced up to the time of publication contain approximately 46 to 52 at.% Al and 1 to 10 at.% M, with M being at least one of the following: vanadium, chromium, manganese, niobium, tantalum, tungsten, and molybdenum (Ref 164, 201, 216, 217, 218, 219, 220). These alloys can be divided into two categories: single-phase (γ) alloys and two-phase (γ + α-2) materials (Ref 201). The (α-2 + γ)/γ phase boundary at 1000 °C (1830 °F) occurs at an aluminum content of approximately 49 at.%, depending on the type and level of solute M. Single-phase γ alloys contain third alloying elements such as niobium or tantalum that promote strengthening and further enhance oxidation resistance (Ref 221, 222). Third alloying elements in two-phase alloys can raise ductility (vanadium, chromium, and manganese) (Ref 164, 201, 218, 219, 220), increase oxidation resistance (niobium and tantalum) (Ref 221 and 222), or enhance combined properties (Ref 201).

Material Processing. The microstructure of the nominally γalloys can be single-phase γ or, in slightly leaner compositions, two-phase γ+ α-2. By appropriate thermo-mechanical processing, the morphology of the phases can be adjusted to produce either lamellar or equiaxed morphologies, or a mixture of the two (Ref 166, 201).

The lamellar structure can lead to refinement of the microstructure, improved ductility (Ref 218, 220), and a decreased microstructure scale by recrystallizing the fine γ grains (Ref 223). Optimum ductility occurs at a content of about 10 vol% α-2; when the α-2 phase content exceeds 20 vol%, ductility can be degraded (Ref 219). This ductility behavior is consistent with the fact that α-2 becomes increasingly brittle with increasing aluminum content over 25 at.% (Ref 177). The α-2 plates contain approximately 35 at.% Al.

Control of the microstructure in single-phase γ alloys requires the optimization of grain size and morphology. In two-phase alloys, the volume ratio of lamellar to equiaxed gamma (LG/γG) must also be controlled (Ref 165, 166, 201, 218, 219). A lamellar volume fraction of about 30% gives rise to the optimum combination of properties, with a desirable high-temperature creep resistance and acceptable levels of tensile strength and ductility (Ref 165). Heat treatment temperature and time strongly affect the LG/γG volume ratio. Thermomechanical processing (TMP) refines the microstructure when processing is conducted in such a way that both the αand γ grains are recrystallized in the (α + γ) phase field. Grain morphology varies considerably depending on composition, solution treatment temperature and time, cooling rate, and stabilization temperature and time (Ref 201). Grain size decreases with reduced aluminum content and with additions of vanadium, manganese, and chromium (Ref 219, 220). The number of annealing twins in the γ phase increases as aluminum content decreases or when manganese or vanadium levels are increased (Ref 219). Chromium additions increase the volume fraction of the lamellar structure (Ref 220).

Mechanical and Metallurgical Properties. The strength and ductility of γ alloys are strongly dependent on alloy composition and TMP conditions (Ref 201). Figure 26 shows this variation in binary γ alloys after a number of TMP treatments. However, the Ti-52Al alloy demonstrates the lowest hardness value at room temperature, regardless of the TMP treatment (Ref 202, 224, 225, 226, 227). At 1000 °C (1830 °F), however, strength tends to decrease gradually with increasing aluminum levels (Ref 201). Tensile strength and hardness vary in the same fashion with variations in aluminum content (Ref 201). Room-temperature tensile elongation is maximum at a composition of approximately Ti-48Al.

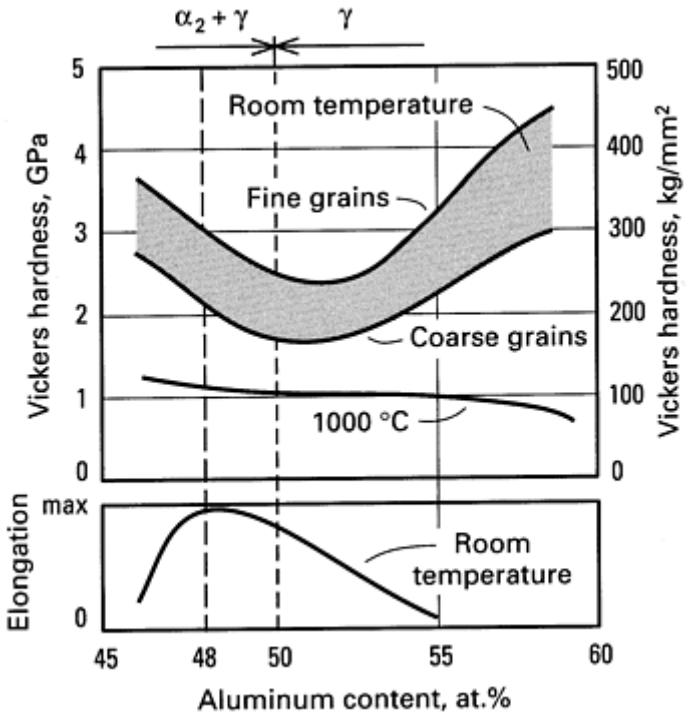

Fig. 26 Effect of aluminum content on room-temperature tensile elongation and hardness of binary γ-titanium aluminide alloys. Hardness values at 1000 °C (1830 °F) are also shown. Note the single-phase γ region and the two-phase (α_2 + γ) region. Source: Ref 201

Ternary alloys of composition Ti-48Al with approximately 1 to 3% of vanadium, manganese, or chromium exhibit enhanced ductility, but Ti-48Al alloys with approximately 1 to 3% of niobium, zirconium, hafnium, tantalum, or tungsten shows lower ductility than binary Ti-48Al (Ref 201). The brittle-ductile transition (BDT) occurs at 700 °C (1290 °F) in Ti-56Al and it occurs at lower temperatures with decreasing aluminum levels. Increased room-temperature ductility generally results in a reduced BDT temperature. Above the BDT temperature, ductility increases rapidly with temperature, approaching 100% at 1000 °C (1830 °F) for the most ductile γ-alloy compositions. The trend bands for variations in yield strength and tensile ductility with test temperature are shown in Fig. 27. The elastic moduli of γ-alloys range from 160 GPa to 176 GPa (23×10^6 to 25.5×10^6 psi) and decrease slowly with temperature (Ref 166, 201).

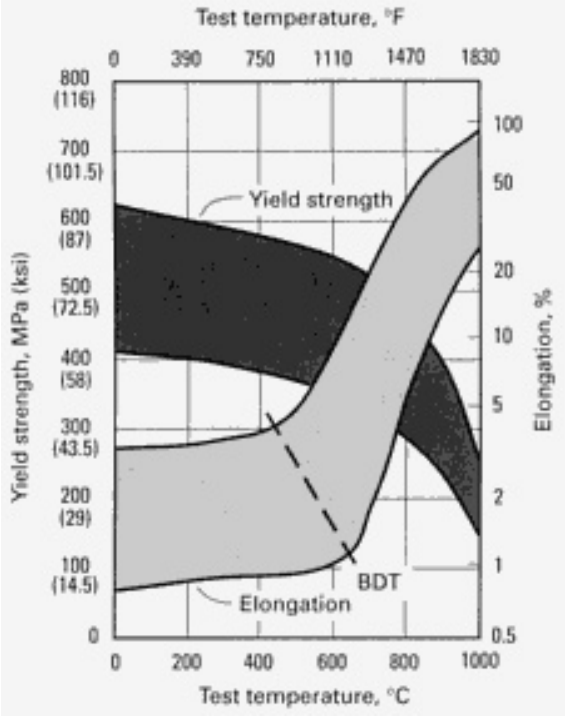

Fig. 27 Ranges of yield strength and tensile elongation as functions of test temperature for γ-TiAl alloys. BDT, brittle-ductile transition. Source: Ref 166, 201

Low-cycle fatigue experiments (Ref 165) suggest that fine grain sizes increase fatigue life at temperatures below 800 °C (1470 °F). Fatigue crack growth rates for γ-alloys are more rapid than those for superalloys, even when density is normalized (Ref 217). Both fracture toughness and impact resistance are low at ambient temperatures, but fracture toughness increases with temperature; for example, the plane-strain fracture toughness (K_{Ic}) for Ti-48Al-1V-0.1C is 24 MPa$\sqrt{m}$ (21.8 ksi$\sqrt{in}$) at room temperature (Ref 165). Fracture toughness is strongly dependent on the volume fraction of the lamellar phase. In a two-phase quaternary γ-alloy, a fracture toughness of 12 MPa$\sqrt{m}$ (10.9 ksi$\sqrt{in}$) is observed for a fine structure that is almost entirely γ; K_{Ic} is greater than 20 MPa$\sqrt{m}$ (18.2 ksi$\sqrt{in}$) when a large volume fraction of lamellar grains are present (Ref 166, 201). Creep properties of γ-alloys, when normalized by density, are better than those superalloys, but they are strongly influenced by alloy chemistry and TMP. Increased aluminum content and additions of tungsten (Ref 228) or carbon (Ref 165) increase creep resistance. Increasing the volume fraction of the lamellar structure enhances creep properties (Ref 165) but lowers ductility. The level of creep strain from elongation upon initial loading and primary creep is of concern because it can exceed projected design levels for maximum creep strain in the part.

Future Directions and Applications. Because of their low density, the titanium aluminides could replace superalloys in many elevated-temperature applications in airframes, engines, and missiles. The great importance attached to structural integrity in advanced engine and airframe designs means that reliability and reproducibility are of major concern, and the low levels of "forgiveness" in the titanium aluminides are problematic. At present, no flying applications exist for the titanium aluminides, although many components have been fabricated from both the α-2 and γ-alloys and have performed quite satisfactorily in ground-based tests.

Other Intermetallics and Development

Research on nickel, iron, and titanium aluminides has recently extended to other aluminides and intermetallics such a trialuminides and silicides. Low ductility and brittle fracture remain the major concerns for structural use of these materials (Ref 22, 23, 24). This article will consider only the intermetallic systems that have the potential for structural applications or that contribute to a general understanding of physical metallurgy and mechanical behavior of this class of materials as a whole. The ordered alloys with low T_c, such as Cu_3Au, are not included in this discussion.

Co_3V and Co_3Ti Alloys

Bulk materials of many ordered intermetallics are brittle because of their low-symmetry crystal structures, which have a limited number of deformation modes. The ductility of these alloys can be substantially improved by controlling the ordered crystal structures--in other words, changing the crystal structure from one of low symmetry (an ordered complex hexagonal structure) to one of high symmetry (an ordered cubic structure) through macroalloying. A prominent example is Co_3V alloyed with iron additions (Ref 13, 14, 15, 16, 17). Iron acts to lower the average electron concentration, thereby controlling the ordered crystal structure in the transition-metal ordered alloy.

The ordered crystal structure in the pseudobinary Ni_3V-Co_3V-Fe_3V alloy systems can be correlated with electron concentration (*e*/*a*), which is defined as the average number of valence electrons per atom (Ref 14, 15, 16, 17, 229, 230, 231). With an increase in *e*/*a* in A_3B alloys containing refractory elements, the ordered structure changes systematically from predominantly cubic to predominantly hexagonal in character (Ref 231). In some cases, a further increase in *e*/*a* causes a change in structure from hexagonal to tetragonal.

The alloy Co_3V forms a complex hexagonal ordered structure in which the unit cell contains six close-packed ordered layers (*abcacb*) and has a hexagonality of 33.3%. The alloy is brittle because of insufficient slip systems available in its low-symmetry ordered structure (Ref 17). The electron concentration of Co_3V can be increased by partial replacement of cobalt (*e*/*a* = 9) with nickel (*e*/*a* = 10) to form $(Ni,Co)_3V$. With an increase of *e*/*a*, the hexagonality of the ordered structure increases systematically from 33.3 to 100%. A further increase in *e*/*a* above 8.54 produces a change in structure from hexagonal to tetragonal, similar to Ni_3V ($D0_{22}$). On the other hand, *e*/*a* in Co_3V can be decreased by the partial substitution of iron (*e*/*a* = 8) for cobalt, producing $(Co,Fe)_3V$. These alloys have an *e*/*a* below 7.89, which stabilizes the $L1_2$ ordered cubic structure with the stacking sequence *abc*. By control of *e*/*a*, the $L1_2$-type cubic ordered structure can be stabilized in $(Ni,Co,Fe)_3V$ and $(Ni,Fe)_3V$.

The importance of the ordered cubic structure in $(Ni,Co,Fe)_3V$ alloys is shown in Fig. 28. The cubic ordered alloys with the compositions $(Fe,Co)_3V$, $(Fe,Co,Ni)_3V$, and $(Fe,Ni)_3V$ are all ductile, with tensile elongations of 40% or higher. On the other hand, the hexagonally ordered alloys Co_3V and $(Ni,Co)_3V$ are brittle, with less than 1% elongation at room temperature. The deformation behavior of ordered cubic alloys is similar to that of fcc materials having 12 slip systems. The brittleness of the ordered hexagonal alloys is attributed to their limited deformation modes in the hexagonal ordered structures. The hexagonal ordered alloys have ductilities too low to permit easy fabrication, whereas the cubic ordered alloys have excellent fabricability at both room and elevated temperatures. The results shown in Fig. 28 demonstrate the feasibility of dramatically improving tensile ductility by control of ordered crystal structures.

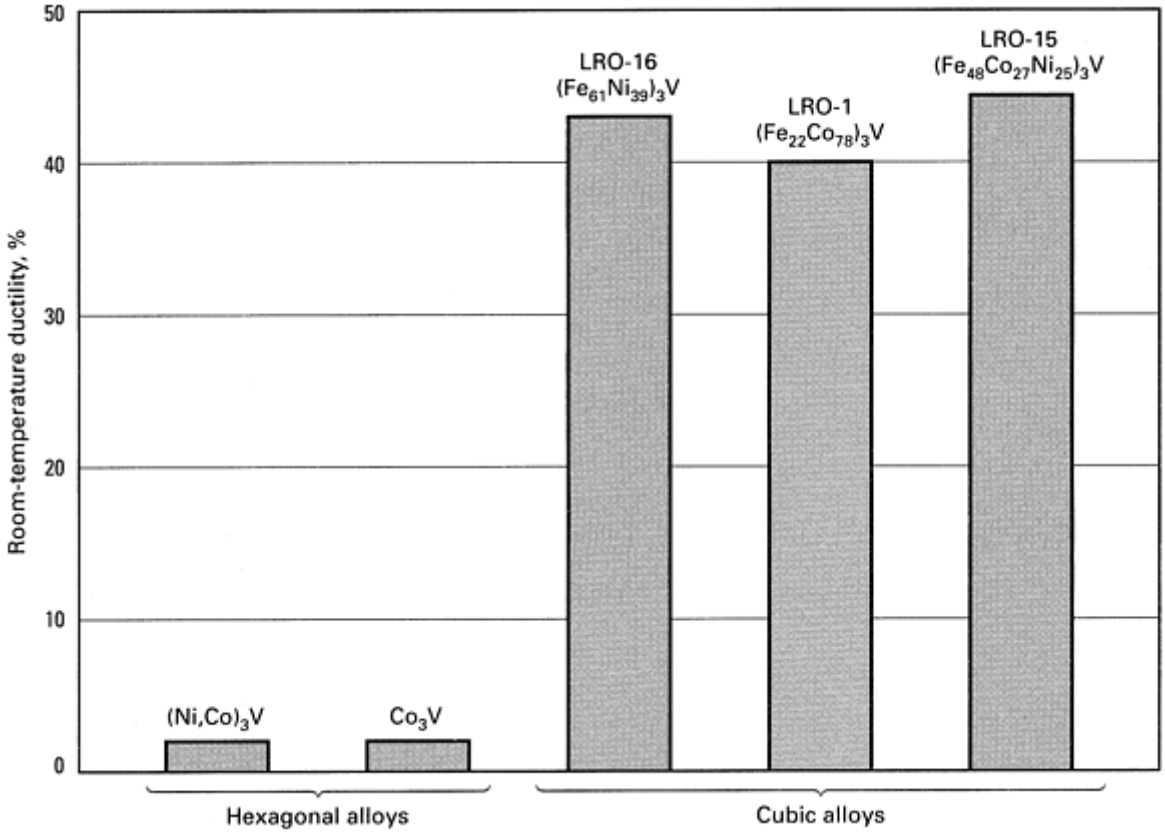

Fig. 28 Comparison of room-temperature tensile elongations of cubic and hexagonal alloys. Source: Ref 17

The $L1_2$-ordered $(Fe,Co,Ni)_3V$ alloys, like many other $L1_2$ alloys, show a positive temperature dependence for yield strength (Fig. 29). Yield strength increases with temperature and reaches a maximum around T_c. Because of this increase, $(Fe,Co,Ni)_3V$ alloys become stronger than conventional disordered solid-solution alloys at elevated temperatures. The strength of $(Fe,Co,Ni)_3V$ alloys decreases sharply above T_c because of the loss of the long-range ordered crystal structure. These alloys have excellent creep and fatigue properties in the ordered state; however, a lack of oxidation resistance limits their use in hostile environments.

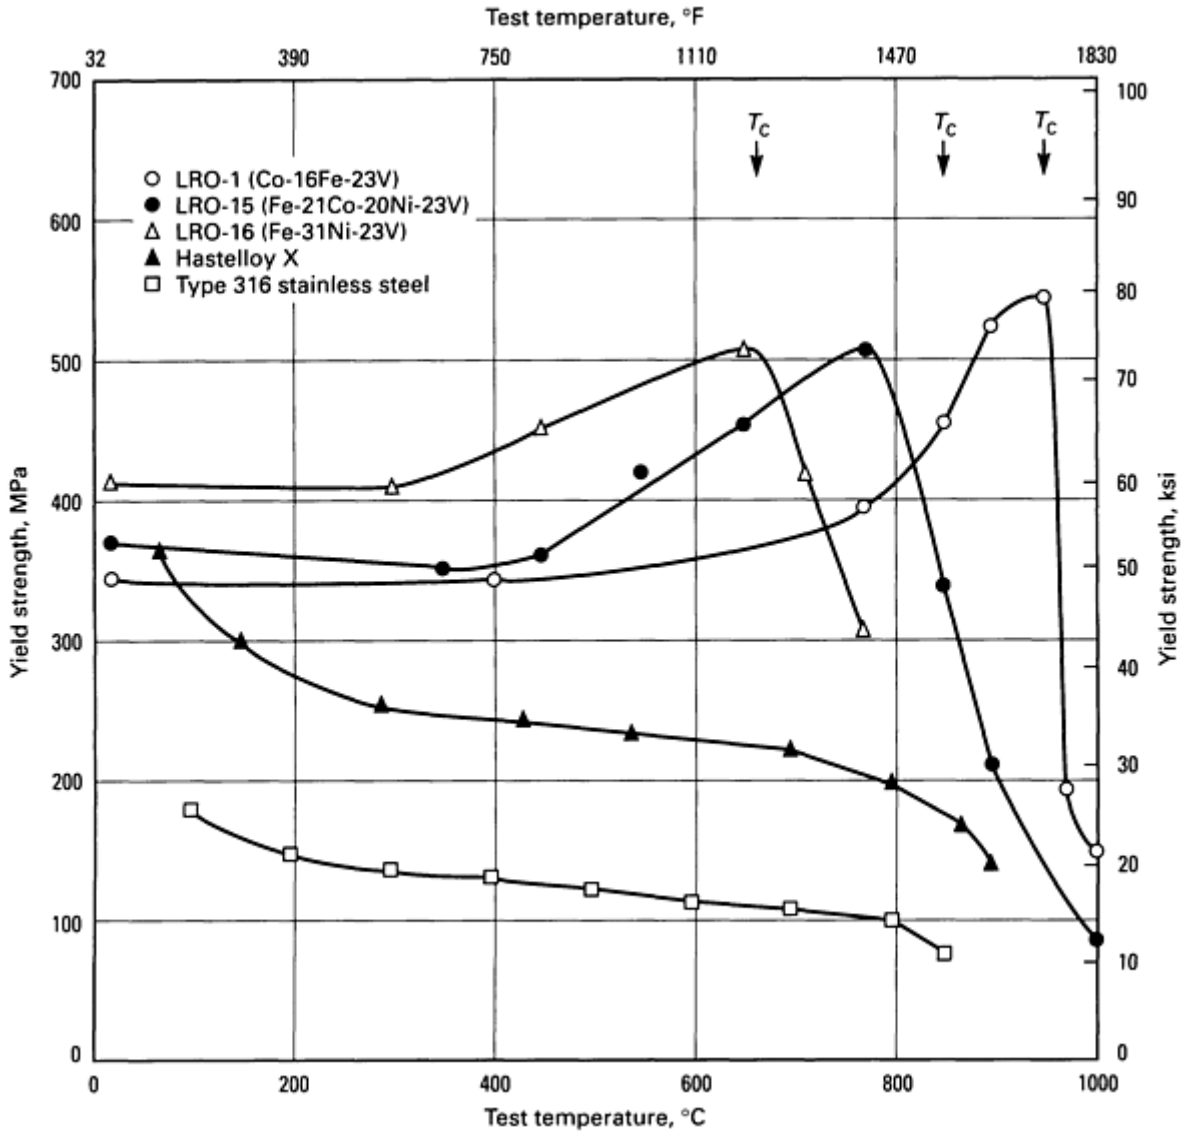

Fig. 29 Variation of yield strength with test temperature for cubic ordered alloys (LRO-1, LRO-15, and LRO-16) and commercial solid-solution alloys Hastelloy X and type 316 stainless steel. T_c, critical ordering temperature. Source: Ref 17

The ordered crystal structure in Cu_3Ti-Ni_3 Ti-Co_3Ti-Fe_3Ti, like that in Ni_3V-Co_3V-Fe_3V, is controlled by electron concentration (Ref 229). The cubic ordered structure ($L1_2$) has been reported to form in Co_3Ti and $(Co,Ni)_3Ti$ alloys. The alloys with the $L1_2$ structure are very ductile, with more than 40% tensile elongation obtained at room temperature in vacuum (Ref 141). However, Co_3Ti shows some degree of environmental embrittlement when tested in air at ambient temperatures.

Structure Maps for Ordered Intermetallics

The foregoing section has shown the importance of controlling ordered crystal structures in improving the mechanical properties of ordered intermetallics. The stability of ordered intermetallic phases is controlled by four alloy variables: valency difference (ΔZ), atomic size difference (ΔR), average number of valence electrons per atom (e/a), and angular dependence of the valence orbitals (Ref 232, 233, 234, 235, 236, 237). The last variable is related to the quantum character of electrons, which is generally neglected by classical approaches (Ref 235). Based on the first three variables, a number of schemes have been developed for representing intermetallic phases as functions of these variables. Each of these has demonstrated some merit in predicting phase stability in a given class of intermetallic phases.

Recently, Pettifor (Ref 237, 238, 239) constructed structure maps for binary intermetallic phases using a single phenomenological parameter called the Mendeleev number (M). Mendeleev numbers are assigned to each alloying

element based on its position in a modified periodic table; these numbers, in principle, include all alloying information from both classical and quantum mechanical considerations. The advantage of the Pettifor scheme is that structure maps for intermetallic phases can be represented by simple two-dimensional plots. Examples of the structure maps and detailed explanations of their use are available in Ref 235, 238, and 239. The maps successfully group different structure types into separate domains, and they can represent all kinds of intermetallic phases, instead of just one kind as in other structure schemes.

The Pettifor structure maps are useful tools for controlling the ordered crystal structures in multicomponent intermetallics. For example, the structure maps predict that the ordered phases adjacent to their domain boundary are relatively less stable with respect to the structure type in the adjacent domain. In other words, these phases can be easily altered from one structure type to the other through control of an average Mendeleev number. Pettifor has recently shown that many ordered crystal phases observed in pseudobinary and ternary intermetallic alloys fit well into the domains of structural stability for binary intermetallic phases (Ref 235). His work has demonstrated that the average Mendeleev number serves as a useful parameter for the control of phase stability in intermetallic phases.

Trialuminides and Cleavage Fracture

Trialuminides are materials of composition Al_3X, where *X* stands for titanium, zirconium, niobium, vanadium, and so on, and they form tetragonal ordered crystal structures ($D0_{22}$ and $D0_{23}$). These aluminides are of technological interest because of their high melting points (≥1350 °C, or 2460 °F), good oxidation resistance, and extremely low density (~4.0 g/cm^3). The trialuminides are, however, extremely brittle, and their brittleness has been attributed to the tetragonal crystal structures and the associated limited slip systems. Recently, considerable effort has been devoted to improving the mechanical properties of trialuminides by controlling their microstructures and changing the ordered crystal structures from tetragonal $D0_{22}$ and $D0_{23}$ to cubic $L1_2$ (Ref 240, 241, 242, 243, 244, 245, 246, 247). Consistent with the Pettifor AB_3 structure map, the cubic ordered structure can be stabilized by lowering the average Mendeleev number, which is accomplished by alloying with moderate amounts (5 to 12 at.%) of chromium, manganese, iron, cobalt, nickel, and copper; these elements are mainly used to substitute for aluminum in $TiAl_3$ and $ZrAl_3$ alloys. These $L1_2$ trialuminide alloys have much better compressive ductility and toughness than Al_3Ti, which has a tetragonal $D0_{22}$ structure, and Al_3Zr, which has a $D0_{23}$ structure; however, all three alloys remain very brittle in tension (Ref 240, 241, 242, 243, 244, 245, 246, 247). Recently, a measurable tensile ductility (~0.5%) based on four-point bend tests has been reported for $Al_{66}Cr_9Ti_{25}$ and $Al_{66}Mn_6Ti_{23}V_5$ (Ref 248). Successful achievement of tensile ductility is expected to spur more interest in the development of ductile trialuminide alloys. No stable cubic ordered structure has been reported for the trialuminide alloys based on Al_3V and Al_3Nb (Ref 246).

A possible way to improve the ductility of the $L1_2$ trialuminide alloys is to lower their hardness by controlling their microstructure and alloy composition. Studies (Ref 241, 243, 249) have found that the hardness of $L1_2$ Al_3Ti and Al_3Zr alloys can be substantially reduced from 350 to 200 HV by alloying additions of, for example, vanadium. However, the vanadium-modified aluminide alloys, even with such low hardness levels, exhibit brittle cleavage fracture with virtually no tensile ductility in a manner no different from that of the higher-hardness $L1_2$ trialuminides. Selected-area electron channeling pattern analyses revealed that the {110}-type planes are the predominant cleavage planes, with {100} and <111> as minor planes. This observation is different from that in Ni_3Al, where the {111}-type planes are the major fracture planes (Ref 249).

Brittle cleavage is generally associated with high hardness and high yield strength. The study of $L1_2$ trialuminides has demonstrated an interesting case where brittle cleavage can take place in soft materials. Table 6 shows the room-temperature mechanical properties of three $L1_2$ trialuminides: Al_3Sc, used as a model material to study cleavage fracture in $L1_2$ trialuminides; $Al_{69}Zr_{25}Fe_6$; and $Al_{66}Ti_{23}Fe_6V_5$. All of these aluminides are soft (≤200 HV) and have yield strengths as low as 105 MPa (15 ksi), indicating no difficulty in the generation of dislocations in these materials. The unusual brittle cleavage fracture has been attributed to intrinsic low cleavage strength and the difficulty in emission of dislocations from crack tips. Total-energy calculations (Ref 250) suggest the formation of directional scandium-aluminum or titanium-aluminum bonds as a possible cause for the observed (110) cleavage in the trialuminides. In addition, the calculated cleavage strength of Al_3Sc is substantially lower than that of Ni_3Al.

Table 6 Mechanical properties of trialuminides

Alloy	Vickers hardness	Yield strength	Fracture toughness	Young's modulus (*E*)	Shear modulus (*G*)	Poisson's ratio(*v*)	Bulk modulus (*K*)	*K*/*G*

Ni_3X Alloys and Intergranular Fracture

The study of grain-boundary fracture in Ni_3Al has been extended to other $L1_2$ intermetallics, particularly Ni_3X alloys, where *X* stands for iron, manganese, aluminum, gallium, silicon, or germanium. In 1985, Takasugi and Izumi (Ref 62, 63) initiated a systematic study of the effect of metallurgical, mechanical, and chemical factors on grainboundary cohesion in $L1_2$ ordered A_3B alloys. They found that the valency difference (ΔZ) between A and B atoms is the dominant factor controlling grain-boundary cohesive strength, and that the tendency for grain-boundary fracture increases with increasing ΔZ. They also considered the importance of the atomic size difference and postulated that a better correlation can be obtained by a combined consideration of both valency and atomic size differences. Their correlation appears to correctly rank the grain-boundary cohesive strength of $L1_2$ ordered nickel-base alloys in the order $Ni_3Fe > Ni_3Mn > Ni_3Al > Ni_3Ga > Ni_3Si > Ni_3Ge$, which is in agreement with the experimental data listed in Table 7.

Table 7 Valency/size effect/electronegativity correlation with ductility in the $L1_2$ Ni_3X alloys

X species	Valency difference (ΔZ)[a]	Lattice, dilation ($a - a_{Ni}/a_{Ni}$)	Electronegativity difference (Pauling)	Type of fracture[b]	
				Undoped alloy	Borondoped alloy
Iron	0.2	+1.0%	-0.08	T	. . .
Manganese	0.9	+2.2%	-0.36	T	. . .
Aluminum	3.0	+1.5%	-0.30	I	T
Gallium	3.0	+1.6%	-0.10	I	T
Silicon	4.0	-0.04%	-0.01	I	M
Germanium	4.0	+1.5%	+0.10	I	I

Source: Ref 63.

(a)

(b) T, transgranular; I, intergranular; M, mixed mode. Unless otherwise noted, data are from Ref 65.

Taub *et al.* (Ref 64, 65, 66), on the other hand, studied grain-boundary fracture in borondoped and undoped binary and pseudobinary intermetallic alloys based on Ni_3X (where *X* stands for aluminum, gallium, silicon, or germanium) that were prepared by melt spinning. They found that both bend ductility and fracture behavior can be better correlated with the electronegativity consideration rather than with the valency difference as proposed by Takasugi and Izumi (Ref 60). In addition to requiring only a single parameter to correlate the data successfully, the electronegativity consideration provides a better understanding of atomic bonding. The electronegativity difference can be generally regarded as a standard scale for measuring a transfer of electrons between atoms. Compared with aluminum, gallium, and silicon atoms, germanium atoms are more electronegative with respective to nickel atoms; consequently, germanium has a greater tendency to pull electron charge from nickel/nickel bonds, thereby further reducing cohesive strength and promoting intergranular fracture in Ni_3Ge. Grain boundaries in Ni_3Ge are weaker than those in Ni_3Al, and boron is considered to be ineffective in increasing the ductility of Ni_3Ge and $Ni_3(Al,Ge)$ alloys containing high levels of germanium.

Takasugi and Izumi and Taub *et al.* have correlated intergranular fracture with the average electron character of the boundary (Ref 63, 64, 65, 66). From this correlation, it is possible to manipulate grain-boundary cohesion by macroalloying, that is, replacing constituent atoms with alloy additions. They showed that a partial replacement of aluminum with iron or manganese in Ni_3Al reduces the average valency and electronegativity differences between the nickel and "aluminum" atoms, thereby improving room-temperature ductility and lowering the propensity for grain-boundary fracture in Ni_3Al (Ref 60). However, the increase in ductility is not as dramatic as that from microalloying with boron, which occupies interstitial sites in Ni_3Al. A combination of both microalloying and macroalloying has also proved to be very effective in increasing the ductility of Ni_3Al alloyed with boron and iron (Ref 61). Beryllium, which was recently verified to occupy the substitutional sites (Ref 251), has only a moderate effect on ductility improvement (Ref 62).

Zr_3Al

Because of its desirable nuclear properties (low-absorption cross section for thermal neutrons), Zr_3Al was studied extensively in the 1970s for potential use as a cladding material for water-cooled nuclear power reactors (Ref 252). Zr_3Al is a line compound formed by the peritectoid reaction at 975 °C (1790 °F) (Ref 36):

$$Zr_2Al + Zr \rightarrow Zr_3Al$$

The aluminide has good oxidation resistance and can be easily fabricated into strip, rod, and tubing (Ref 252). The fabrication can best be done by hot working at a temperature within the $\beta Zr + Zr_2Al$ two-phase field, followed by annealing below the peritectoid temperature to produce near-single-phase Zr_3Al. Working of Zr_3Al is limited to a reduction in area of about 30% (Ref 253).

Deformation and fracture in Zr_3Al have been studied extensively (Ref 252). The yield strength of the aluminide is sensitive to grain size and obeys the Hall-Petch relationship. Figure 30 shows curves for true stress versus true strain as a function of temperature for Zr_3Al with a grain size of 5 μm. The aluminide is quite ductile at low temperatures, with a ductility of 30% at room temperature for specimens prepared by electropolishing. The ductility at ambient temperatures drops when surfaces are damaged by machining or abrading with SiC paper to 1.5 and 15%, respectively (Ref 255, 256, and the fracture mode changes from transgranular to intergranular. This result clearly indicates that the aluminide is very notch sensitive. Yield strength is insensitive to temperatures up to about 600 °C (1110 °F); above that temperature, strength decreases substantially. The aluminide is stronger than zirconium-base alloys such as Zircaloy-2 and Zr-2.5Nb at intermediate temperatures (300 °C, or 570 °F), (Ref 252).

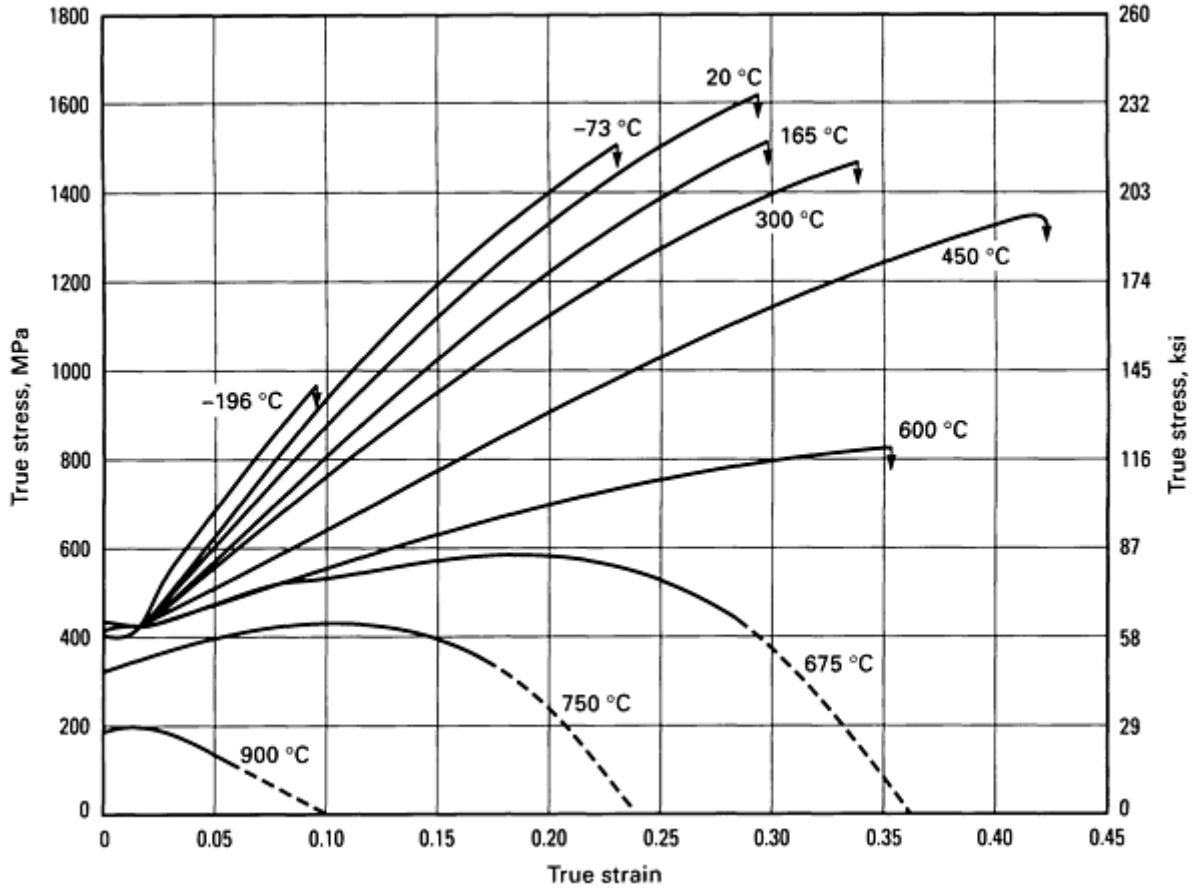

Fig. 30 True stress versus true strain as a function of temperature for Zr_3Al with a grain size of 5 μm. Testing conducted at a strain rate of 2.7 × 10^{-4} s^{-1}. Source: Ref 254

The structure and properties of Zr_2Al have also been characterized in irradiation conditions (Ref 252). The aluminide shows significant swelling upon irradiation. Susceptibility to notch sensitivity is suppressed by fast-neutron irradiation to relatively low exposures; however, the alloy undergoes an embrittling crystalline-to-amorphous phase transformation when irradiated to higher doses at temperatures up to 400 °C (750 °F). The aluminide will remain an experimental material until the problem of radiation damage can be alleviated by some metallurgical means.

$L2_1$ Heusler Alloys

As mentioned before, the aluminide NiAl is relatively weak at elevated temperatures and has, in particular, poor creep resistance. An effective way to improve the creep properties of NiAl is to introduce a Heusler phase ($L2_1$) in it (Ref 257). All the elements of the IVB and VB groups in the periodic table are known to form Heusler-type ternary compounds in the form of Ni_2AlX, where *X* stands for titanium, tantalum, hafnium, and so on. The unit cell of Heusler alloys is composed of eight *B*2 unit cells in which nickel atoms occupy the corner sublattices and aluminum and titanium atoms form an ordered array on the body-centered sublattices. The Heusler alloys are generally hard and brittle at ambient temperatures, and their hardness can be related to the size difference between *X* and aluminum atoms and also to internal strains resulting from the complex crystal structure itself. For example, room-temperature hardness is approximately 5 GPa (510 HV) for Ni_2AlTi and approximately 8 GPa (815 HV) for Ni_2AlHf (Ref 258). The fracture mode is basically transgranular cleavage in Ni_2AlHf at temperatures below 600 °C (1110 °F). Above that temperature, the hardness drops and the compression ductility increases abruptly because of the onset of thermally activated processes.

Compared with NiAl for structural applications. Heusler alloys have two major disadvantages; higher brittleness at low temperatures (<600 °C, or 1110 °F) and relatively low melting temperatures. The Heusler alloys are much harder and more brittle than NiAl (Ref 258, 259). They show limited room-temperature ductility (<3%) in compression tests and have been reported to have nil ductility in tension. The melting point of all known Heusler phases (≤1400 °C, or 2550 °F), (Ref 258, 260) is lower than that of NiAl by 250 °C (450 °F). The advantage of the Heusler alloys is that they are stronger

and more creep resistant than NiAl at elevated temperatures. Single-phase Ni_2AlTa showed a yield strength of 540 MPa (78 ksi) when tested at 970 °C (1780 °F) at a low strain rate of 1×10^{-5} s^{-1} (Ref 259). In comparison, NiAl exhibited a yield strength of less than 30 MPa (4 ksi) under the same test conditions.

Some efforts have been devoted to developing two-phase alloys based on NiAl(β) and Ni_2AlX(β') phases (Ref 257, 258, 259, 260, 261, 262, 263); these attempts are analogous to the development of γ/γ' superalloys. The lattice misfit between βand β' phases varies with the *X* elements; misfit is near zero for NiAl/Ni_2AlTa (Ref 259), approximately 1% for NiAl/Ni_2AlTi (Ref 257), and approximately 5% for NiAl/Ni_2AlHf (Ref 258). Consequently, coherent precipitates exist in NiAl/Ni_2AlTa, and no coherency exists between NiAl and Ni_2AlHf. Strutt ***et al.*** (Ref 261, 262) reported the excellent creep resistance of Ni_2AlTi and β/β' alloys at high temperatures. As shown in Fig. 31, the creep strength of β' is better than β(NiAl), and the β/β' alloy is as strong as the advanced directionally solidified superalloy MAR-M 200 (Ref 257). The excellent creep resistance, superior oxidation resistance, and low density of β/β' alloys certainly warrants their further development for high-temperature structural applications.

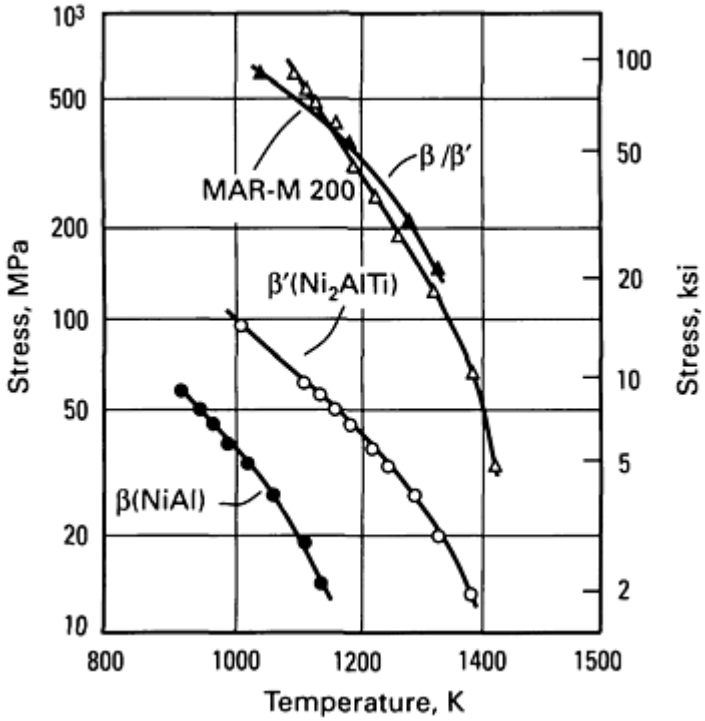

Fig. 31 Creep strength, defined as the stress to maintain a creep rate of 10^{-7} s^{-1} versus temperature for β, β', β/β', and nickel-base alloy MAR-M 200. Source: Ref 257

Silicides

Silicides have been used as commercial materials because of their excellent oxidation and corrosion resistance in hostile environments. For example, $MoSi_2$ is currently used for heating elements at temperatures to 1800 °C (3270 °F). Ni_3Si is the major constituent of the commercial alloy Hastelloy D, a corrosion-resistant alloy with the unique ability to resist attack by sulfuric acid solutions. This section briefly describes the recent work on a number of silicides, including Ni_3Si, Fe_3Si, $MoSi_2$, Nb_3Si, and Ti_5Si_3. Other potential uses for silicides include high-temperature structural materials and magnetic materials.

Ni_3Si Alloys. The silicide Ni_3Si has an $L1_2$ ordered crystal structure existing below the peritectic temperature of approximately 1035 °C (1900 °F) (Ref 36). It is of commercial interest because of its excellent corrosion resistance in acid environments, particularly sulfuric acid solutions. The engineering use of Ni_3Si is limited by its poor ductility at ambient temperatures and lack of fabricability at high temperatures (Ref 64, 66, 264, 265, 266, 267). Because of these problems, the commercial Ni_3Si alloy, Hastelloy D, has to be used in the cast condition with relatively poor mechanical properties.

Grain boundaries in Ni_3Si, like those in Ni_3Al, are intrinsically brittle, as evidenced by Auger spectroscopic analyses (Ref 264, 265, 266). As shown in Fig. 32, the ductility of Ni_3Si can be effectively improved by reducing the silicon concentration below 20 at .% or by microalloying with boron, carbon, or beryllium. A dramatic improvement in room-temperature ductility was obtained by adding boron to Ni-18.9Si-3.2Ti (at.%). The increase in ductility from 3% for Ni-22.5Si to 30% for Ni-18.9Si-3.2Ti-0.1%B is accompanied by a change in fracture mode from brittle grain-boundary fracture to ductile dimple failure. Auger analyses showed that boron strongly segregates to grain boundaries, thereby suppressing intergranular fracture.

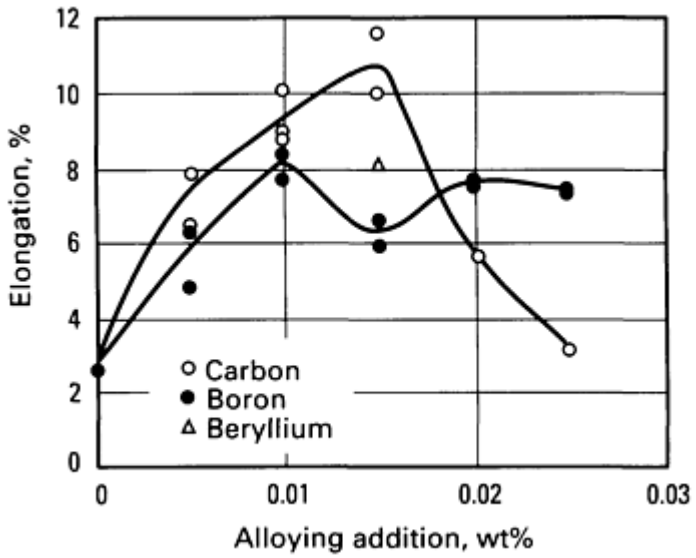

Fig. 32 Effect of microalloying with boron, carbon, and beryllium on the room-temperature ductility of Ni-22.5Si. Source: Ref 267

Just like Ni_3Al, ductile Ni_3Si alloys show a severe reduction in ductility at intermediate temperatures (400 to 800 °C, or 750 to 1470 °F) when tested in tension in air (Ref 267). The loss in ductility is due to dynamic embrittlement involving oxygen in air. The embrittlement can reduced and the ductility improved by alloying with moderate amounts (4 to 6%) of chromium.

In the early 1970s, it was reported that additions of titanium greatly improved the as-cast properties of Ni_3Si alloys but reduced their hot fabricability (Ref 268, 269). A recently conducted systematic study (Ref 265, 267) of alloying effects for the development of wrought Ni_3Si alloys found that macroalloying with niobium and vanadium is an effective as that with titanium in improving the room-temperature ductility of Ni_3Si alloys. On the other hand, the alloying elements molybdenum, iron, and chromium are beneficial to hot fabricability. Some Ni_3Si alloys containing these three elements showed a superplastic behavior (approximate elongation of 500 to 600%) when tested at 1020 to 1100 °C (1870 to 2010 °F) in air. The strength of Ni_3Si at temperatures up to 700 °C (1290 °F) can be significantly improved by the addition of up to 1% Hf. Some alloys, such as Ni-18.9Si-3.2Cr-0.6Hf-0.15B (at.%) are, in fact, as strong as nickel-base superalloy IN-718 at room and intermediate temperatures. These ductile, strong Ni_3Si alloys have the potential to be used as structural materials for chemical and petrochemical applications.

Fe_3Si Alloys. The iron silicide, Fe_3Si, forms the $D0_3$ structure with a high T_c (1240 °C, or 2265 °F), whereas the iron aluminide, Fe_3Al, has the same structure with a much lower T_c (540 °C, or 1000 °F) (Ref 36). A commercial alloy named Sendust based on Fe_3Si and Fe_3Al has been developed for magnetic applications (Ref 270, 271, 272, 273, 274, 275, 276); its typical composition is Fe-9.6Si-5.4Al (wt%). Sendust has been used as a magnetic head core material because of its superior magnetic properties and resistance to wear and corrosion. The alloy is hard and brittle at ambient and elevated temperatures; consequently, it is difficult to fabricate into useful forms.

Single crystals of Sendust deform by <111>{110} and <111>{112} slip systems, depending on the crystal orientation (Ref 271). Polycrystalline Sendust is very strong at room temperature, with a yield strength of approximately 1240 MPa (180 ksi) and an ultimate tensile strength of approximately 1900 MPa (275 ksi) in compression tests (Ref 272). The yield strength decreases moderately at temperatures below 600 °C (1110 °F), and it decreases sharply above that temperature.

The corresponding fracture mode changes from predominantly transgranular cleavage to a mixed mode of cleavage and grain-boundary separation. The cleavage planes are of the {100} type.

Steady-state deformation of Sendust at high temperatures is governed by grain-boundary sliding, migration, and dynamic recrystallization. A careful control of test temperature and strain rate results in extensive deformation and ductile fracture (Ref 273). Figure 33 defines the critical condition for the ductile-to-brittle transition observed in Sendust. Extrapolation of the critical line in Fig. 33 to higher temperatures gives optimum conditions for hot forging and rolling of polycrystalline Sendust; these extrapolated conditions have been supported by experimental data. Hot-rolled materials exhibited better magnetic properties because the segregation of alloying elements introduced during solidification was eliminated by hot rolling (Ref 274). The development of the hot fabrication scheme substantially reduced the production cost of Sendust for magnetic head core applications.

$MoSi_2$ and Refractory Silicides. Molybdenum disilicide ($MoSi_2$) is a line compound with a very high melting point (T_m = 2020 °C, or 3670 °F) (Ref 36). It has an ordered tetragonal structure ($C11_b$) in which the unit cell contains three bcc lattices. $MoSi_2$ is attractive because of its high electrical and thermal conductivities and excellent oxidation resistance at high temperatures. The silicide is capable of forming a thin adhesive self-healing protective layer of silica glass on its surfaces when exposed to oxidizing atmospheres at temperatures up to 1800 °C (3270 °F). $MoSi_2$ has been used

commercially for electrical heating elements in high-temperature furnaces under the trade name of Kanthal (Ref 277). The Kanthal materials, which contain roughly 80% $MoSi_2$ and 20% glass ceramic compounds, are prepared by P/M processing. The ceramic component is added to improve the ductility of these materials at high temperatures and also to increase their electrical resistance. The lifetime of Kanthal heating elements can be as long as 5 years. However, $MoSi_2$ is prone to fast intergranular oxidation with severe material damage when exposed to air at 500 to 800 °C (930 to 1470 °F) (Ref 278). This problem can be alleviated by rapid heating to above 800 °C (1470 °F), or pre-heating to high temperatures for the formation of protective silica films.

Recently, considerable attention (Ref 278, 279, 280, 281) has been given to the development of $MoSi_2$ as a high-temperature structural material for use at temperatures up to approximately 0.8 T_m (1550 °C, or 2820 °F). $MoSi_2$ is very brittle and hard (750 HV) at ambient temperatures. Figure 34 shows strength as a function of test temperature for $MoSi_2$. From 20 to 1250 °C (70 to 2280 °F), the yield strength is around 320 MPa (46 ksi) and is independent of temperature; however, it decreases abruptly above 1300 °C (2370 °F). The silicide exhibits a brittle-to-ductile transition around 925 °C (1700 °F), and above that temperature fracture strength increases sharply, as indicated by the line above the yield stress trend line in Fig. 34. Single crystals of $MoSi_2$ and WSi_2 have been successfully grown by floating-zone techniques. Studies of deformation in these crystals at 900 to 1500 °C (1650 to 2730 °F) revealed that slip occurs mainly on {110} and {013} planes (Ref 279, 280).

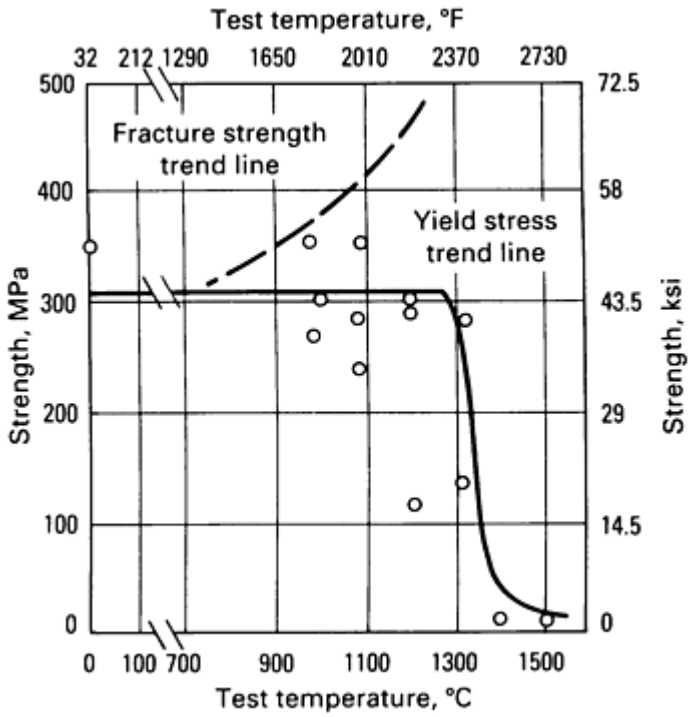

Fig. 34 Strength of $MoSi_2$ as a function of temperature. Data points determined by various investigators and compiled in Ref 281.

As shown in Fig. 34, $MoSi_2$ is not strong at high temperatures, particularly above 1300 °C (2370 °F). Consequently, efforts have been initiated to develop composite materials based on $MoSi_2$ (Ref 281, 282). Both ceramic fibers (or particulates) and ductile metal wires have been selected as reinforcement components. The ceramics, which include silicon carbide (SiC), titanium carbide (TiC), and zirconium diboride (ZrB_2), are compatible with $MoSi_2$, whereas the metal wires, which include niobium, tantalum, and tungsten, react with the silicide to form protective layers of Mo_5Si_3 that slow down interdiffusional processes (Ref 281). Some limited data have demonstrated pronounced improvements in high-temperature strength and room-temperature fracture toughness from these reinforcements. Further studies are required to optimize processing parameters.

Other refractory silicides, including Nb_5Si_3 (Ref 281, 283) and Ti_5Si_3 (Ref 284, 285), have also been studied recently because of their extremely high melting points (>2000 °C, or 3630 °F) and their potential for good oxidation resistance. These silicides form complex ordered crystal structures and are very hard and brittle at ambient temperatures. For example, Ti_5Si_3 showed essentially brittle cleavage fracture with a hardness as high as 1000 HV (Ref 285). The

mechanical properties of the monolithic silicides do not appear to be significantly improved by material processing and alloy additions, and current efforts are thus mainly devoted to the development of two-phase structures with silicides as the precipitate phase (Ref 283, 284).

Figure 35 shows the existence of a pseudobinary eutectic between Ti_5Si_3 and Ti_3Al. The eutectic line determined allows control of microstructural variables including morphology, volume fraction, and the size of individual microconstituents in the titanium-silicon-aluminum ternary alloys. Coarse platelets observed in hypereutectic compositions severely embrittle the alloys. On the other hand, the fine two-phase mixture formed at the eutectic compositions provides better mechanical properties and warrants further study. Fine precipitation of Nb_5Si_3 in a niobium matrix results in a pronounced improvement in fracture toughness at ambient temperatures and in bend strength at temperatures up to 1400 °C (2550 °F) (Ref 283).

Specific Gravity Versus Melting Point Diagrams for High-Temperature Intermetallics

The search for high-temperature low-density intermetallic compounds for aircraft and space applications has prompted the compilation (Ref 286, 287, 288) of structure-insensitive properties of 293 binary intermetallics that melt at temperatures at 1500 °C (2730 °F) and above. The properties include specific gravity, melting point, and elastic modulus; these properties are basically insensitive to processing history, heat treatment, impurities, and resultant microstructures. Figure 36 shows locations of the systems on a specific gravity (ρ) versus melting point (T_m) diagram. The data points are

essentially distributed on the upper left side of the diagram and are bounded by an envelope line. Data points located near the envelope line represent the most promising materials for aerospace applications.

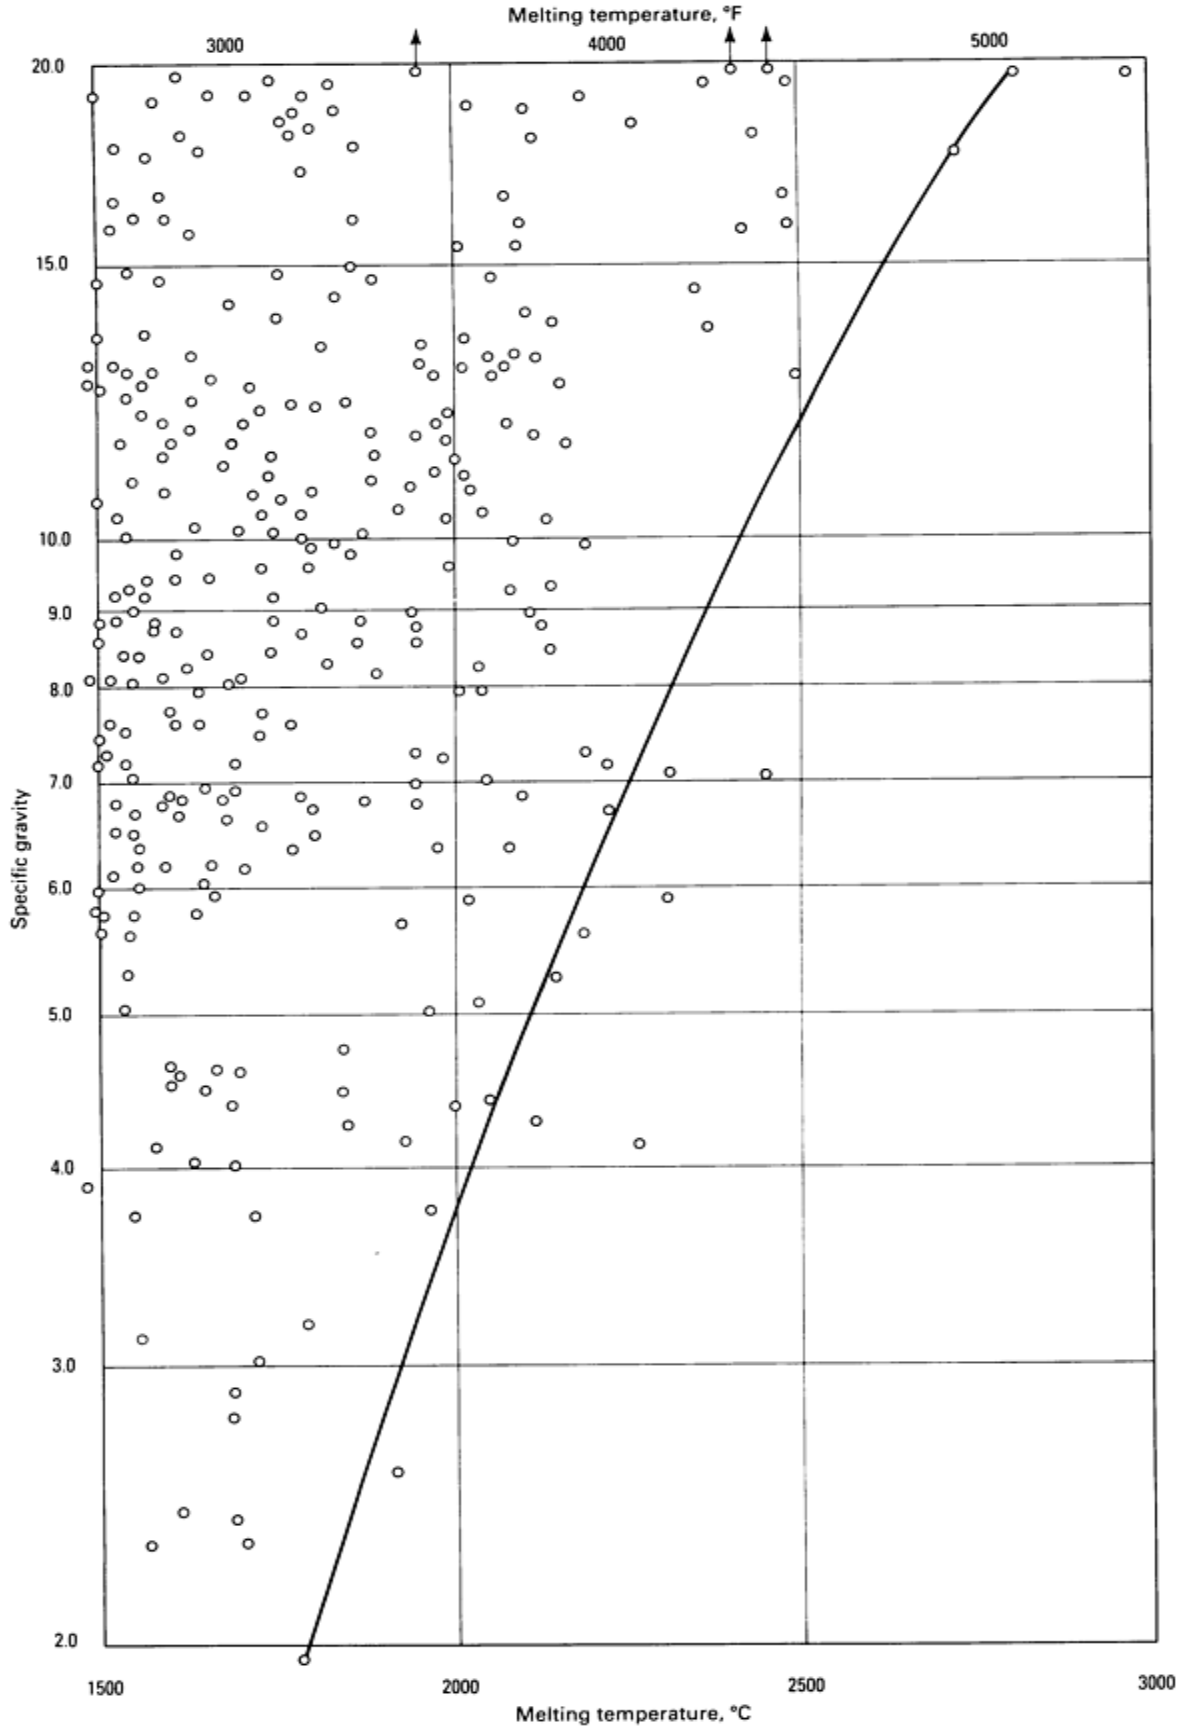

Fig. 36 Melting temperature versus specific gravity for 293 binary intermetallic compounds. The solid line is an empirical approximate

envelope to the data. Source: Ref 286

The low ρ and high T_m envelopes derived for various types of intermetallic compounds are located separately when plotted in Fig. 36 (Ref 286). The envelopes for closely packed ordered structures like $L1_2$ and $D0_{22}$ are located near the upper left corner, and the envelopes for refractory silicides with $D8_8$-type structures and beryllides with C_{14} and C_{15} ordered structures are close to the overall envelope line shown in Fig. 36. Because of their low density, high melting point, and excellent oxidation resistance, beryllides are promising materials for aerospace applications, and development activities in this area have increased recently (Ref 289, 290, 291, 292).

A compilation and representation of data in terms of specific gravity, melting point, elastic modulus, and crystal structures provides a useful guide for preliminary ranking of intermetallics for various uses, particularly aerospace applications. However, other characteristics, including such structure-sensitive properties as low-temperature toughness and high-temperature strength and creep resistance, should also be considered when developing and selecting materials for specific applications.

Summary

Ordered intermetallic compounds based on aluminides and silicides constitute a unique class of metallic materials that have promising physical and mechanical properties for structural applications at elevated temperatures. The attractive properties of these compounds include excellent high-temperature strength, superior resistance to oxidation and corrosion, high melting points, and relatively low material density. However, major drawbacks of ordered intermetallics are their poor ductility and low fracture resistance at ambient temperatures.

For about the past ten years, substantial efforts have been devoted to research and development of intermetallics, and significant progress has been made in understanding their susceptibility to brittle fracture and in improving their ductility and toughness at both low and high temperatures. In a number of cases, significant tensile ductility has been achieved at ambient temperatures by controlling ordered crystal structures, increasing deformation modes, enhancing bulk and grain-boundary cohesive strengths, and controlling surface compositions and test environments. Success in these areas has inspired parallel efforts aimed at improving strength properties.

The alloy design work has been centered primarily on aluminides of nickel, iron, and titanium, and this work has resulted in substantial improvements in the mechanical and metallurgical properties of these materials at ambient and elevated temperatures. At the present time, the ductile aluminide alloys based on Ni_3Al, Fe_3Al, FeAl, and Ti_3Al compositions have been developed to the stage of being ready or close to ready for structural applications. Further research is required to develop a data base that includes information on tensile, creep, fracture toughness, low- and high-cycle fatigue, crack growth, and elastic modulus properties of these aluminides in specific applications.

The research and development work on nickel, iron, and titanium aluminides has recently extended to other aluminides and intermetallics such as Al_3X trialuminides and refractory silicides. Their susceptibility to brittle fracture and poor

toughness remains the major factor limiting the potential structural uses of these materials. However, remarkable progress has been made in improving their low-temperature toughness and high-temperature strength. The recent development of new physical metallurgy tools for ordered intermetallics such as structural maps (Ref 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239) and specific gravity versus melting point diagrams (Ref 286, 287, 288) is expected to accelerate the alloy development of these materials.

Ordered intermetallics with improved ductility and toughness have been considered for elevated-temperature structural applications that require high-temperature strength, low material density, and corrosion resistance. Titanium aluminides (Ti_3Al and TiAl) with high specific strengths have been developed for jet engine, aircraft, and related structural applications. Nickel aluminides based on Ni_3Al that have a combination of good strength, ductility, and oxidation resistance are currently being developed for use as high-temperature dies, heating elements, and hot components in heat engines and energy conversion systems. It has been found that Fe_3Al and FeAl aluminides possess excellent corrosion resistance in oxidizing, sulfidizing, and molten salt environments. As shown in Fig. 21, the iron aluminide alloys exhibit corrosion rates lower than those of the best existing iron-base alloys (including existing coating materials) by more than two orders of magnitude when tested in a severe sulfidizing environment at 800 °C (1470 °F) (Ref 126). A combination of low material cost and density with adequate ductility and fabricability makes iron aluminide alloys extremely attractive for structural applications in corrosive environments. Because of the superior corrosion resistance of aluminides and silicides, they should make a major impact on next-generation corrosion-resistant materials.

Ordered intermetallics have been employed in many areas besides structural applications. Molybdenum disilicide has been used commercially for electrical heating elements in high-temperature furnaces since 1956 (Ref 277). The $Fe_3(Si,Al)$ alloy with the trade name of Sendust has been developed for magnetic applications because of its superior magnetic properties as well as its wear and corrosion resistance (Ref 270, 271, 272, 273, 274, 275, 276). The NiTi alloy called Nitinol (Ref 293, 294) is currently the major material used as a shape memory alloy for systems control in the building, automobile, and automation industries (see the article "Shape Memory Alloys" in this Volume). Considerable efforts are now being devoted to the development of new shape memory alloys based on intermetallics for use at temperatures above ambient (>70 °C, or 160 °F).

Dispersion-Strengthened Nickel-Base and Iron-Base Alloys

J.J. deBarbadillo and J.J. Fischer, Inco Alloys International, Inc.

Introduction

MECHANICAL ALLOYING (MA) was originally developed for the manufacture of nickel-base superalloys strengthened by both an oxide dispersion and γ' precipitate. Now in its third decade of advancement, mechanical alloying provides a means for producing powder metallurgy (P/M) dispersion-strengthened alloys of widely varying compositions with a unique set of properties. At present, commercial quantities of material are available in the nickel-, iron-, and aluminum-base alloy systems.

It has been known for some time that the strength of metals at high temperature could be increased by the addition of a dispersion of fine refractory oxides. While many methods can produce such dispersions in simple metal systems, these techniques are not applicable to the production of the more highly alloyed materials required for gas turbines and critical industrial applications. Conventional P/M techniques, for example, either do not produce an adequate dispersion or do not permit the use of reactive elements such as aluminum and chromium. These elements confer beneficial characteristics, including corrosion resistance and intermediate temperature strength. In contrast, the mechanical alloying process was developed to introduce a fine inert oxide dispersion into superalloy matrices that contain reactive alloying elements.

Mechanical Alloying Alloy Applications

MA ODS (oxide dispersion-strengthened) alloys were used first in aircraft gas-turbine engines and later in industrial turbines. Components include vane airfoils and platforms, blades, nozzles, and combustor/augmentor assemblies. As experience was gained with production, fabrication, and use of the alloys, this knowledge was applied to the manufacture of component parts in numerous industries. These include diesel-engine glow plugs, heat-treatment fixtures (including shields, baskets, trays and mesh belts, and skid rails for steel plate and billet heating furnaces), burner hardware for coal- and oil-fired power stations, gas sampling tubes, thermocouple tubes, and a wide variety of components used in the production or handling of molten glass.

Mechanical Alloying Process

The mechanical alloying process may be defined as a method for producing composite metal powders with a controlled microstructure. The process involves repeated fracturing and rewelding of a mixture of powder particles in a highly energetic ball charge. On a commercial scale, the process is carried out in vertical attritors or horizontal ball mills.

During each collision of the grinding balls, many powder particles are trapped and plastically deformed. The process is illustrated schematically in Fig. 1. Sufficient deformation occurs to rupture any absorbed surface-contaminant film and expose clean metal surfaces. Cold welds are formed where metal particles overlay, producing composite metal particles.

At the same time, other powder particles are fractured. Figure 1 shows two metallic constituents as indicated by light and cross-hatched particles, although in a commercial alloy there may be several constituents.

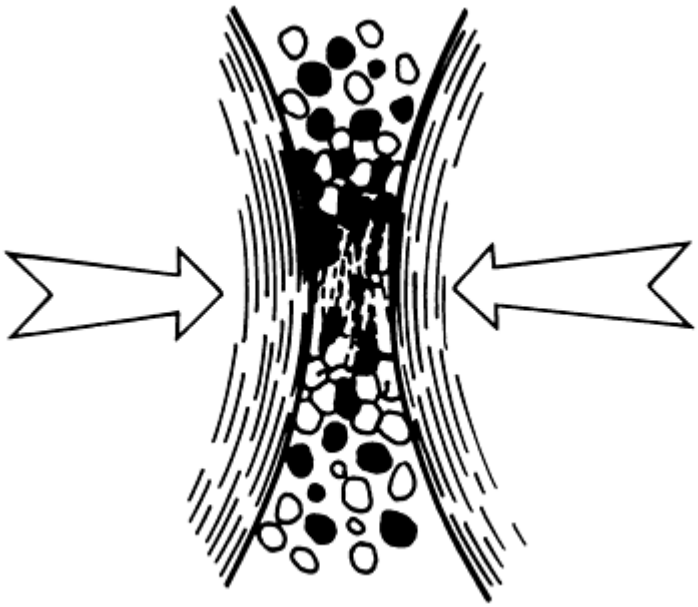

Fig. 1 Schematic depicting the formation of composite powder particles at an early stage in the mechanical alloying process

As the process progresses, most of the particles become microcomposites similar to the one produced in the collision of Fig. 1. The cold welding, which tends to increase the size of the particles involved, and the fracturing (of the particles), which tends to reduce particle size, reach a steady-state balance. This leads to a relatively coarse and stable overall particle size. The internal structure of the particles, however, is continually refined by the repeated plastic deformation.

Production of ODS Superalloy Powders. A uniform distribution of submicron refractory oxide particles must be developed in a highly alloyed matrix for the production of ODS alloys. This requires a powder mixture more varied in composition and particle size than indicated schematically in Fig. 1. A typical powder mixture may consist of fine (4 to 7 μm) nickel powder, -150 μm chromium, and -150 μm master alloy. The master alloy may contain a wide range of elements selected for their roles as alloying constituents or for gettering of contaminants. About 2 vol% of very fine yttria, Y_2O_3 (25 nm, or 250 Å) is added to form the dispersoid. The yttria becomes entrapped along the weld interfaces between fragments in the composite metal powders. After completion of the powder milling a uniform interparticle spacing of about 0.5 μm (20 μin.) is achieved.

Consolidation and Property Development. The production of powder containing a uniform dispersion of fine refractory oxide particles in a superalloy matrix is only the first step in achieving the full potential of this type of alloy. These powders must be consolidated and worked under conditions that develop coarse grains during a secondary recrystallization heat treatment. A schematic representation of key operations in the production sequence of a selected product is shown in Fig. 2. It must be emphasized that while the powder-making process is unique to mechanical alloying, all succeeding operations are done on standard mill equipment used to produce wrought high-performance alloys. MA ODS alloys are now commercially available as bar, plate, sheet, tube, wire, shapes, and forgings. However, not all alloys are available in all product forms.

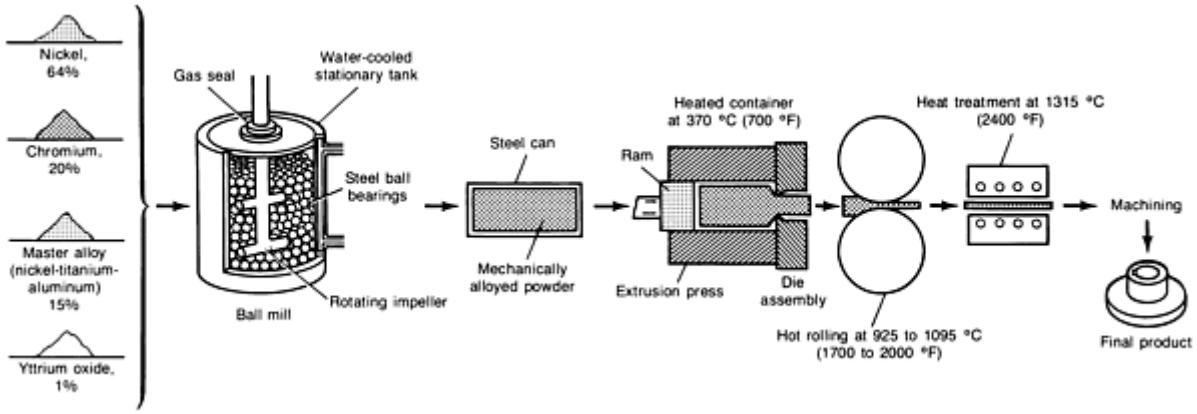

Fig. 2 Schematic showing typical process operations used in the production of MA ODS products

As noted previously, the final properties of MA ODS alloys are dependent on the grain structure as well as the presence of the fine dispersoid. In most products, a grain-coarsening anneal at about 1315 °C (2400 °F) is provided after fabrication. In bar stock, for example, relatively coarse grains are formed that are elongated in the direction of extrusion and working. This elongated structure is necessary for achievement of maximum elevated-temperature properties. Grain aspect ratio, the average grain dimension parallel to the applied stress divided by the average grain dimension perpendicular to the applied stress, has a strong effect on elevated-temperature stress-rupture properties. For many bar products, a high grain aspect ratio is desirable. Plate and sheet products tend to exhibit pancake-shape grains. Through careful control of processing conditions, these grains can be made to be equiaxed in the plane of the sheet, thus providing nearly isotropic properties in the plane of the sheet. Structures for tubing and forgings may be more complex.

Additional information is available in the article "Production of Nickel-Base Powders" in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook.*

Commercial Alloys

The most common mechanically alloyed ODS alloys include MA 754, MA 758, MA 956, MA 6000, and MA 760.

Alloy MA 754

Alloy MA 754 was the first mechanically alloyed ODS superalloy to be produced on a large scale. This material is basically a Ni-20Cr alloy strengthened by about 1 vol% Y_2O_3 (see Table 1). It is comparable to TD NiCr (an earlier ODS material strengthened by thoria, ThO_2) but has a nonradioactive dispersoid, and because of its higher strength, has been extensively used for aircraft gas-turbine vanes and high temperature test fixtures.

Table 1 Nominal composition of selected mechanically alloyed materials

Alloy designation	Ni	Fe	Cr	Al	Ti	W	Mo	Ta	Y_2O_3	C	B	Zr
MA 754	bal	. . .	20	0.3	0.5	. . .	. . .	. . .	0.6	0.05	. . .	. . .
MA 758	bal	. . .	30	0.3	0.5	. . .	. . .	. . .	0.6	0.05	. . .	. . .
MA 760	bal	. . .	20	6.0	. . .	3.5	2.0	. . .	0.95	0.05	0.01	0.15
MA 6000	bal	. . .	15	4.5	2.5	4.0	2.0	2.0	1.1	0.05	0.01	0.15

MA 956	. . .	bal	20	4.5	0.5	. . .	. . .	. . .	0.5	0.05	. . .	. . .

Microstructure. The microstructure of a commercially produced rectangular bar shows the elongation of the grains along the direction of working. Grain width in the long transverse direction is somewhat greater than the grain thickness. The details of the grain structure in the longitudinal and transverse sections are shown in Fig. 3. The longitudinal view shows the maximum and minimum grain dimensions, whereas the transverse view shows the extreme irregularity of grain boundaries typical of ODS materials. Although it is not obvious from the photomicrograph, this alloy possesses a strong (100) crystallographic texture in the longitudinal direction. This texture has been associated with optimum thermal fatigue resistance.

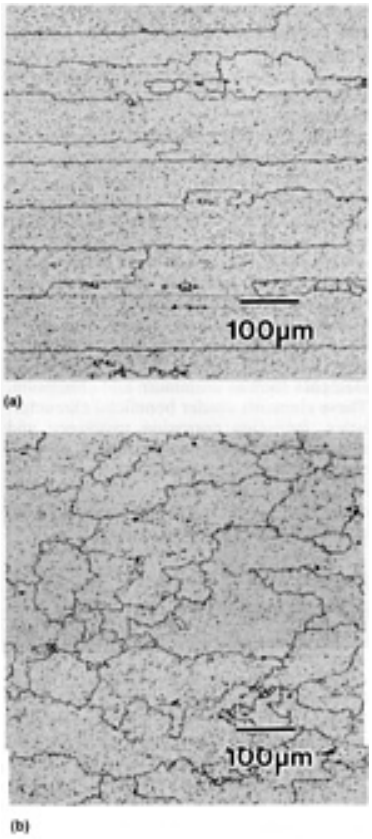

Fig. 3 Alloy MA 754 microstructure shown from two different views. (a) Longitudinal. (b) Transverse. Note high grain aspect ratio shown in longitudinal section (a).

The oxide dispersoid distribution in MA 754 is shown in Fig. 4. The very fine, dark particles are the uniform dispersion of stable yttrium aluminates formed by the reaction between the added yttria, excess oxygen in the powder, and aluminum added to the getter oxygen. The larger dark particles are titanium carbonitrides.

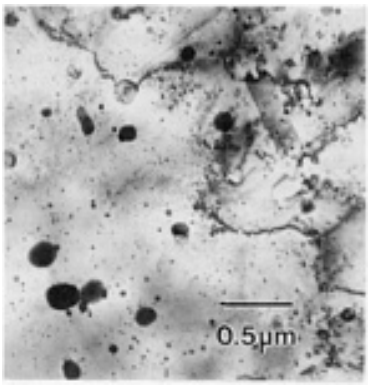

Fig. 4 Transmission electron microscopy (TEM) photomicrograph of alloy MA 754 microstructure showing uniform distribution of fine oxides and scattered coarser carbonitrides

Elevated Temperatures Strength. The tensile properties of MA 754 bar are shown in Fig. 5(a), 5(b), and 5(c). The properties shown are for the longitudinal direction. Long transverse strength is similar, but ductility is considerably lower.

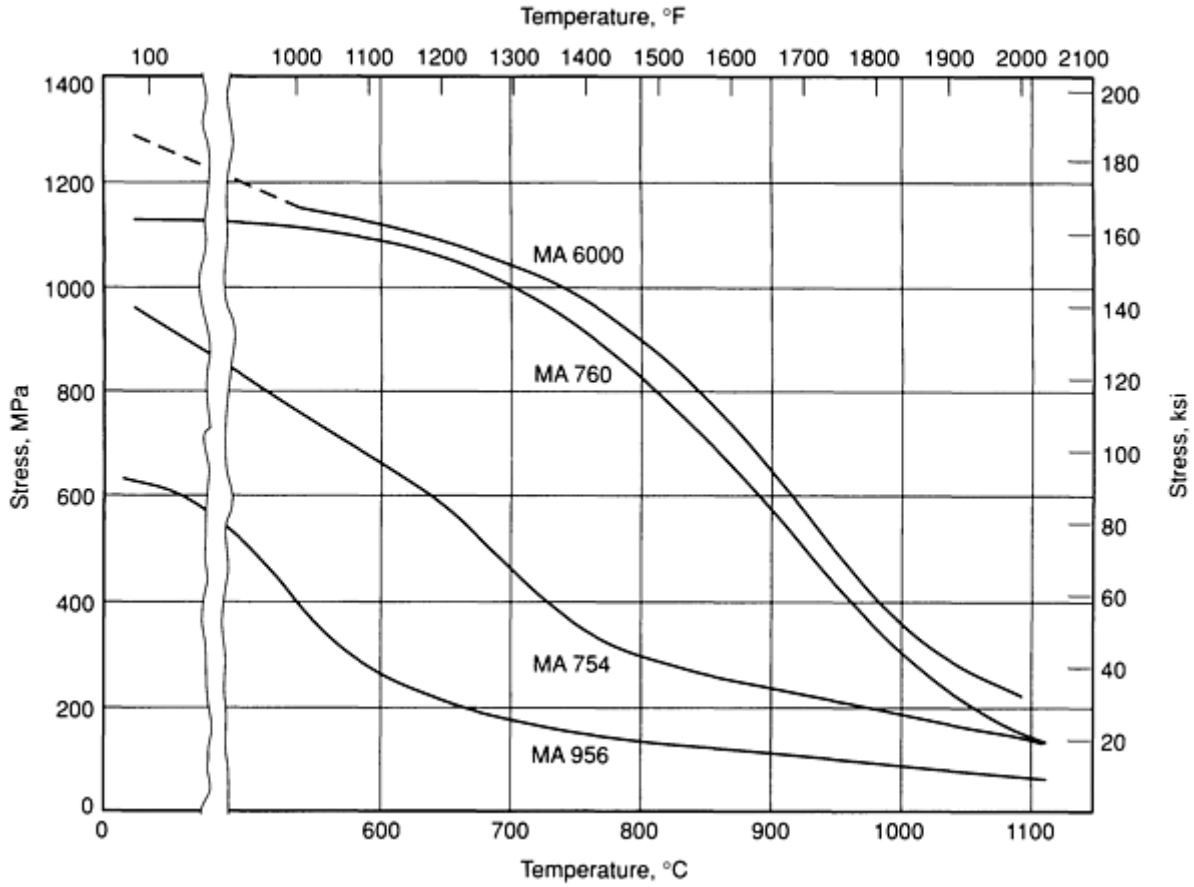

Fig. 5(a) Effect of temperature on the tensile strength of selected MA ODS alloys. Data is for longitudinal direction.

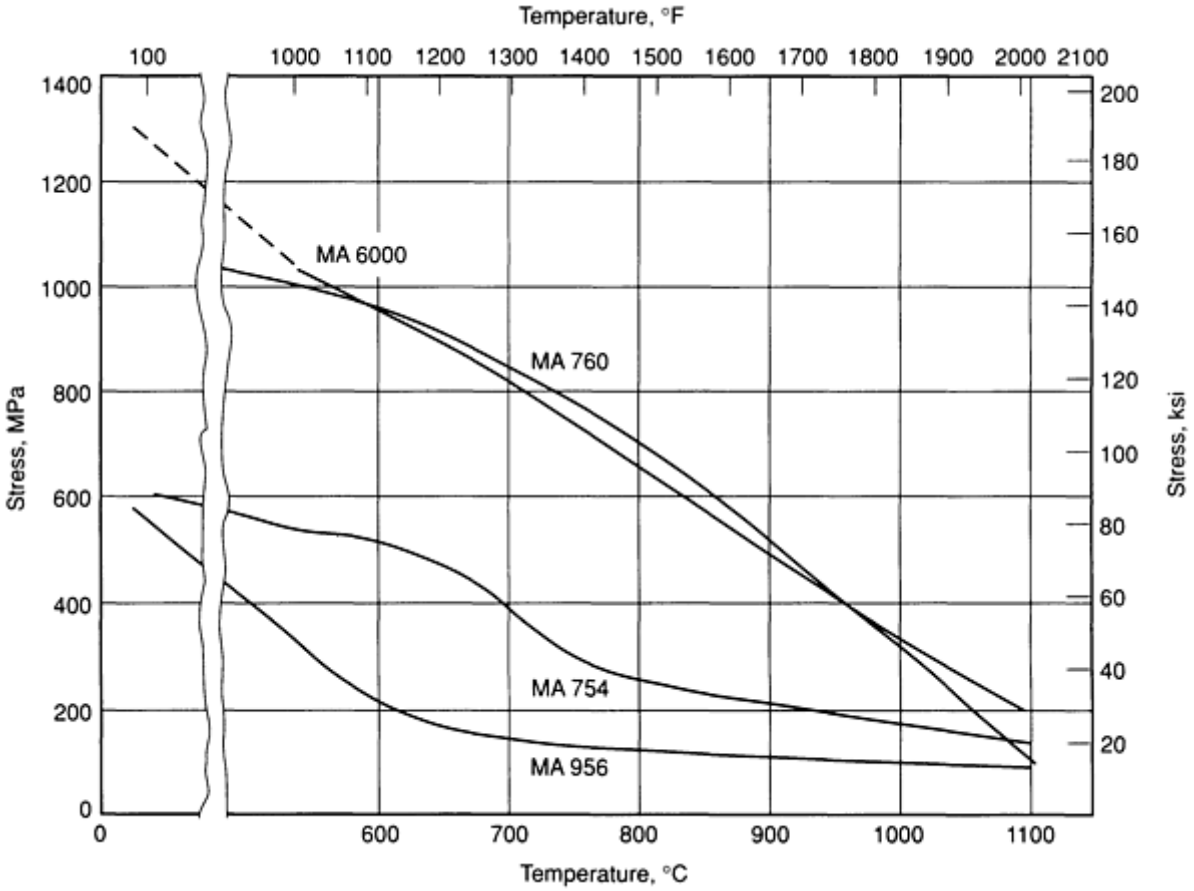

Fig. 5(b) Effect of temperature on the yield strength (0.2% offset) of selected MA ODS alloys. Data is for longitudinal direction.

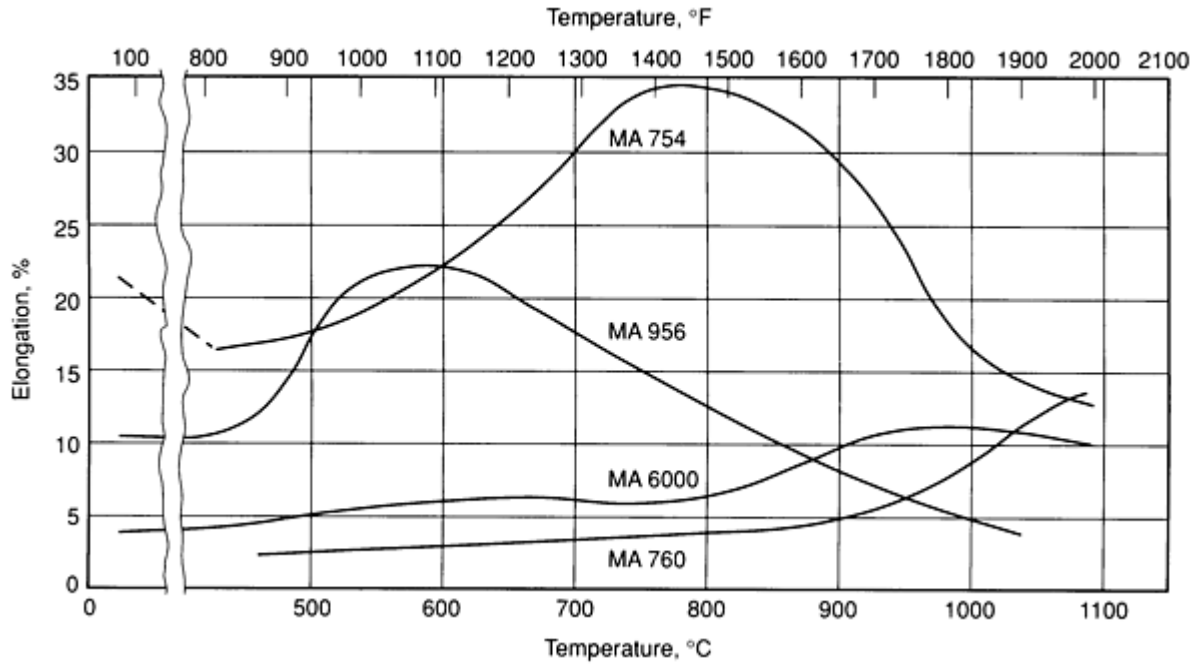

Fig. 5(c) Effect of temperature on the elongation of selected MA ODS alloys. Data is for longitudinal direction.

In Fig. 6, the 1095 °C (2000 °F) longitudinal stress-rupture properties of MA 754 bar are compared to those of TD NiCr, thoriated nickel bar, alloy MAR-M 509 (a cast cobalt-base alloy), and alloy 80A, a conventional nickel-base alloy having a composition similar to the matrix of MA 754. MA 754, like other ODS materials, has a very flat log stress-log rupture life slope compared to conventional alloys.

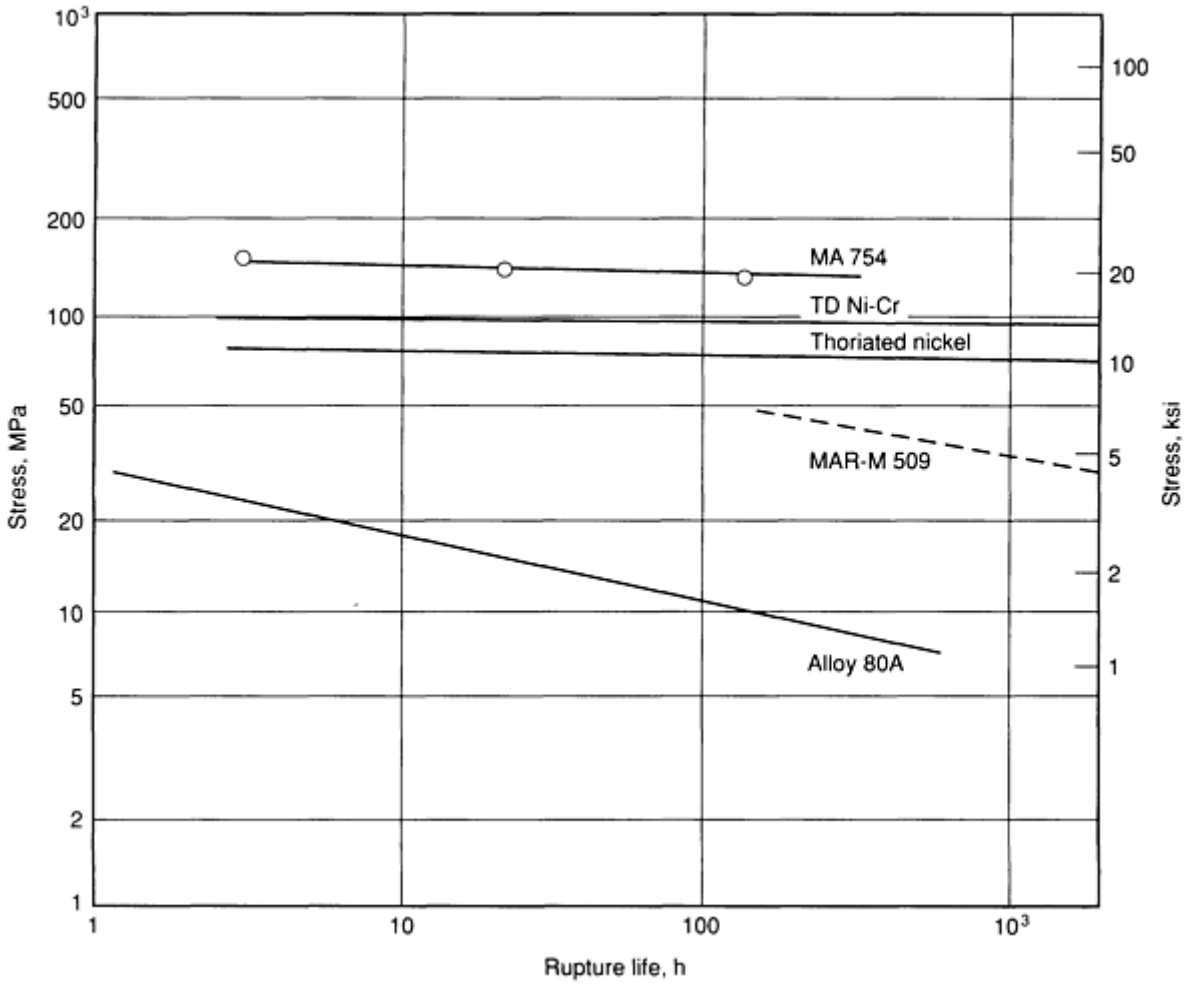

Fig. 6 Comparison of stress-rupture properties of alloy MA 754 bar to other alloy material bars at 1095 °C (2000 °F)

The elevated-temperature stress-rupture properties of MA 754 bar are dependent on testing direction, as indicated in Table 2. The rupture-stress capability in the longitudinal direction is consistently higher than that in the long transverse direction, reflecting the differences in grain aspect ratio in the two directions. When MA 754 is produced as cross-rolled plate with coarse equiaxed pancake grains, equal longitudinal and transverse stress-rupture properties are observed. In this form, the rupture strength is about 80% that of the longitudinal bar.

Table 2 Stress-rupture properties of Alloy MA 754 bars

Temperature	Longitudinal		Long transverse	
	Stress to produce rupture in		Stress to produce rupture in	
	100 h	1000 h	100 h	1000 h

°C	°F	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi
650	1200	284	41.2	256	37.2	241	35.0	208	30.2
760	1400	214	31.1	199	28.8	172	25.0	149	21.6
870	1600	170	24.7	158	22.9	108	15.6	91	13.2
980	1800	136	19.7	129	18.7	63	9.1	46	6.6
1095	2000	102	14.8	94	13.6	38	5.5	24	3.5
1150	2100	90	13.1	78	11.3	23	3.4	17	2.4

Physical Properties. Important physical properties of alloy MA 754 are given in Table 3. The relatively high melting point, 1400 °C (2550 °F), and low room-temperature modulus of elasticity in the longitudinal direction 151 GPa (22×10^6 psi) are especially important. The low modulus, indicating a strong (100) crystallographic texture in the direction of the long grain dimension, has been shown to give superior thermal fatigue resistance.

Table 3 Physical properties of selected mechanical alloying ODS materials

Alloy	Melting point		Modulus of elasticity		Mass density		Coefficient of expansion, at 20 to 980 °C (70 to 1800 °F)	
	°C	°F	GPa	psi × 10^6	g/cm^3	lb/$in.^3$	µm/m · K	µin./in. · °F
MA 754	1400	2550	151	22	8.3	0.30	16.9	9.41
MA 956	1480	2700	269	39.0	7.2	0.26	14.8	8.22

Alloy MA 758

Alloy MA 758 is a higher-chromium version of MA 754 (see Table 1). This alloy was developed for applications in which the higher chromium content is needed for greater oxidation resistance. The mechanical properties of this alloy are similar to those of MA 754 when identical product forms and grain structures are compared. This alloy has found applications in the thermal processing industry and is also used in the glass-processing industry.

Alloy MA 956

The production of alloy MA 956 demonstrates the ability to add large amounts of metallic aluminum by mechanical alloying (see Table 1). This material is a ferritic iron-chromium-aluminum alloy, dispersion-strengthened with yttrium aluminates formed by the addition of about 1 vol% of yttria. Because of its generally good hot and cold fabricability, MA 956 has been produced in the widest range of product forms of any MA ODS alloy. In sheet form, this alloy is produced by a sequence of hot and cold working, which yields large pancake-shape grains following heat treatment. This grain structure ensures excellent isotropic properties in the plane of the sheet. MA 956 is used in the heat-treatment industry for

furnace fixturing, racks, baskets, and burner nozzles. It also is used in advanced aerospace sheet and bar components, where good oxidation and sulfidation resistance are required in addition to high-temperature strength properties.

Mechanical Properties. The tensile properties of MA 956 are shown in Fig. 5(a), 5(b), and 5(c). The tensile strength of this alloy is quite a bit lower than that of the other MA materials at low temperatures. However, the strength-versus-temperature curve is extremely flat so that the strength of this alloy exceeds that of all non-ODS sheet materials at approximately 1095 °C (2000 °F).

The stress-rupture properties of MA 956, at elevated temperatures in both the longitudinal and transverse directions, are given in Table 4.

Table 4 Stress-rupture properties of Alloy MA 956 sheet

Temperature		Longitudinal						Transverse					
		Stress to produce rupture in						Stress to produce rupture in					
		10 h		100 h		1000 h		10 h		100 h		1000 h	
°C	°F	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi
980	1800	84	12.2	75	10.9	67	9.7	72	10.4	70	10.2	63	9.1
1100	2010	64	9.3	57	8.3	51	7.4	64	9.3	57	8.3	. . .	. . .

Physical Properties. Alloy MA 956 has a very high melting point (1480 °C, or 2700 °F), a relatively low density (7.2 g/cm^3, or 0.26 lb/in.^{3}) compared to competitive materials, and a relatively low thermal expansion coefficient (see Table 3). This combination of properties makes the alloy well suited for sheet applications such as gas-turbine combustion chambers.

Alloy MA 6000

Alloy MA 6000 has a composition based on an alloy-development philosophy similar to that of the more sophisticated cast and wrought superalloys. This is because it contains a critical balance of elements to produce strength at intermediate and elevated temperatures, along with oxidation and hot-corrosion resistance. Alloy MA 6000 combines γ' hardening from its aluminum, titanium, and tantalum content for intermediate strength, with oxide dispersion-strengthening from the yttria addition for strength and stability at very high temperatures. Oxidation resistance comes from its aluminum and chromium contents, while titanium, tantalum, chromium, and tungsten act in concert to provide sulfidation resistance. The tungsten and molybdenum also act as solid solution strengtheners in this alloy. MA 6000 is an ideal alloy for gas-turbine vanes and blades where exceptional high-temperature strength is required.

Microstructure. Alloy MA 6000 has a highly elongated coarse grain structure that results from the thermomechanical processing (TMP) followed by high-temperature annealing. It has proved useful to utilize zone annealing to achieve the optimum grain aspect ratio for this alloy. As a result, the only product forms presently available are bar or small forgings.

Zone annealing is performed by slowly passing a heating element dow the axis of the bar. In practice, either resistance or induction heating can be used. A typical zone annealing speed is 100 mm/h (4 in./h).

The microstructure of MA 6000 is shown in Fig. 7. Note the high-volume fraction of γ' (45 to 50 vol%), and the very fine dispersoid particles present in both the γ' (dark irregular particles) and lighter matrix.

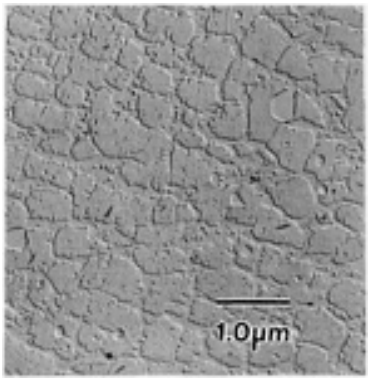

Fig. 7 Microstructure of heat-treated alloy MA 6000, showing high-volume fraction γ' and dispersoid phases

Mechanical Properties. The elevated-temperature properties of alloy MA 6000, in terms of the specific rupture strength for 1000-h life as a function of temperature, are compared with those of directionally solidified alloy DS MAR-M 200 containing hafnium and a thoriated nickel alloy bar in Fig. 8. This diagram clearly shows the effect of the two strengthening mechanisms in alloy MA 6000. At intermediate temperatures, around 815 °C (1500 °F), the strength of MA 6000 approachers that of the complex, highly alloyed alloy DS MAR-M 200 containing hafnium and is almost four times that of an unalloyed ODS metal such as thoriated nickel (TD nickel). At high temperatures (~1095 °C, or 2000 °F), where the alloy DS MAR-M 200 containing hafnium has lost most of its strength due to growth and dissolution of it's γ' precipitate, MA 6000 has useful strength due to the presence of the oxide dispersion. At temperatures between these extremes, the strength of MA 6000 is superior to both the cast nickel-base superalloy and the ODS metal because the two strengthening mechanisms supplement one another.

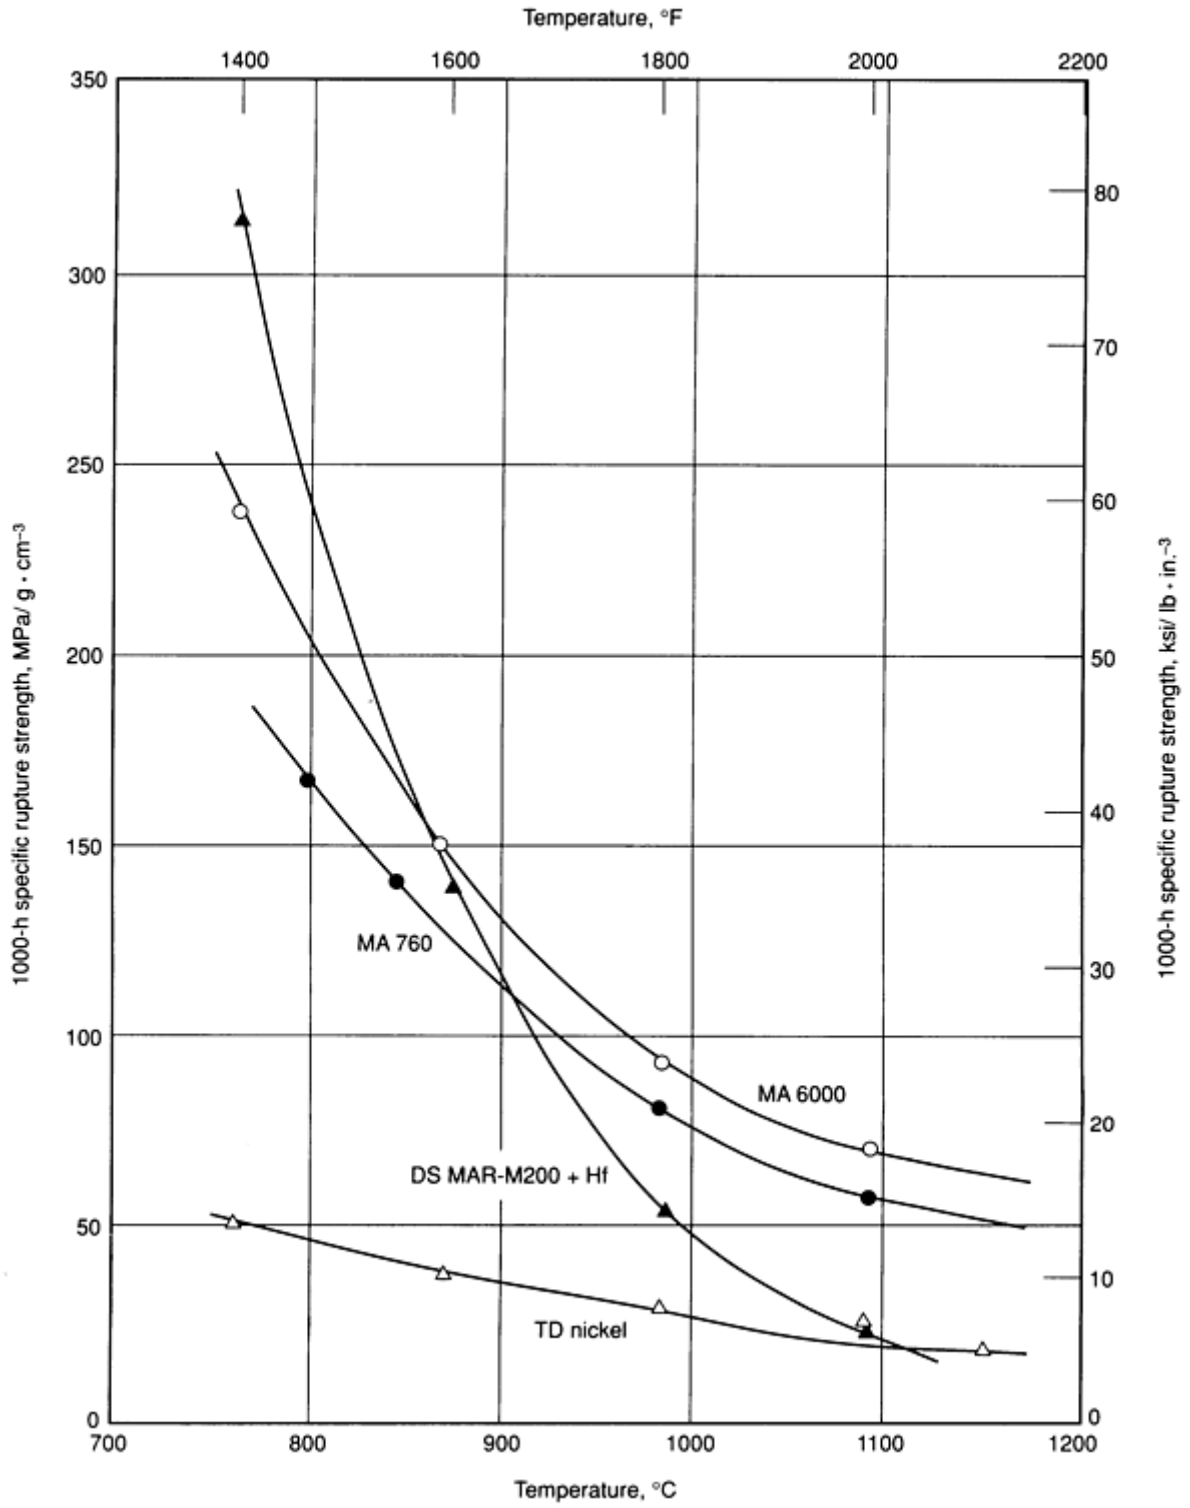

Fig. 8 Effect of temperature on the 1000-h specific rupture strength of MA 760, MA 6000, DS MAR-M 200, and TD nickel

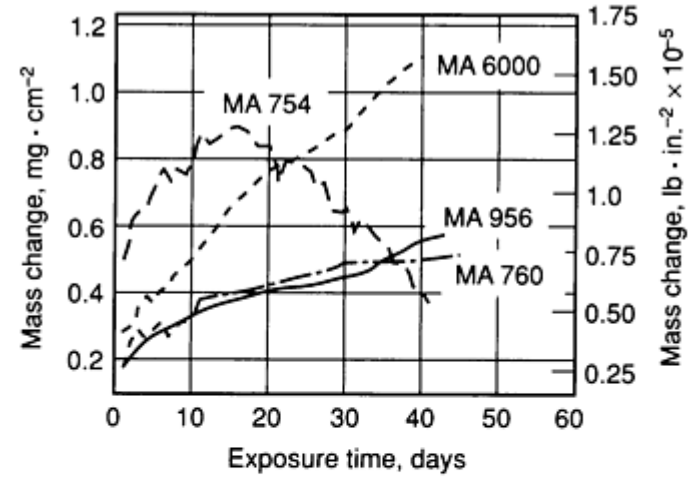
Alloy MA 760

Alloy MA 760 is an age-hardened nickel-base alloy with a composition designed to provide a balance of high-temperature strength, long-term structural stability, and oxidation resistance. Its primary use is expected to be for industrial gas turbines. The composition of this alloy is shown in Table 1. It is similar to MA 6000 in that its strength is supplemented by γ' age hardening. Its properties also benefit from zone annealing to give coarse elongated grains. The stress-rupture properties of alloy MA 760 exceed those of MA 754 but are exceeded by those of MA 6000 (see Fig. 5(a), 5(b), 5(c), and 8).

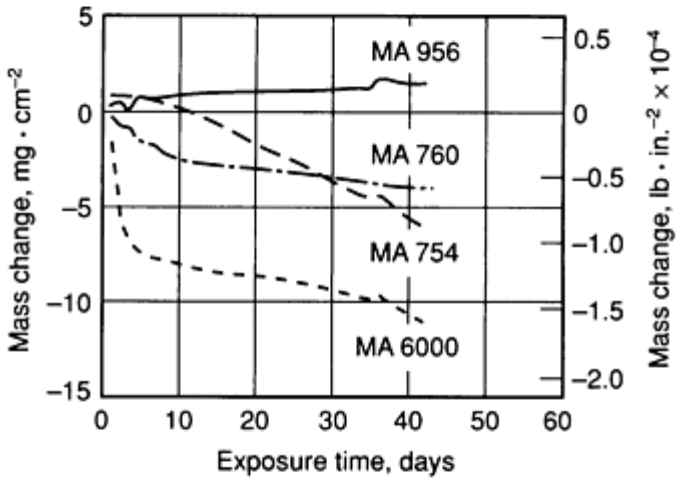
Oxidation and Hot-Corrosion Properties

Because the MA ODS alloys are normally used uncoated at very high temperatures in hostile environments, the resistance of the alloys to oxidation, carburization, sulfidation, and oxide fluxing is important. While all of the alloys are resistant to the effects of these deleterious chemical processes, the relative resistance varies with specific alloy and environment.

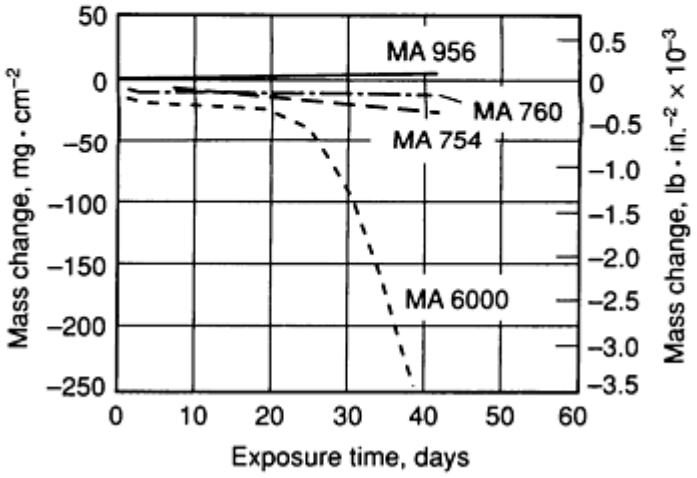
Figure 9 shows the resistance of the MA ODS alloys to cyclic oxidation at various temperatures. All of the alloys form protective scales at 1000 °C (1830 °F), and thus are highly resistant to oxidation. At higher temperatures, the relatively low-chromium MA 6000 shows increased weight loss, whereas the other alloys are highly stable. Under the most severe conditions, MA 6000 would require coating for long-time exposure. Coatings and procedures suitable for this alloy have been reported in the technical literature. The oxidation resistance of MA 956 is unsurpassed by any existing commercial sheet alloy. However, accelerated oxidation may occur in this alloy during long-time exposure at temperatures above 1200 °C (2190 °F) depending on the environment.



(a)



(b)



(c)

Fig. 9 Effect of temperature on mass change for four mechanically alloyed materials exposed to air containing 5% H_2O vapor. (a) 1000 °C (1830 °F). (b) 1100 °C (2010 °F). (c) 1200 °C (2190 °F)

Evaluation of oxidation-sulfidation resistance of gas-turbine alloys is frequently done in a burner-rig test. Representative data for selected alloys tested at 927 °C (1700 °F) is shown in Fig. 10. MA 956 exhibits extremely high resistance to this form of attack. MA 6000, though less resistant than MA 956, was comparable to the cast alloy IN-738 in this test.

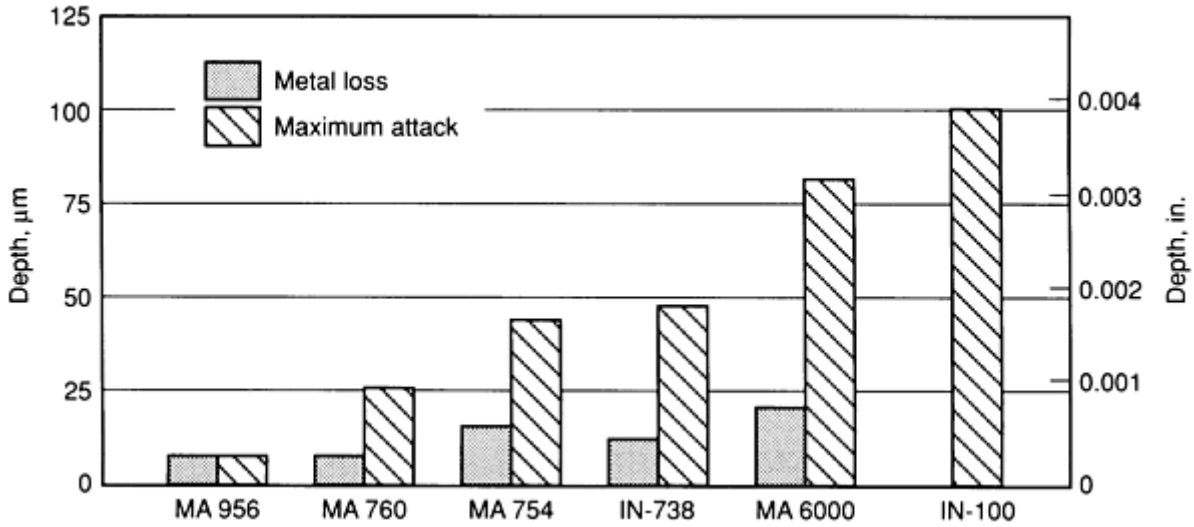


Fig. 10 Comparison of the oxidation-sulfidation resistance of MA ODS alloys with that of superalloys IN-738 and IN-100. Tested in a burner rig for 500 h at 925 °C (1700 °F) using an air-to-fuel ratio that varied from 27:1 to 21:1. JP-5 fuel contained 0.3% S. Temperature test cycle consisted of the alloy held at temperature for 1 h and then cooled for 3 min. No metal loss data for IN-100 because sample was destroyed in 50 h. Metal loss is defined as loss of diameter due to oxide and sulfide scale formation. Maximum attack is defined as loss of diameter due to internal oxidation and sulfidation.

The MA ODS materials have also been evaluated in a wide range of specialized environments. MA 956 has proved to be especially resistant to carburization, as illustrated in Table 5.

Table 5 Comparison of the carburization resistance of Alloy MA 956 with Alloy 800

Test duration was 100 h at 1095 °C (2000 °F) temperature in a H_2 + 2% CH_4 atmosphere

Alloy	**Weight change**		**Metal loss**		**Maximum attack**	
	Undescaled, mg/cm^3 (lb/in.^{3} × 10^{-6})	**Descaled, mg/cm^3 (lb/in.^{3} × 10^{-6})**	**µm**	**in.**	**µm**	**in.**
MA 956	0.07 (2.5)	-0.42 (-15)	10	0.0004	10	0.0004
Alloy 800	33.74 (1225)	29.89 (1085)	132	0.00528	7615	0.3046

These alloys also show excellent resistance to attack by molten glass. C glass and lime glass are two glasses whose effect on mechanically alloying materials has been evaluated. These glasses have the following compositions:

Compound	**Composition, wt%**

	C glass	Lime glass
SiO_2	65	73
Al_2O_3	4	1.7
Na_2O	8.5	16.3
CaO	14	4.7
MgO	3	3.1
B_2O_3	5	. . .
H_2O	. . .	0.4
Li_2O	. . .	0.15

Based on a 5-day immersion test, MA 754 and MA 758 demonstrate high corrosion resistance to molten C glass:

Alloy	Metal loss	
	mm	mil
MA 754	0.04	1.6

Based on a 240-h immersion test in lime glass at 1150 °C (2100 °F), MA 754 has corrosion-resistance properties intermediate between those of MA 956 and MA 758:

Alloy	Mass change	
	$mg \cdot cm^{-2}$	$lb \cdot in.^{-2} \times 10^{-4}$

MA 956	4	0.57
MA 754	28	4.0
MA 758	42	6.0

It is well known that the relative performance of alloys in glass is dependent upon glass composition, temperature, impurity level, velocity, and other factors. Consequently, the tabular information shown in this section should be considered only as illustrated of the generally high resistance of MA ODS alloys in these molten glass environments.

Fabrication of MA ODS Alloys

The mill product forms available vary from alloy to alloy, depending on factors such as ease of fabrication and applicable forming methods.

Bars. All of the alloys are available as bars, and much of the data reported in the literature refer to bar properties. All of the bar products can be precision forged, and MA 754 forged airfoils have been in commercial use for years. The high-temperature properties of forgings can be equivalent to those of annealed bar, provided that care is taken in the design of the part and the thermomechanical processing is controlled to produce the desired grain structure and orientation. Forgings of MA 6000 and MA 760 with optimal properties in the airfoil axis can be obtained by zone annealing after forging. Both seamless and flat-butt-welded rings with desired properties in the hoop direction have been made from MA 754 and MA 758.

Plate products are available for MA 754, MA 758, and MA 956. Equiaxed properties can be obtained through control of rolling conditions. Plate is readily amenable to a variety of hot-forming operations, including hot shear spinning. Optimal formability and minimum flow stress is obtained when the plate is in the fine-grain (unrecrystallized) condition. The standard grain-coarsening anneal is then applied to the formed component.

Sheet. The only alloy currently available in sheet form is MA 956. This material, which is readily cold rolled to standard sheet tolerance, is commercially available in gages down to thicknesses of 0.25 mm (0.010 in.) and widths up to 610 mm (24 in.). A wide variety of components have been cold formed from MA sheet by standard metal-forming operations. Experience has shown that warming to about 95 °C (200 °F) is necessary to prevent cracking because this alloy undergoes a ductile-to-brittle transition in the vicinity of room temperature.

Additional Product Forms. MA 956 has also been produced in a number of other forms for special applications. These forms include pipe, thin-wall tube, and fine wire.

Joining of MD ODS Alloys

Many applications for MA ODS alloys require some method of joining. Procedures that involve fusion of the base metal destroy the unique microstructure that is responsible for the high-temperature strength of these alloys. Accordingly, fusion welds that are needed for attachment or positioning for brazing should be located in areas of relatively low stress. Procedures such as gas-tungsten-arc welding (GTAW), electron-beam welding (EBW), and pulsed laser-beam welding (LBW) have all been used successfully on a limited scale. MA 956 sheet assemblies have also been made using resistance spot welding (RSW).

As might be expected, nonfusion processes are required in order to obtain tensile and stress-rupture properties approaching those of the parent metal. Vacuum diffusion bonding (DB) and diffusion brazing (DFB) are now used extensively for assembly of aircraft engine components. Riveting operations using similar alloy rivets have also been applied for nonaircraft applications.

Cemented Carbides

A.T. Santhanam, P. Tierney, and J.L. Hunt, Kennametal Inc.

Introduction

CEMENTED CARBIDES belong to a class of hard, wear-resistant, refractory materials in which the hard carbide particles are bound together, or cemented, by a soft and ductile metal binder. These materials were first developed in Germany in the early 1920s in response to demands for a die material having sufficient wear resistance for drawing tungsten incandescent filament wires to replace the expensive diamond dies then in use. The first cemented carbide to be produced was tungsten carbide (WC) with a cobalt binder. Although the term cemented carbide is widely used in the United States, these materials are better known internationally as hard metals.

Tungsten carbide was first synthesized by the French chemist Henri Moissan in the 1890s (Ref 1). There are two types of tungsten carbide: WC, which directly decomposes at 2800 °C (5070 °F), and W_2C, which melts at 2750 °C (4980 °F) (Ref 2, 3). Early attempts to produce drawing dies from a eutectic alloy WC and W_2C were unsuccessful, because the material had many flaws and fractured easily. The use of powder metallurgy techniques by Schroeter in 1923 paved the way for obtaining a fully consolidated product (Ref 4). Schroeter blended fine WC powders with a small amount of iron, nickel, or cobalt powders and pressed the powders into compacts, which were then sintered at approximately 1300 °C (2400 °F). Cobalt was soon found to be the best bonding material. Over the years, the basic WC-Co material has been modified to produce a variety of cemented carbides, which are used in a wide range of applications, including metal cutting, mining, construction, rock drilling, metal forming, structural components, and wear parts. Approximately 50% of all carbide production is used for metal cutting applications.

This article discusses the manufacture and composition of cemented carbides and their microstructure, classifications, physical and mechanical properties, and applications. New tool geometries, tailored substrates, and the application of thin, hard coatings to cemented carbides by chemical vapor deposition and physical vapor deposition are examined for metal cutting applications. The current status of cemented carbides in nonmetal cutting applications will also be covered. This article is limited to tungsten carbide cobalt-base materials. Information on metal-bonded titanium carbide materials and steel-bonded tungsten carbide is given in the article "Cermets" in this Volume. Extensive reviews of the scientific and industrial aspects of cemented carbides are available in Ref 5, 6, 7, and 8.

Manufacture of Cemented Carbides

Cemented carbides are manufactured by a powder metallurgy process consisting of a sequence of steps in which each step must be carefully controlled to obtain a final product with the desired properties, microstructure, and performance. The steps include:

- Processing of the ore and the preparation of the tungsten carbide powder
- Preparation of the other carbide powders
- Production of the grade powders
- Compacting or powder consolidation
- Sintering
- Postsinter forming

The sintered product can be directly used or can be ground, polished, and coated to suit a given application.

Preparation of Tungsten Carbide Powder. There are two methods by which tungsten carbide powders are produce from the tungsten-bearing ores. Traditionally, tungsten ore is chemically processed to ammonium paratungstate and tungsten oxides. These compounds are then hydrogen-reduced to tungsten metal powder. The fine tungsten powders are blended with carbon and heated in a hydrogen atmosphere between 1400 and 1500 °C (2500 and 2700 °F) to produce tungsten carbide particles with sizes varying from 0.5 to 30 μm (Fig. 1). Each particle is composed of numerous tungsten carbide crystals. Small amounts of vanadium, chromium, or tantalum are sometimes added to tungsten and carbon powders before carburization to produce very fine (<1 μm) WC powders.

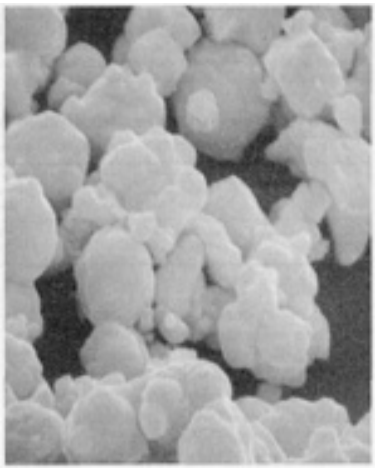

Fig. 1 Tungsten carbide particles produced by the carburization of tungsten and carbon. 10,000×

In a more recently developed and patented process, tungsten carbide is produced in the form of single crystals through the direct reduction of tungsten ore (sheelite) (Ref 9). The ore is mixed with iron oxide, aluminum, carbon, and calcium carbide. A high-temperature exothermic reaction ($2Al + 3FeO \leftrightarrow Al_2O_3 + 3Fe$) at about 2500 °C (4500 °F) produces a molten mass that, when cooled, consists of tungsten carbide crystals dispersed in iron, and a slag containing impurities. The crystalline WC (Fig. 2) is then chemically separated from the iron matrix.

Fig. 2 Tungsten carbide single crystals produced by the direct reduction of tungsten ore. 200×

Tungsten-titanium-tantalum (niobium) carbides are used in steel-cutting grades to resist cratering or chemical wear and are produced from metal oxides of titanium, tantalum, and niobium. These oxides are mixed with metallic tungsten powder and carbon. The mixture is heated under a hydrogen atmosphere or vacuum to reduce the oxides and form solid-solution carbides such as WC-TiC, WC-TiC, WC-TiC-TaC, or WC-TiC-(Ta, Nb)C. The menstruum method can be used to produce WC-TiC solid solution. In this method, the individual carbides are dissolved in liquid nickel. Solid-solution carbides are then precipitated during cooling (Ref 10).

Production of Grade Powders. Cemented carbide grade powders may consist of WC mixed with a finely divided metallic binder (cobalt, nickel, or iron) or with additions of other cubic carbides, such as TiC, TaC, and NbC, depending on the required properties and application of the tool. Intensive milling is necessary to break up the initial carbide crystallites and to blend the various components such that every carbide particle is coated with binder material. This is accomplished in ball mills, vibratory mills, or attritors that use carbide balls. The mills are usually lined with carbide sleeves, although mills lined with low-carbon steel or stainless steel are also used.

Milling is performed under an organic liquid such as heptane or acetone to minimize heating of the powder and to prevent its oxidation. The liquid is distilled off after the milling operation. A solid lubricant such as paraffin wax is added to the powder blend in the final stages of the milling process or later in a blender. The lubricant provides a protective coating to the carbide particles and prevents or greatly reduces the oxidation of the powder. The lubricant also imparts strength to the pressed or consolidated powder mix.

After milling, the organic liquid is removed by drying. In a spray-drying process commonly used in the cemented carbide industry, a hot inert gas such as nitrogen impinges on a stream of carbide particles. This process free-flowing spherical powder aggregates.

Powder Consolidation. A wide variety of techniques are used to compact the cemented carbide grade powders to the desired shape. Carbide tools for mining and construction applications are pill pressed (pressure applied in one direction) in semiautomatic or automatic presses. Metal cutting inserts are also pill pressed, but may require additional shaping after sintering. Cold isostatic pressing, in which the powder is subjected to equal pressure from all directions, followed by green forming, is also a common practice for wear and metal forming tools. Rods and wires are formed by the extrusion process.

Unlike most other metal powders, cemented carbide powders do not deform during the compacting process. Generally, they cannot be compressed to much above 65% of the theoretical upper limit for density. Despite this low green density, carbide manufacturers have developed the technology for achieving good dimensional tolerances in the sintered product.

Sintering and Postsintering Operations. The first step in the sintering process is the removal of the lubricant (dewaxing) from the powder compact. The pressed compacts are normally set on graphite trays coated with a graphite paint. The compacts

are first heated to about 500 °C (900 °F) in a hydrogen atmosphere or vacuum using either semicontinuous or batch-type graphite furnaces.

After lubricant removal, the compacts are heated in a vacuum (0.1 Pa, or 10^{-3} torr) to a final sintering temperature ranging from 1350 to 1600 °C (2460 to 2900 °F), depending on the amount of the cobalt binder and the desired microstructure. The dewaxing and sintering operations can also be performed in a single vacuum cycle using furnaces equipped to condense the lubricant and remove it from the heating chamber.

During the final sintering operation, the cobalt melts and draws the carbide particles together. Shrinkage of the compact ranges from 17 to 25% on a linear scale, producing a virtually pore-free, fully dense product.

In the 1970s, the cemented carbide industry took advantage of hot isostatic pressing (HIP) technology, in which vacuum-sintered material is heated again under a gaseous (argon or helium) pressure of 100 to 150 MPa (15 to 20 ksi). (Ref 11). The temperatures of this additional process are 25 to 50 °C (45 to 90 °F) below the sintering temperature. The high temperatures and pressures employed in the HIP furnace remove any residual internal porosity, pits, or flaws and produce a nearly perfect cemented carbide.

The latest advancement in sintering technology is the sinter-HIP process, which was developed in the early 1980s (Ref 12). In this process, low-pressure hot isostatic pressing (up to about 7 MPa, or 1 ksi), is combined with vacuum sintering, and the pressure is applied at the sintering temperature when the metallic binder is still molten. With this process, void-free products can be produced at costs only slightly higher than those of vacuum sintering.

Postsinter Forming. A large number of cemented carbide products are shaped after sintering because of surface finish, tolerance, and geometry requirements. This forming operation is both time consuming and expensive. The sintered material is formed with metal-bonded diamond or silicon carbide wheels, turned with a single-point diamond tool, or lapped with diamond-containing slurries.

Cemented Carbides for Machining Applications

The performance of cemented carbide as a cutting tool lies between that of tool steel and cermets. Compared to tool steels, cemented carbides are harder and more wear resistant, but also exhibit lower fracture resistance and thermal conductivities than tool steel. Cermets, on the other hand, are more wear resistant than cemented carbides, but may not be as tough. Any comparison of cermets and cemented carbides, however, depends on the percent of binder material and the type and size of carbide grains. Cermets are described in more detail in the article "Cermets" in this Volume and in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Compositions and Microstructures

The performance of carbide cutting tools is strongly dependent on composition and microstructure, and the properties of cemented carbide tools depend not only on the type and amount of carbide but also on the carbide grain size and the amount of binder metal. The basic physical and mechanical properties of refractory metal carbides used in the production of cemented carbide tools are given in Table 1. Tungsten carbide and molybdenum carbide have hexagonal crystal structures, whereas the carbides of titanium, tantalum, niobium, vanadium, hafnium, and zirconium are cubic. They undergo no structural changes up to their melting points.

Table 1 Properties of refractory metal carbides

Carbide	Hardness, HV (50 kg)	Crystal structure	Melting point		Theoretical density, g/cm^3	Modulus of elasticity		Coefficient of thermal expansion, µm/m · K

Tungsten Carbide-Cobalt Alloys. The first commercially available cemented carbides consisted of tungsten carbide particles bonded with cobalt. These are commonly referred to as straight grades. These alloys exhibit excellent resistance to simple abrasive wear and thus have many applications in metal cutting. Table 2 lists the representative properties of several straight WC-Co alloys.

Table 2 Properties of representative cobalt-bonded cemented carbides

Nominal composition	Grain size	Hardness, HRA	Density		Transverse strength		Compressive strength		Modulus of elasticity		Relative abrasion resistance[(a)]	Coefficient of thermal expansion, μm/m · K		Thermal conductivity, W/m · K

(a) Based on value of 100 for the most abrasion-resistant material

The commercially significant alloys contain cobalt in the range of 3 to 25 wt%. For machining purposes, alloys with 3 to 12% Co and carbide grain sizes from 0.5 to more than 5 μm are commonly used.

The ideal microstructure of WC-Co alloys should exhibit only two phases: angular WC grains and cobalt binder phase. Representative microstructures of several straight WC-Co alloys are shown in Fig. 3. The carbon content must be controlled within narrow limits. Too high a carbon content results in the presence of free and finely divided graphite (Fig. 4), which in small amounts has no adverse effects in machining applications. Deficiency in carbon, however, results in the formation of a series of double carbides (for example, Co_3W_3C or Co_6W_6C), commonly known as η-phase, which causes severe embrittlement. Because the formation of η-phase involves the dissolution of the original carbides into the cobalt binder, η-phase appears as an irregularly shaped phase in the microstructure (Fig. 5).

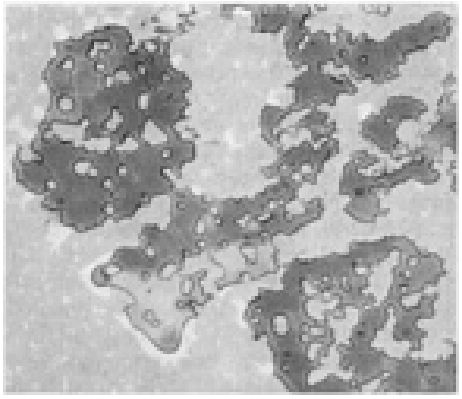

Fig. 5 η-phase microstructure. Micrograph shows a $(Co_3W_3)C$-η- phase in detail. η-phase appears as various shades of gray with clearly defined grain boundaries. Light gray WC particles surrounded by η-phase are rounded because of the solubility of tungsten carbide in the binder. 85WC-8(Ta,Ti,Nb)C-7Co alloy etched with Murakami's reagent for 3 s. 900×

Submicron Tungsten Carbide-Cobalt Alloys. In recent years, WC-Co alloys with submicron carbide grain sizes (Fig. 6) have been developed for applications requiring more toughness or edge strength. Typical applications include indexable inserts and a wide variety of solid carbide drilling and milling tools. Grain refinement in these alloys is obtained by small additions (0.25 to 3.0 wt%) of tantalum carbide, niobium carbide, vanadium carbide, or chromium carbide. Additions can be made before carburization of the tungsten or later in the powder blend. Vanadium carbide is the most effective grain growth inhibitor. Chromium carbide, in addition to being an efficient grain growth inhibitor, imparts excellent mechanical properties. Tantalum carbide is not as effective as vanadium carbide or chromium carbide in grain refinement.

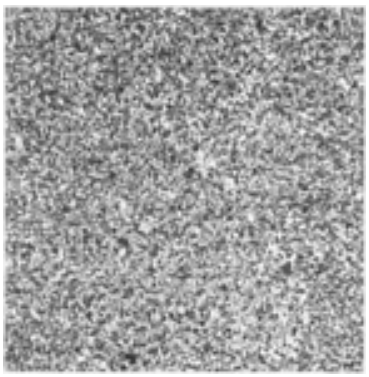

Fig. 6 Submicron carbide grain size. 94WC-6Co alloy. Etched with Murakami's reagent for 2 min. 1500×

Alloys Containing Tungsten Carbide, Titanium Carbide, and Cobalt. The tungsten carbide-cobalt alloys, developed in the early 1920s, were successful in the machining of cast iron and nonferrous alloys at much higher speeds than were possible with high-speed steel tools, but were subject to chemical attack or diffusion wear when cutting steel. As a result, the tools failed rapidly at speeds not much higher than those used with high-speed steel. This led to the development of WC-TiC-Co alloys.

Tungsten carbide diffuses readily into the steel chip surface, but the solid solution of tungsten carbide and titanium carbide resists this type of chemical attack. Unfortunately, titanium carbide and WC-TiC solid solutions are more brittle and less abrasion resistant than tungsten carbide. The amount of titanium carbide added to tungsten carbide-cobalt alloys is therefore kept to a minimum, typically no greater than 15 wt%. The carbon content is less critical in WC-TiC-Co alloys than in WC-Co alloys, and the η-phase does not appear in the microstructure unless carbon is grossly inadequate. In addition, free graphite rarely occurs in these alloys.

Steel-Cutting Grades of Cemented Carbide Alloys. The WC-TiC-Co alloys have given way to alloys of tungsten carbide, cobalt, titanium carbide, tantalum carbide, and niobium carbide. The tungsten carbide-cobalt alloys containing TiC, TaC, and NbC are called complex grades, multigrades, or steel-cutting grades. Adding TaC to WC-TiC-Co alloys partially overcomes the deleterious effects of TiC on the strength of WC-Co alloys. Tantalum carbide also resists cratering and improves thermal shock resistance. The latter property is particularly useful in applications involving interrupted cuts. Tantalum carbide is often added as (Ta, Nb)C because the chemical similarity between TaC and NbC makes their separation expensive. Fortunately, NbC has an effect similar to TaC in most cases. The relative concentrations of tantalum carbide and niobium carbide in these alloys are dependent on the raw material used, the desired composition, the properties, and the microstructure.

Unlike the WC-Co alloys, the microstructure of WC-TiC-(Ta,Nb)C-Co alloys shows three phases: angular WC grains, rounded WC-TiC-(Ta,Nb)C solid-solution grains, and cobalt binder. The solid-solution carbide phase often exhibits a cored structure, indicating incomplete diffusion during the sintering process. Representative microstructures of several WC-TiC-(Ta,Nb)C alloys are shown in Fig. 7. The size and distribution of the phases vary widely, depending on the amounts and grain sizes of the raw materials employed and on the method of manufacture. Similarly, the properties of these complex alloys also vary widely, as indicated in Table 2 for a few representative steel-cutting grades.

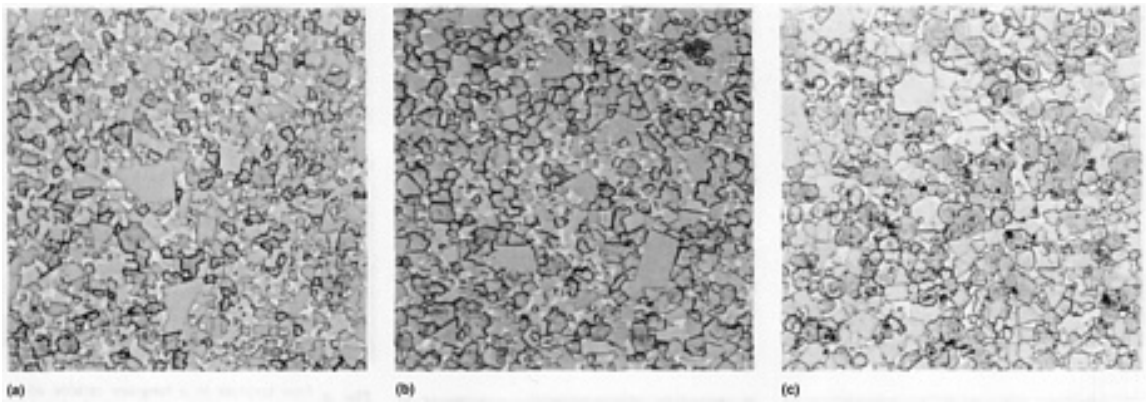

Fig. 7 Representative microstructures of steel-cutting grades of cemented tungsten carbide. (a) 85WC-9(Ta,Ti,Nb)C-6Co alloy, medium grain size. (b) 78WC-15(Ta,Ti,Nb)C-7Co alloy, medium grain. (c) 73WC-19(Ta,Ti,Nb)C-8Co alloy, medium grain. The gray, angular particles are WC, and the dark gray, rounded particles are solid-solution carbides. The white areas are cobalt binder. All etched with Murakami's reagent for 2 min. 1500×

Classification of Cemented Carbides

There is no universally accepted system for classifying cemented carbides. The systems most often employed by producers and users are discussed below. Each system has inherent strengths and weaknesses in describing specific materials, and for this reason close cooperation between user and producer is the best means of selecting the proper grade for a given application.

C-Grade System. The U.S carbide industry uses an application-oriented system of classification to assist in the selection of proper grades of cemented carbides. This C-grade system does not require the use of trade names for identifying specific carbide grades (Table 3). Although this classification simplifies tool application, it does not reflect the material properties that significantly influence selection of the proper carbide grade. Additionally, the definitions of work materials involved in this classification scheme are imprecise. There is also no universal agreement on the meanings of the terms used to describe the various application categories. Despite these limitations, the C-grade classification has been successfully used by the manufacturing industry since 1942.

Table 3 C-grade classification of cemented carbides

C-grade	Application category
Machining of cast iron, nonferrous, and nonmetallic materials	

C-1	Roughing
C-2	General-purpose machining
C-3	Finishing
C-4	Precision finishing
Machining of carbon and alloy steels	
C-5	Roughing
C-6	General-purpose machining
C-7	Finishing
C-8	Precision finishing
Nonmachining applications	
C-9	Wear surface, no shock
C-10	Wear surface, light shock
C-11	Wear surface, heavy shock
C-12	Impact, light
C-13	Impact, medium
C-14	Impact, heavy

ISO Classification. In 1964, the International Organization of Standardization (ISO) issued ISO Recommendation R513 "Application of Carbides for Machining by Chip Removal." The basis for the ISO classification of carbides is summarized in Table 4.

Table 4 ISO R513 classification of carbides according to use for machining

Designation[(a)]	**Groups of application**	
	Material to be machined	**Use and working conditions**

P 01	Steel, steel castings	Finish turning and boring; high cutting speeds, small chip section, accuracy of dimensions and fine finish, vibration-free operation
P 10	Steel, steel castings	Turning, copying, threading, and milling; high cutting speeds, small or medium chip sections
P 20	Steel, steel castings, malleable cast iron with long chips	Turning, copying, milling, medium cutting speeds and chip sections; planing with small chip sections
P 30	Steel, steel castings, malleable cast iron with long chips	Turning, milling, planning, medium or low cutting speeds, medium or large chip sections, and machining in unfavorable conditions[(b)]
P 40	Steel, steel castings with sand inclusion and cavities	Turning, planing, slotting, low cutting speeds, large chip sections with the possibility of large cutting angles for machining in unfavorable conditions[(b)] and work on automatic machines
P 50	Steel, steel castings of medium or low tensile strength, with sand inclusion and cavities	For operations demanding very tough carbide: turning, planing, slotting, low cutting speeds, large chip sections, with the possibility of large cutting angles for machining in unfavorable conditions[(b)] and work on automatic machines
M 10	Steel, steel castings, manganese steel, gray cast iron, alloy cast iron	Turning, medium or high cutting speeds; small or medium chip sections
M 20	Steel, steel castings, austenitic or manganese steel, gray cast iron	Turning, milling; medium cutting speeds; and chip sections
M 30	Steel, steel castings, austenitic steel, gray cast iron, high-temperature resistant alloys	Turning, milling, planning; medium cutting speeds; medium or large chip sections
M 40	Mild free-cutting steel, low-tensile steel, nonferrous metals, and light alloys	Turning, parting off, particularly on automatic machines
K 01	Very hard gray cast iron, chilled castings of over 85 scleroscope hardness, high-silicon aluminum alloys, hardened steel, highly abrasive plastics, hard cardboard, ceramics	Turning, finish turning, boring, milling, scraping
K 10	Gray cast iron over 220 HB, malleable cast iron with short chips, hardened steel, silicon aluminum alloys, copper alloys, plastics, glass, hard rubber, hard cardboard, porcelain, stone	Turning, milling, drilling, boring, broaching, scraping
K 20	Gray cast iron up to 220 HB, nonferrous metals; copper, brass, aluminum	Turning, milling, planing, boring, broaching, demanding very tough carbide
K 30	Low-hardness gray cast iron, low-tensile steel, compressed wood	Turning, milling, planing, slotting, for machining in unfavorable conditions[(b)] and with the possibility of large cutting angles

K 40	Softwood or hardwood, nonferrous metals	Turning, milling, planing, slotting for machining in unfavorable conditions[(b)] and with the possibility of large cutting angles

(a) In each letter category, low designation numbers are for high speeds and light feeds; higher numbers are for slower speeds and/or heavier feeds. Also, increasing designation numbers imply increasing toughness and decreasing wear resistance of the cemented carbide materials.

(b) Unfavorable conditions include shapes that are awkward to machine; material having a casting or forging skin; material having variable hardness; and machining that involves variable depth of cut, interrupted cut, or moderate to severe vibrations.

In the ISO system, all machining grades are divided into three color-coded groups:

- Highly alloyed tungsten carbide grades (letter P, blue color) for machining steel
- Alloyed tungsten carbide grades (letter M, yellow color, generally with less TiC than the corresponding P series) for multipurpose use, such as steels, nickel-base superalloys, and ductile cast irons
- Straight tungsten carbide grades (letter K, red color) for cutting gray cast iron, nonferrous metals, and nonmetallic materials

Each grade within a group is assigned a number to represent its position from maximum hardness to maximum toughness. P-grades are rated from 01 to 50, M-grades from 10 to 40, and K-grades from 01 to 40. Typical applications are described for grades at more or less regular numerical intervals. Although the coated grades had not been developed at the time the ISO classification system was prepared, one should be able to classify them as easily as the uncoated grades.

Tool Wear Mechanisms

The cutting of metals involves extensive plastic deformation of the workpiece ahead of the tool tip, high temperatures, and severe frictional conditions at the interfaces of the tool, chip, and workpiece. Most of the work of plastic deformation and friction is converted into heat. In cutting, about 80% of this heat leaves with the chip, but the other 20% remains at the tool tip, producing high temperatures (≥1000 °C, or 1800 °F) (Ref 13). The stresses on the tool tip are also high; the actual values are dependent on the workpiece material and the machining conditions. In addition, the tool may experience repeated impact loads during interrupted cuts, and the freshly produced chips may chemically interact with the tool material. The cutting tool is thus subjected to a variety of hostile conditions.

The performance of a tool material is dictated by its response to the above conditions existing at the tool tip. High temperatures and stresses can cause blunting from the plastic deformation of the tool tip, and high stresses may lead to catastrophic fracture. In addition to plastic deformation and fracture, the service life of cutting tools is determined by a number of wear processes, such as crater wear, attrition wear, flank or abrasive wear, thermal fatigue, and depth-of-cut notching.

Crater wear (Fig. 8a and b) occurs on the rake face, where the tool temperatures are higher. Crater wear is caused by a chemical interaction between the rake face of the insert and the hot metal chip flowing over the tool. This interaction may involved diffusion or dissolution of the tool material into the chip. The chemical inertness of the tool material (or its coating) relative to the work-piece material is a requisite property for crater resistance.

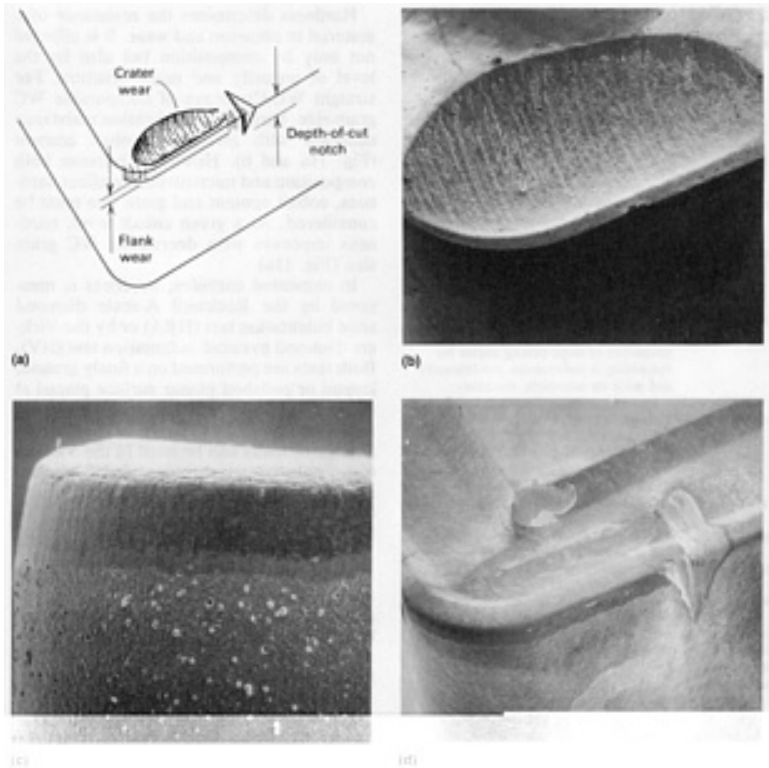

Fig. 8 Crater wear, flank wear, and depth-of-cut notch wear processes. (a) Schematic of wear mechanisms. (b) Crater wear on a cemented carbide tool produced during the machining of plain carbon steel. 15×. (c) Abrasive wear on the flank face of a cemented carbide tool produced during the machining of gray cast iron. 75×. (d) Depth-of-cut notching on a cemented carbide tool produced during the machining of a nickel-base superalloy. 15×

Attrition Wear and Built-Up Edge. If machining is done at relatively low speeds, and if the tool tip temperature is not high enough for crater wear or deformation to be significant, attrition may become the dominant wear process. The attrition process may occur when there is an intermittent flow of workpiece material, and this condition is usually associated with a built-up edge (Fig. 9). Built-up edge occurs at low metal cutting speeds and is not a serious problem as long as the edge remains intact on the tool. When machining gray cast iron, built-up edges to not break away from the tool. However, when machining steel at low speeds, built-up edges break off easily. This may result in attrition wear if small fragments of tool material are carried away as the built-up edge breaks off. In some cases, large chunks of tool material may even be carried away. Built-up edge and attrition wear can be minimized by increasing the metal cutting speed, by selecting fine-grain WC-Co alloys, and/or by using positive-rake tools with smooth surface finishes.

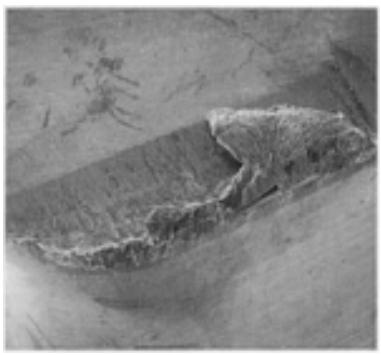

Fig. 9 Built-up edge on a cemented carbide tool. The built-up edge was produced during the low-speed machining of a nickel-base alloy. 20×

Flank or abrasive wear (Fig. 8a and c) is often observed on the flank face and is related to the hardness of the tool material or coating. Harder materials provide greater flank and abrasive wear resistance.

Cemented carbide tools may be subjected to abrasive wear when abrasive particles (such as sand on the surface of castings) or hard carbide or alumina inclusions are present in the workpiece materials. Tools with lower binder contents and/or finer carbide grain sizes can resist abrasive wear.

Thermal Fatigue. Cemented carbide tools sometimes exhibit a series of cracks perpendicular to the tool edge when applied to interrupted cutting operations such as milling (Fig. 10). These thermal cracks are caused by the alternating expansion and contraction of the tool surface as it is heated during the cut and cooled outside the cut. The cracks initiate on the rake face, then spread across the edge and down the flank face of the tool. With prolonged intermittent cutting, lateral cracks appear parallel with, and close to, the cutting edge. The thermal and lateral cracks may join together and cause small fragments of tool material to break away. The resistance of WC-Co tools to thermal fatigue can generally be improved by TaC additions.

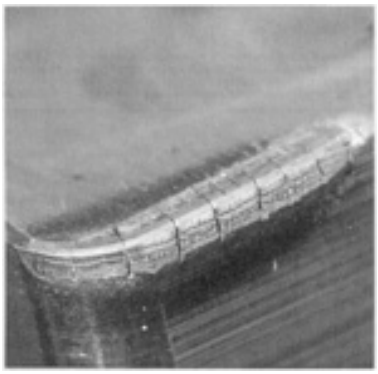

Fig. 10 Thermal cracks in a cemented carbide insert. The thermal cracks are perpendicular to the cutting edge, and the mechanical cracks are parallel to the cutting edge. 15×

Depth-of-cut notching (Fig. 8a and d) consists of a high degree of localized wear on both the rake face and the flank face at the depth of the cut line, Notching is common when machining materials that work harden, such as austenitic stainless steels or high-temperature alloys. This type of wear is attributed to the chemical reaction of the tool material with the atmosphere or to abrasion by the hard, sawtooth outer edge of the chip. Depth-of-cut notching may lead to tool fracture; it can be minimized by:

- Increasing the fracture toughness of the tool material
- Increasing the lead angle (for round inserts) or the side cutting angle (for other insert shapes)
- Chamfering the tool edge
- Varying the depth of cut if multiple passes are made

Cemented Carbide Properties

Evaluation of the physical and mechanical properties of tool materials is an important prerequisite to the selection of grades for a given metal cutting application and for tool material development. A number of industry, national, and ISO standards have been developed for determining the selected properties of cemented carbides (Table 5).

Table 5 Test methods for determining the properties of cemented carbides

Property	Test method		
	ASTM/ANSI	CCPA[(a)]	ISO

Abrasive wear resistance	B 611	P112	. . .

Young's modulus	E 111	P106	3312

(a) Cemented Carbides Producers Association

Hardness determines the resistance of a material to abrasion and wear. It is affected not only by composition but also by the level of porosity and microstructure. For straight WC-Co alloys of comparable WC grain size, hardness and abrasion resistance decrease with increasing cobalt content (Fig. 11a and b). However, because both composition and microstructure affect hardness, cobalt content and grain size must be considered. At a given cobalt level, hardness improves with decreasing WC grain size (Fig. 11a).

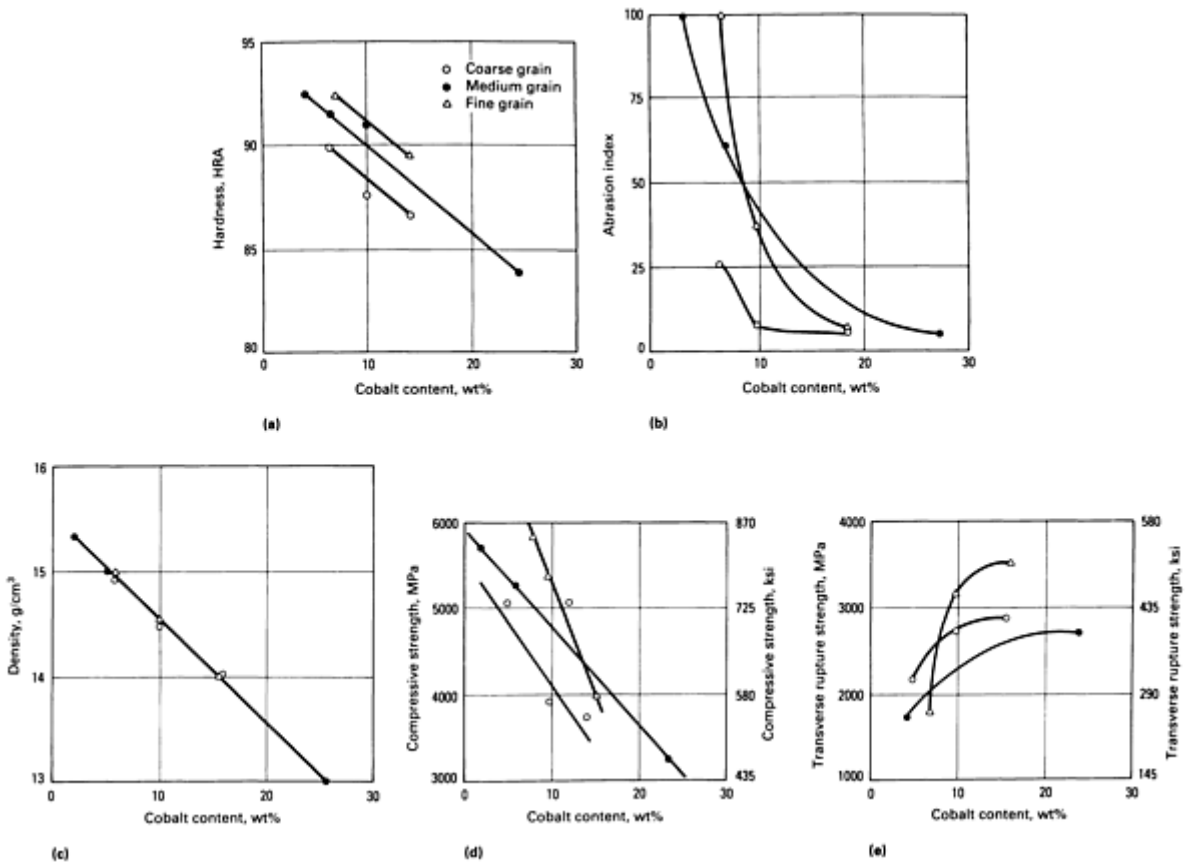

Fig. 11 Variation in properties with cobalt content and grain size for straight WC-Co alloys. (a) Variation in hardness. (b) Variation in abrasion resistance. (c) Variation in density. (d) Variation in compressive strength. (e) Variation in transverse rupture strength

In cemented carbides, hardness is measured by the Rockwell A-scale diamond cone indentation test (HRA) or by the Vickers diamond pyramid indentation test (HV). Both tests are performed on a finely ground, lapped or polished planar surface placed at right angles to the indentor axis. The Rockwell A test employs a load of 60 kg, whereas a range of loads can be used in the Vickers test. For cemented carbides used in machining applications, hardness values range from 88 to 94 HRA and from 1100 to 2000 HV.

Although the Rockwell scale has been used for decades as a measure of hardness, a true indication of the resistance to plastic deformation in metal cutting operations can be obtained only by measuring hardness at elevated temperatures. Measurements of hardness over a wide range of temperatures are therefore valuable for tool selection.

Hardness testers with high-temperature capability (up to 1200 °C, or 2200 °F) are commercially available and are being increasingly used by the cemented carbide industry. Figure 12 shows hot hardness data for a number of cemented carbides. The hardness of these materials decreases monotonically with increasing temperatures.

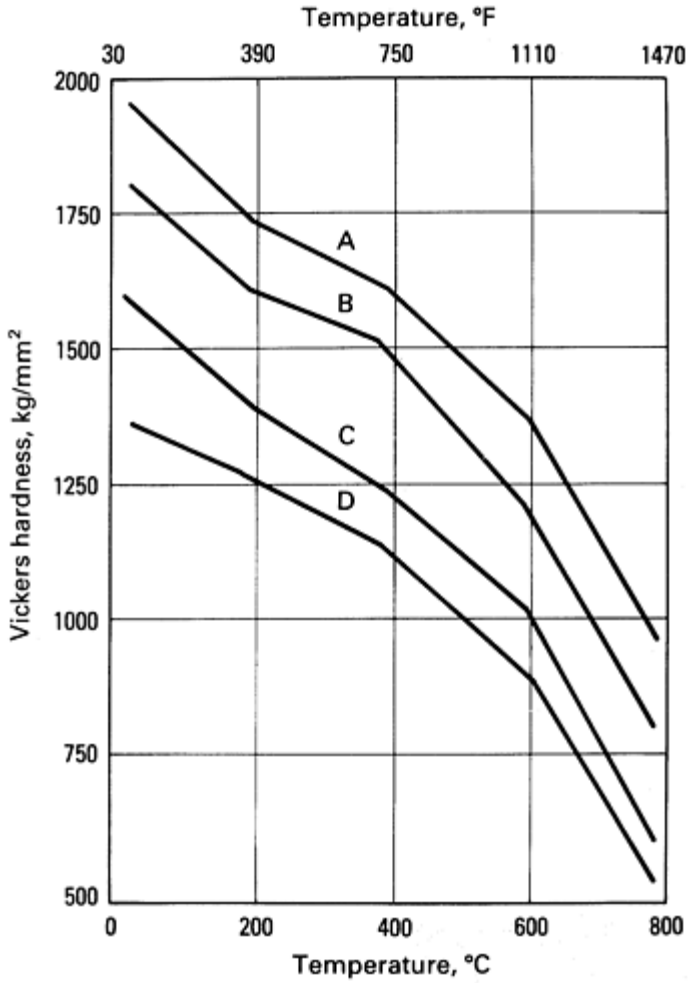

Fig. 12 Variation in microhardness with temperature. Microhardness is based on a 1 kg load, and all alloys are of medium WC grain size. A, 97WC-3Co alloy; B, 94WC-6Co; C, 80WC-12(Ti,Ta,Nb)C-8Co; D, 86WC-2TaC-12Co

Compressive Properties. One of the unique properties of cemented carbides is their high compressive strength. Uniaxial compression tests can be performed on straight cylindrical samples or on cylinders having reduced diameters in the middle to localize fracture. The compressive strengths of cemented carbides are greater than those of most other materials. Typical values of compressive strength range from 3.5 to 7.0 GPa (0.5 to 1.0 × 10^6 psi).

The ductility of cemented carbides is generally low at room temperature, so there is little difference between their yield strength and fracture strength. At higher temperatures, however, these materials exhibit a small but finite amount of ductility. Measurement of yield strength is therefore more appropriate at elevated temperatures. High-temperature compressive yield strength is typically measured at 0.2% offset strain. Compression tests are performed in a high-temperature furnace (typically with resistance heating) under a vacuum or in an inert atmosphere. Figure 13 shows yield strength data for selected straight and alloyed WC-Co grades. Like hardness, the compressive yield strengths of cemented carbides decrease monotonically with increasing temperature; the rate of decrease depends on the composition and the microstructure. As in metallic materials, fine-grain alloys tend to lose their yield strengths more rapidly with increasing temperature than coarse-grain grades, although at room temperature the former can exhibit high yield strengths.

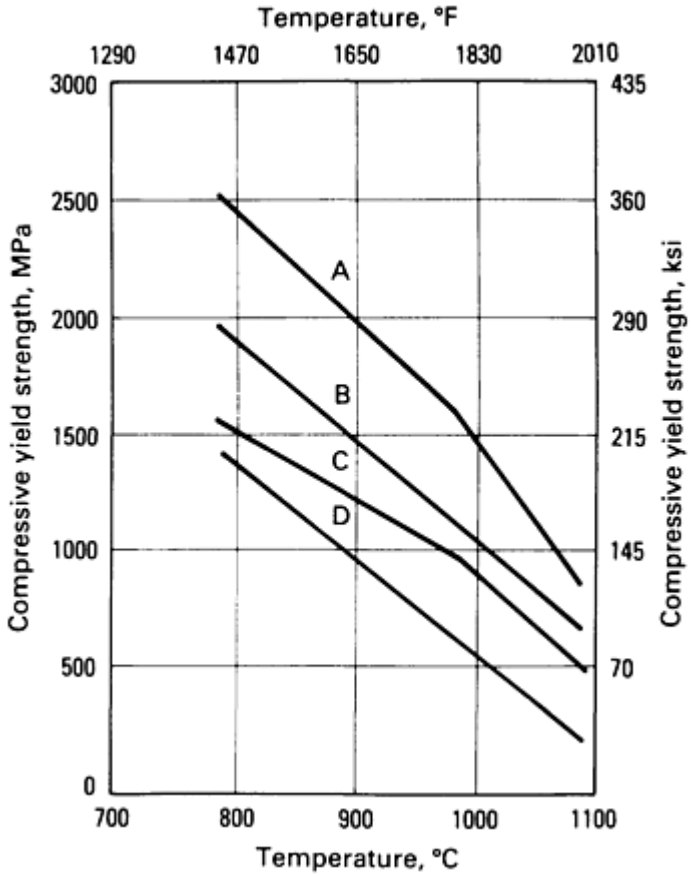

Fig. 13 Variation in compressive yield strength with temperature. Measured at 0.2% offset strain; all alloys characterized by medium grain size. A, 73WC-22(Ti,Ta,Nb)C-5Co alloy; B, 80WC-12(Ti,Ta,Nb)C-8Co; C, 86WC-8(Ti,Ta,Nb)C-6Co; D, 86WC-2TaC-12Co

Transverse Rupture Strength. The most common method of determining the fracture strength of cemented carbides is the transverse rupture test. In this test, a rectangular test bar is placed across two sintered carbide support cylinders, and a gradually increasing load is applied by a third carbide cylinder at the midpoint between the supports. Transverse rupture strength is determined from the dimensions of the test bar, the distance between the supports, and the fracture load. A disadvantage of this test is the large scatter in the experimental data resulting from surface defects introduced into the test specimens during processing. Nevertheless, it is an excellent quality control test, and it is particularly useful for large carbide components.

Figure 11(e) shows the variation in transverse rupture strength with cobalt content. In metal cutting applications, no clear relationship has been established between transverse rupture strength and turning performance. However, there appears to be a good correlation between transverse rupture strength and milling performance (Ref 14). During milling, the tool is subjected to tensile stresses as it leaves the cut, and a material with high transverse rupture strength should be able to resist fracture under these conditions.

Fracture toughness is less sensitive than transverse rupture strength to such extrinsic factors as specimen size, geometry, and surface finish. Fracture toughness is measured by the critical stress intensity factor K_{Ic} (Ref 15, 16, 17). This parameter indicates the resistance of a material to fracture in the presence of a sharp crack and thus provides a better measure of the intrinsic strength of the cemented carbide than transverse rupture strength. A variety of specimen geometries have been used in this test, including the single-edge notched beam, the double cantilever beam, the compact tension specimen, and the double torsion specimen. The carbide industry in the United States generally uses commercial equipment for fracture toughness evaluation. The fracture toughness of cemented carbides increases with cobalt content and with WC grain size (Fig. 14). On the other hand, cubic carbide additions lessen the fracture toughness of WC-Co alloys.

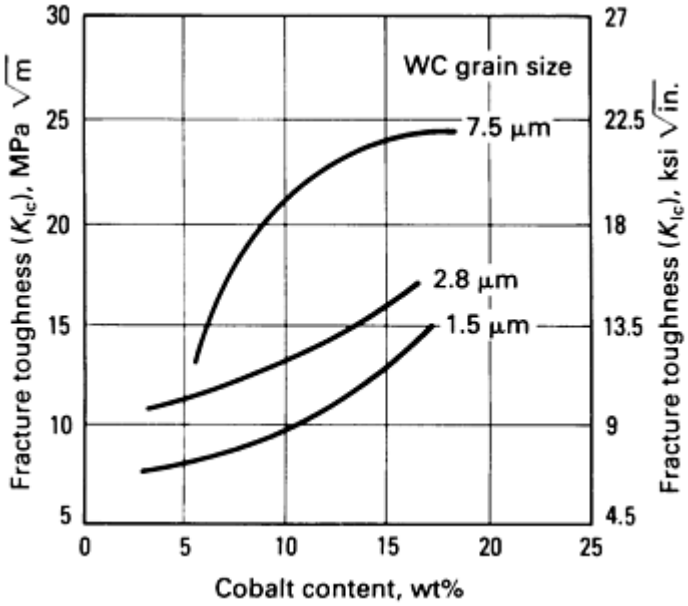

Fig. 14 Variation in toughness (K_{Ic}) with cobalt content for WC-Co alloys with different WC grain sizes. Source: Ref 15

As with the other mechanical properties, attention is focused on the development of test techniques to evaluate fracture toughness at elevated temperatures. Figure 15 shows K_{Ic} data for a number of cemented carbides from room temperature to about 1000 °C (1800 °F). Depending on the composition of the cemented carbide, the K_{Ic} parameter is insensitive to temperature, up to about 600 °C (1100 °F), but increases rapidly at higher temperatures. This behavior is reminiscent of the ductile-to-brittle transition observed in quenched-and-tempered steels.

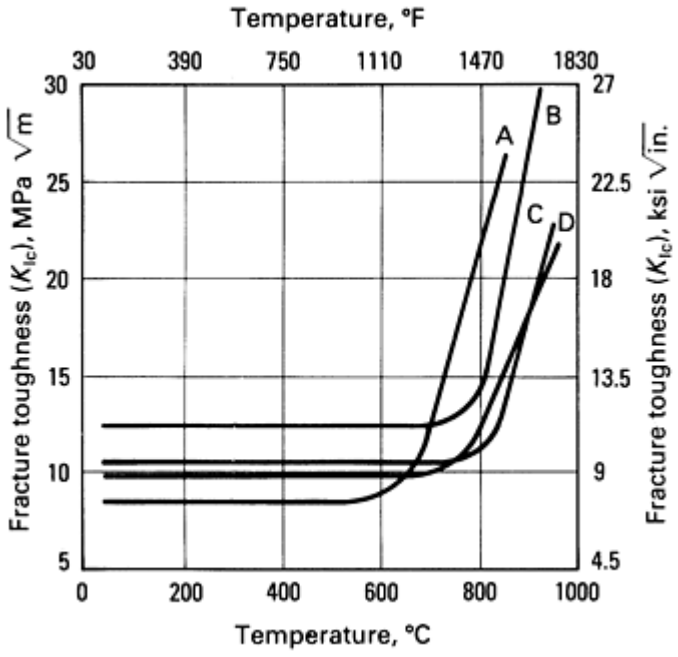

Fig. 15 Variation in fracture toughness (K_{Ic}) with temperature for a number of WC-Co base alloys. A, 86WC-2TaC-12Co; B, 85WC-9(Ti,Ta,Nb)C-6Co; C, 80WC-12(Ti,Ta,Nb)C-8Co; D, 96WC-4Co

The density, or specific gravity, of cemented carbides is very sensitive to composition and porosity in the sample and is widely used as a quality control test. Density values of cemented carbides range from 15 g/cm^3 for low-cobalt straight. WC-Co alloys to about 10 or 12 g/cm^3 for highly alloyed carbide grades (Fig. 11c).

Magnetic Properties. Tungsten carbide-cobalt alloys lend themselves to the analysis of magnetic properties because cobalt is ferromagnetic. The properties measured are magnetic saturation and coercive force. Both free cobalt and solid solutions of cobalt and tungsten contribute to magnetization. The magnetic saturation of pure cobalt is 201 × 10^{-6} T m^3/kg. With additions of tungsten to cobalt, the magnetic saturation decreases steadily from 201 × 10^{-6} to about 151 × 10^{-6} T m^3/kg. In this range, the cemented carbide is characterized by two or three phases (WC and Co, or WC, a solid-solution carbide, and Co). Values below 151 × 10^{-6} T m^3/kg indicate the presence of η-phase. The solubility of tungsten in cobalt is inversely proportional to carbon content. Lower-carbon alloys have more tungsten dissolved in cobalt and are characterized by lower magnetization. Magnetic saturation thus provides an accurate measure of the changes in carbon content in the cemented carbide alloy and is widely used as a quality control test.

The coercive force varies considerably with increasing sintering temperature and indicates the structural changes that take place during sintering. The coercive force of WC-Co alloys reaches a maximum at the optimum sintering temperature and decreases at higher temperatures because of grain growth. Therefore, measurement of the coercive force permits control of the sintering process. The factors influencing the coercive force and complex, varied, and interactive. For a given cobalt and carbon content, the coercive force provides a measure of the degree of distribution of the carbide phase in the microstructure. Commercial units are available for the rapid measurement of magnetic saturation and coercive force in cemented carbides.

Porosity. The properties of a cemented carbide are dependent on its density, which in turn is critically dependent on composition and porosity. Porosity is evaluated on the as-polished material. The American Society for Testing and Materials (ASTM) has established a standard procedure (B 276) that rates three types of porosity:

- Type A, covering pore diameters less than 10 μm
- Type B, covering pore diameters between 10 and 25 μm
- Type C (Fig. 4), covering porosity developed by the presence of free carbon

Type A porosity is rated at a magnification of 200×, while types B and C porosity are rated at 100×. The degree of porosity is given by four numbers ranging in value from 02 to 08. The number provides a measure of pore volumes as a percentage of total volume of the sample.

Thermal Shock Resistance. As discussed earlier in this article, cutting tool materials are subjected to thermal shocks during interrupted cutting operations such as milling. Resistance to thermal shock is therefore an important property that determines tool performance in milling. No laboratory test has yet been developed that can consistently predict the resistance to thermal shock of a tool. However, empirical parameters have been suggested that can be used to evaluate tool materials for their probable resistance to thermal shock (Ref 18). A commonly used parameter is $\sigma k/E\alpha$, where σ is the transverse rupture strength, k is the thermal conductivity, E is Young's modulus, and α is the coefficient of thermal expansion. Table 6 lists representative values of this parameter for a number of WC-Co alloys. In general, the higher the value of $\sigma k/E\alpha$, the better the thermal shock resistance.

Table 6 Thermal shock resistance parameters for cemented carbides

Composition, wt%	WC grain size	Transverse rupture strength, σ		Thermal conductivity (*k*), W/m · K	Young's modulus, *E*		Coefficient of thermal expansion (α), μm/m · K	Thermal shock resistance ($\sigma k/E\alpha$), k W/m
		MPa	ksi		GPa	10^6 psi		
97WC-3Co	Medium	1590	230	121	641	93	5.0	60

94WC-6Co	Medium	2000	290	100	648	94	5.4	57
90WC-10Co	Fine	3100	450	80	620	90	6.0	67
71WC-12.5TiC-12TaC-4.5Co	Medium	1380	200	35	565	82	6.5	13
72WC-8TiC-11.5TaC-8.5Co	Medium	1720	250	50	558	81	6.8	23

Abrasive Wear Resistance. Most producers of cemented carbides use a wet-sand abrasion test to measure abrasion resistance. In this test, a sample is held against a rotating wheel for a fixed number of revolutions while the sample and wheel are immersed in a water slurry containing aluminum oxide particles. Comparatively rankings are reported, usually on the basis of a wear rating based on the reciprocal of volume loss. Although standard test procedures are available, carbide producers have not agreed on a single test method, and so the values of abrasion resistance cited in the literature vary widely. Because of this variance, it is almost impossible to make valid comparisons among test results reported by different producers. It is also fallacious to use abrasion resistance as a measure of the wear resistance of cemented carbide materials when they are used for cutting steel or other materials; abrasion resistance in a standard test does not correspond directly to wear resistance in machining operations.

Generally, the abrasion resistance of cemented carbides decreases as cobalt content or grain size is increased (Fig. 11b). Abrasion resistance is also lower for complex carbides than for straight WC grades having the same cobalt content.

Coated Carbide Tools

One of the challenges in the design of cemented carbide tools is the optimization of toughness associated with straight WC-Co alloys with the superior crater wear resistance of alloyed carbides containing high levels of titanium carbide. This challenge has led to the development of coated carbide tools.

Coated carbides account for a major portion of all commercial metal cutting inserts sold in the United States. The success of coated carbides is based on their proven ability to extend tool life on steels and cast irons by a factor of at least two to three. This is accomplished by a reduction in wear processes, especially at higher cutting speeds.

Laminated Coatings. An important development in the production of coated carbide tools occurred in the 1960s, when laminated tips consisting of a base of WC-Co alloy with a sintered layer of high TiC composition were produced. This development not only enabled higher cutting speeds in steel machining but also reduced crater wear on the tool. Although metal cutting productivity increased with the use of these laminated tools, the thermal expansion mismatch between the substrate and the surface layer caused thermal stresses during metal cutting, and the laminate tended to spall during use.

Chemical Vapor-Deposited Coatings. Further development of laminated tools was superseded in 1969 by the application of a thin layer (~5 μm, or 200 μin.) of hard TiC coating to the cemented carbide tool by chemical vapor deposition (CVD) (Ref 19). The impetus for this development came from the Swiss Watch Research Institute, where vapor-deposited TiC coatings had been used on steel watch parts and cases to combat wear on these components.

The CVD coating process consists of heating the tools in a sealed reactor with gaseous hydrogen at atmospheric or lower pressure; volatile compounds are added to the hydrogen to supply the metallic and nonmetallic constituents of the coating. For example, TiC coatings are produced by reacting $TiCl_4$ vapors with methane (CH_4) and hydrogen (H_2) at 900 to 1100 °C (1650 to 2000 °F). The reaction is:

$$TiCl_4(g) + CH_4(g) + H_2(g) \quad € \quad TiC(s) + 4HCl(g) + H_2(g)$$

During the TiC deposition process, a secondary reaction often occurs in which carbon is taken from the cemented carbide substrate:

$$TiCl_4(g) + C(s) + 2H_2(g) \rightarrow TiC(s) + 4HCl(g)$$

The resulting surface decarburization leads to the formation of a brittle η-phase at the coating/substrate interface (Fig. 16) and sometimes to premature tool failure due to excessive chipping and insufficient edge strength (Ref 20, 21). These problems are particularly prevalent in severe machining operations involving interrupted cuts.

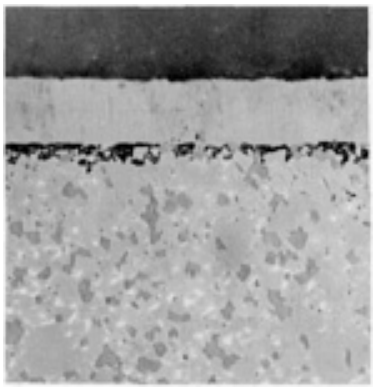

Fig. 16 Decarburization of a TiC coating. Micrograph shows the η-phase at the coating/substrate interface of an 85Wc-9(Ti,Ta,Nb)C-6Co alloy with an 8 μm (315 μin.) TiC coating. Etched with Murakami's reagent for 3 s. 1500×

Performance inconsistencies have been largely eliminated by a number of metallurgical and processing innovations. These include improvements in CVD coating technology, which have resulted in coatings with greater uniformity of thickness, more adherence, and more consistent morphology and microstructure with minimum interfacial η-phase and associated porosity (Ref 22).

Compositions of CVD coatings have also evolved from single-layer TiC coatings with narrow application ranges to multilayer hard coatings. Multilayer coatings have a nominal total thickness of about 10 μm (400 μin.) and use various combinations of TiC, TiCN, TiN, Al_2O_3, and occasionally HfN (Fig. 17).

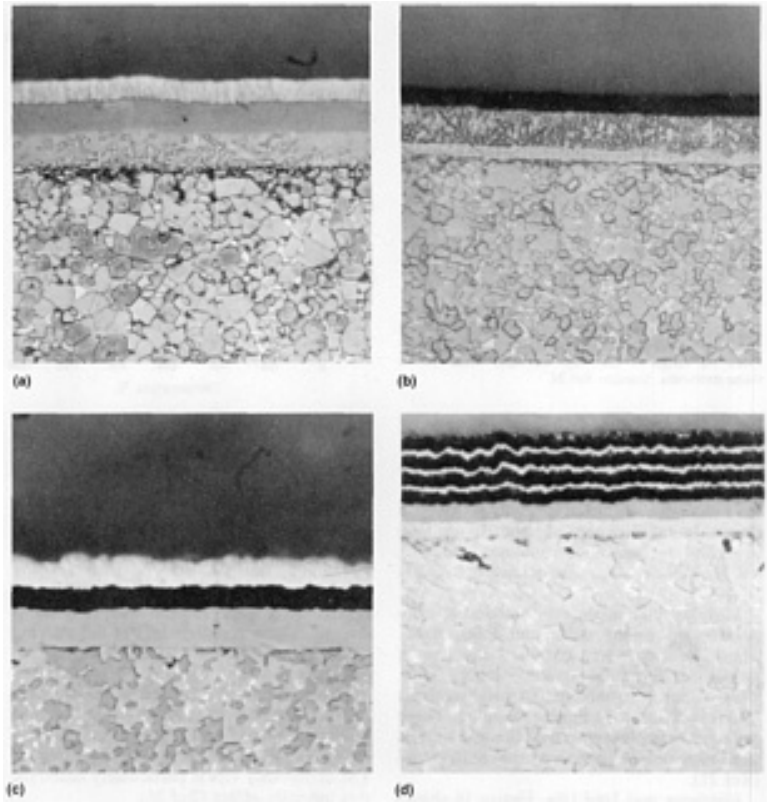

Fig. 17 Multilayer coatings of carbide substrates. (a) 73WC-19(Ti,Ta,Nb)C-8Co alloy with a TiC/TiCN/TiN coating of about 10 μm (400 μin.) in total thickness. (b) 85WC-9(Ti,Ta,Nb)C-6Co with a TiC/Al_2O_3 coating about 9 μm (350 μin.) thick. (c) 85WC-9(Ti,Ta,Nb)C-6Co with a TiC/Al_2O_3/TiN coating about 10 μm (400 μin.) thick. (d) 88WC-7 (Ti,Ta,Nb)C-5Co with TiC/TiCN coating supporting multiple alternating coating layers of Al_2O_3 and TiC. All etched with Murakami's reagent for 3 s. 1500×

Multilayer coatings are intended to suppress both crater wear and flank wear. There is also a trend toward the use of multiple alternating coating layers (Fig. 17d), which are believed to produce finer grain sizes and to minimize chipping. These improvements increase tool life and extend the range of application of the coated tool (Ref 23).

Hardness and Tool Life. Figure 18 shows the room-temperature Vickers microhardness of various hard coatings deposited on cemented carbide substrates. The range of hardness for WC-Co alloys is shown for reference. The compounds TiC and TiB_2 have the highest relative hardness of about 3000 kg/mm^2 and offer the best protection against abrasive wear. With increases in temperature, however, TiC loses hardness rapidly, whereas Al_2O_3 retains its hardness to higher temperatures.

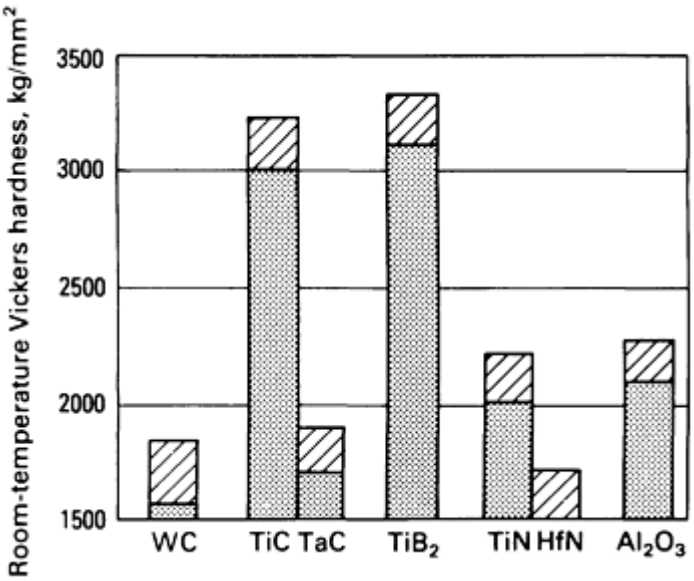

Fig. 18 Room-temperature microhardness of hard coating materials. The hatched area indicates the range of hardness normally observed in these materials. Source: Ref 24

At 1000 °C (1800 °F), which is the temperature typically reached on the rake face of the tool during high-speed machining (Ref 13), Al_2O_3 has the highest hardness, followed by TiN and then TiC (Fig. 19). For comparison, the hardness of WC-Co substrates is also shown in Fig. 19. The hot hardness data indicate that the TiC coating would be more effective at the flank face, which rarely exceeds 600 °C (1100 °F) during machining. At lower speeds, TiC also offers adequate rake face protection from abrasive wear. On the other hand, Al_2O_3 would provide better abrasion resistance at higher speeds, as judged from its high hardness at elevated temperatures.

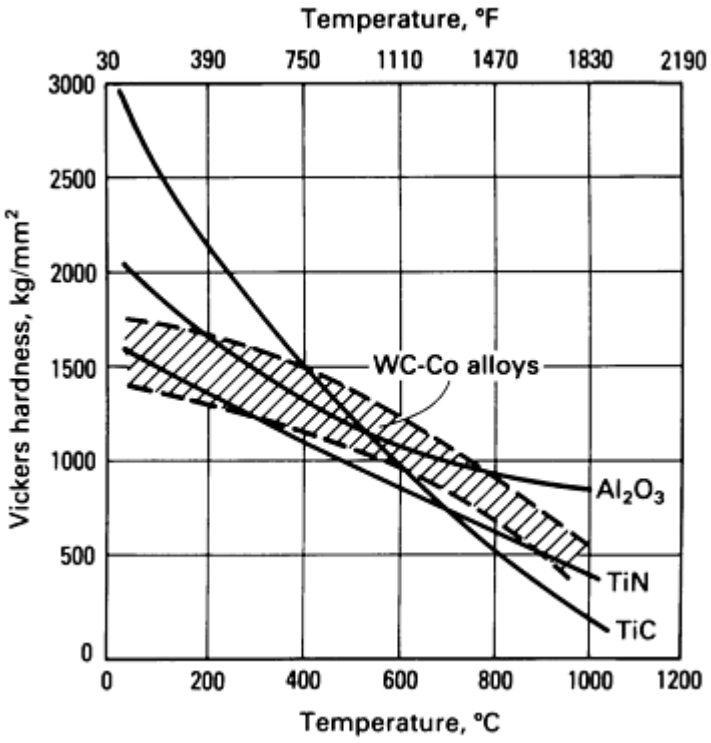

Fig. 19 Temperature dependence of hardness of TiC, Al_2O_3, and TiN. The range of hardness of WC-Co alloys is also shown.

These concepts are illustrated in tool life plots (Fig. 20) based on flank wear criterion for TiC, TiN, and Al_2O_3 coated cemented carbide inserts in turning 1045 steel and gray cast iron workpiece materials. At lower speeds, the TiC coating provides the longest tool life, followed by TiN and Al_2O_3. At higher speeds, the ranking is altered. These rankings reflect the varying temperature dependence of their microhardness shown in Fig. 19.

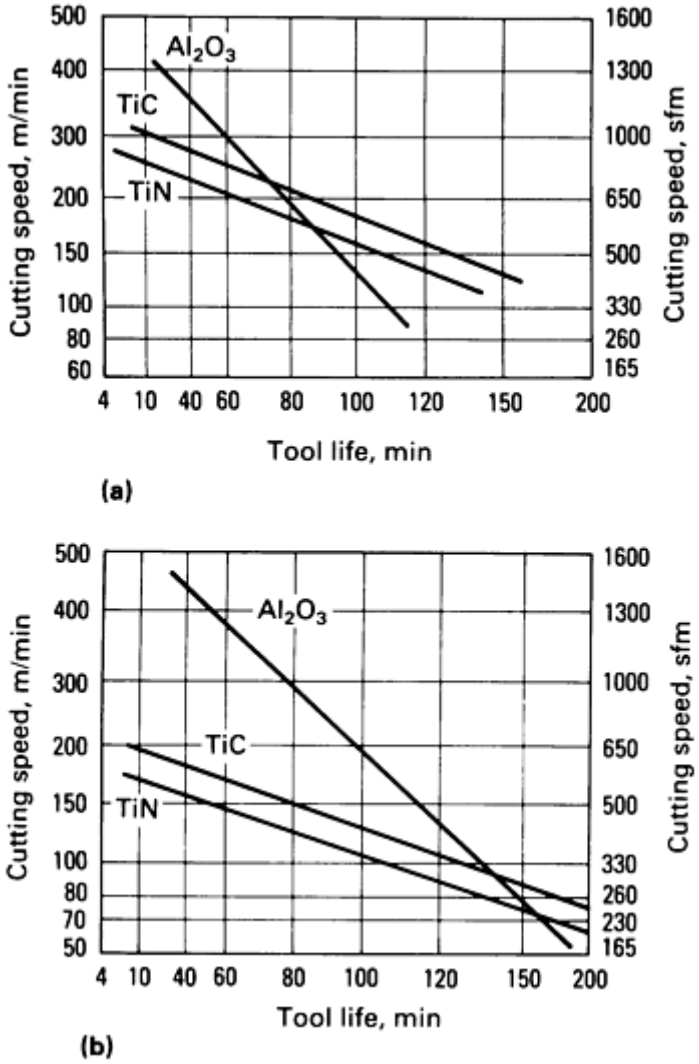

Fig. 20 Tool life diagrams of coated inserts. Tool life is based on a 0.25 mm (0.01 in.) flank wear criterion. (a) Turning 1045 steel with a 2.5 mm (0.1 in.) depth of cut and a 0.40 mm/rev (0.016 in./rev) feed rate. (b) Turning SAE G4000 gray cast iron with a 2.5 mm (0.1 in.) depth of cut and a 0.25 mm/rev (0.01 in./rev) feed rate. Source: Ref 25

Hard coatings also reduce frictional forces at the chip/tool interface, which in turn reduces the heat generated in the tool and thus results in lower tool tip temperatures. The compound TiN is particularly noted for this lubricity effect (Ref 26).

Diffusion Wear. The standard free energy of formation is given in Fig. 21 for WC, TiN, TiC, and Al_2O_3 from room temperature to about 2000 °C (3600 °F). This thermodynamic property gives an indication of the extent to which these materials will undergo diffusion wear. The most stable of these materials at all temperatures is Al_2O_3.

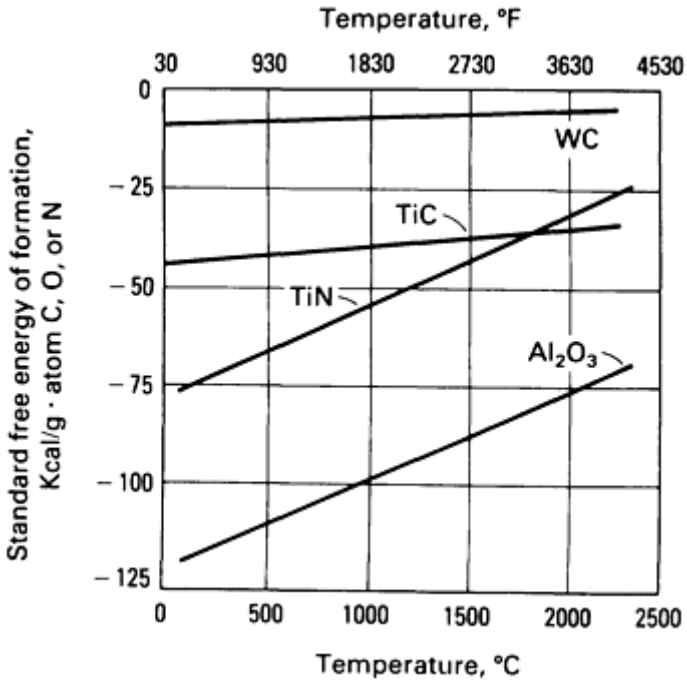

Fig. 21 Variation in the standard free energy of formation of WC, TiN, TiC, and Al_2O_3 with temperature. This parameter gives an indication of the extent to which these materials will undergo diffusion wear.

The dissolution rate of coating materials into the workpiece can also determine the rate of diffusive wear on the tool (Ref 24). The relative dissolution rates of various coating materials into steel at different temperatures are given in Table 7. The dissolution rate of Al_2O_3 in steel is an order of magnitude lower than the dissolution rates of other refractory compounds. Therefore, Al_2O_3 is the most crater-resistant material and is a very effective coating for cemented carbide tools used in the high-speed machining of steel.

Table 7 Relative dissolution rates of coating materials into iron

Rates are relative to TiC.

Material	**Dissolution rate at:**		
	100 °C (212 °F)	**500 °C (930 °F)**	**1100 °C (2000 °F)**
WC	1.1×10^{10}	5.4×10^{4}	3.2×10^{2}
TiC	1.0	1.0	1.0
TaC	2.3	1.2	8.0×10^{-1}
TiB_2	9.9×10^{1}	8.5	2.8
TiN	1.0×10^{-8}	1.8×10^{-3}	2.2×10^{-1}

HfN	2.5×10^{-12}	3.8×10^{-5}	2.5×10^{-2}
Al_2O_3	1.1×10^{-24}	8.9×10^{-11}	4.1×10^{-5}

Source: Ref 24

Thermal Expansion and Coating Adhesion. The high temperatures employed for CVD coating generally ensure good bonding between the substrate and the coating. However, coating adhesion can be adversely affected by stresses caused by the thermal expansion mismatch between the substrate and the coating. Table 8 lists the thermal properties of various coating materials as well as WC-Co substrates. The thermal expansion mismatch is lowest for TiC and highest for TiN, whereas the thermal expansion coefficients of the coating materials listed are higher than those of the substrates. As a result, hard coatings on cemented carbide substrates are in residual tension at room temperature. Because the stresses are most severe at tool corners, the CVD-coated tools must be honed before coating. Another reason for honing is to minimize the formation of η-phase, which tends to develop to a greater extent at sharp tool edges.

Table 8 Tool material thermal properties

Material	Melting point		Coefficient of thermal expansion, μm/m · K	Thermal conductivity, W/m · K		
	°C	°F		100 °C (212 °F)	500 °C (930 °F)	1000 °C (2000 °F)
WC-Co	. . .	. . .	5-6	38-80	. . .	. . .

WC	~2800	5070	~5	120	. . .	. . .
TiC	3100	5612	7.7	33	37	41
TiN	2950	5342	9.4	21	23	26
Al_2O_3	2050	3722	8.4	28	13	6
$M_{12}C$	. . .	. . .	7-10	. . .	. . .	. . .

Cobalt Enrichment. Although the early coated tools substantially improved metal cutting productivity, they were prone to catastrophic fracture when applied at high feed rates or in intermittent cutting operations. One solution to the problem of coating-related tool fracture is to improve the fracture toughness of the substrate by increasing its cobalt content and/or by increasing the binder mean free path (mean thickness of the binder between WC grains). Unfortunately, this approach results in decreased deformation resistance, which can cause tool tip blunting.

A major breakthrough in resolving this conflict between fracture toughness and deformation resistance occurred in the late 1970s, when a TiC/TiCN/TiN-coated tool was developed with a peripheral cobalt-enriched zone (10 to 40 μm, or 400 to 1600 μin., thick), which provided superior edge strength while maintaining the edge and crater wear resistance of the coating layers (Ref 27). The cobalt-enriched zone contained essentially a straight WC-Co composition with nearly three times the nominal cobalt level, while the bulk of the tool insert, containing higher levels of solid-solution cubic carbide

and less cobalt, provided the necessary deformation resistance. Thus, a single tool combined the fracture resistance of a high-cobalt alloy with the deformation resistance of a lower-cobalt alloy.

The ability of the cobalt-enriched tool to resist edge chipping and catastrophic fracture is illustrated in Fig. 22, which compares a cobalt-enriched insert with a nonenriched tool after an edge strength test. Tool failures such as that shown in Fig. 22(b) can ruin the workpiece and result in excessive production downtime. Such tool failures can be particularly damaging in flexible machining systems and in untended machining centers.

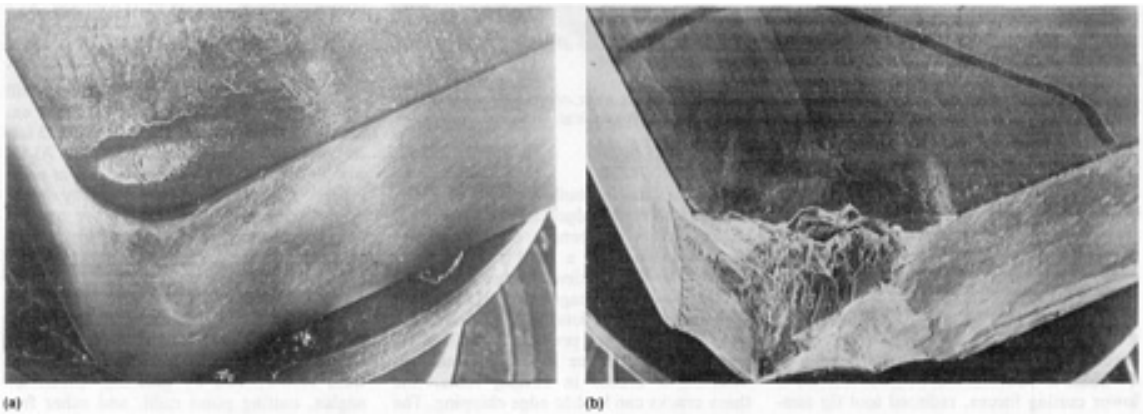

Fig. 22 Scanning electron macrographs of cobalt-enriched and nonenriched tools after a slotted-bar strength test. Machining parameters: depth of cut, 2.5 mm (0.1 in.); speed, 107 m/min (350 sfm); feed, 0.50 mm/rev (0.02 in./rev). The workpiece was AISI 41L50 steel; average hardness: 26 HRC. (a) Cobalt-enriched tool after 1200 impacts. 10×. (b) Nonenriched tool after 220 impacts. 11×

The development of the cobalt-enriched tool permitted the use of heavy interrupted cuts, such as those encountered in scaled forgings and castings. However, optimum performance was obtained only at lower speeds. Further refinements to the cobalt enrichment concept have expanded the application range of this type of tool to higher speeds (Ref 28). Cutting speeds for cobalt-enriched tools range from 60 to 300 m/min (200 to 1000 sfm), with feeds ranging from 0.1 to 1 mm/rev (0.005 to 0.050 in./rev). These capabilities are suitable for most metal removal applications. Two typical cobalt-enriched microstructures that can cover such a range of machining speeds and feeds are illustrated in Fig. 23 and 24.

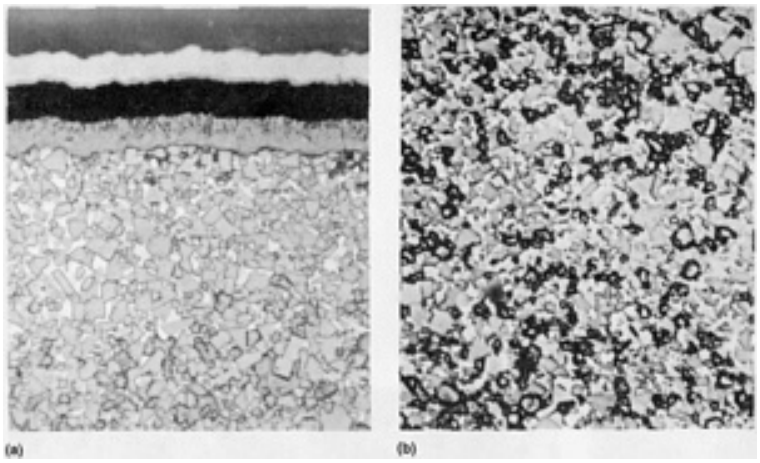

Fig. 24 Microstructure of a second-generation cobalt-enriched coated tool. 85WC-9(Ti,Ta,Nb) C-6Co tool with a TiC/Al_2O_3/TiN coating. (a) Cobalt-enriched periphery (beneath the coating). (b) Bulk microstructure. Both etched with Murakami's reagent for 2 min. 1500×

Physical vapor deposition (PVD) has recently emerged as a commercially viable process for applying hard TiN coatings onto high-speed steel tools (Ref 29). Physical vapor deposition typically employs lower temperatures (~500 °C, or 900 °F) than chemical vapor deposition. Therefore, the PVD process is attractive for use with cemented carbide tools because the lower deposition temperature prevents η-phase formation and provides for refinement of the grain size of the coating layer.

It has been shown by standard three-point bend tests that CVD coatings reduce the transverse rupture strength of cemented carbide tools by as much as 30% because of the presence of interfacial η-phase and/or tensile residual stress within the coating (Fig. 25). On the other hand, PVD coatings do not produce η-phase. In addition, PVD coatings may induce a compressive residual stress, depending on the deposition technique. Therefore, PVD coatings do not degrade the transverse rupture strength of the carbide tools (Ref 30, 31).

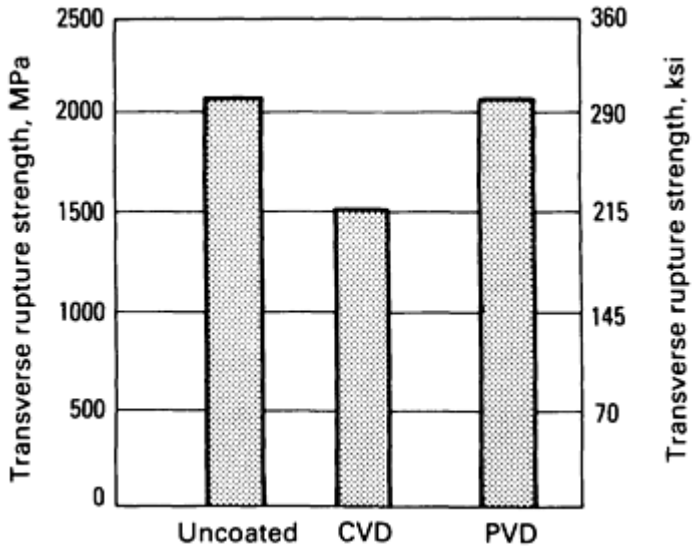

Fig. 25 Comparison of the transverse rupture strength of uncoated and coated carbide tools. Measured by a three-point bend test on 5 × 5 × 19 mm (0.2 × 0.2 × 0.75 in.) specimens of 73WC-19(Ti,Ta,Nb) C-8Co

Another advantage of the PVD process is its ability to coat uniformly over sharp cutting edges (Fig. 26). A sharp edge is desirable in a cutting tool because it leads to lower cutting forces, reduced tool tip temperatures, and finer finishes. In many cases, CVD coatings cannot be applied over sharp cutting edges without heavy η-phase formation and/or coating

buildup, both of which can lead to rapid edge failures. The PVD coatings offers the benefit of the abrasive wear resistance of a hard coating layer without the degradation of edge strength.

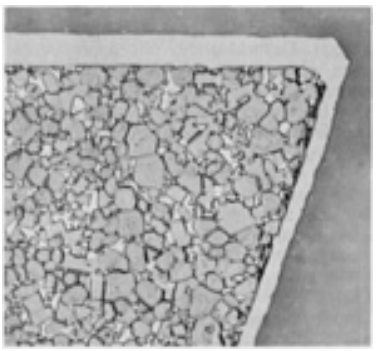

Fig. 26 An example of PVD TiN coating on a sharp cemented carbide tool. Etched with Murakami's reagent for 3 s. 1140×

The above advantages of PVD coatings are especially beneficial in operations such as milling. As noted previously, milling operations can produce severe thermal and mechanical cracks in cutting tools, and these cracks can lead to edge chipping. The CVD coatings often aggravate this situation through stress raisers, such as thermally induced cracks within the coatings as well as interfacial η-phase. These problems can be minimized by honing the cutting edge, by reducing the coating thickness, and by controlling η-phase formation, but they can be eliminated by the use of PVD coatings. As a result, PVD-coated milling tools have recently become a commercial reality (Ref 32).

It should be noted that PVD coatings will not replace CVD coatings to any great extent in the near future. Currently, PVD has certain limitations. For example, Al_2O_3 coating is not feasible, and multilayer coatings have not yet been commercially developed. Additionally, methods have not yet been developed for coating complex tool geometries.

Tools and Toolholding

Early carbide metal cutting tools consisted of carbide blanks brazed to steel holders or milling cutters. Tools that became dull were resharpened by grinding. Clearance angles, cutting point radii, and other features could also be ground into the tools to suit particular cutting situations. Special chip-breaker grooves designed to curl and break the chips generated in metal cutting were also ground into the early tools.

Although these early carbide metal cutting tools provided significant increases in metal cutting productivity, certain disadvantages have become apparent. Regrinding changes the size of the tool; therefore, the cutting tool/workpiece relationship must be readjusted each time the tool is resharpened. Maintaining consistent geometry is difficult with reground tools, and part quality can suffer. Further, because the braze joint can withstand only a limited range of temperature, the selection of usable carbide compositions is restricted, and CVD coating technologies cannot be applied. Nevertheless, brazed tools are still used in applications such as circular saws and small-diameter drills where mechanical clamping is impractical.

Indexable Carbide Inserts. The now-familiar prismatically shaped indexable inserts were introduced in the 1950s. These so-called throwaway inserts resembled brazed tools except that the carbide was secured in the holder pocket by a clamp rather than a braze. When a cutting edge wore, a fresh edge was simply rotated or indexed into place. Several other holding methods were subsequently developed.

The most popular holding method employs a pin that passes through a hole in the insert and forces it into the holder pocket (Fig. 27). Clamps are still widely used, often in conjunction with a holding pin (Fig. 28). Another common holding style employs a screw with a tapered head that fits a conical hole in the insert and thus holds the insert securely (Fig. 29).

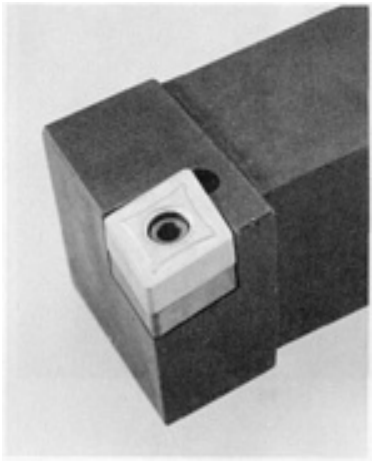

Fig. 27 Indexable insert secured by pin

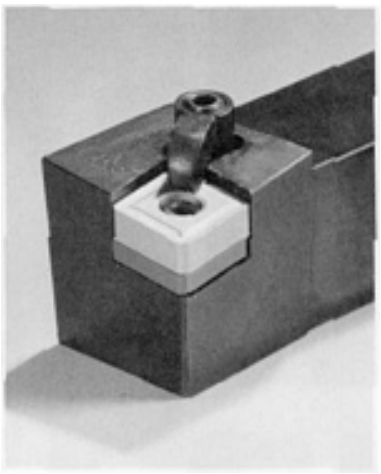

Fig. 28 Pin-and-clamp method of securing an indexable insert to a steel toolholder

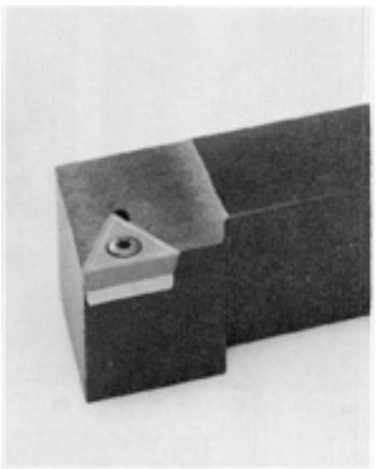

Fig. 29 Screw-on method of securing an indexable insert to a toolholder

Consistency and ease of replacement are the main advantages of indexable insert tooling. Consistent positioning of the cutting edge from index to index simplifies machine tool setup and helps ensure uniform product quality. The use of indexable inserts also eliminates labor costs for regrinding and permits CVD-coated tools and a wide variety for carbide compositions to be utilized.

Indexable carbide inserts are available in both positive and negative geometries (Fig. 30). Negative-rake inserts have excellent resistance to breakage and are well suited to difficult operations involving interrupted cuts. Negative-rake inserts can also be used on both sides, effectively doubling the number of cutting edges available per insert. Although positive-rake inserts can be used on only one side, they cut with lower force, reduce the possibility of distorting the workpiece, and help produce better surface finishes. Both negative- and positive-rake inserts are available in a range of tolerances.

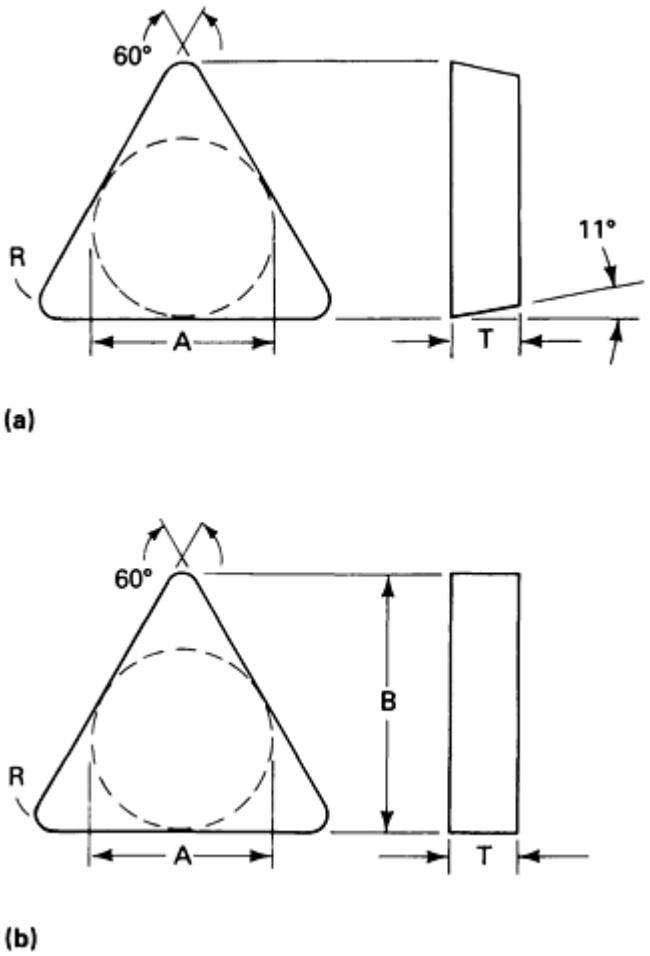

Fig. 30 Positive-and negative-rake geometries. (a) Triangle positive-rake insert. (b) Triangle negative-rake insert

Chipbreaking. In metal cutting operations the relative motion of the tool and workpiece produces a localized shear deformation in the work material immediately ahead of the tool's cutting edge. Workpiece material is thereby removed in the form of chips. The shape and length of the chips depend on machining conditions, type of workpiece material, and cutting tool geometry (Fig. 31). Chips forms not interfering with the cutting operation and easily disposed of are considered acceptable. Unacceptable chip forms include long, stringy chips that can tangle and be hazardous to the machine tool, operator, and workpiece finish, or excessively tight chips which can break cutting tools and scar the workpiece. Each manufacturing plant or shop typically sets standards for acceptable chips based on safety, machine setup, part finish, chip disposal systems, and other factors.

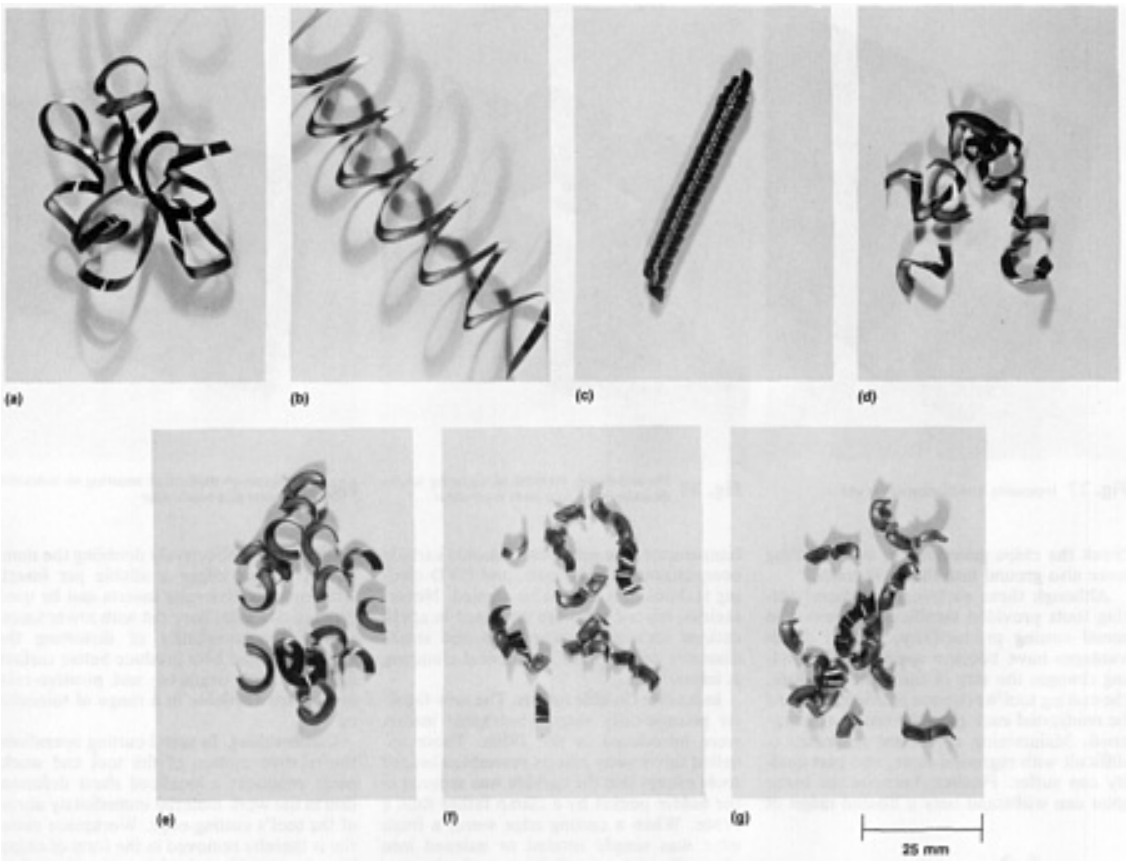

Fig. 31 Types of chips produced in metal cutting operations. (a) Uncontrolled chip, unacceptable. (b) Coil over 75 mm (3 in.) long (loose or tight), unacceptable. (c) Coil less than 75 mm (3 in.) long (loose or tight), acceptable. (d) Short coils; single C-shaped chips, acceptable. (e) Single C- or 6-shaped chips, acceptable. (f) Single with some double C-shaped chips, acceptable. (g) Multiple C-shaped chips, unacceptable

Indexable inserts often feature chip-breaker grooves to control chip formation (Fig. 32). In addition to providing chip control, these grooves often produce lower cutting forces. In fact, advanced chip-control geometries can give negative rake inserts the force-reducing capabilities of positive-rake designs. Customized chip-control geometries are available for special workpiece materials and operations.

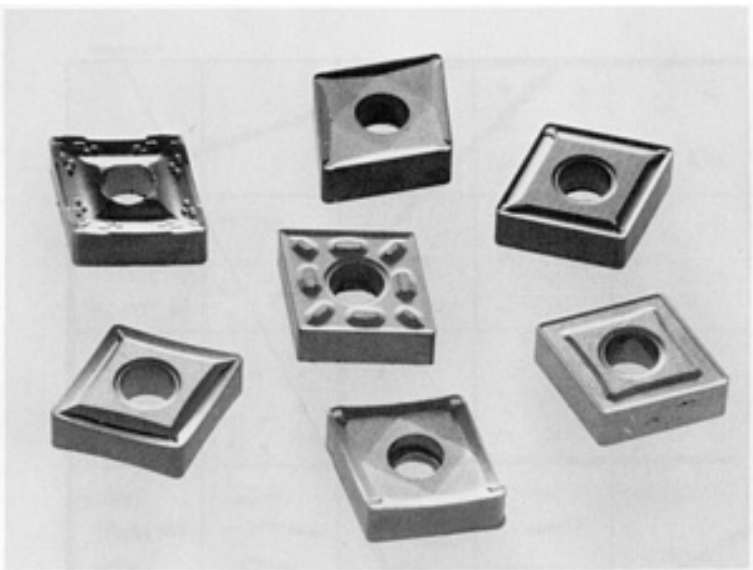

Fig. 32 Indexable inserts with chip-breaker styles

Figure 33 illustrates the variety of chip forms produced by a given workpiece material, insert geometry, and cutting speed as a function of feed rate and depth of cut. Note the range of feed rate and depth of cut combinations that produce acceptable chip forms in this particular situation.

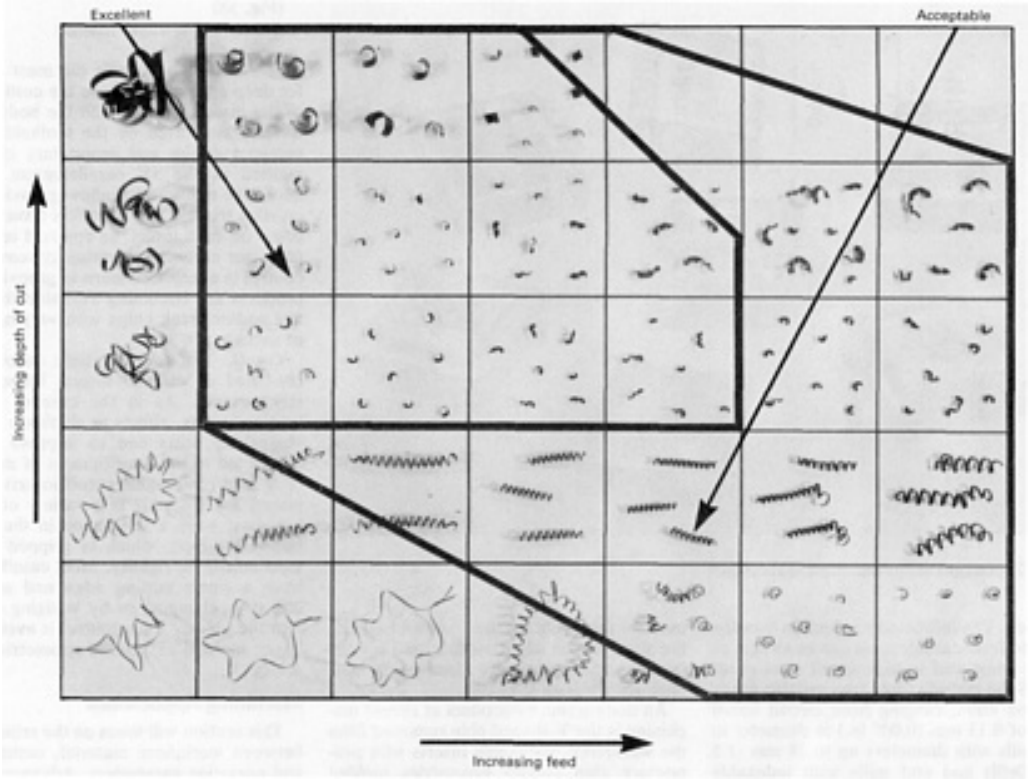

Fig. 33 Types of chips formed as a function of feed rate and depth of cut for a given tool geometry and cutting speed

Tool manufacturers usually provide diagrams that map out application ranges in terms of feed rate and depth of cut for the various chip-control geometries they offer. After cutting speed and insert grade are chosen for a certain workpiece material, these charts enable users to choose geometries to match desired feed rate and depth of cut. Figure 34 presents a simplified version of such a diagram. For high depth of cut and feed rates, roughing geometries would be recommended; for medium depths of cut and feed rates, general purpose geometries are preferred; and for shallow depths of cut and fine feeds, finishing geometries would be chosen. In actual operation, chip control can vary with workpiece material changes, insert nose radii and lead angle, and tool wear; even so, feed rate and geometry are the predominant factors in consistent control of chips.

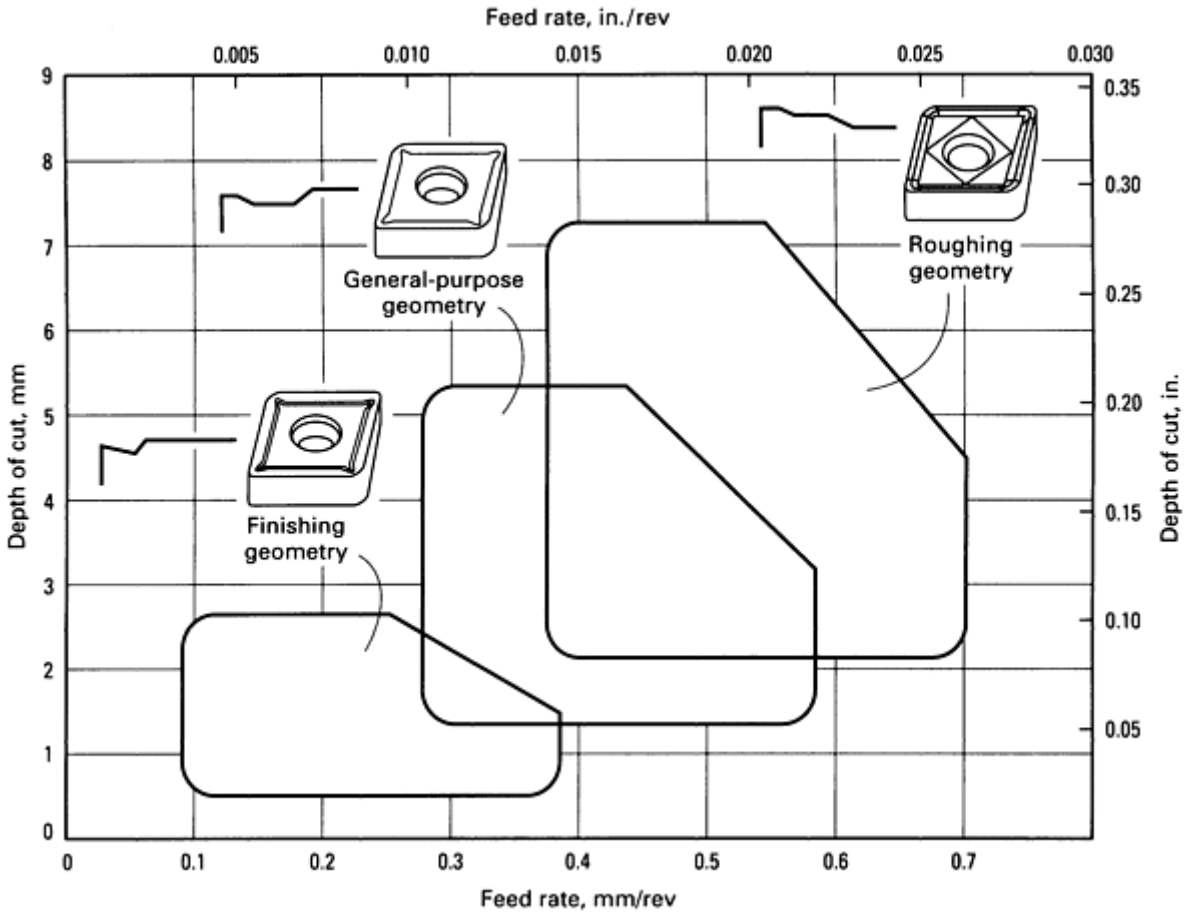

Fig. 34 Simplified diagram showing the application range of different insert geometries in terms of feed and depth of cut

Edge preparation refers to the practice of modifying the cutting edge itself after the correct overall geometry has been produced on the tool. Edge preparations are applied for two reasons: to prevent the chipping and premature failure of a too-sharp and therefore weak cutting edge, or to provide a slightly rounded (honed) edge that will optimize the effect of CVD coating. The edge preparations most commonly used are hones or chamfers (Fig. 35).

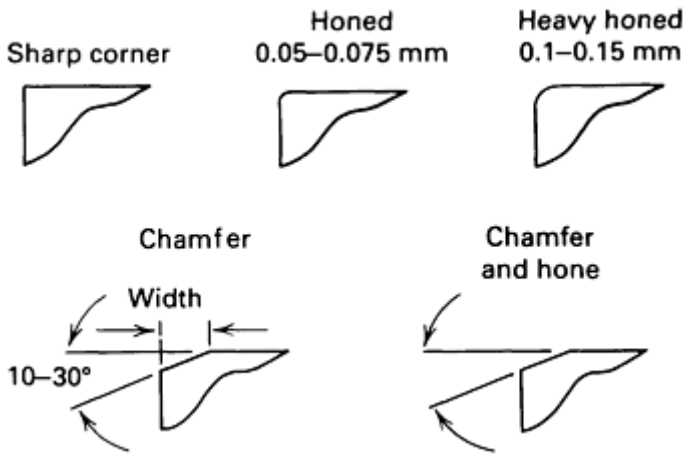

Fig. 35 Various edge preparations for metal cutting tools

The edge preparation of brazed tools is most often applied by hand with a stone. Because the radius desired is very small (commonly 0.025 to 0.075 mm, or 0.001 to 0.003 in.), it is very difficult to achieve consistent performance. Too little hone can lead to microchipping and subsequent rapid edge wear; too much hone is very much like a preworn edge and also results in shorter tool life. Indexable carbide inserts, especially coated inserts, are usually equipped with a machine-applied hone of the size the manufacturer considers proper for the insert size, style, grade, and application. In general, only enough hone to prevent chipping should be used.

Cemented carbide tools intended for use in heavy-duty machining applications are often chambered to provide maximum resistance to edge chipping. Although this may result in the loss of some tool life, the trade-off is reasonable if the mode of failure with honored inserts has been breakage rather than wear. Inserts intended for the machining of nonferrous and some aerospace alloys are generally supplied with sharp edges to reduce cutting forces and thus improve tool life.

Drills and end mills are available in both solid cemented carbide and indexable insert versions. The increased production benefits realized from carbide tools can be as high as 6 to 1 compared to high-speed steel products. Solid carbide tools are available in the smallest sizes, ranging from circuit board drills of 0.13 mm (0.005 in.) in diameter to end mills with diameters up to 38 mm (1.5 in.). Drills and end mills with indexable inserts are generally available in sizes ranging from 16 mm ($\frac{5}{8}$ in.) in diameter up to about 75 mm (3 in.) (Fig. 36 and 37). Solid carbide tools have the advantages of greater rigidity, more cutting edges, and greater precision than comparable tools with indexable inserts. Indexable inserts offer the advantage of repeatability, require no resharpening, and permit the use of a wider variety of grades.

Fig. 36 Metal cutting drills with indexable carbide inserts

Fig. 37 End mills with indexable carbide inserts

Threading. A number of methods are available for producing thread forms. These can be divided into two major categories: forming the thread, and machining (or cutting) the thread. A common thread forming process is thread rolling, which utilizes two diametrically opposed dies to cold form a thread into a workpiece. A frequent (and sometimes desirable) by-product of this process in certain materials is work hardening at the root of the thread.

Threads are typically machined by one of two methods: tapping, or single-point machining utilizing an indexable insert/toolholder system. Tapping is used where the diameter of the hole is too small for an indexable carbide/toolholder system and/or the machining speed is too slow for carbide. The three popular insert/toolholder systems used for threading are the laydown triangle, the stand-up (on edge) triangle, and several versions of a proprietary stand-up 55° parallelogram design (Fig. 38).

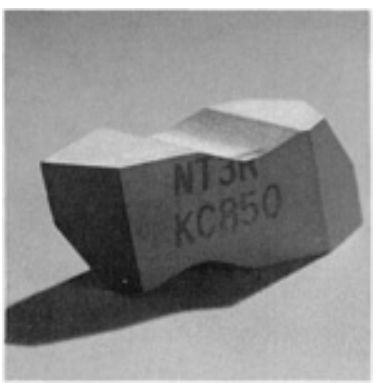

Fig. 38 Proprietary 55° parallelogram carbide inserts

An undesirable by-product of thread machining is the V-shaped chip removed from the workpiece. Indexable inserts with proprietary chip control geometries molded into the top rake surface of the cutting edge are becoming available, and they control and break the chips with varying levels of success. In the more common thread forms, multitooth thread-chasing inserts (Fig. 39) are available as a means of reducing the number of passes required to complete a thread, thus improving productivity. An increasingly popular option available for many thread forms is the cresting insert, which machines the full thread form. Non-cresting inserts machine the root and flanks but not the crest of the thread.

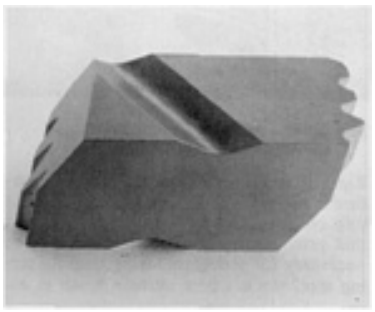

Fig. 39 A multitooth thread-chasing insert

Thread milling, a thread machining method that is useful when turning is not possible, is performed on multiaxis computer numerical control machines capable of helical interpolation (Fig. 40). A disadvantage of thread milling is that the thread form it produces is slightly imperfect because of the inability of the cutting tool to clear the helical angle of the thread form as it exits the part. However, the threads are sufficiently accurate for all but the most demanding applications.

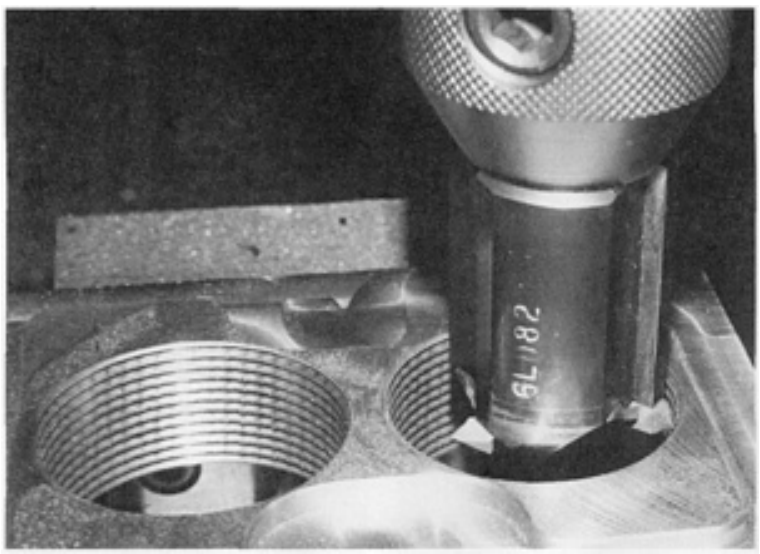

Fig. 40 Thread milling with indexable inserts

Grooving. There are three different grooving insert styles in common use:

- 90° V-bottom (Fig. 41)
- Proprietary stand-up 55° parallelogram (Fig. 38)
- Stand-up (on-edge) triangle

The V-bottom system is the most suitable for deep grooving because the cutting edge of the insert is wider than the body and is directly supported by the toolholder. The compact design and proprietary clamping method of the 55° parallelogram system maximize rigidity in shallow grooving. The on-edge triangle system offers three cutting edges on each insert, as opposed to two in the other common grooving systems. Chip control is a major concern in grooving, and products are becoming available that control and/or break chips with varying levels of success.

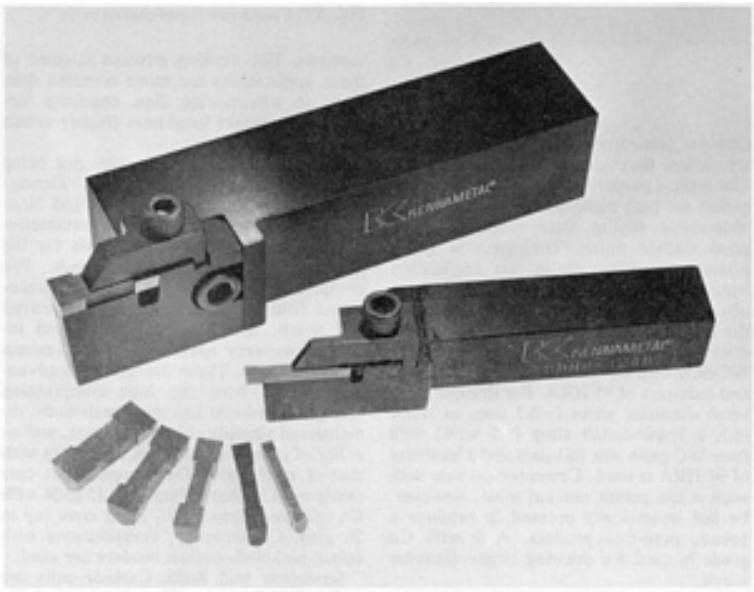

Fig. 41 90° V-bottom (dogbone) grooving inserts and toolholders

Cutoff. The early carbide cutoff tools consisted of carbide inserts brazed onto steel shanks. As in the case of carbide turning inserts, efforts to eliminate tool resharpening costs and to improved performance led to the development of mechanically held replaceable cutoff inserts. These inserts are available in a variety of styles, but most have a vee shape in the top or bottom surface, which is gripped by the steel holder for rigidity. Most cutoff inserts have a single cutting edge and are held either by clamping or by wedging directly into the holder. Chip control is available in either molded or ground geometries (Fig. 42).

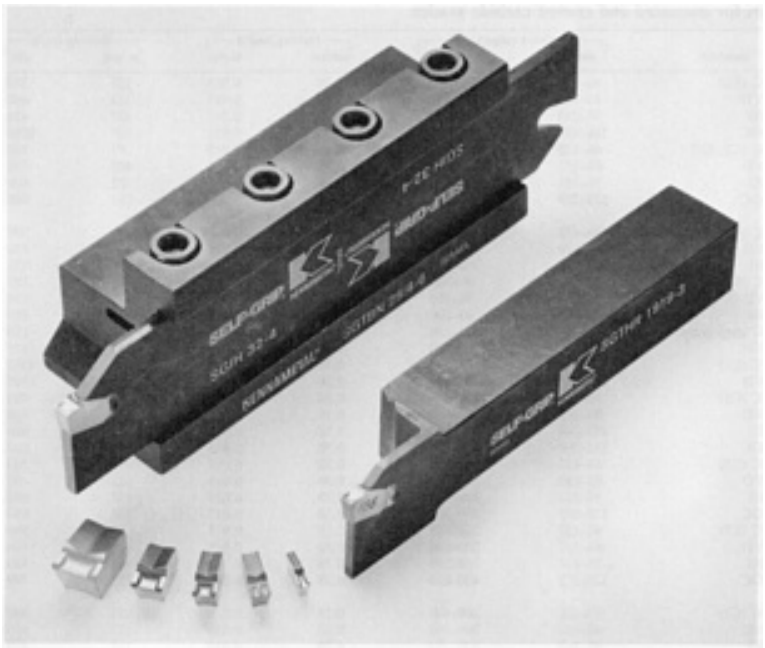

Fig. 42 Cutoff inserts and toolholders

Machining Applications

This section will focus on the relationship between workpiece material, cutting tool, and operating parameters. Advances in cemented carbides discussed earlier in this article have produced a wide selection of tool materials. Suggestions are given here to simplify the choice of cutting tool for a given machining application.

Workpiece Materials. Selection of appropriate cutting-tool grades and machining parameters depends initially on a number of workpiece material parameters; chemical composition, microstructure, and hardness. The effects of composition on machinability are often complicated by the synergistic effects of the elements comprising the workpiece alloy. In steels, for example, only generalized observations can be made on the role of various alloying elements on machinability. Workpiece microstructure is a result of the fabrication technique and heat treatment employed to provide desired properties. Variations in microstructure can have a profound effect on machinability. Workpiece hardness is the easiest parameter to document and is therefore widely used as a factor in rating machinability of a material.

Once the workpiece material is understood, the next step is to choose the right cutting-tool grade and machining parameters. Speed is critical in achieving long tool life, whereas feed rate is important in minimizing the cutting time. The combination of grade, speed, and feed rate determines machining productivity.

Gray Cast Iron. Among the various classifications of cast iron, ferritic and pearlitic gray irons are easiest to machine. The graphite in these materials acts as a lubricant during the cut and produces discontinuous chips. Cast iron is easily machined with negative-rake inserts. Coolants are usually not required but sometimes are used to control dust.

Ductile Nodular Iron. Irons with nodular graphite are stronger than the gray irons and tend to produce curled chips like those from a steel workpiece, rather than the flake-type chip produced in machining gray iron. A C5 carbide grade with a groove-type chip-control geometry is often an appropriate choice in machining these materials.

Austenitic stainless steel is characterized by low thermal conductivity, high work-hardening rate, high ductility and toughness, and high tensile strength. This gummy material produces high temperatures at the chip/tool interface, leading to built-up-edge and tool failure. Tools should be sharp-edged, with positive rakes and adequate chip-control capability. Coolant should be used wherever possible.

Nickel-Base Alloys. These materials are widely used in aerospace industry where their heat and corrosion-resistance properties are fully utilized. They are very abrasive and are susceptible to work hardening. Generally, tools with negative rakes are used in roughing applications, whereas positive-rake tools are employed for finishing. No matter which rake is used, the key is to keep the cutting edge sharp.

Titanium alloys are characterized by low elastic modulus, high strength, high reactivity, and a tendency to work harden. In machining these alloys, rigidity of the tool and a high tool-clearance angle are essential. The cutting edge should be sharp, the speeds slow, and the coolant generous, but the tool should not dwell in the cut because it may work harden the surface of the workpiece. Uncoated fine-grain carbide (C2) is usually the best cutting-tool material for titanium; PVD-TiN-coated tools are also showing promise.

Aluminum is relatively easy to machine, and cutting speeds can be very high, but chip disposal can be a problem. Sharp cutting edges and coolants are helpful when fine workpiece surface finish is desired. On high-silicon aluminum, diamond tools offer the best performance.

Free-machining steels include additives that dramatically increases their machinability. The common additives are lead, sulfur, phosphorus, tellurium, bismuth, and boron. These steels can be machined at dramatically higher speeds than other steels, and good surface finishes can be obtained with negative or positive tools. Chip control is usually not a problem. For a given speed, much longer tool life can be obtained on the free-machining steels than on plain carbon steels.

Plain Carbon Steels. The machinability of plain carbon steels depends on workpiece carbon content. Plain carbon steels, with carbon content <0.25%, are soft and gummy and require positive-rake tools with sharp cutting edges if a good surface finish is desired. Tool failure while machining these materials is usually caused by buildup on the cutting edge

and microchipping of the insert. As the carbon content increases, crater wear becomes the predominant tool-failure mechanism. At lower carbon contents, crater wear is less of a concern, but chip control becomes more difficult.

Alloy steels have higher hardness levels, higher yield strengths, and higher tensile strengths than plain carbon steels. Alloy steels are more difficult to machine than plain carbon steels; decreasing the carbon content of alloy steels improves machinability. Flank wear is the nominal mode of tool failure in alloy steel machining, but crater wear becomes more dominant as machining speed and/or carbon content increases. Machinability can also be a problem with chromium-molybdenum steels, which tend to be abrasive to the tool material. Higher nickel-alloy steels present another machinability challenge because they show a tendency to work harden. Like austenitic stainless steels, higher-nickel-alloy steels require positive-rake tools for productive machining.

Martensitic and Ferritic Stainless Steel. Ferritic stainless steels are not difficult to machine, although some produce stringy chips. Martensitic stainless steels follow the more traditional machining responses to carbon level: higher carbon levels increase the hardness and promote formation of chromium carbide. This decreases machinability and causes abrasive wear to the cutting tool. Sharp-edged positive-rake tools with chip control should be used for both martensitic and ferritic stainless steels.

Cutting tool grades of cemented carbide include coated carbides, uncoated alloyed carbides, and uncoated straight carbides. Selection is discussed below.

Uncoated Straight WC-Co Grades. Despite the advent of coated cemented carbide tools in the late 1960s, uncoated straight WC-Co grades still find a place in many machining operations. Grades in the K30 and K20 categories (C2 and C3) are typically used in machining gray cast iron, high-temperature alloys, austenitic stainless steels, nonferrous alloys (aluminum), and nonmetals. The higher cobalt K40 (C1) grades are also often used on difficult-to-machine workpieces such as chilled cast iron and heat-treated steels, where cutting tool strength and shock resistance have increased importance.

Although cutting-tool materials such as SiAlONs and whisker-reinforced ceramics have provided increases in machining productivity on nickel-base alloys, similar improvements have not occurred in the machining of titanium alloys. Submicron carbide grades (fine-grained carbide) K40 to K20 (C1 to C3) have shown the capacity to enhance machining productivity in titanium alloys, nickel-base materials, and other high-temperature alloys.

Uncoated alloyed carbide grades (P40 to P10, or C5 to C8) are primarily used in machining carbon steels, free-machining steels, tool steels, alloy steels, ferritic stainless steels, and malleable irons. They are widely used when machines do not have sufficient horsepower to utilize the high metal-removal capabilities of advanced coated tools. Uncoated alloyed carbides also find application in brazed form tools, which are typically made with highly specialized geometries mirroring the part being machined. Uncoated alloyed carbide grades are often employed in high positive, sharp-edged geometries for machining special part configurations with thin wall sections and tight tolerances. These parts cannot be subjected to high forces during machining. The CVD-coated tools, which are honed prior to coating, are not as effective in these applications. The recently developed PVD-TiN-coated carbides and cermets with sharp or near-sharp edges are also proving effective in such applications.

Coated Carbide Grades. More than 60% of the metal cutting inserts currently sold in the United States are CVD coated. Coated carbide tools provide abrasion resistance, crater resistance, and edge-buildup resistance, while permitting the use of higher machining speeds. This is illustrated in the tool-life diagram shown in Fig. 43, which compares the performance of a P40 (C5) grade with and without TiC-TiCN-TiN coating and a typical Al_2O_3-coated grade in turning SAE 1045 steel.

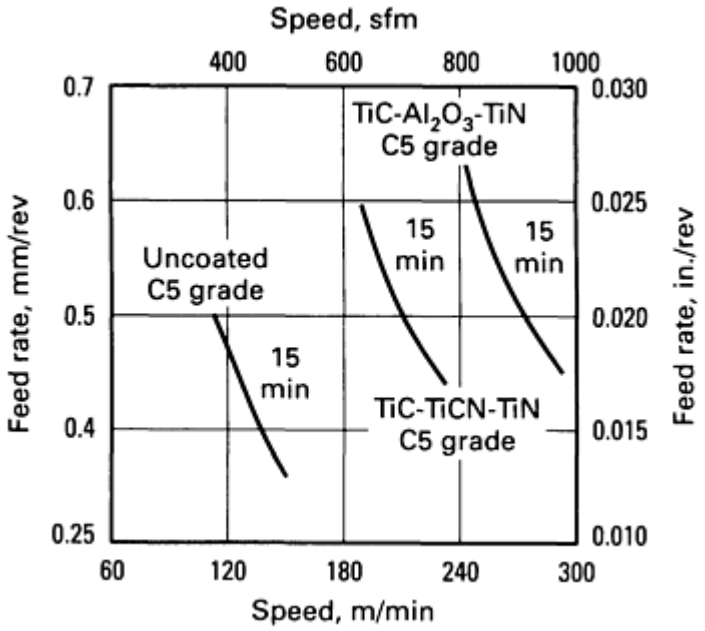

Fig. 43 Tool life comparison of a coated and an uncoated carbide tool. Constant tool life (15 min) plot for an uncoated P40 (C5) carbide and coated P40 (C5) carbides in turning SAE 1045 steel. The depth of cut was 2.5 mm (0.100 in.).

The TiC-TiCN-TiN-coated tools are generally used at cutting speeds higher than those used with uncoated tools, but lower than those employed with Al_2O_3-coated tools. The coatings provide good wear characteristics for machining both irons and steels. Combined with specially designed cobalt-enriched substrates, these coatings can also add new dimensions to tool life improvement, especially in interrupted cuts. In these applications the impact strength of the cobalt-enriched substrate works as a partner with wear-resistant coatings.

The TiC-Al_2O_3- and TiC-Al_2O_3-TiN-coated tools are generally employed at higher speeds than the TiC-TiCN-TiN-coated tools. When machining steels at high speeds, the alumina layers provide excellent crater resistance. These grades work well on both irons and steels but are not recommended for materials such as aluminum or titanium. The new alternating multiple-layer coatings (Fig. 17d) are proving to be very effective in the machining of steels and irons.

PVD coatings can be applied to sharp or near-sharp insert edges without the deleterious effect of η-phase formation at the coating-substrate interface. The sharp, tough PVD-coated tools are particularly well suited to milling, drilling, grooving, and threading applications. They have also been found to perform well on difficult-to-machine materials such as high-temperature alloys and austenitic stainless steels. Another application of PVD-coated tools is low-speed cutting, where the lubricious effect of the fine-grain TiN coatings helps improve tool life.

Machining Parameters. Recommended speed and feed ranges and starting points for uncoated and coated carbide grades for many common workpiece materials are shown in Table 9. More detailed operating parameters can be obtained from cutting tool suppliers or from independent sources, such as the Metcut Machinability Data Base.

Table 9 Recommended speed and feed ranges for uncoated and coated carbide grades

Material	Hardness, HB	Grade[(a)]	Speed range[(b)]		Starting feed[(c)]		Starting speed	
			m/min	sfm	mm/rev	in./rev	m/min	sfm

Carbides for Nonmachining Applications

Almost 50% of the total production of cemented carbides is now used for nonmetal cutting applications such as metal and nonmetallic mining, oil and gas drilling, transportation and construction, metalforming, structural and fluid-handling components, and forestry tools. New applications are constantly being identified for carbides, largely because of their excellent combination of properties, including abrasion resistance, mechanical impact strength, compressive strength, high elastic modulus, thermal shock resistance, and corrosion resistance. This section addresses the current status of cemented carbides in nonmachining applications and highlights the specific property requirements and compositions employed. More extensive treatment of carbides used in nonmachining applications is available in Ref 33, 34, 35, 36, 37, and 38.

Compositions and Classification of Carbides

Compositions. The majority of cemented carbides used in mining, construction, oil and gas drilling, and metalforming applications is comprised of straight tungsten carbide-cobalt grades. Alloyed carbides are used only in special applications. A remarkable feature of these metal-bonded carbide alloys is that they can be tailored to provide different combinations of abrasion resistance and toughness by controlling the amount of cobalt and WC grain size. In general, cobalt contents vary from 5 to 30 wt% and WC grain sizes range from <1 to >8 μm and sometimes even up to 30 μm. The selection of a proper grade for a given application depends on an understanding of the complete process and the dominant failure mechanisms observed in the tool material.

Classification of Carbides. The C-grade classification for metal cutting carbide grades adopted by the U.S. carbide industry was discussed earlier in this article. This system has been expanded to include an array of nonmachining applications, as shown in Table 3.

Metalforming Applications

Cemented carbides are employed in metalforming applications because of their combination of high compressive strength, good abrasion resistance, high elastic modulus, good impact and shock resistance, and ability to take and retain excellent surface finish. Typical applications in this category include drawing dies, hot and cold rolling of strips and bars, cold heading dies, forward and back extrusion punches, swaging hammers and mandrels, and can body punches and dies. Table 10 lists nominal composition and properties of representative carbides and their applications. In applications that require high-impact strength, grades with 11 to 25 wt% Co are used. The higher-cobalt grades can survive more severe impacts. If impact strength is not a consideration, alloys with 6 to 10 wt% Co are selected. When wear resistance is of paramount importance, grades with lower cobalt contents and finer grain sizes are suitable choices. Cemented carbide compositions with higher cobalt contents (up to 30 Wt%) and very coarse grain sizes (up to 30 μm) are employed in hot metalforming applications that demand high toughness and thermal shock resistance. When gall resistance (resistance to metal "pickup" on the tool) is needed, alloy carbides with tungsten-titanium carbide and tantalum-niobium carbides are used. For corrosion resistance applications, grades with finer WC grain sizes and lower cobalt contents are preferred because corrosion in general attacks the cobalt binder, leaving the carbide particles uncemented and making them susceptible to abrasive wear. Tungsten carbides with either nickel binder or combinations of nickel, cobalt, and chromium are also used in applications that require corrosion resistance.

Table 10 Nominal composition and properties of representative cemented carbides and their applications

Typical application	Binder content, wt%	Grain size	Hardness, HRA
Heavy blanking punches and dies, cold heading dies	20 to 30	Medium	85
Heading dies (severe impact), hot forming dies, swaging dies	11 to 25	Medium to coarse	84
Back extrusion punches, hot forming punches	11 to 15	Medium	88
Back extrusion punches, blanking punches and dies for high shear strength steel	10 to 12	Fine to medium	89
Powder compacting dies, Sendzimir rolls, strip flattening rolls	6	Fine	92
Extrusion dies (low impact), light blanking dies	10 to 12	Fine to medium	90
Extrusion dies (medium impact), blanking dies, slitters	12 to 16	Medium	88
Corrosion resistant grades, valves and nozzles, rotary seals, bearings	6 to 12	Fine to medium	92
Corrosion resistant grade with good impact resistance for valves and nozzles, rotary seals and bearings	6 to 10 Ni	Medium	90
Deep draw dies (nongalling), tube sizing mandrels	10 Co with TiC and TaC	Medium	91

Drawing Dies. As noted earlier in this article, the impetus for the synthesis of WC and subsequent development of cemented carbides came from the wiredrawing industry, where they are employed even today. The critical properties needed for this application are high compressive strength, metal-to-metal sliding wear resistance, and good surface finish. Toughness is not a primary consideration in this application because no impact is involved. The dies are often supported

in steel cases to withstand the tensile hoop stresses developed during drawing. The most commonly used grade is WC-6Co with medium grain size (1 to 2 μm) and hardness of 92 HRA. For drawing very small diameter wires (~0.1 mm, or 0.004 in.), a lower-cobalt alloy (~5 wt%) with finer WC grain size (≤1 μm) and a hardness of 94 HRA is used. Cemented carbide with such a low cobalt content must, however, be hot isostatically pressed to produce a sound, pore-free product. A 9 wt% Co grade is used for drawing larger diameter wires.

Cemented carbides are also employed for drawing tubes, rods, bars, and complex sections. The working stresses in some of these applications are more complex than those in wiredrawing dies, requiring carbides with higher toughness (higher cobalt contents).

Rod Mill Rolls. Carbide rolls are being increasingly used in Morgan. Demag, Ashlow, Krupp, Hille, Moeller, and Neumann mills to provide improved productivity and efficiency over steel rolls for the production of hot-rolled steel rods. The comparative advantages are closer dimensional control, truer roundness, improved rod finish, nongalling tendency, and increased delivery speeds up to 4500 m/min (15,000 ft/min). These performance advantages result from the high compressive strength, hardness and wear resistance, dimensional stability, heat resistance, and rigidity of cemented carbides compared with that of steel rolls. The compositions currently used for hot rolling have 15 to 30 wt% Co with very coarse WC grain sizes (up to 20 μm). Occasionally, compositions with cobalt-nickel-chromium binders are used.

Sendzimir Mill Rolls. Carbide rolls are well suited for the cold reduction and finishing of strip products in Sendzimir mills. Rigidity and dimensional stability are particularly important in this application. The rolls are produced by hot isostatic pressing that provides the pit-free, smooth surface necessary for reducing, sizing, and flattening steel stock where surface finish is extremely critical. The rolls maintain true stock thickness across their entire width to deliver consistently high dimensional accuracy. In addition, improved wear life and an ability to operate at higher speeds than steel rolls provide greater productivity. The compositions used in these applications have medium levels of cobalt (~5.5 wt%) with medium WC grain size (1 to 2 μm).

Wire Flattening Rolls. Carbide rolls are successfully employed to flatten alloy steel wires into strips. The rigidity of the carbide produces uniform thickness across the width of the strip, and the high polish on the rolls imparts a very smooth surface to the steel strip. In addition, roll life is increased many times over that of most tool steel rolls due to the superior wear resistance of tungsten carbide alloy. A high-cobalt alloy (~12 wt%) is employed in this application.

Rebar Rolls. Successful application of carbides in rod mill rolls led to their use in high-speed twist-free mills to produce concrete reinforcing rods. In this application, the rod has ribbed patterns embossed on the surface that are formed by appropriate negative depressions on the roll. The high hardness, wear resistance, and compressive strength of carbide can provide an order of magnitude improvement in tool life over that of steel or cast iron rolls. Typically, a 25 to 30 wt% Co grade is employed in this application.

Slitter Knives. The high abrasive resistance and edge strength of carbides make them suitable for use as slitter knives for trimming steel cans and stainless and carbon steel strips and for cutting abrasive materials in the paper, cellophane, and plastic industries. The carbides are also used in slitting magnetic tapes for audio, video, and computer applications. The grades currently used in these applications are of medium to submicron grain sizes with 6 to 10 wt% Co. The fine grain size offers a sharp cutting edge, good surface finish, and high edge strength, which ensures high edge reliability.

Cold-Forming Applications. Cemented carbides are useful materials in cold-forming equipment such as punches and dies for extrusion or heading punches and dies. The high compressive strength and deformation resistance of cemented carbide make it practical to form a variety of parts not economically produced with steel punches and dies. Some examples of parts produced with cemented carbide punches and dies are wrist pins, bearing races, valve tappets, spark plug shells, bearing retainer cups, and propeller shaft ends. The punches range in size up to 100 mm (4 in.) in diameter and 500 mm (20 in.) in length and can produce 50,000 to 500,000 pieces between reworking, which presented nearly a tenfold increase in life over steel punches.

Back extrusion punches have to withstand heavy shock as well as deformation associated with the process. Generally, a WC-12Co alloy is used. When the compressive load on the punch becomes high, a lower-cobalt alloy (~11 wt%) is a more appropriate choice. For forward and backward extrusion dies, a WC-16Co grade is recommended. Applications with more severe impact may require compositions with higher cobalt contents (~20 wt%). By the same token, a lower-cobalt grade (~12 wt% Co) is selected for less severe impact situations. Submicron carbides with hardness in the range of 92 to 93 HRA may also be used for punches. By a judicious choice of cobalt content, it is possible to obtain improved wear resistance while retaining adequate compressive strength in the fine-grain materials.

In cold-heading applications involving the manufacture of nuts, bolts, screws, and other components with formed heads, the dies have to withstand considerable stress and repeated impacts and must therefore possess good fatigue strength. Alloys of 20 to 30 wt% Co with medium grain sizes (2 to 3 μm) and hardnesses of 84 to 85 HRA are selected.

Can Making. The can-making industry employs cemented carbides for blanking, piercing, and drawing sheet metal into the required shapes. The two-piece cans that are popular today are produced by a draw-iron method which employs carbide punches and thin-walled carbide ironing dies. The carbides provide the fine surface finish and high polish required in this application, as well as high resistance to "pickup" due to cold welding or galling. The alloys used for the punches generally have medium grain sizes with 11 to 12 wt% Co and hardness values in the range 89 to 90 HRA. For can-ironing dies, similar grades are used, sometimes with TiC and TaC additions for galling resistance. Submicron-grain carbides with improved wear resistance are also employed for can-ironing dies.

Stamping Punches and Dies. The high elastic modulus of carbides combined with their ability to incorporate fine details makes them ideal tool materials for stamping punches and dies. As in many other metalforming applications, fine-grain carbides are chosen for punches because of their edge retention capability and higher abrasion resistance.

Structural Components

The physical and mechanical properties of cemented tungsten carbides (Table 2) make them appropriate materials for a wide range of structural components, including plungers, boring bars, powder compacting dies and punches, high-pressure dies and punches, pulverizing hammers, carbide feed rolls and chuck jaws, and many others. The predominant wear factors in most applications are high abrasion, attrition, and erosion.

Boring Bars and Plungers. The high elastic modulus of carbides combined with their high compressive strength and wear resistance makes them ideal candidates for use in boring bars, long shafts, and plungers, where reduction in deflection, chatter, and vibration are concerns. In boring machines, for example, the static stiffness of a carbide boring bar is three times that of an alloy steel bar because of the difference in modulus of elasticity of the two materials. With its greater static stiffness, a carbide bar can make three times as heavy a cut with the same deflection, or it can make an equal cut with one-third as much deflection and consequently with greater accuracy. The following data permit comparison of the performance of a steel and a carbide bar:

Item	**Steel bar**	**Carbide bar**
Rough boring		
Feed, mm/rev (in./rev)	Oil 0.1 (0.005)	0.2 (0.007)
Speed, rev/min	180	350
Depth of cut, mm (in.)	4.8-6.4 ($\frac{3}{16}$-$\frac{1}{4}$)	4.8-6.4 ($\frac{3}{16}$-$\frac{1}{4}$)
Finish boring		
Number of cuts	2	1
Feed, mm/rev (in.rev)	0.1 (0.005)	0.1 (0.005)

Speed, rev/min	150	400
Depth of cut, mm (in.)	0.8 (0.030)	0.2 (0.007)
Finish, μm (μin.)	3.8 (150)	2.3 (90)

Powder Compacting Dies and Punches. Tungsten carbide punches and dies are successfully employed in compacting metal, ceramic, and carbide powders prior to sintering. The dies are generally made of 6 wt% Co grade with a medium grain size and hardness of 92 HRA. Powder compacting punches, rams, and core rods employ a higher cobalt grade (~11 wt% Co) and ~90 HRA. They can be made of solid carbide or as a composite that uses tungsten carbide in the wear areas. More recently, fine-grain carbides with 10 wt% Co are also employed in these applications.

High-Pressure Dies and Punches. Another successful application area for carbides as dies and pistons is in the manufacture of synthetic diamonds. The high compressive strength of carbides allows them to withstand the ultrahigh pressures (>7 GPa, or 1×10^6 psi) generated within the reaction chamber. The carbides are held by large steel retaining rings to keep them in compression. The pistons use carbides with ~6 wt% Co to take advantage of their compressive strength and abrasion resistance. The dies on the other hand, use carbides with higher cobalt levels (10 to 12 wt%) and medium grain sizes (2 to 3 μm), because, in addition to high compressive strength, the dies require adequate fracture toughness.

Fluid-Handling Components

The rigidity, hardness, and dimensional stability of cemented carbide, coupled with its resistance to abrasion, corrosion, and extreme temperatures, provide superior performance in fluid-handling applications. Several typical examples are discussed below.

Seal Rings. As operating environments have become more demanding, use of cemented carbides for axial mechanical seal ring has become more common. In situations involving corrosion, abrasion, high temperatures and pressures, and high speeds of rotation, carbides provide reliable service. Although often higher in initial cost, these alloys provide impressive savings in long-range costs because they reduce the frequency of maintenance downtime. Because of their dimensional stability and resistance to deformation, carbide seal rings retain their flatness and fine finish and are therefore used over a wide range of temperatures, from sealing hot gases to cryogenic liquids.

For seal rings facing extreme corrosion, a nearly binderless carbide of tantalum and tungsten is employed. For moderate corrosion, alloys with cobalt-chromium binder provide longer service life. A WC-Ni alloy is preferred where other carbides are not sufficiently corrosion resistant.

Bearings, Valve Stems, Valve Seats. One of the common uses of tungsten carbide bearings is in shaft sleeves and bushings in centrifugal pumps. A variety of fluids, from water to highly abrasive slurries and corrosive liquids such as sulfuric acid, flow through such pumps. Carbide bearings can be used in direct contact with these fluids, thereby eliminating the need for bearing seals. In waste disposal plants, cemented carbide valve stems and seats have successfully replaced stainless steel components in combating the highly abrasive and corrosive slurry of sludge, sand, and water.

The high hardness of carbides minimizes wear by preventing abrasive particles from embedding themselves in the surface and continuing to abrade the mating surface. With most other bearing materials, it is necessary to isolate the bearing from the abrasive particles to avoid frequent downtime for bearing changes.

Nozzles are used to control and direct the spray of powders and liquids in, for example, dusting chemicals no crops, directing coolants onto hot steel, and spraying latex paints, and are also used in sand and grit blasting equipment. All these applications involve highly corrosive and abrasive materials. Cemented carbide is an excellent choice for these nozzles because it can outwear steel 100 to 1 and will thereby maintain the spray pattern and quantity of flow for a longer period of time, extending the service life of the nozzle. Each nozzle application dictates its own configuration. Many applications can use a small carbide nozzle insert held to other base materials by epoxy, braze, shrink fit, or taper fit. This permits the use of carbide without major redesign of a nozzle assembly or the need to manufacture a complex shape from solid carbide.

Transportation and Construction Applications

Among the diverse applications of cemented carbides is a wide range of tools and components for the transportation and construction industries. Examples include tools for road planing, soil stabilization, asphalt reclamation, vertical and horizontal drilling, trenching, dredging, tunnel boring, and forestry, as well as components such as snow-plow blades, tire studs, and street sweeper skids.

Road Planing. Carbide-tipped tools provide a productive method for planing pavement surfaces. Mounted on a rotating drum (Fig. 44) of a road planer, carbide tools strip away concrete or asphalt pavement surfaces to any depth up to 250 mm (10 in.). The rotatable carbide-tipped road planing bit is secured in a steel block by means of a retainer sleeve, which may have a flange to improve bit rotation and provide easy bit changing. The bit rotation results in a self-sharpening effect and contributes to long tool life.

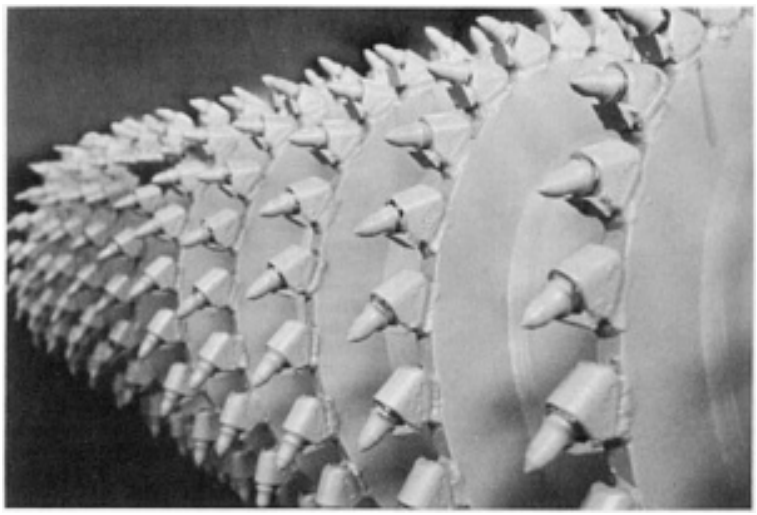

Fig. 44 Carbide-tipped tools mounted on a rotating drum of a road planing machine

The composition of the carbide used in road planing depends on the type of pavement surface. Concrete pavements comprising coarse aggregates are inherently harder than asphalt and require a more impact-resistant grade. In addition to impact resistance, adequate abrasion resistance and fracture toughness are also required. Alloys with ~9.5 wt% Co and coarse WC grain size (10 to 20 μm) can be successfully used for planing concrete pavement. Asphalt pavements require a more abrasion-resistant grade (for example, WC-6Co). In some asphalt planing, the steel bit body holding the carbide undergoes more wear than the carbide because of the undercutting of the steel body by the abrasive asphalt fragments.

Trenching Tools. Tungsten carbide cutter bits for asphalt/concrete trenchers are being increasingly used to make slotting cuts for utility maintenance and have developed in parallel with road planers. Bucket wheel machines equipped with carbide-tipped tools have broadened the application range of trenchers. For example, bucket wheel trenchers have successfully excavated such difficult grounds as Arctic permafrost and Florida coral.

Soil stabilization refers to the mixing and pulverizing of hard soil as a preliminary step in new highway construction or as preparation for resurfacing. The requirements of the tool material are abrasion resistance combined with impact resistance (no heat is generated in the process). Drum mixers for soil stabilization operations are "laced" with cemented carbide-faced tines, or blades. Uniformity of mixing over long distances and avoidance of frequent tool changes are important advantages. The carbides must withstand high-stress abrasion and impact loading. Alloys commonly used have a nominal cobalt content of 10 wt% and medium grain size.

Asphalt Reclamation. Carbide-tipped tools are also employed in continuous asphalt reclamation systems, integrated with road planers to recycle old petroleum-base road surfacing material. The tools are either rotatable or nonrotatable and are designed for making deep cuts in soft to medium-hard abrasive material. A 9 to 10 wt% Co alloy with coarse tungsten carbide grain size performs well in this application.

Skids for Street Sweepers. Because of their superior abrasion resistance, carbide skids are outlasting steel or rubber skids on street sweepers by a factor of 30 to 1 and are eliminating downtime resulting from skid replacement. The long-wearing qualities of cemented carbide skids also help the sweepers ride higher and avoid hang-ups on manholes, railroad tracks, and other obstacles.

Snowplow Blades. Carbide-tipped blades improve snowplowing efficiency by providing a wear life up to 20 times longer than steel blades and by eliminating frequent blade changes. Because abrasion resistance and mechanical impact resistance are essential in this application, alloys with 10 to 12 wt% Co and medium to coarse WC grain size are used. The carbide inserts are either brazed or mechanically bolted into the cutting edge. The blades come in different length segments which can be combined to equip most plows.

As a companion to snowplow blades, carbide snowplow shoes increase blade life through better weight distribution of the blades and the snowplow frame. The carbide shoes also prevent blade wear caused by digging when plowing shoulders. Because the wear on the blade and shoe are similar, no adjustment is needed during operation.

Tire Studs and Golf Shoe Spikes. Cemented carbide tire studs provide excellent traction on icy highways. The wear resistance of tungsten-carbide alloys ensures long wear life for the tire studs, but has also resulted in government regulation of their use because of concerns about pavement damage. Carbide studs have also been used to replaced steel spikes in golf shoes. Carbide studs last the lifetime of the shoe, and their taper design minimizes the problem of grass and mud buildup.

Vertical Drilling. Large down-hole construction tools, up to about 380 mm (15 in.) in diameter, are designed with a fixed array of conical cemented carbide cutter bits and a single-blade pilot bit, for water well drilling, pile driving operations, foundation work, and a host of other construction applications. The materials penetrated with these tools are alluviums, clay and sand strata, till, shales, and other soft sedimentary rocks.

Larger bore diameters, from 400 to 600 mm (16 to 24 in.), are drilled with vertical auger bolt-on tooling, for which rotary bitbody arms are designed to accept arrays of carbide conical cutter bits and a center pilot bit assembly (Fig. 45). The carbide-tipped auger has eliminated the need for blasting and air hammers in drilling rocky of frozen ground. Alloys with ~10 wt% Co and medium grain size are preferred in this application. As in most other wear parts, carbide-tipped cutters outlast steel teeth, thereby minimizing tooling costs and tool replacements. Because the cutting action is smooth, the wear and tear on augers, connectors, and drive motors is minimized.

Fig. 45 Vertical auger with carbide-tipped tools used in heavy construction

Horizontal Drilling. In horizontal drilling projects such as laying of oil, gas, and water pipelines, carbide-tipped auger heads are dramatically improving the boring productivity. They are particularly helpful in drilling in unconsolidated terrains and soft to medium rock formations. The conical carbide bits in the auger heads are self-sharpening and are easily replaced. Larger auger heads are designed with wing cutters to facilitate the withdrawal of the auger from the drilled hole.

Chain Ditchers and Ditching Saws. Cemented carbides have successfully replaced steel tools in ditching operations, where carbide-tipped chain links can increase productivity in rocky or frozen ground. The tough, self-sharpening carbide can cut through sandstone shale up to 760 mm (30 in.) thick at 30 m/h (100 ft/h) with minimal bit changing.

Ditching saws tooled with conical cemented carbide bits are used to cut through asphalt and reinforced concrete. The carbides must withstand impact loading and high-stress abrasion. Generally, alloys with 9 to 10 wt% Co and medium to coarse WC grain size are used.

Tunnel and Shaft Boring. Carbide-tipped cutters can help speed production on tunnel-boring projects. They are ideal for use on moles and other tunnel-boring equipment to penetrate boulders, hard-packed glacial till, and solid rock.

Forestry Tools. Cemented carbide cutting tools are well established in forest product and woodworking industries and account for much higher levels of productivity, closer dimensional tolerances, better surface finishes, and lower tool maintenance costs. Examples are circular saws, debarking tools, edging and planing tools, and miscellaneous woodworking tools for both commercial and home use.

Heavy-duty tungsten carbide-tipped circular saws for log end cuts and ripping are subjected to a variety of wear mechanism: abrasive wear, corrosive wear of cobalt binder by organic acids, and mechanical impact from tramp metal and rock. The saw-tip alloys have 10 to 12 wt% Co with moderately fine WC grain size (1 to 2 μm) to provide good edge strength and impact resistance. To increase corrosion resistance, nickel is sometimes substituted, either partially or wholly, for cobalt as a binder.

Heavy-duty log-debarking tungsten carbide tools are subjected to the same type of wear processes as the circular saw tips, although the main emphasis here is on high fracture toughness.

Cemented carbide-tipped circular saws and edging and planing tools for the dimension lumber, plywood, particle board, and composite industries are exposed to less impact and corrosion but greater abrasive wear conditions. The carbide alloys are correspondingly lower in binder content (~ wt% Co), relatively finer grained, and higher in hardness.

Tungsten carbide saws, knives, and cutter heads of many designs enable high dimensional accuracy and precision joinery in commercial woodworking shops and in home-use equipment. Because high abrasion resistance and high edge strength are essential in these tools, the carbide alloys have very fine grain structures (≤1 μm), high hardnesses (93 RA), and lower cobalt contents (~6 wt%).

Mining and Oil and Gas Drilling

Recovery of natural resources from the surface of the earth is an important economic activity in which cemented carbides play a crucial role. Included in this category are recovery of metallic ores and nonmetals by underground or open pit mining practices, recovery of minerals such as coal, potash, and trona, and drilling for oil and gas. The method of excavation and the types of tools employed in each of the above application areas depend on the type of geostrata which is involved. The applications can be broadly classified into three types:

- Rotary drilling
- Roto-percussive drilling
- Flat-seam underground mining

Rotary Drilling. There are a number of rotary drilling methods that employ carbide-tipped bits. Two-pronged bits (Fig. 46a) are used for smaller holes. Conical bits can be used for core drilling when mounted on cylinders or for tunnel excavation when attached to large drilling heads. For small boring bits, speeds of rotation usually vary from 100 rev/min (for rock) to 1500 rev/min (for coal). Rotary drilling is efficient and gives high penetration rates in softer rocks; however, in hard abrasive rock, tool wear and fracture are severe.

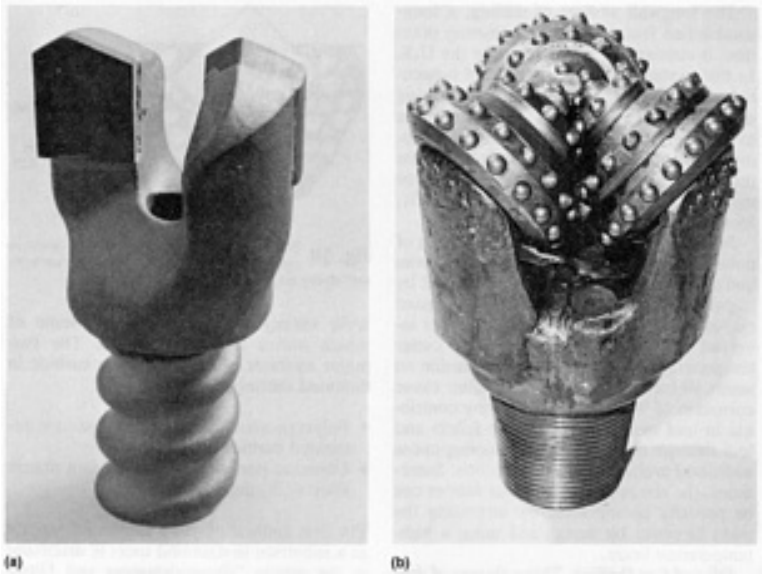

Fig. 46 Two examples of rotary gas drilling bits. (a) Two-pronged carbide bit used in rotary drilling of small holes. (b) Tricone rotary roller bit with embedded carbide button heads

In harder rock formations, a rolling conical cutter rock bit, called a "tricone" bit, with embedded hemispherical carbide button heads, is employed (Fig. 46b). Rotary drilling may be used for drilling either small or large holes and for raise hole boring.

Roto-percussive drilling is employed on harder rocks. In this operation, a blunt chisel-like cemented carbide insert is impacted against the rock, which is locally pulverized by impact. The insert is indexed around by rotation and again impacted by pneumatic means. Although the hardest rocks can be drilled in this manner, the penetration rate is significantly slower than that obtained by rotary drilling in softer rocks. The demands on the carbide insert are also severe, requiring good impact strength.

A major development in percussive tools is the use of a number of hemispherical carbide button bits (Fig. 47) instead of the chisel-shape inserts. There are several advantages to this design. First, the bits are self-sharpening so that deeper holes can be drilled before regrinding. Secondly, button bits are more reliable because they are held by an interference fit that can be accurately controlled by precise machining. The button bit design is more suited to drilling harder rocks than softer and tougher rocks. For example, on limestones the chisel design is still favored, whereas for drilling larger holes in hard rocks the button bit is preferred.

Fig. 47 Button-type carbide percussive drill bits. A carbide cross bit is in the foreground.

Flat-Seam Underground Mining. Excavation of coal, potash, trona, and so forth, from a relatively level bed is carried out by flat-seam mining using brazed carbide tools. These formations usually contain layers of soft and hard material. As a result, both the carbide and the braze may be subjected to thermal stresses.

Underground Mining of Metallic Ores. Recovery of metallic ores from rock veins is carried out by roto-percussive drilling using either chisel-type tungsten carbide inserts brazed to a steel tool holder or domed carbide compacts in button rock bits. In the case of brazed carbide bits, the inserts wear by severe abrasion and chipping. Button bits, on the other hand, show mainly abrasive wear. In button bits, improved steel support for the cutting elements permits use of alloys with lower cobalt contents and associated high abrasive wear resistance, without compromising chipping resistance. Cobalt contents generally range from 5 to 7 wt% with medium-fine tungsten carbide grain structure.

Open Pit Mining. Rotary blast-hole bits are used for open-pit mining for both metals and nonmetals. The bits, mainly of tricone style with tungsten carbide compacts set in alloy steel cones, are used for blast holes up to about 430 mm (17 in.) in diameter. Chipping of the compact is the more important failure mechanism in this application, and carbide alloys with higher cobalt contents, usually in the 7 to 10 wt% range, are commonly employed. Additionally, blast-hole drills are often fitted with drill stabilizer bars featuring flush tungsten carbide buttons to reduce gage wear and increase the cutting efficiency of the bit (Fig. 48).

Fig. 48 Rotary blast-hole tricone bit with embedded carbides and fitted with carbide stabilizer bars

Coal Mining Tools. Continuous drum mining equipment is often fitted with conical carbide cutter bits (Fig. 49a) designed to penetrate the coal face with a cleaving action and remove little, if any, of the adjacent rock. The bits are subjected to abrasive wear and high-impact loading; however, the tungsten carbide inserts are well supported in pockets in steel tool shanks, allowing long bit life. The most frequently used alloys contain about 7 to 9 wt% Co with a relatively coarse WC grain size (~3 μm).

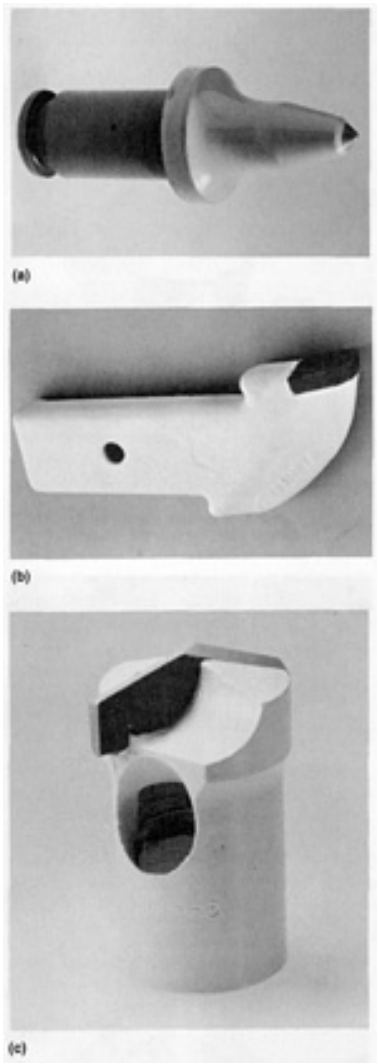

Fig. 49 Examples of some carbide bits used in coal mining. (a) Conical carbide bit. (b) Flat mining bit with brazed tungsten carbide insert. (c) Tungsten carbide roof-drilling bit with provision for center vacuum

Flat cutter bits (Fig. 49b) with tungsten carbide inserts butt-brazed to the tool shank are also used in continuous drum miners. Alloys with ~9 wt% Co and moderately coarse grain size (2 to 3 μm) are used for these flat bits. Similar alloys are also used for two-prong rotary-bit auger mining systems.

Tungsten carbide roof-drilling bits (Fig. 49c) are widely employed for anchor bolt drilling in underground mining operations. This application is especially severe, involving heavy abrasion and high mechanical and thermal stresses. Alloys of moderate to low binder contents (6 to 7 wt% Co) and medium to coarse tungsten carbide grain sizes are successfully employed.

The longwall system of mining, a long-established feature of British mining practice, is coming into wider usage in the U.S. In this system, conical, radial, and tangential cutter bits are used on coal shearing drums. Thermal cracking of the carbide due to high temperatures developed during mining and impact damage are dominant failure mechanisms, calling for relatively coarse microstructures and higher cobalt levels, frequently ~11 wt%, in the carbide bit.

Potash and Trona Mining Tools. Mining of potash salts in deep strata in Saskatchewan and some trona in Wyoming is carried out by rotors laced with brazed, flat-type tungsten carbide cutter bits. High frictional forces involved in the operation often raise cutter temperatures, causing incipient salt fusion on insert surfaces. The fused salts often cause corrosion of WC grains and thereby contribute to tool wear. Thermal braze failure and tool damage during machine retooling cause additional problems in this application. Sometimes, the above-mentioned wear factors can be partially counteracted by increasing the mass in cutter bit design and using a high-temperature braze.

Oil and Gas Drilling. Three classes of drill bit dominate oil and gas drilling:

- *Steel tricone bits* for relatively shallow bore holes in soft to medium-hard sedimentary rocks
- *Tungsten carbide tricones* for deeper bores penetrating metamorphic and crystalline rocks
- *Diamond oil bits* for deep bore holes in hard, crystalline rocks

The middle class, tricone bits with arrays of tungsten carbide buttons, is the dominant drilling tool for both exploration and production holes. Heavy-impact loading and high-stress abrasion require larger button sizes and special button shapes. The carbide used is moderately coarse grained with cobalt levels ranging from 10 to 14 wt%. As in blast-hole bits, gage wear is controlled by flush-set tungsten carbide buttons on bit-body clearance surfaces.

Drilling tool design has become extremely competitive in the oil and gas drilling industry. Many new designs have emerged in recent years. One of the most notable is the polycrystalline diamond cutter supported by a base of tungsten carbide; individual cutters are set in an array on the bit crown surface. Penetration is comparatively rapid and cuttings flow well in this design. The tungsten carbide base for each cutter is designed for high impact resistance. The polycrystalline diamond drill bit operates at a depth in between that of steel and tungsten carbide tricone drill bits. Polycrystalline diamond is discussed in the article "Superabrasives and Ultrahard Tool Materials" in this Volume.

Use of Tungsten Carbide in Diamond Cutting Tools. Diamond tools are available in a wide variety of product forms, some of which utilize tungsten carbide. The two major methods of using tungsten carbide in diamond cutting tools are:

- Polycrystalline diamond bonded to a cemented carbide substrate
- Diamond particles embedded in a matrix alloy with tungsten carbide

The first method of using cemented carbide as a substrate in diamond tools is discussed in the article "Superabrasives and Ultrahard Tool Materials" in this Volume.

In the second method, a matrix alloy is embedded with diamond, which may consist of relatively coarse diamond firmly held on the surface by a matrix alloy (Fig. 50) or smaller diamonds dispersed within the matrix. In diamond drill bits, the use of diamonds set on the surface (Fig. 50) is referred to as a surface-set bit. A bit with diamond dispersed in the alloy matrix is referred to as an impregnated bit.

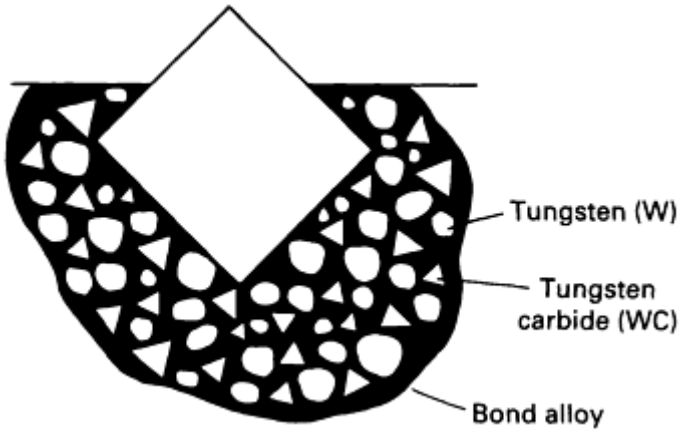

Fig. 50 Schematic of a coarse diamond particle embedded in a matrix alloy of a "surface-set" diamond drill bit

Diamond tools are employed in a variety of industries; mineral exploration and development, oil and gas exploration and production, and concrete, asphalt and dimension stone cutting. Most diamond drill bits for mineral exploration are designed to recover core samples. Oil bits, on the other hand, are generally used to bore full holes up to about 610 mm (24

in.). All diamond drill bits are designed for rotary drilling machines, with fluid flushing systems for cuttings recovery and drill bit cooling.

The matrix alloys used in diamond tools must support the diamonds firmly and must themselves wear at rates designed to keep the diamonds exposed for maximum cutting efficiency. Alloys that are too hard or wear resistance will not be removed rapidly enough to keep fresh diamond edges exposed. Alloys that are too soft will allow excessive exposure and consequent loss of the diamonds. Tungsten has emerged over the years as the ideal metal for bonding diamonds due to its affinity for carbon in the diamond and consequent bonding that occurs without damage to the diamond. In conjunction with tungsten, WC is used in the matrix formulations to protect diamonds against erosion and certain types of abrasion.

Powder metallurgy techniques are employed in the manufacture of diamond tools. There are many types of tungsten and tungsten carbide powders but only a few perform effectively in diamond tool matrix compositions. Conventional WC powders, produced by solid-state diffusion carburization of tungsten metal powder, are irregular in shape (Fig. 1) and exhibit poor flow and packing characteristics. The chill-cast, eutectic tungsten carbide, WC/W_2C, is carbon deficient and easily forms brittle double carbides (eta phase) during the manufacturing process. However, macrocrystalline tungsten carbide (Fig. 2) and tungsten metal powders derived from it meet the matrix powder requirements in terms of particle sizes and morphologies and are therefore widely used in matrix-powder formulations.

The functions of the tungsten and tungsten carbide in diamond tooling can be achieved only if they are effectively bonded together with appropriate auxiliary metals. The metals most commonly used to form the matrix bond are cobalt, nickel, copper, iron, and various compositions of copper/nickel/zinc, copper/zinc, and copper/manganese.

There are three basic methods by which diamond drill bits are manufactured. The most commonly employed is the infiltration process. This method is ideal for the production of surface-set bits because it does not dislocate the diamonds from their positions in the molds. The hot press method is a single-stage process that assures good quality control. The cold press-sinter process permits use of rapid mechanical pressing methods and neutral or reducing furnace atmospheres. The latter assures an oxygen-free environment which is important to the protection of diamonds, especially in matrix, compositions that require high sintering temperatures. The hot press and cold press-sinter processes are used primarily in the manufacture of impregnated diamond tools.

Matrix alloys made by powder metallurgy methods also play an essential part in the manufacture of circular diamond saws for concrete and asphalt highway repair, general concrete cutting in the construction industries, and in the dimension stone industries. They are also essential for the manufacture of thin-wall diamond coring bits for boring conduit openings in cured concrete structures.

Cermets

John L. Ellis, Consultant, and Claus G. Goetzel, Consultant and Lecturer

Introduction

CERMET is an acronym that is used world wide to designate "a heterogeneous combination of metal(s) or alloy(s) with one or more ceramic phases in which the latter constitutes approximately 15 to 85% by volume and in which there is relatively little solubility between metallic and ceramic phases at the preparation temperature" (Ref 1, 2). A good definition of the term ceramic can be found in the *Ceramic Glossary* (Ref 3): "Any of a class of inorganic, nonmetallic products which are subject to a high temperature during manufacture or use. Typically, but not exclusively, a ceramic is a metallic oxide, boride, carbide, or a mixture or compound of such materials; that is, they include anions that play important roles in atomic structures and properties." With particular reference to cermets, this definition of the ceramic component could be broadened to include nitrides, carbonitrides, and silicides.

In a broad sense, cermets are akin to the hard and refractory particulate kind of materials within the general class of metal-matrix composites (see the article "Metal-Matrix Composites" in this Volume). There is a good deal of overlap in the literature, especially in the range of comparable volume fractions of the respective particulate and metallic components. In contrast to composite laminates, the combination of metal and nonmetal in cermets occurs on a microscale. The nonmetallic phase is usually not fibrous, but consists of more or less equiaxed fine grains that are well dispersed in and bonded to the metal matrix. If either the ceramic or the metallic component is predominantly fibrous, the material should be designated as a fiber composite. The bond between the nonmetallic phase and the metal matrix makes important contributions to the cermet; it is strongly affected by the phase relations, solubilities, and wetting properties that exist in the relationship between the ceramic and metallic components.

The size of the ceramic component varies, depending on the system and application. It can be as coarse as 50 to 100 μm, as in some types of cermets based on uranium dioxide (UO_2) that are used for nuclear reactor fuel elements, or as fine as 1 to 2 μm, as in the micrograin type of cemented carbides. If the ceramic component is even finer and is present in small amounts, the material can be considered to belong to the class of dispersion-strengthened alloys and therefore fall outside the accepted definition of cermets.

The basic objective of combining metal and ceramic on an intimate scale is to incorporate the desirable qualities and suppress the undesirable properties of both materials. The most outstanding example of the desirable properties obtained from combining metal and ceramic materials involves the hard-metal types made from cemented carbides (see the article "Cemented Carbides" in this Volume). Cemented carbides have enjoyed a steady expansion over the past six decades. Over that time, the development of the hard-metal/cermet tool materials has moved away from the early tungsten-base carbides to carbide-and nitride-base composition of increasing complexity (Table 1).

Table 1 History of cermet product development and marketing

Year	Composition	Trademark	Manufacturer
1930-1931	WC-Co	G1	Krupp-Widia

Source: Ref 4 and Kennametal, Inc.

Cermets originally were used for cutting tool applications. Some 45 years ago (Ref 2, 5), they began to be considered for use in more taxing applications, such as propulsion systems. The expectations were that the systems. The expectations were that the refractory behavior, strength, and corrosion resistance of the ceramic phase could be mated advantageously on a proportional basis with the high ductility and thermal conductivity of the metallic phase, and that some superior new materials would become available for a multitude of high-temperature applications.

Unfortunately, these goals were not fulfilled, despite a major effort in the United States and Europe during the 1950s. The degree of ductility and toughness imparted by the metallic binder phase remains inadequate for most critical applications, such as turbojet and stationary gas turbine blades or nozzle vanes. In other areas, however, cermets have proven their value as engineering materials, notably in tools based on titanium carbide (TiC) or titanium carbonitride (TiC,N), and in some types of nuclear fuel elements. Cermets based on uranium carbide (UC), offer potential for advanced fuel elements. Cermets based on Zirconium boride (ZrB_2) or silicon carbide (SiC), and others containing aluminum oxide (Al_2O_3, silicon dioxide (SiO_2), boron carbide (B_4C), or refractory compounds combined with diamonds, possess unique properties. Several are used commercially in a wide range of applications that includes hot-machining tools; shaft seals; valve components and wear parts; ultrahigh-temperature exposed ducts, nozzles, and other rocket engine components; furnace fixtures and hearth elements; grinding wheel; and diamond-containing drill heads and saw teeth.

A significant application of cermets involves cutting tool materials that utilize titanium carbide or titanium carbonitrides as the hard refractory phase. Frequently, molybdenum carbide (Mo_2C) and other carbides are also built into these cermet formulations. The cratering and flank wear resistance properties of the titanium carbide and titanium carbonitride cermet tool materials are better than those of the conventional cemented-carbide (that is, cobalt-bond tungsten carbide) tool. In comparison to ceramic cutting tools, these cermets permit heavier cuts, which, at high speed, results in greater amount of metal removal at a comparable level of tool life. Cermets clearly possess characteristics of a cutting tool material that is capable of filling the gap between conventional cemented carbides and ceramics (see *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Classification

Cermets can be classified according to their hard refractory component. In this system, the principal categories of cermets are determined by the presence of six components: carbides, carbonitrides, nitrides, oxides, borides, and miscellaneous carbon-aceous substances.

The metallic binder phase can consist of a variety of elements, alone or in combination, such as nickel, cobalt, iron, chromium, molybdenum, and tungsten; it can also contain other metals, such as stainless steel, superalloys, titanium, zirconium, or some of the lower-melting copper or aluminum alloys. The volume fraction of the binder phase depends entirely upon the intended properties and end use of the material. It can range anywhere from 15 to 85%, but for cutting tool applications it is generally kept at the lower half of the scale (for example, 10 to 15 wt%) (Ref 4).

The metallic bond for each cermet is selected in order to produce the desired structure and properties for the specific application. Th iron group metals and their alloys dominate as in the cemented tungsten carbide class of hard metals; nickel and, to a lesser extent, cobalt and iron possess a desirable combination of relatively high hardness and good ductility. However, the binder for a cermet can also be chosen from the group of more reactive metals, such as titanium or zirconium, or it can be selected from series of refractory metals that includes chromium, niobium, molybdenum, and tungsten. Lower-melting metals and alloys, primarily those based on copper and aluminum, round out the list of binders at the bottom of the temperature scale. Aluminum, however, is more commonly associated with metal-matrix composites.

Carbide-base cermets are by far the largest category of cermets, even if the term is used in its narrower sense and excludes the broad field of cemented-carbide cutting tools and wear parts based on tungsten carbide (WC). Since the inception of cermet technology, the dominant concept has been that of a material based on TiC as the primary hard and refractory constituent, with the bonding provided by any of a variety of lower-melting ductile metals or alloys (much the same as those used for cemented tungsten carbides). The TiC cermets have found use in tool and wear resistance applications; in selected high-stress, high-temperature systems; and in corrosive environments. Cermets based on SiC and B_4C, which generally are classified as metal-matrix composites, have gained considerable industrial significance in wear and corrosion resistance, or antifriction, applications; they are also used in nuclear reactor applications. Cermets with a chromium carbide (Cr_3C_2) base have been used for variety of corrosion resistance applications and as gage blocks; however, they have apparently lost much of their industrial usage.

Carbonitride-base cermets can be produced with or without additions of various other carbides (of which Mo_2C is the most important); they are bonded with the common cemented-carbide binders. At present, these materials are the primary cermets for tool applications. Their enhanced strength, which makes them suitable for high-speed cutting tools, is based on a greatly improved bond between the hard carbide grains and the binder metal. The improved bond is a consequence of a miscibility gap in the quaternary TiC, TiN, MoC, and MoN system that results in a so-called spinodal decomposition into two isostructural phases (Ref 6) with inherently better wettability to the binder (Ref 4).

Nitride-base cermets constitute a special class of tool materials. Titanium nitride (TiN) and especially cubic boron nitride (CBN) produce excellent cutting materials if they are combined with a hard binder metal. Titanium nitride and zirconium nitride (ZrN) bonded with their respective metallic elements have been develop for special heat- and corrosion-resistant purposes.

Oxide-base cermets constitute a category that includes UO_2 or thorium dioxide (ThO_2), which are used for a major fissions component in nuclear reactor fuel elements; Al_2O_3 or other highly refractory oxides, used for components in liquid-metal manipulation (for example, pouring spouts) and general furnace parts; and SiO_2, used for a minor constituent in friction elements. Combinations of Al_2O_3 with TiC are suitable for hot-machining tools.

Boride-base cermets have a boride of one of the transition metals as the dominant phase. These cermets provide excellent high-temperature corrosion resistance to attack by active metals, such as aluminum, in the molten or vapor state. A combination of ZrB_2 and SiC is resistant to erosion from the propulsion gases of chemical rockets.

Carbon-containing cermets are materials that contain graphite in varying proportions. They are used for electrical brushes and contacts or as minor constituents to provide some lubrication in friction elements. Also included in this category are diamond particles within metal matrices that are used in special tools.

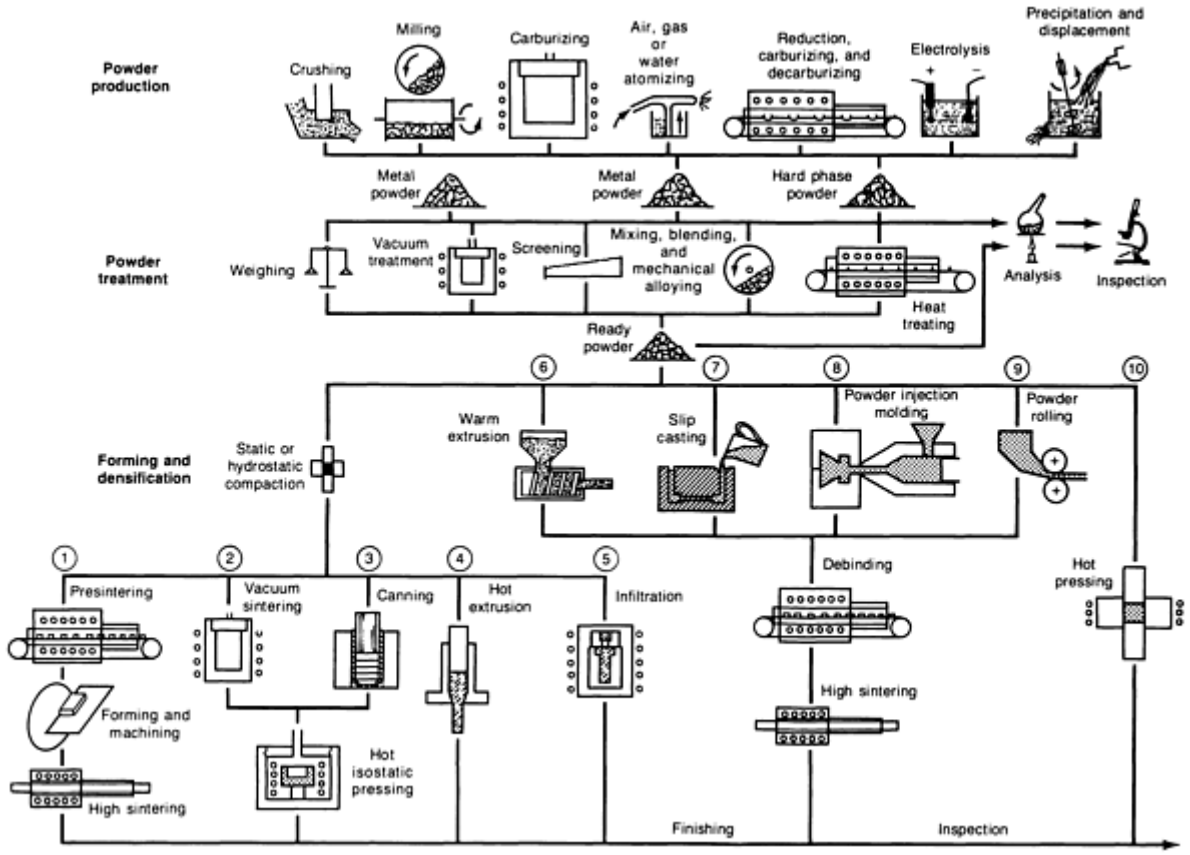
Fabrication Techniques

The methods used for powder preparation, forming, firing or sintering, and post-treatments of cermets generally are similar to conventional ceramic and powder metallurgy (P/M) processing techniques. Figure 1 is a flow chart of the various P/M techniques applicable to cermets. Table 2 summarizes the relative characteristics of the major forming methods that are practiced in producing carbide-base and most other types of cermets. The principal processes are cold forming and sintering, pressure sintering, and infiltration.

Table 2 Cermet forming techniques

Technique	Size capability	Shape capability	Mold or die requirements	Production	
				Rate	Labor
Static cold pressing	Limited by press capacity	Prismatic shapes without undercuts	Hardened steel or carbide dies	High	Low to moderate
Hydrostatic cold pressing	Limited by capacity of pressure vessel	Simple or complex shapes	Rubber molds	Low	High
Powder rolling	Limited width, long length	Flat and thin	. . .	High	Low
Warm extrusion	Limited by equipment size	Long pieces with uniform cross section	Hardened steel or carbide dies	High	Low
Powder injection molding	Small pieces	Complex shapes with undercuts	Hardened steel or carbide dies	High	Low
Static hot pressing	Limited by press capacity	Prismatic shapes without undercuts	Graphite or ceramic molds	Low	High
Hot isostatic pressing	Limited by capacity of pressure vessel	Simple or complex shapes	. . .	Medium	Low to high
Hot extrusion	Depending on press capacity	Long pieces with uniform cross sections	Alloy steel dies	High	Low

Infiltration	Depending on equipment	Intricate shapes feasible	Graphite and ceramic molds	Low	High



Production method	**Products**
1. Presintering	Cemented-carbide parts and cermets
2. Vacuum sintering	Steel-bonded carbides (standard pieces) and cermets
3. Canning	Steel-bonded carbides (special pieces)
4. Hot extrusion	Aluminum cermets with moderate amounts of hard-phase additions
5. Infiltration	TiC parts with nickel- or cobalt-base infiltrants and other cermets with about 55-85 vol% hard phase
6. Warm extrusion	Cemented-carbide rods or other slender cermet parts
7. Slip casting	Cermets with high proportions of hard phase

8. Powder injection molding	A wide variety of cermet compositions
9. Powder rolling	Aluminum, copper, and other nonferrous metals with moderate additions of hard-phase components
10. Hot pressing	A wide variety of cermet compositions

Fig. 1 Powder metallurgy production methods for cermet and cemented-carbide products

The cold-pressing process includes static uniaxial and isostatic multiaxial compaction. The powder mixtures are compacted at pressures of 35 to 100 MPa (5 to 14.5 ksi). The predominant method involves pressing dry wax-lubricated powder in hardened steel dies with double-action opposing punches. For long rods or tubes of uniform cross section, these dies are used for the extrusion of a paste in which the powder particles are embedded in suitable organic binder or wax. To form complex or large shapes, the dry powder is placed in a pliable mold and compacted from all sides by hydrostatic pressure inside a sealed, reinforced steel cylinder.

Powder Preparation. The first step in the cermet production process is the mixing and milling of the ingredient powders. The mixtures, consisting of the hard-phase substance in powder form and the pure metal or metals in the proper proportions required for the composition of the binder alloy, are milled in ball mills. The balls are made of tungsten carbide or, more frequently, of a highly sintered cermet. The mill can be lined with the same type of cermet material to reduce the possibility of mixture contamination. In addition to conventional ball mills, high-energy vibratory ball mills and attrition mills are used. With the later type of mills, substantial savings in milling time, energy, and floor space can be achieved. During the milling process, the hard phase particles are comminuted and thoroughly coated with binder metal. Organic liquids such as hexane are used in the process to minimize the rise in temperature and prevent oxidation. After the powders have been milled to a particle size of 325 mesh or finer, the mixtures are dried before further processing and use. A lubricant is then added, and those powder mixtures destined for compaction in automatic presses are agglomerated so that they can flow freely from the hopper to the compacting die.

Static Cold Pressing. Cold-pressing methods for cermet powder mixtures generally follow the well-known powder-compacting techniques used in conventional powder metallurgy. Small cermet parts needed in reasonably large quantities are compacted in special hard-metal dies by automatic presses with double-action opposing punches (Fig. 2). Whether solid or segmented, the dies are shrunk into a strong, tough, heat-treated steel retainer.

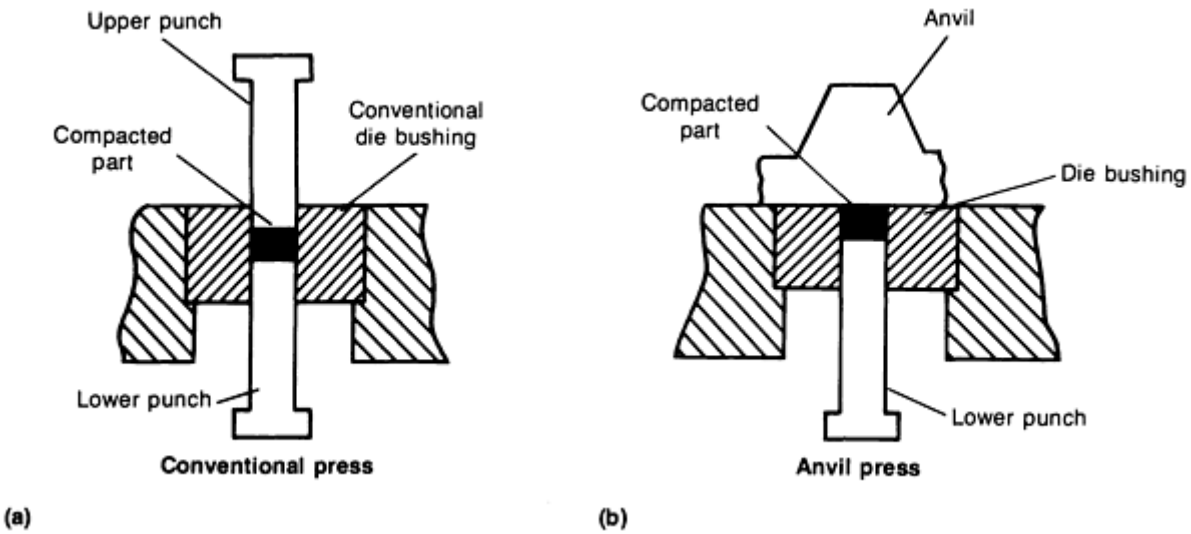


Fig. 2 Static cold pressing with (a) a conventional press and (b) an anvil press. The anvil press has no upper punches; therefore, the

misalignment, breakage, and wear problems associated with those punches are eliminated. Courtesy of PTX-Pentronix, Inc.

The automatic compaction cycle consists of filling powder in the die, compacting the powder, ejecting the compact, and removing it. Two methods are used for ejecting the compact from the die. In the first method, the lower punch moves upward and pushes the bottom of the pressed piece to the level of the die table. In the second method, the die is force down (withdrawn) over the lower punch until the bottom of the compact is on level with the top of the die (Fig. 3). The second method is gaining favor with many specialists because it allows building shorter, less expensive tools, and because it provides better support for the fragile compact during ejection.

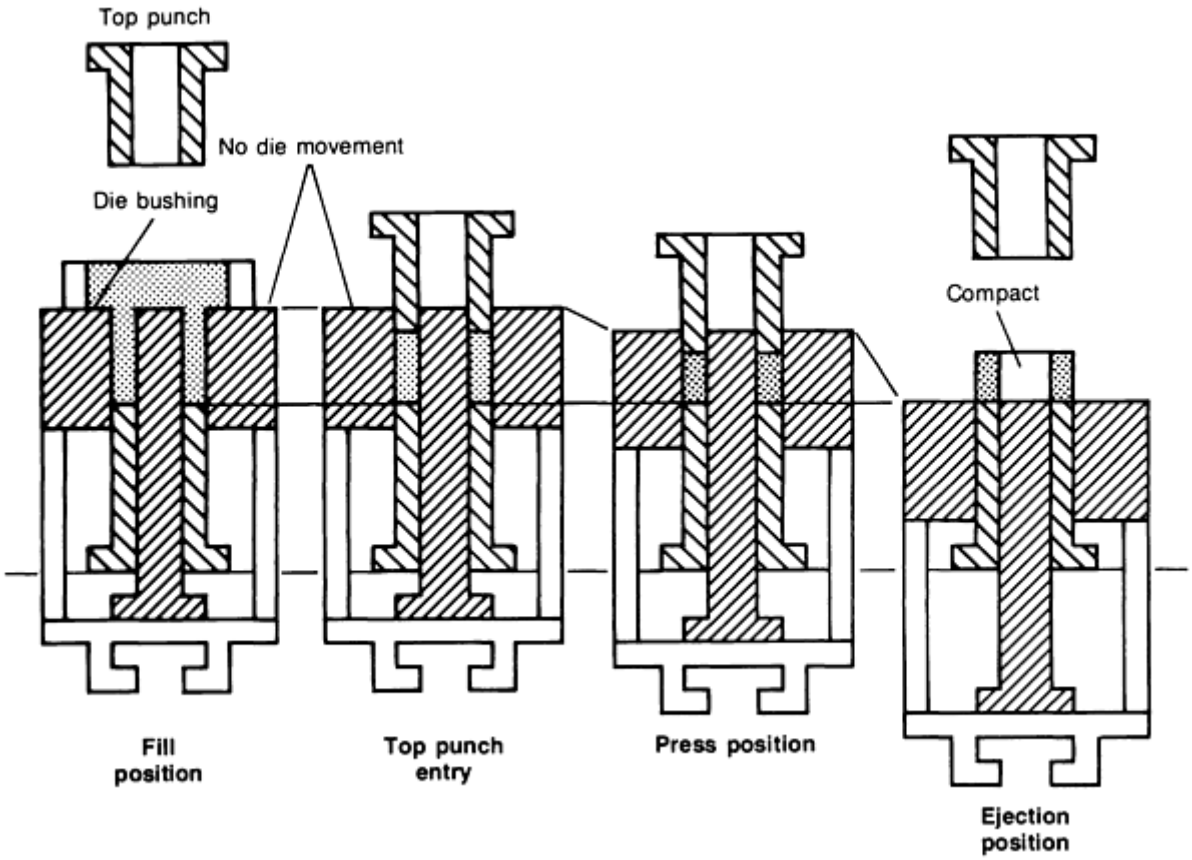

Fig. 3 Withdrawal press cycle with controlled die motion (top and bottom pressure). Courtesy of Dorst America

Another interesting variation, particularly for the compaction of fragile cermets, is provided by the so-called anvil press (Fig. 2b). In this method, the powder is pressed against the anvil by the upward motion of a single lower punch. The anvil is then laterally removed to allow ejection of the compact by the continued upward motion of the punch. Because this cold-pressing technique is a single-action pressing method, an anvil press is acceptable only for relatively thin single-level pieces. Yet, where applicable, the anvil press saves tool costs; in addition, it reduces the ejection path to a minimum, which is an important factor for fragile cermets.

Medium-to-large rectangular pieces are compacted on hydraulic presses in multiple-section dies held together by powerful steel frames. These frames are capable of counteracting the large internal forces that are exerted on the powder mass and transmitted radially to the die sections. Often, at the completion of the cycle, the dies are opened for the careful removal of the fragile cermet compact.

For round pieces it is preferable to use double-action hydraulic presses with a built-in ejection action. These presses can use either one of the two ejection methods:

- If the die is mounted on a hydraulically activated floating platen, a single-action press will adequately

provide the effect of a double-action press. In this case ejection is accomplished by the withdrawal method

- When a full-power double-action hydraulic press is available (obviously a heavier and more expensive machine than the single-action press), the die can be mounted on the stationary platen. The compact is ejected by raising the lower punch to the level of the die table at the completion of the pressing cycle.

Cold compaction of simple cermet shapes gives generally good results when using adequately lubricated powder mixtures, well-designed tooling, and sturdy presses. Even though the compacts are fragile, they should nevertheless be firm, have adequate green strength and well-formed edges, and be free of laminations or other internal defects. Depending on the composition of the cermet, compaction problems can arise that require modifications in the equipment or the process. Generally, the higher the proportion of the hard phase, the greater the difficulties that arise in compaction; these difficulties may not be evident until after sintering. Also, more problems can be expected with iron-, nickel-, or cobalt-base cermets than with the softer, more malleable aluminum-base compositions. Larger pieces, as measured both in diameter and height, intensify the problems associated with composition. Air entrapment, bridging, laminations, intermittent voids, and variable density throughout the compact are just a few of the problems encountered in the cold compaction of cermets (Ref 7).

Some of these problems can be overcome by adding more lubricant to the mixture, by increasing the taper of the compacting die, or by slowing down the compaction process. Die wall lubrication between pressings often helps to eliminate compaction or ejection problems. Adequate preloading of the die and die lapping in the pressing direction are other precautions that help to overcome problems.

Even for the simplest forms, such as cylindrical or rectangular single-level blanks, not all problems encountered can be solved by the conventional static cold-pressing technique. This is one reason by P/M specialists depend heavily on other, more sophisticated forming processes for the fabrication of a wide variety of products.

Cold Hydrostatic Pressing. High-quality cermet compacts require uniform densification throughout. This can be ideally accomplished by cold hydrostatic pressing. In this method, pressure is applied simultaneously and uniformly from all sides toward the center of gravity of the powder mass while all friction of powders against the die wall is completely eliminated. In order to compact simple or even relatively complex shapes by this method, dry powders are filled into a pliable mold. The powders are settled, and air is removed on a vibrating table; the mold is then sealed and placed into a reinforced steel cylindrical vessel filled with a fluid. After the vessel is closed, hydraulic pressure is built up, thereby compressing the powder contained in the mold. The two hydrostatic pressing methods frequently used for pressing cermets are the wet-bag method and the dry-bag method.

The wet-bag method involves placing one or more powder-filled molds inside a hydrostatic pressing vessel (Fig. 4). The powder-filled mold is pliable and is placed within a perforated container for support. Inside the vessel, the powder-containing mold is completely surrounded by hydraulic fluid. Depending on the size of the vessel and the individual mold, often a number of molds can be placed in the vessels and compacted simultaneously. The entire process--loading the vessel with one or several molds, building up and holding the pressure, releasing the pressure, and reopening and unloading the vessel--is relatively slow. Moreover, filling the mold, assembling the mold, loading the molds into the pressure vessel, and unloading and removing the pressed piece after completion are slow, manual processes that require meticulous attention to detail.

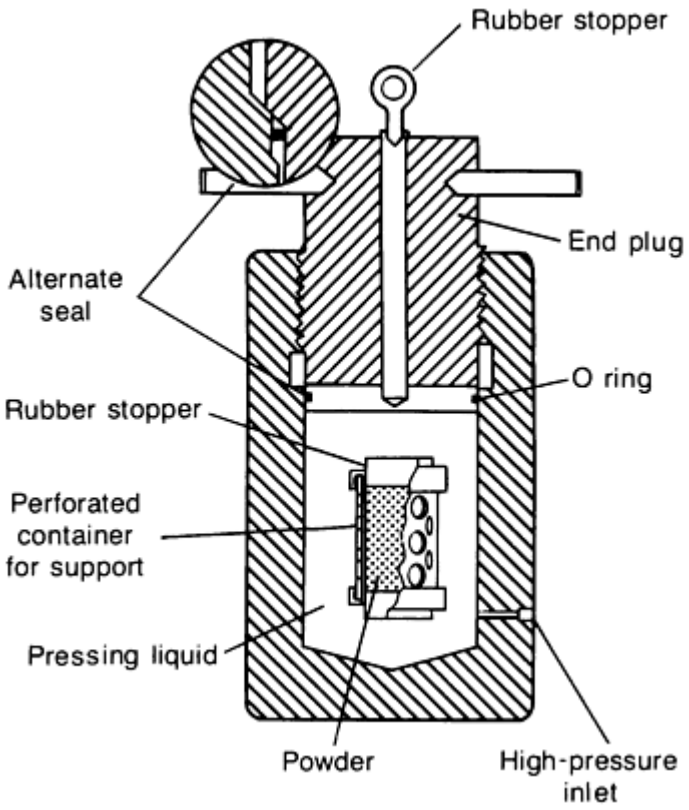

Fig. 4 Schematic of a cold hydrostatic vessel with a wet-bag powder mold. Source: Ref 7

Dry-bag pressing uses a flexible mold that is permanently sealed in the pressure vessel (Fig. 5). After the mold cavity has been filled with a controlled quantity of powder, the cover plate is closed, and hydraulic pressure is applied. After the pressure is released, the molded piece is removed, and a new cycle commences. Dry-bag pressing is a much faster production process than the wet-bag method and lends itself to automation. Much of this technology has been developed for producing near-net shape ceramic pieces, for example, automotive spark plug bodies. Each dry-mold setup requires special engineering and development (Ref 8).

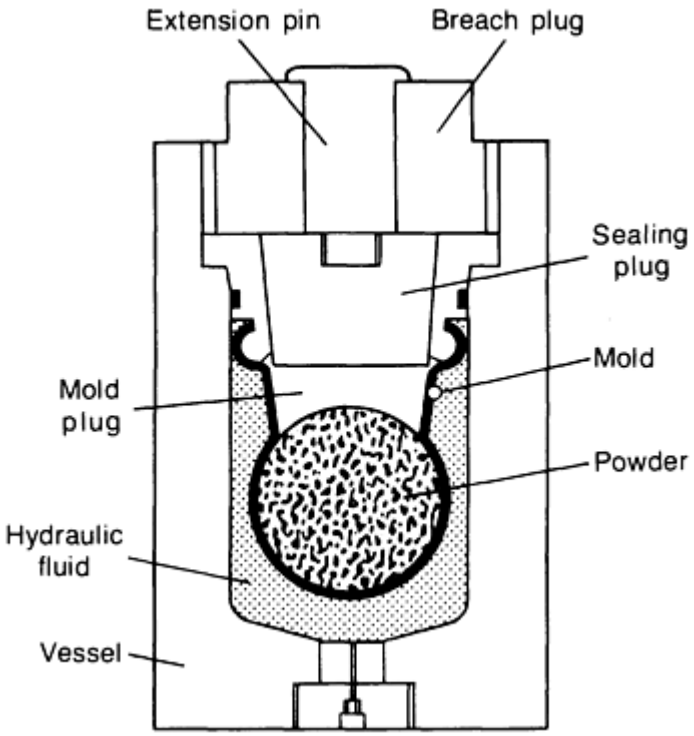

Fig. 5 Schematic of dry-bag hydrostatic pressing equipment. Courtesy of Olin Energy Systems

Advantages and Disadvantages. Hydrostatic pressing offers the following advantages (Ref 7):

- Pressed cermet pieces have a uniform density regardless of size and shape
- Wet-bag method is well suited for large pieces and often is the only practical method for pressing such pieces
- Slender pieces with high ratios of length to cross section are feasible
- Mold cost is low compared to that of rigid compacting dies. Low production quantities can thus be economically produced, especially by the wet-bag method
- Undercuts and varying cross sections are feasible with either the dry-bag or wet-bag method
- Little or no lubricant is required
- Process is well suited for research and development work

The disadvantages of hydrostatic pressing are:

- Dimensional control of compacts if limited. Mold design must accommodate the radial and axial shrinkage caused by hydrostatic pressing as well as the shrinkage that occurs during subsequent sintering
- Surfaces of compacts are less smooth than those of die-pressed pieces
- A high liquid-phase sintering step or encapsulation is necessary before hydrostatically pressed cermet pieces can be densified by hot isostatic pressing
- Equipment cost is high, and equipment utilization can be low
- Labor cost is relatively high

For difficult-to-press cermet compositions with high loading of the hard phase and/or relatively hard metal and alloy binders, cold hydrostatic pressing often is a convenient production method; sometimes it is the only reliable method for working with certain compositions.

Warm Extrusion of Cement Powder Mixtures. The process of warm extruding cemented ultrafine carbide powder with an admixture of plasticizers has been known for many years. It is successfully used for cermets as well as for forming simple prismatic shapes that have a high ratio of length to cross sections. Cylindrical and triangular shapes and other cross sections can be readily extruded; even tubes are feasible (Ref 9).

Depending on the plasticizer used (for example, polystyrene with an admixture of diphenyl and diphenyl-ether), extrusion requires a temperature somewhere between 160 and 175 °C (320 and 350 °F). Slow and complete debinding under vacuum prior to high sintering is critical in order to avoid distortion, cracking, or microporosity. Screw extruders similar to those used in the plastics industry are adapted to this process (Fig. 6). For the production of a high-quality product, but isostatic pressing is recommended.

Power rolling (roll compacting) is a well-known forming process in conventional powder metallurgy that may find application in cermet production. In this process, cermet powder mixtures are fed from a hopper into the gap of a rolling mill and emerge as a continuous strip or sheet. While the horizontal arrangement of the rolls is most convenient for feeding the powder from the hopper into the roll gap (Fig. 7), the vertical arrangement is preferable for feeding the emerging fragile strip horizontally into a series of subsequent operations. The vertical arrangement requires more carefully engineered devices for feeding the powder uniformly into the roll gap (Ref 7).

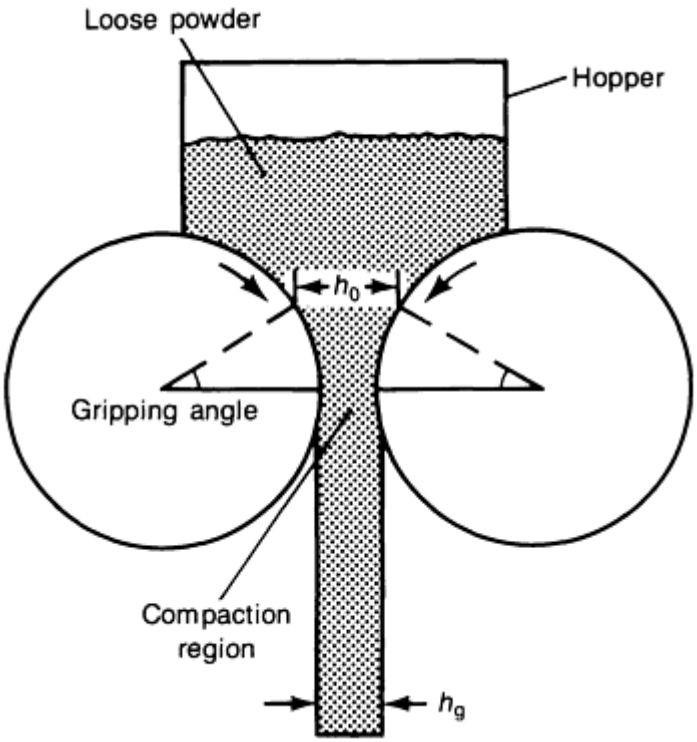

Fig. 7 Schematic of powder rolling with saturated feed and horizontal roll arrangement. Compression ratio, h_0/h_g. Source: Ref 7

In contrast to the starting material in slab rolling, the loose powder used in powder rolling has no strength before entering the roll gap and must flow freely or be forced into the gap. During the roll compacting process, the density and physical properties of the powder mixture change. For cermet powder compositions, the feasibility of roll forming a strip of sufficient density and strength depends upon a number of factors, including, but not limited to, the roll diameter and speed, the degree of loading of the cermet mixture with hard-phase substances, the ductility of the metallic phase, and the amount of plasticizer added to the mixture. The presence of the hard component adds to the friction of the powders against the roll and to the internal friction of the powder mixture during the compacting step. This is a favorable characteristic of cermet powders for roll forming; however, it is offset to some extent by the inherently low green strength of the resultant sheet or strip.

The sheet thickness that can be compacted with a given diameter roll is quite limited. A ratio of roll diameter to strip thickness between 600 to 1 and 100 to 1 seems to be the range for various metal powders (Ref 7). It is reasonable to assume that the middle-to-lower range applies to cermets. Special devices are required to prevent the powders from flowing laterally out of the roll gap. A uniform flow of powders over the entire width of the roll is essential for obtaining uniform density in the roll-formed strip. Edge cracking can occur, particularly with heavier strips. An optimum strip thickness has to be established experimentally. Thicker strips are too stiff to be coiled, and thinner ones are too fragile.

Rolling speed is another variable that can only be optimized through experimentation with a given cermet powder composition. Pure metal powders without hard phase have been roll compacted at speeds of 30 m/h (100 ft/h). It remains to be seen whether an output anywhere near this order of magnitude can be obtained with cermets.

A complete powder-rolling line for continuous operation includes debinding and sintering furnaces, rerolling stands, and, if necessary, one or more reannealing furnaces. Up-coiling equipment is needed at the end of the line. This equipment constitutes a major capital investment that is warranted only by a large and continuous demand for the product. Although labor costs for such an operation are low, it may be some time before this line production method finds applications in cermets. A simpler arrangement (Fig. 8) is feasible if, after a debinding step (not shown) and continuous atmosphere sintering, a product emerges of sufficient strength and ductility to permit upcoiling. Roll-compacting arrangements have been proposed for producing a sandwich-type strip consisting of two layers of different compositions.

Slip casting, a method for forming metal powders into a desired shape, follows a technique that has been used for ceramics for a long time. This method uses an aqueous suspension of cermet powders (the slip) that is poured into a porous plastic mold. The liquid is absorbed by the mold, and the powder is deposited on the mold wall. In the case of hollow shapes, the excess slip is drained off after the deposit reaches the required wall thickness; for solid parts the slip must remain and slowly dry.

The water-base slip has low viscosity in order to facilitate pouring, yet it should be stable during standing in order to avoid demixing. Demixing can be a serious problem with cermet powders, particularly those having a substantial difference of specific weight between the hard phase and the binder metal; it can lead to differences in composition and properties from one end of a cermet part to another. Variations in composition can lead to cracks during drying or subsequent sintering. In order to control the viscosity of the slip at the optimum level, it is generally necessary to use a deflocculant and to control the pH.

A typical slip casting mold that has the negative of the form to be cast is shown in Fig. 9. After slow drying, the slip cast part needs a debinding step followed by high sintering.

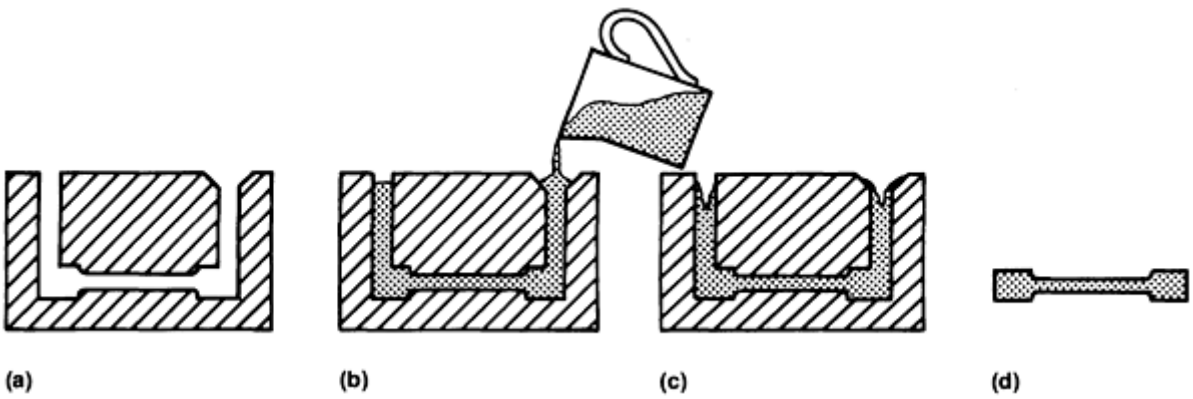

Fig. 9 Schematic of metal powder slip casting. (a) Assembled mold. (b) Filling the mold. (c) Absorbing water from the slip. (d) Finished piece, removed from the mold and trimmed. Source: Ref 7

The resultant part has a higher density than the tap density of its original powder mixture. The fine powders that frequently are used to facilitate slip casting can lead to superior properties in the sintered part (Ref 7).

Slip casting and mold making together are more art than technology. They require knowledge of parameters such as slip viscosity and suspension stability, wetting agents and deflocculants, and slip-mold interaction and mold release. Other important parameters are wall-building rate and casting crack formation. Slip casting requires only a small investment; however, it is labor intensive and is not well suited for mass production. At the present state of technology, cermet parts of a certain complexity are more likely to be suitable for injection metal molding than for slip casting. The former process is more capital intensive, but it is better suited for a medium-to-large production volume.

The P/M injection molding (MIM) process has evoked a great deal of interest since it was first developed in the early 1970's. Commercialization has been slow, mostly because of the long cycle that is required from concept to the point of shipping acceptable parts to a customer. Intensive research and application engineering continues in many laboratories, and more rapid growth is expected in the future (Ref 10, 11).

On a laboratory basis, cermet parts have been made by this process, and its commercialization is underway, particularly in the field of cemented carbides. However, the bulk of current MIM experience is in the area of structural ferrous and nonferrous parts.

The powder injection molding process for cermets (Fig. 10) involves mixing and blending the ingredient metal and hard-phase powders with a suitable polymer binder and then granulating the mixture. The granulated product is heated and injection molded under pressure. The polymer imparts viscous flow characteristics to the mixture to aid in forming, mold filling, and uniform packing. After demolding, the binder is removed, and the remaining cermet structure is densified by sintering and, perhaps, by hot isostatic pressing (Ref 10).

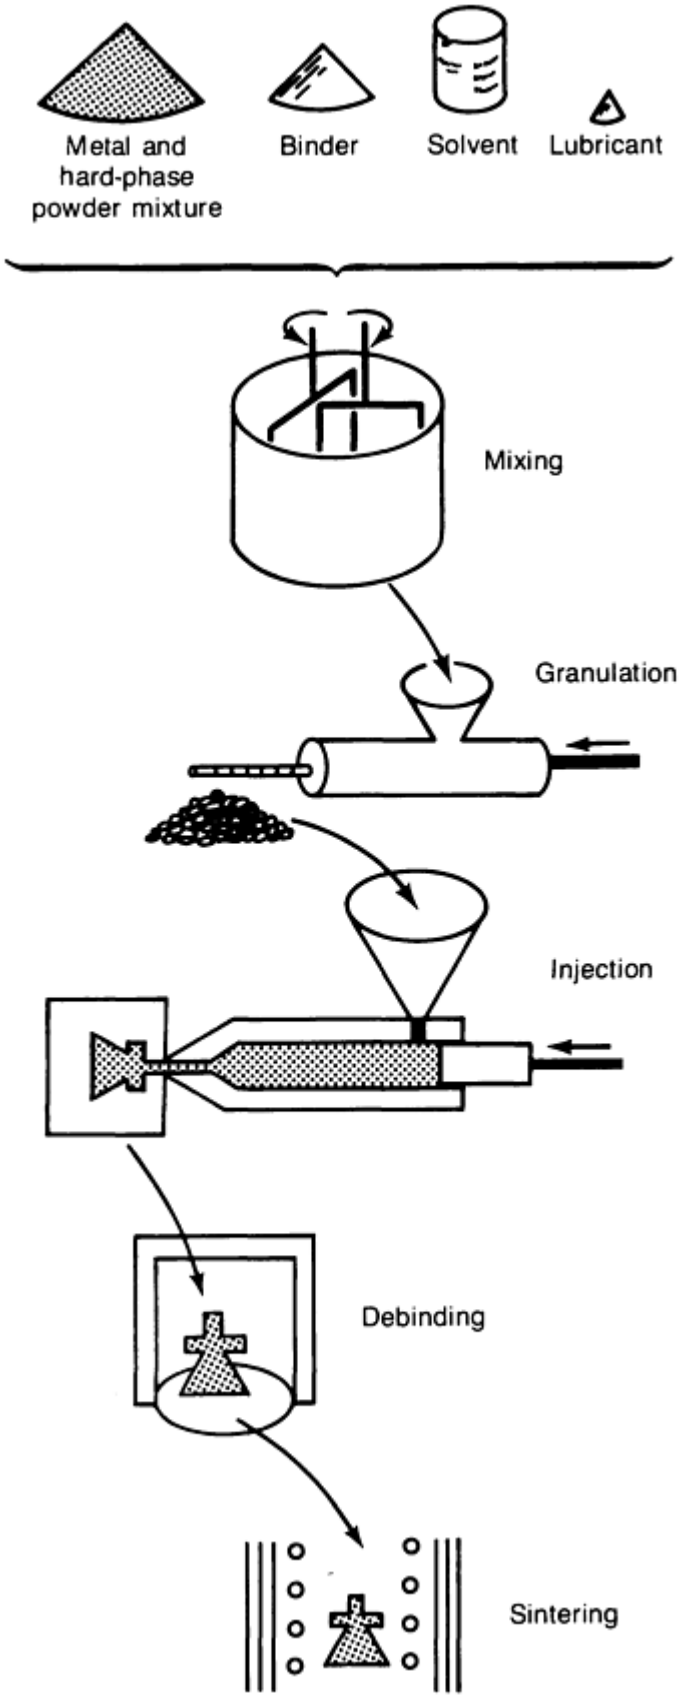

Fig. 10 Schematic of MIM process for cermets. Source: Ref 10

Binder compositions and debinding techniques are the main differences among the various MIM processes. There is no universal binder. A primary requirement of the binder is that it allow flow and packing into the mold cavity. It must wet

the powder, and it should be designed to minimize debinding time and defects. A multiple-component binder that is not chemically intersoluble allows for progressive extraction in debinding: As one compound is removed and the pores partially opened, the remaining binder holds the particles in place and maintains the shape of the compact. The remainder then vaporizes through the open pores without generating an internal vapor pressure that might cause compact failure. Waxes with additives are most frequently used as binders. The phases of the molding operation are:

- Clamping and filling of the mold
- Maintaining pressure while the compact becomes solid
- Retraction of filling mechanism
- Opening of the mold and ejection of the compact

Mold filling depends on the viscous flow of the feedstock into the mold cavity. The viscosity depends on temperature, shear rate, binder chemistry, powder interfacial chemistry, and loading (Ref 10).

Thermal debinding is the most frequently used technique, but capillary wicking and solvent extraction can also be considered as an alternative method. Complete debinding is required before commencing the sintering cycle. Most cermets require a liquid-phase sintering cycle to achieve complete densification of the compact. A modern furnace that combines debinding, high-vacuum sintering, and a final pressure-sintering cycle can accomplish all of these steps economically.

Applications and Advantages of the MIM Process for Cermets. In recent years, major progress has been made in using the MIM process for the production of heat engine components, military hardware, computers, and aerospace and automotive components. The powder injection molding process offers new opportunities in advanced materials manufacturing (Ref 11), and it offers potential advantages for use in cermet manufacturing technology. General aspects of applying the MIM process in cermet manufacturing include:

- In principle, the MIM process is applicable to cermets without modification of the injection molding machines or the typical mold designs (Fig. 11)
- The production of small- to medium-size complex shapes by the MIM process is feasible, provided that the geometry of the shapes allows for demolding. When this requirement is met, multiple levels, reentrant angles, and undercuts can be accommodated
- On small parts, tolerances of ±3 μm/mm (0.003 in./in.) after sintering can be obtained on conventional P/M parts with the MIM process. Larger tolerances would be needed on cermets to allow for shrinkage when liquid-phase sintering is needed for complete densification
- Small runs (of as few as 2000 parts) are feasible for conventional P/M parts. Because of the higher price level of cermets and the relatively high cost of competitive forming techniques, runs of similar or even smaller size could be economically attractive for cermet parts produced by the MIM process
- With proper debinding techniques and a liquid-phase sintering cycle (perhaps followed by hot isostatic pressing), high-quality parts with good physical properties could be produced by the MIM process
- Excessive mold wear caused by the hard phase during the injection molding of a cermet composition, particularly one with high loading, does not seem to be a serious problem in the MIM process. Future experience will demonstrate if such a mold wear problem exists and to what extent it affects the economics of using the MIM process for cermets

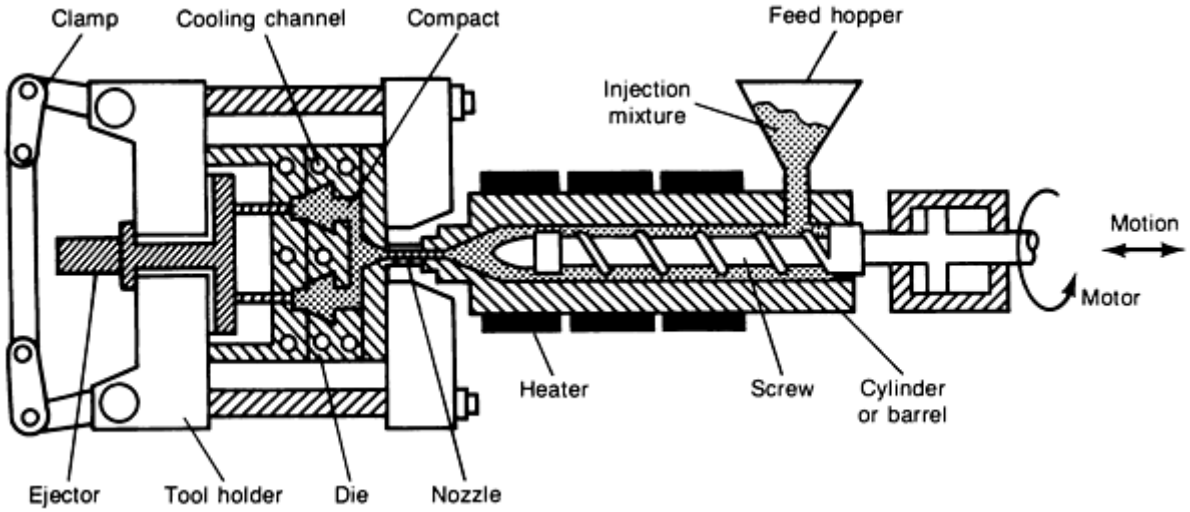

Fig. 11 Mold and injection mechanism for the MIM process. Source: Ref 10

Sintering. Not all cermets require liquid-phase sintering, but the majority use this process to convert the green compacts into solid, strong, and dense products. Sintering temperatures depend entirely on the ceramic-metal system involved and on the choice between solid- and liquid-phase sintering. Typical temperatures range from 850 to 1050 °C (1560 to 1920 °F) for products that contain a bronze, silver, or copper metal matrix; 1300 to 1500 °C (2370 to 2730 °F) for cemented carbides and borides; and 1700 to 2200 °C (3100 to 4000 °F), or even higher, for certain ceramic oxide-base cermets.

For applications requiring fine machining and grinding, as in many cemented-carbide parts and tools, presintering is performed at 1000 to 1100 °C (1830 to 2010 °F) to bond the metallic contact points and give enough green strength to the body so that it can withstand rough machining. Allowance is made for the substantial shrinkage that occurs during subsequent sintering.

Depending on the green density, cermet compacts can shrink during liquid-phase sintering by as much as 18 to 26% linear (45 to 60% by volume). In systems with good sinterability, virtually all porosity is eliminated (Ref 12).

During all sintering processes, particularly during the liquid-phase process, many complicated metallurgical phenomena take place that depend on temperature, furnace atmosphere (hydrogen, inert gas, or vacuum), and the dynamics of the particular ceramic-metal system. For example, metals change into alloys; the hard phase partially dissolves in the liquid phase and changes the composition of the latter phase; portions of the liquid phase can diffuse into the hard phase; and reprecipitation of some elements dissolved in the liquid phase can take place during the cooling portion of the cycle. Also, if carbon is present in the furnace atmosphere (perhaps from the furnace furniture), it will reach with oxygen or other elements. The phenomena that occur during the sintering of WC-cobalt systems have been investigated very thoroughly over a long period of time. Ample literature on the basic system and many of its alloy variations is available (Ref 12).

Mechanism of Liquid-Phase Sintering. While not strictly a cermet, the liquid-phase sintering of heavy alloys consisting of tungsten-nickel-copper has interesting ramifications that are applicable to the cermet field (Ref 7). This liquid-phase sintering process includes these principal features:

- The hard phase is partially soluble in the liquid phase during sintering. At temperature, the liquid phase is limited so that the compacts keep their shape
- The sintering temperature must be high enough so that an appreciable amount of liquid phase is present. When these conditions are met, densification takes place
- The finer the particle size of the hard phase, the more rapid and complete the densification of the compact
- Final density is independent of the compacting pressure. To reach theoretical density, compacts pressed at low pressure will shrink correspondingly more than those pressed at high pressure
- The microstructure will show grain growth when compared to the particle size of the original hard-

phase powder. This grain growth can be appreciable and is dependent on the sintering time and temperature

When the original hard-phase particles are angular (for example, titanium carbide), they can become rounded during the sintering process. However, this is not always the case because some angular hard substances (for example, tungsten carbide) seem to possess shape memory. During the reprecipitation of dissolved elements from the liquid phase during cooling, angular contours reappear on the hard-phase particles of these substances.

Furnaces. Continuous high-temperature sintering furnaces have been used in the cemented-carbide and refractory metal industries for many years. They are equipped with a hydrogen or protective atmosphere with a low dew point to reduce residual oxygen in the compacts and to prevent oxidation. Continuous pusher-type furnaces equipped with silicon carbide or molybdenum heating elements have been particularly successful and are used for sintering a large volume of small parts. Batch-type vacuum furnaces have become very popular in the last 30 to 40 years. When there is a choice between pusher-type continuous furnaces and batch-type furnaces, the equipment and operating costs favor the former.

In a typical operation, the parts are laid out without packing on graphite plates that are stacked with spacers within the furnace. When direct contact between the graphite and the compacts is undesirable, the plates are lined with an inert ceramic. It is essential to use vacuum equipment when highly reactive powder mixtures are sintered. The optimum level of vacuum to be reached during liquid-phase sintering varies greatly depending on the hard-phase binder system being treated. Several advanced furnace designs provide for initial operation using a hydrogen atmosphere, with a switch to vacuum at a later stage in the sintering cycle. Others provide a pulsating cycle of hydrogen pressure alternating with vacuum.

Static Hot Pressing. Hot pressing is a cermet production method in which the pressure and temperature are applied simultaneously. The powder mixtures are either compacted directly in the hot press mold or prepressed cold in dies and then transferred to the hot press tools of the pressure-sintering furnace. Pressures are considerably lower than for the cold press method. They can range from deadweight loads up to 3 MPa (500 psi) for pressure sintering (of friction elements, for example), or from 10 to 35 MPa (1500 to 5000 psi) for hot pressing; the lower end of the hot-pressing range applies to liquid-phase systems.

Sintering temperatures are reached by induction or resistance heating of the mold, or by direct induction or resistance heating of the powder compact. In the former case, the mold material consists of graphite. This is the more practical process because usually no controlled atmosphere supply is required. The latter method requires ceramic molds, which are sensitive to thermal shock, break easily on product removal, and are costly to produce accurately of the dimensions of the mold opening. The advantage of direct compact heating--that the tooling and surrounding area can remain cool--can be offset by a temperature gradient and the resulting microstructure segregation effects in the product. For most systems with readily oxidizing metal matrices, a controlled atmosphere is required.

The densification effect of conventional static hot pressing is more pronounced than the effect that can be achieved by cold pressing and subsequent sintering. Heating the cermet powder mixture increases its plasticity and produces larger areas of inter-particle contact. The surface shearing action that occurs during the process mechanically disrupts surface oxide films and generates clean bonding surfaces (Ref 13). Shape limitations are similar to those for static cold pressure. Prismatic single-level pieces that have no undercuts or reentrant angles are preferred; however, shallow details in the punch faces are acceptable. Very large pieces are well suited for this process.

A typical graphite induction-heated vacuum furnace (Fig. 12) with graphite tooling is capable of double-action hot compacting or repressing of a 125 mm (5 in.) diam billet at pressures up to 90 Mg (100 tons) and temperatures up to 2300 °C (4200 °F) in a high-vacuum or controlled atmosphere. The fully pressed compact is ejected from the die while still hot to reduce cooling time, minimize sticking, and prolong mold life. Items produced in this type of furnace include WC-Co draw dies and friction elements, Al-B_4C billets, stable oxide components, and some boride-base cermets.

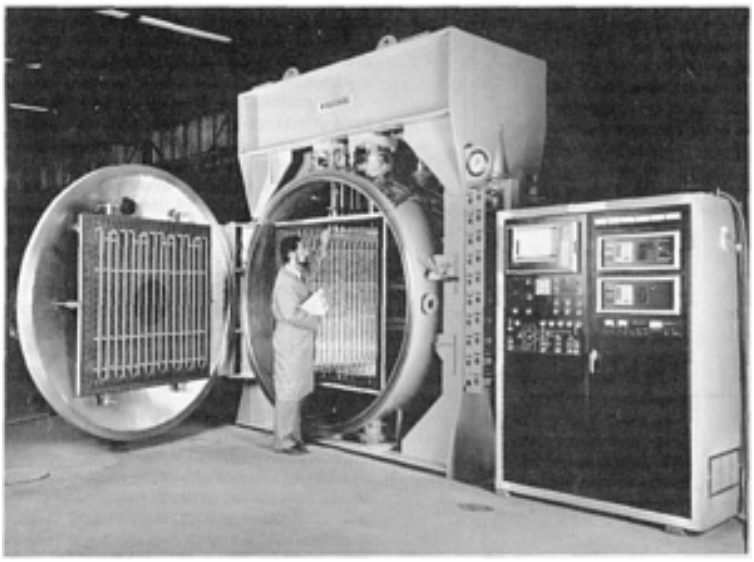

Fig. 12 Production-scale 225 Mg (250 ton) vacuum hot press. Courtesy of Vacuum Industries, Inc.

Among the various cermet production processes, static hot pressing in such a furnace is the only reliable single-step method for producing a fully dense, high-quality, near-net shape compact from a cermet mixture. However, graphite die life is limited, and cermet compositions that do not react with graphite are preferred. In order to avoid a cermet-graphite reaction, ceramic molds can be used for hot pressing, although they are more fragile and costly than cermet molds. The complete hot press setup (including a vacuum system or atmosphere generator power system, hydraulic system, controls, and instrumentation) is expensive. In addition, static hot pressing is labor intensive because products are pressed one at a time. Therefore, hot isostatic pressing may be more appropriate for many sensitive high-temperature consolidation tasks involving small- and medium-size pieces. For large and very large pieces, vacuum hot pressing is often used because large equipment is readily available (Ref 14). For example, Fig. 12 shows a 225 Mg (250 ton) vacuum hot press with double-action bottom rams and a 1070 mm (42 in.) square platen; the press has a maximum operating temperature of 1315 °C (2400 °F).

Hot isostatic pressing (HIP) has become increasingly popular as a means for producing carbide-base and other cermets of very high and uniform density. Internal flaws and micro- or macroporosity are virtually eliminated in the resultant product. Isostatic pressing is a batch process accomplished in water-cooled pressure vessels capable of withstanding internal pressures of up to 210 MPa (30 ksi). Heating up to a temperature of 1600 °C (3000 °F) is achieved with a high-frequency or resistance furnace mounted inside the pressure vessel. The pressure medium is an inert gas, usually argon. The pressure medium can also be helium (Ref 8), which at the pressure employed (100 to 150 MPa, or 15 to 20 ksi) has a density close to that of water. More detailed information on HIP equipment is contained in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook.*

Hot isostatic pressing was originally developed for use in gas pressure-assisted diffusion bonding processes such as the encapsulation of nuclear fuel elements (uranium oxide, for example) in a zircaloy sheath. This was soon followed by applications such as powder consolidation and densification of difficult-to-sinter substances and cermet composition (Ref 13). Hot isostatic pressing is most successfully applied in the cemented-carbide industry and in the manufacture of steel-bonded titanium carbide. Notwithstanding the ease with which these cermets sinter to high density, they often have slight localized porosity in the range up to 50 μm; on occasion they have voids in the range from 0.25 to 2.5 mm (0.01 to 0.1 in.) caused by random or accidental contamination.

Hot isostatic pressing is an improvement over static hot pressing in that it eliminates the need for costly and highly perishable molds. However, before compacts are submitted to isostatic pressing, they need to have a sufficiently dense structure (at least at the skin) to inhibit gas penetration. Compacts with lower density and interconnecting pores require a gas-tight encapsulation of some sort before being treated. Three methods are in common use to accomplish this encapsulation (Ref 13). In the first method, compacts are formed and sintered to 95% or more of theoretical density, and the resultant continuous, dense surface structure acts as an impenetrable envelope to the high-pressure gas. Alternatively,

the density is raised to a sufficiently high level that no interconnecting porosity remains within the compact. This method is used primarily for small- and medium-size pieces.

The second method involves a steel can that is prepared in accordance with the desired form of the compact. The can is filled with a powder mixture that is densely packed by vibration or pressing. (A cold-compacted or hydrostatically pressed piece could be encapsulated in the steel can instead of the powder mixture.) After loading, the can is closed tightly be welding and then evacuated. This method is most commonly used for medium- and large-size pieces, in situations where the additional cost of a perishable can is economically bearable.

The third method is the Ugine-Sejournet process, in which vitrified glass is used to encapsulate the compact. This method may be more economical than the steel can method.

None of the methods for preventing the high-pressure gas from penetrating the compact are inexpensive. Fortunately, the HIP process is flexible enough to allow for the simultaneous hot isostatic pressing of a number of freestanding or encapsulated compacts. The process cost can be apportioned according to the volume occupied by each piece in the available furnace space.

The cemented-carbide and P/M products that undergo HIP processing are of substantially higher quality than those produced by any other process. The higher quality is a result of the near theoretical densities produced by HIP processing. Pieces with near theoretical densities have high strength levels and reliable physical properties. Hot isostatic pressing is a capital-intensive batch process; when the encapsulation method is used, it is labor intensive as well.

Hot extrusion of cermet billets is unique among the various cermet processes because it is essentially a solid-state process. All of the other previously discussed densification processes involve a liquid phase.

During hot extrusion of powdered material, large hydrostatic compression forces occur. A unidirectional force component first compresses the powder material to full density and then forces the material through the die. Depending on the configuration of the front surface of the extrusion die, a large shear component can absorb as much as one-half of the total energy needed for extrusion. The total amount of one-step deformation (ratio of the cross section of the billet to the cross section of the die opening) is much larger than in any other cermet hot-working process

Methods. The three basic methods for the hot extrusion of powder mixtures (including some cermets) are shown in Fig. 13. The first method (Fig. 13a) is applicable to loose, coarse magnesium powder or pellets (see the article "Forging and Hot Pressing" in *Powder Metal Technologies and Applications,* Volume 7 of *ASM Handbook*). The material is poured into the hot extrusion container where it heats up to extrusion temperature within 30 s. The rapid advance of the extrusion tool compacts the heated powder and extrudes it though the die. In the second method (Fig. 13b), aluminum-base cermet powder mixtures are transformed into extrusion billets by the cold pressing and hot densification of individual compacts. These billets are then extruded in a conventional manner (Ref 15).

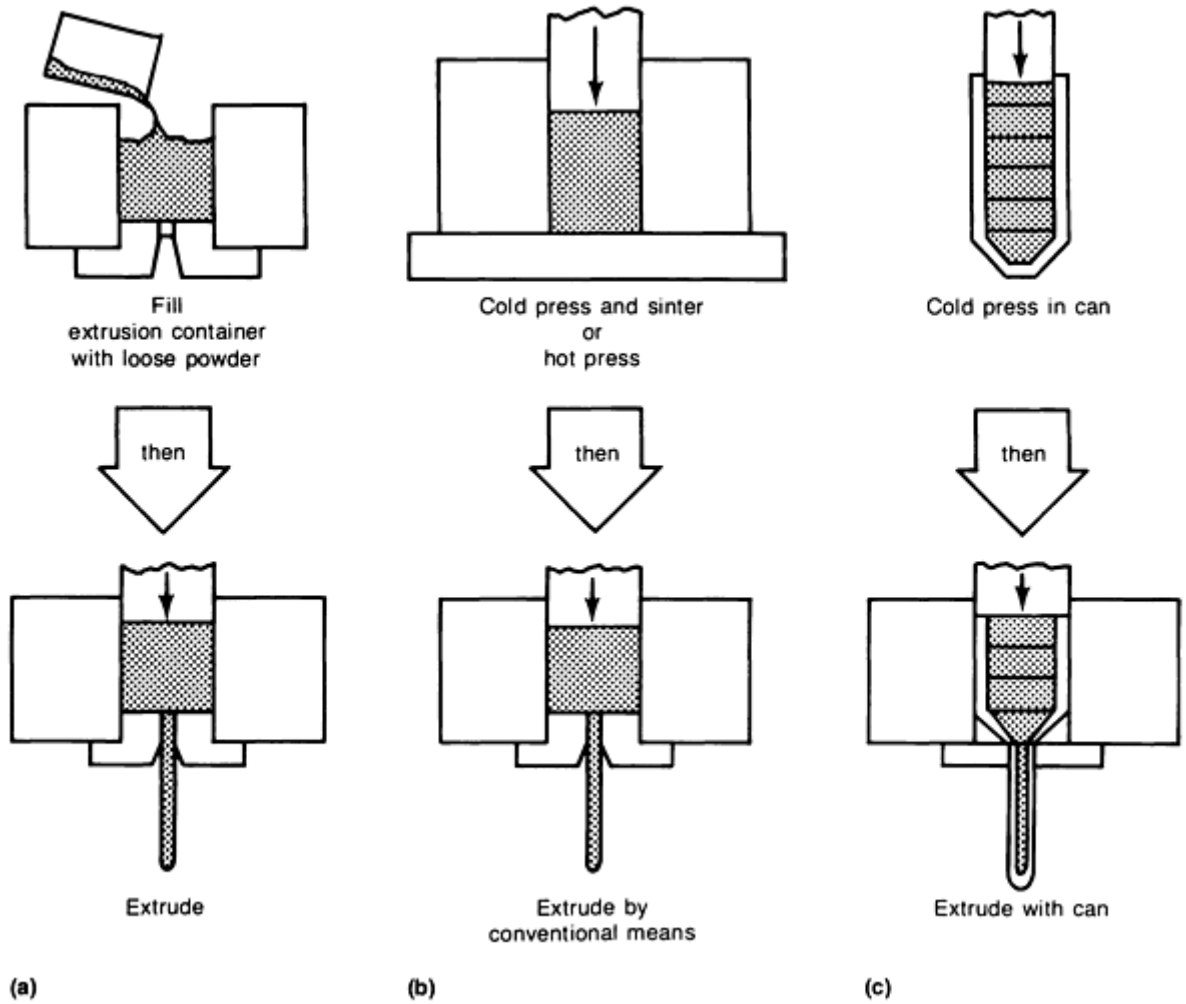

Fig. 13 Three methods for the hot extrusion of powder mixtures. (a) Loose-powder method. (b) Billet method. (c) Steel can method. Source: Ref 7

A third widely used technique (Fig. 13c) consists of filing cold powder mixtures into steel cans and compacting the mixtures by means of a penetrating punch while the can is supported in a packing die. (Prepressed compacts can be used instead of the powder mixtures, thus eliminating the compacting step.) A closure is welded over the open end of the can and the air is evacuated from the can. The can is then heated and extruded. As an alternative, a penetrating punch can force the open can and the powder mixture through the extrusion die. In both version of this method, the extruded product will be sheathed by a thin layer of the material used for canning. This layer must be removed by mechanical stripping or etching.

Application. Hot extrusion is an attractive forming and densification process for cermets. Unfortunately, its application in this broad field has serious limitations caused by the loading of the nonmetallic material, the choice of the metallic component, and the degree of interaction between the two substances. Precise limitations on the volumetric amount of nonmetallic substance have not been established, but when this substance exceeds about 18 to 25 vol%, the composite material exhibits hot shortness to such an extent that the problems of edge cracking, internal lamination, and distortion of the extruded product become intolerable. When the nonmetallic phase occurs in the form of very fine powders, the hot shortness problems are aggravated; they are also aggravated when the nonmetallic substance interacts with the metallic component at the extrusion temperature to form new phases or eutectoids. How to deal with these complex problems for each particular pairing of cermet components is beyond the scope of this review. A careful study of the constitution diagram of the binder metal and the hard phase before undertaking any serious work is recommended.

Like metal alloy billets, cermet billets are much easier to extrude when aluminum or aluminum alloys are used for the metallic components. Billet densification and extrusion occur at lower temperatures and pressures. The expensive canning and decanning process can generally be avoided, as can the use of a protective atmosphere. Moreover, straightening and

finishing of the extruded product often can be performed at room temperatures. Defects due to hot shortness in extruded aluminum-base products occur only at higher levels of loading with hard-phase substances.

Compared with cermets containing aluminum or aluminum alloys, cermets with iron, nickel, cobalt, or alloys of these metals as the metallic phase are more technically demanding and more costly extrude. For example, billet heating and hot compacting require a controlled atmosphere, billet canning is practically unavoidable, and a glass process is required for lubrication and reduction of die wear. Postextrusion finishing, such as the removal of can material, straightening, finish rolling, and so on, also requires more costly processes. The extruded cermet product can be expected to be harder, stiffer, less malleable, and more brittle than the metal binder component. Because of the higher extrusion temperature, metallurgical interaction between the matrix metal or alloy and the hard-phase cermet component is far more likely to occur, particularly if the letter is a nonmetallic compound of the carbide or boride group. Oxide-base hard-phase components are less likely to interact with the metallic component.

The undesirable interaction between the hard substance and the metallic component of the cermet is easier to control with the solid-state extrusion process than with any densification process involving a liquid phase. Also, in spite of the aforementioned limitations and problems, hot extrusion continues to attract the attention of product development engineers as a possible production method for certain cermets, particularly those with an aluminum base. It has the potential to be a relatively low labor cost, yet capital-intensive, mass-production process for high-technology rod or strip material.

Combination Sintering-Compacting. Combination debinding, sintering, and pressure consolidation furnaces have been developed in an attempt to simplify the manufacturing process for cermets and similar products. As stated before, a debinding step is essential before sintering green products that contain admixed lubricants, organic binders, or plasticizers. These additives are needed in varying proportions for static cold pressing, warm extrusion, powder roll compacting, slip casting, and injection metal molding of cermets. After debinding and during liquid-phase sintering, the green compacts shrink to nearly complete density. When densification progresses to the point that pressurized gas can no longer penetrate into the compact, hot isostatic compacting occurs. Gas compacting the already-sintered dense cermet at high gas pressures and at a temperature near that of liquid-phase formation improves the product quality by eliminating all residual porosity, internal flaws, and defects.

Recent experience with WC-Co compacts has shown that using a lower isostatic pressure of only 2.7 MPa (390 psig) can produce compacts with strength and densification nearly equal to those of compacts produced by the high-pressure HIP process (Table 3). Based on these findings, multimode single-chamber pressure furnaces have been developed that are capable of operating in vacuum, with partial pressure, and with positive gas pressure up to 10 MPa (1500 psig); the furnaces operate at temperatures between 1450 and 2200 °C (2640 and 3390 °F) (Ref 16).

Table 3 Comparison of transverse rupture strength for various cemented carbides after hot isostatic pressing and pressure sintering

Processing method	Density		Hardness, HRA	Transverse rupture strength	
	g/cm^3	lb/in.^{3}		MPa	ksi

Source: Ref 16

This new furnace concept of combining three operations is one cycle offers several advantages over separate sintering and hot isostatic pressing operations:

- Debinding, sintering, and densification under pressure take place in one cycle and in a single vessel
- During the various stages of the process, the compacts do not come in contact with air
- Controlling the cycle with an electronic microprocessor ensures automatic operation and a high degree of program reproducibility (Fig. 14)
- Transfer of parts from one process step to another is avoided, saving labor cost and process time
- Combining processes saves energy

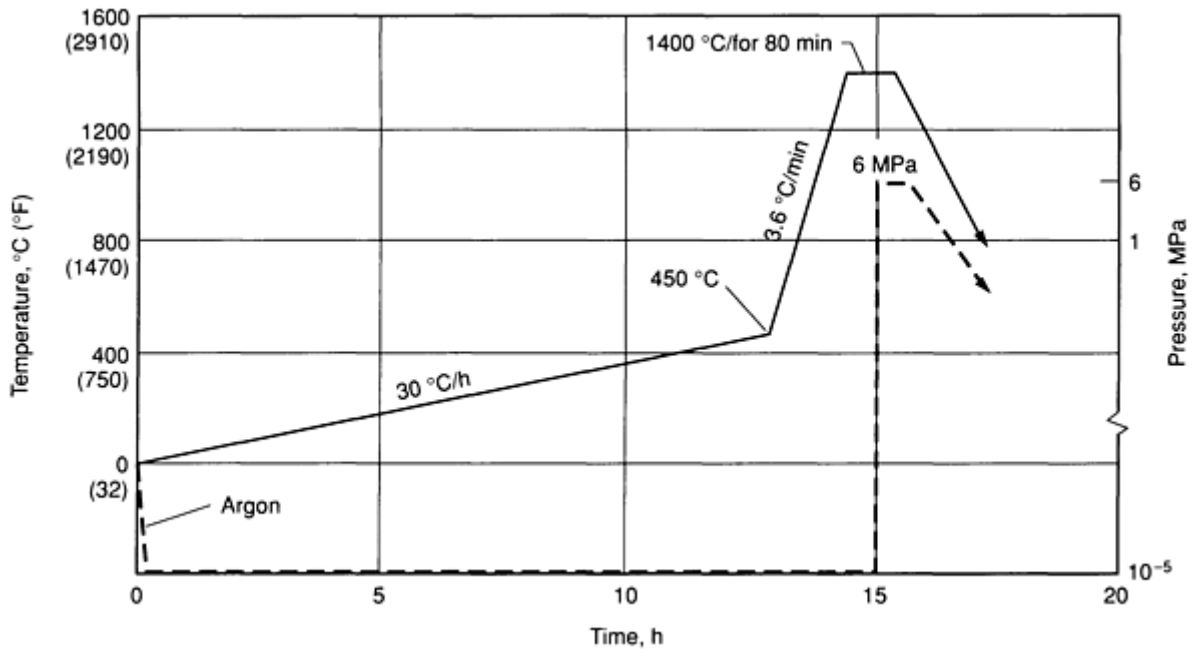

Fig. 14 Schematic cycle diagram for low-pressure dewaxing and overpressure sintering. Source: Ref 17

Infiltration is a process that is similar to liquid-phase sintering, except that the solid phase is first formed into a porous skeleton body, and the liquid-metal phase is introduced during sintering from the outside and allowed to penetrate the pore system. Excessive shrinkage associated with *in situ* liquid-phase sintering is avoided, and dimensional stability of the product is obtained, except for about 1% growth that is due to a thin surface film formed by the liquid metal.

This technique is used for systems of two or more components that have widely differing melting temperatures. Aside from hot pressing, infiltration is the only powder processing method that can obtain essentially full density of a near-net shape. All of the other densification processes involve substantial shrinkage and thus destroy shape and dimensional accuracy. By machining, hydrostatic pressing, or powder injection molding the skeletal preforms prior to infiltration, complexities in part design, such as undercuts, reentrant angles, and multiple levels, can be realized to an extent not possible in parts of comparable high density that are made by extrusion or hot pressing. The other unique feature of infiltration is that--under suitable conditions of low contact angles and limited solubilities between the high- and low-melting phases--systems of completely inter-twined continuous networks can be obtained. This is of considerable importance for making products that must be combine high thermal or electrical conductivity with acceptable levels of strength and abrasion or erosion resistance.

The procedure used of TiC cermets involves two steps (Ref 18). First, an approximately 60% dense carbide skeleton body of near-net shape is formed by mixing the TiC powder with a small percentage of nickel binder and wax, cold pressing the mixture at about 35 MPa (5000 psi) into a slab, vacuum sintering the slab at about 1300 °C (2370 °F), and then machining the contour (for example, a turbine blade). The second step consists of inserting the skeleton shape into a mold assembly that contains the metal in a ceramic tundish on top and provides for the gravity feeding of the liquid to the skeleton at the preferred contact faces. An infiltration arrangement of this type is shown in Fig. 15.

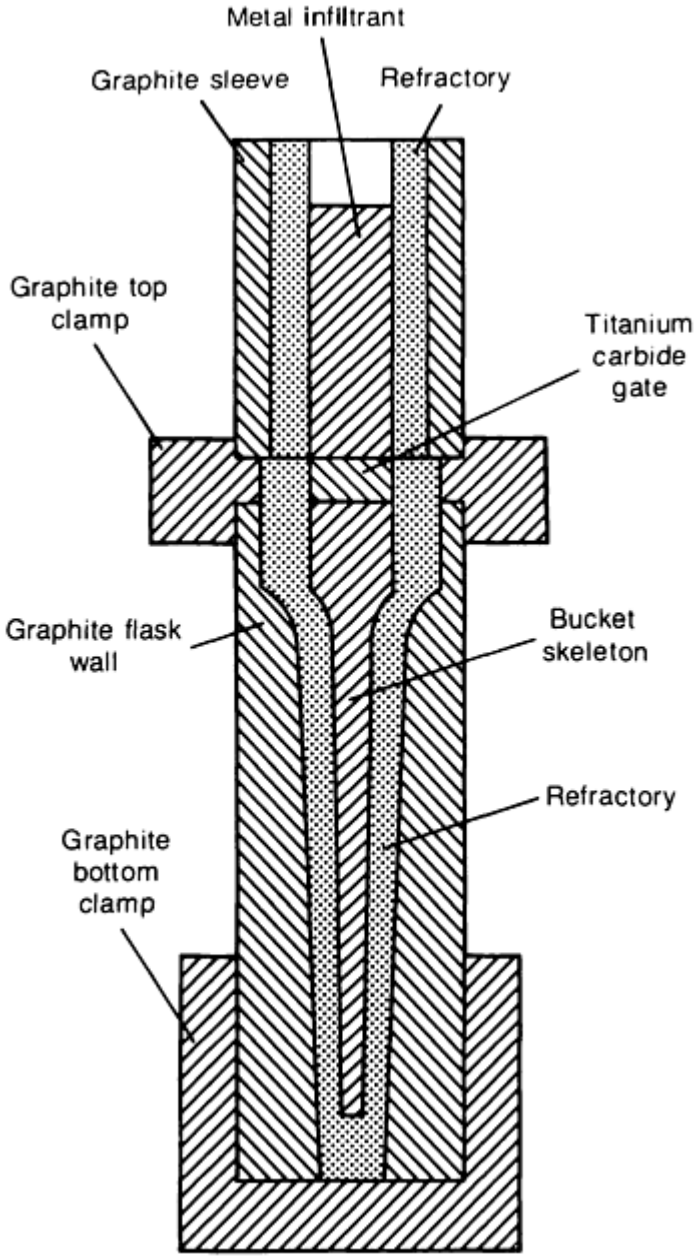

Fig. 15 Cermet turbine blade infiltration mold assembly. Source: Ref 19

The mold assembly is made of graphite, and its cavity is lined with a refractory ceramic in powder form that interfaces with the TiC skeleton. The ceramic liner is chosen so that it does not react with the titanium carbide up to infiltration temperature and also so that it shrinks at a controlled rate, permitting the formation of a uniform gap all around. The mold assembly is heated in a vacuum furnace to about 1400 to 1500 °C (2550 to 2730 °F); that is, well above the melting temperature of infiltrating alloys, such as 80Ni-20Cr and 70Co-24Cr-6Mo. During infiltration, the liquid metal first fills the gap between the liner and the skeleton exterior by capillary forces and then penetrates the interior of the porous TiC part. After furnace cooling, the fully infiltrated product can be readily extracted by fragmenting the sintered ceramic liner without degrading the graphite mold assembly, which can be reused.

Graded cermet parts can be produced by varying the density of the TiC skeleton through the use of a special die filling and multiple-step pressing. For example, a turbine blade can be made that has a high concentration of titanium carbide and, therefore, high strength at the center of the foil and in the transition to the root. The turbine blade also has a metal-rich jacket around the foil and especially at the mechanical shock-sensitive blade edges, as well as around the serrated root needed for blade attachment to the turbine disk.

The infiltration process has been successfully applied to other cermet systems; it has been especially successful when used with interfacial reactions. An example of such an application is the production of complex ceramics that are reinforced by microscopic-size platelets of another compound and bonded by a third species (Ref 20). The preformed ceramic is a metalloidal carbide, the binder is a relatively high-melting reactive metal, and the platelets are the reaction product of the carbide and binder. The unique composite microstructure of such a platelet-reinforced ceramic is obtained by gravity infiltration of the molten metal into a porous preform or bed of the carbide. In the case of a B_4C ceramic and a zirconium metal infiltrant, controlled oxidation at the contact faces produces a new phase, ZrB_2, that precipitates abundantly in the form of platelets that reinforce the ceramic (Fig. 16a). A similar result is achieved with SiC preforms or fillers that are infiltrated with molten aluminum metal under oxidizing conditions; the reaction product in this case is Al_2O_3 (Fig. 16b).

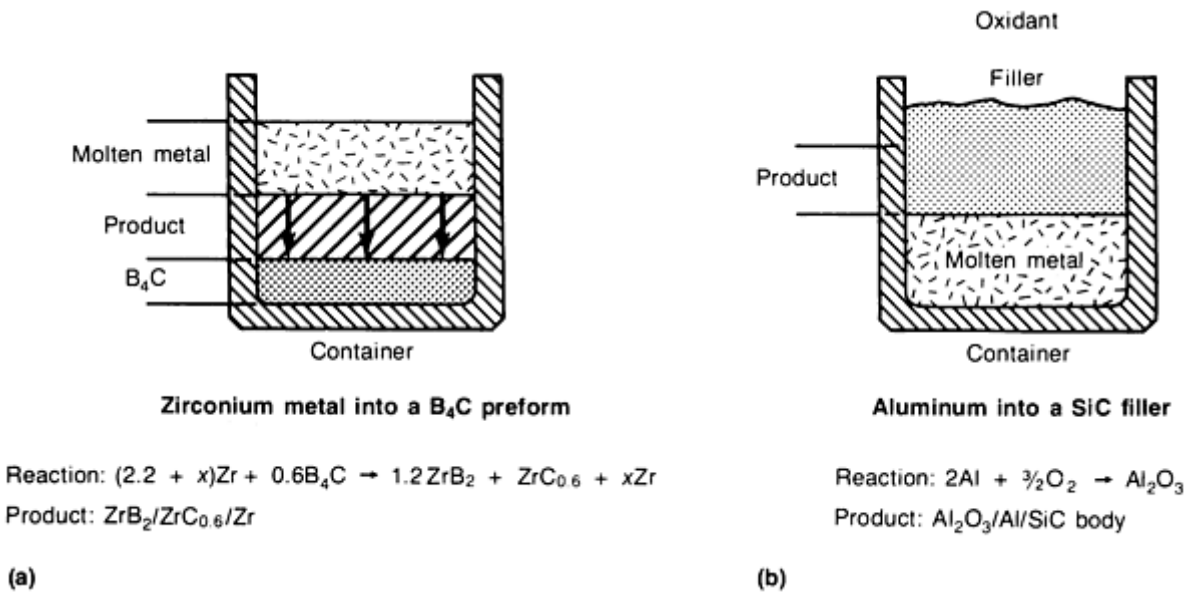

Fig. 16 Schemes for the formation of platelet reinforcements in reaction-infiltrated cermets. (a) Zirconium infiltrant. (b) Aluminum infiltrant. Source: Ref 20

The container or mold used in the infiltration process is made from graphite, and it is shaped in accordance with the configurations of the desired product; the process is conducted in an argon atmosphere. The infiltration and reaction temperature depends on the melting point and liquidity of the metal. It can be as high as 2000 °C (3630 °F) in the system involving zirconium. The time to complete penetration and reaction is in the 1 to 2 h range, and the end product typically contains 5 to 15% residual binder metal. The platelet-reinforced infiltrated ceramic system of the type $ZrB_2/ZrC_x/Zr$ exhibits a good combination of high strength, high fracture toughness, and high thermal conductivity. This combination makes it an interesting candidate material for rocket engine components and wear parts (Ref 21). Other systems that have been successfully produced or are potentially workable by the infiltration process include TiB_2 ceramics combined with nickel as second phase (Ref 22), TiC with steel (Ref 23), WC with cobalt (Ref 24), AIN with aluminum (Ref 25), and Al_2O_3 with aluminum (Ref 26).

Infiltration processing of boron carbide and boride-reactive metal cermets has also been used successfully in the development of high-strength, hard, and lightweight products that offer an interesting combination of toughness with high thermal and electrical conductivity (Ref 27). The process involves the infiltration of molten reactive metals, particularly aluminum, into chemically treated boron carbide, or it can use metal-boride starting constituents, such as powders or low aspect ratio fibers, that have been consolidated into a porous ceramic precursor sponge. This process is an alternative to the infiltration of the molten aluminum into thermally modified precursor sponges. Conventional or colloidal chemistry is used in the chemical reaction-controlled casting and infiltration procedures. The potential also exists for consolidating the precursor sponges by injection molding in either a single-step or a two-step process. The key to the process lies in controlling the surface chemistry of the starting constituents. In the two-step process, the first step is the production of highly configured geometries that can be molded by using chemically pretreated binders. In the second step, the binder is volatilized from the precursor, leaving it as a skeleton ready for infiltration.

Bonding and Microstructure

The physiochemical aspects of the bond between the dissimilar phases, and the size of the ceramic grains embedded in the metallic matrix are vitally important to the properties and performance of cermets. Reference 28 contains a discussion of the fundamentals involved in the bonding mechanism, particularly the TiC-metal systems.

Bonding. In general, because of the basic difference in the nature of the ceramic and metallic components in cermets, none of the known solid-state bonds applies by itself. Instead, combinations are formed among ionic bonds, covalent bonds, and metallic bonds. The first type predominates in cermets based on oxide ceramics, and little force beyond simple adhesion exists to hold onto the metallic phase. The second bond type applies chiefly to systems involving silicon and carbon, such as graphite, diamond, and SiC. The strength of this bonds is also rather limited. The cermet gains substantially in its mechanical cohesiveness only where metallic bonding combines with covalent bonding. The metal-carbide and metal-boride systems are examples of cermet types in which this combination occurs.

Solubility. The high bond strength between metal and ceramic in cemented carbides and borides is further enhanced by mutual or partial solubility. During sintering, the active surfaces of the carbide or boride particles are dissolved in the liquid phase, and the carbon, boron, and transition metal atoms are reprecipitated on the solid particles during cooling. Depending on the system, these elements remain dissolved in the binder phase in levels that range from trace amounts to several percent.

Even in other cermet types, this partial solubility mechanism is beneficial because it generates a metalloid interface. Metals are known to bond more readily to metalloids, such as silicides and borides, than to oxides. For example, in the Cr-Al_2O_3 system, a surface layer of chromium oxide (Cr_2O_3) on the chromium particles forms a solid solution with Al_2O_3 during sintering in a closely controlled, mildly oxidizing atmosphere. The result is greatly enhanced bonding (Ref 29, 30). Similar metal-metalloid-oxide transition-type bond enhancement can be obtained with an intermediate layer of copper oxide (CuO) in the Cu-Al_2O_3 system, or with a layer of titanium nitride (TiN) in the nickel-magnesium oxide (Ni-MgO) system (Ref 28).

Wetting. Another important aspect of the bonding mechanism is the wettability of the solid phase by the liquid metal component. This is controlled by the surface energies of the system during liquid-phase sintering (Ref 28). In Fig. 17, the wetting ability is indicated by the contact angle (θ) that is formed by a liquid drop resting on a solid substrate. The relationships among the surface force vectors are given by the equation:

$$\sigma_{SV} - \sigma_{SL} = \sigma_{LV} \cos \theta$$

where σ_{SV}, σ_{SL}, and σ_{LV} are the surface energies of the solid-vapor interface, solid-liquid interface, and liquid-vapor interface, respectively. The contact angle is a parameter that can be measured with precision. In metal-ceramic oxide systems, the surface energy of the liquid-vapor interface of the metal is greater than the surface energy of the solid-vapor interface of the oxide, and the contact angle is much larger than 90°. Consequently, during liquid-phase sintering or infiltration in a neutral atmosphere, the liquid metal is not retained in the pores of the solid, but tends to sweat out. If the contact angle is less than 90°, however, the liquid metal phase is retained in the pore system of the ceramic; as the contact angle approaches 0, the bond becomes stronger. This is the case with the cemented carbides that have cobalt binders.

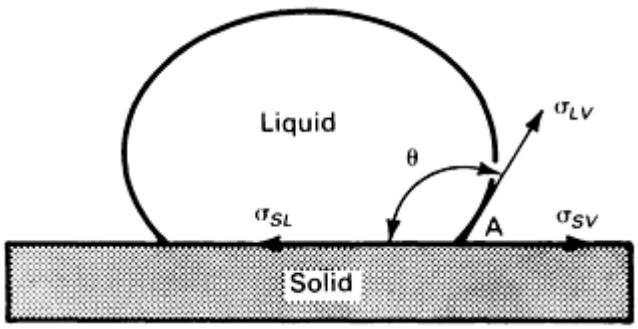

Fig. 17 Surface forces acting at the point of intersection of a liquid resting on a solid. See text for explanation of symbols. Source: Ref 28

Microstructure. The nature of the bond in cermets is very closely related to the microstructure. This is especially significant for the carbide cermets, which have properties that are greatly affected by variables such as the shape, size, and dispersion of carbide grains; the amount of carbide grains in the metal matrix; the composition and structure of the matrix; and, of course, the degree of bonding of the two phases (Ref 31). Although these variables act in conjunction with one another, they can be singled out for specific effects.

A very fine carbide grain size tends to increase strength and hardness, but a somewhat coarser size of about 2.2 μm can provide an increase in the fracture toughness of cemented carbides (Ref 32). Sharp corners prevail in WC grains and cause only minimal harm to the strength of low-binder cemented-carbide grades; in cermets with higher metal contents, however, they affect the localized stress raisers in the ductile metal matrix.

A good dispersion of the carbide grains in the metal matrix provides isolation of the grains, which limits the tendency of a crack initiated in one grain to propagate to others that are coalesced with the first. The same reasoning applies to any secondary hard phases that might form during sintering and bridge the original grains. Chromium carbide and nickel aluminide (Ni_3Al) are examples of reaction products from the matrix that can deposit on the carbide grains of TiC cermets and thereby contribute to the continuity of the brittle hard-phase structure (Ref 30).

The volume fraction of carbide in the cermet has a major influence on the mechanical and physical properties of the end product. Because of the mutual solubility and enhanced bond between the disparate phases, the rule of mixture does not strictly apply to the TiC systems. Generally, strength and hardness increase, and the coefficient of thermal expansion decreases with carbide content. Ductility improves as the metal matrix becomes the continuous phase and as it increase sufficiently in volume to avoid a triaxial state of stress.

The composition of the matrix is important in several respects. High ductility and toughness are essential to relieve the stresses caused by the hard phase and to provide a modicum of safety against catastrophic failure in service. Alloy selection must entail consideration of the matrix as a possible source for the brittle reaction products that can coalesce with the carbide grains into a continuous hard phase. The composition of the metal matrix also influence such properties as oxidation and corrosion resistance, machinability, and weldability.

Good bonding between the carbide and metallic phase is essential because the bond must translate the stresses from one phase to the other. Therefore, any gaps between the surface of a carbide particle and the matrix are detrimental. The importance of these bonds is emphasized by the example of bond improvement in Ni-TiC by the addition of molybdenum. The contact angle of liquid nickel on the TiC in hydrogen is 17°, but the angle changes to almost 0 with the molybdenum additions. As can be seen from micrographs of the two compositions (Fig. 18), the molybdenum-free version suffers excessive carbide grain growth, whereas the Ni-Mo-TiC displays a fine-grain, well-dispersed carbide phase in a continuous metal matrix (Ref 28). Cermets of this type contain molybdenum with nickel in the binder alloy rather than in a solid solution of the carbide $(Ti, Mo)C_{1-x}$. During sintering, the molybdenum reacts with the TiC particles to form a case of $(Ti, Mo)C_{1-x}$ that surrounds the TiC core of each particle. This mechanism tends to enhance the wettability of the carbide phase by the binder. The result is strength enhancement, but basic brittleness and, in particular, chip and notch sensitivity are not relieved.

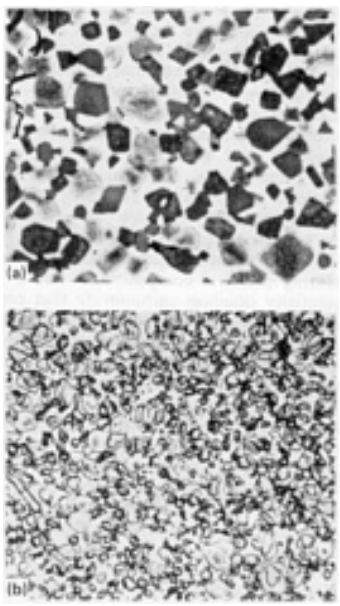

Fig. 18 Microstructure of titanium carbide cermets sintered 1 h in vacuum at 1400 °C (2550 °F) on graphite. (a) 50 wt% TiC and 50 wt% Ni. 1000×. (b) 50 wt% TiC, 37.5 wt% Ni, and 12.5 wt% Mo. 1000×. Source Ref 28

Complexing of Cermet Composition to Improve Deformation Resistance and Fracture Toughness. Major improvements in the deformation resistance of TiC cermets and concomitant reductions in brittleness are possible by complexing either the binder alloy or the carbide phase, or both (Ref 33). Complexing the binder alloy involves the addition of aluminum, which can produce substantial solid-solution strengthening if correctly applied (that is, in an optimized binder composition such as 22.5% Ni, 10% Mo, and (~7 at.% (Al + Ti). An improvement in the compressive yield strength of the carbide phase is achieved by forming a solid solution of the TiC with 10 wt% VC. The addition of approximately 10 wt% TiN greatly enhances the deformation resistance of the cermet. This enhancement is believed to be at least partially the result both of a grain refinement effect and of the solid-solution hardening of the carbide phase.

If the ratio of titanium nitride to titanium carbide is increased, the resulting carbonitride cermet undergoes a change in microstructure that, under controlled conditions, can greatly improve the strength and fracture toughness of the cement. In the early 1970s, it was discovered that, in the quaternary systems Ti-Mo-C-N and Ti-W-C-N, a miscibility gap exists in the otherwise complete solid solutions among TiC, TiN, MoC, and MoN (Ref 6). Under controlled processing conditions, the homogeneous single-phase solid-solution (Ti, Mo) (C, N) decomposes spontaneously or spinodally into two isostructural phases (α' and α") with nearly identical lattice parameters but differing chemical compositions. The α' is essentially titanium carbonitride that contains virtually all of the nitrogen of the original mixture. The α" phase contains only small amounts of nitrogen but nearly all of the molybdenum or tungsten. The microstructure of vacuum-sintered cermets containing the carbonitride with a nickel-molybdenum binder consists of hard particles; it has a nitrogen-rich titanium carbonitride α' core encased in a molybdenum-rich α" rim. This α" phase exhibits better wettability by the binder alloy during liquid-phase sintering under vacuum and produces a cermet of greatly enhanced strength.

Incremental improvements in deformation resistance and fracture toughness are achieved by further complexing the cermet compositions without changing the essential structural features (Ref 4). Present optimization trends encompass the hard component as well as the binder. In the former, the titanium carbonitride solid solution is diluted with Mo_2C, NbC, TaC, VC, and WC, singly or in combination, up to about 40 wt%. The binder is a solid solution of nickel and cobalt, in varying proportions, and generally amounts to 10 to 15 wt% of the entire cermet composition. The alloy is strengthened composition. The alloy is strengthened by titanium and molybdenum absorbed by diffusion from the hard particles during liquid-phase sintering. Aluminum added initially (for example, by nickel-coated aluminum particles) contributes to a further increase in strength, especially at temperatures encountered in tool-cutting operations (Ref 33).

Cermets exhibiting an entirely different microstructure are also possible (Ref 21). Hexagonal platelets of micrometer size can be dispersed inside spheroidal or otherwise equiaxed grains, and both hard components are bonded by softer metal. These microstructural features are the result either of a direct chemical reaction in the starting ingredients during sintering or of a chemical reaction with an extraneous element. The boron-carbide and zirconium system is an example of the former process; the reaction results in an intimate mixture of ZrB_2 platelets and rounded ZrC_x grains evenly dispersed in the unalloyed zirconium matrix. In reactions involving oxygen in gaseous or solid form and various combinations of hard compounds, a variety of particle geometries can be produced in the binder matrices (Ref 26). Typical systems are AlN-Al, TiN-Ti, ZrN-Zr, and SiO-Al. Oxygen can enter the system directly or from an adjacent source such as Al_2O_3 or $BaTiO_3$ contact faces.

Oxide Cermets

This class of material combines oxide ceramic and metallic constituents on a microscopic scale. Thus, it fits the term cermet in the true sense of the word. More than most other mechanically mixed combinations of interstitial compounds and metallic phases, oxide cermets are negatively affected by poor thermal shock resistance and inadequate fracture toughness that limit their usefulness in a great many situations involving high temperatures and dynamic stresses. Some of these materials, however, possess excellent resistance to oxidation or corrosion at high temperatures, and others exhibit unique physical properties, such as nuclear fission. Generally, oxide cermets can be produced to withstand high-temperature stresses greater than those tolerated by most nonmetallic oxide ceramics.

About a half dozen different oxide-ceramic-metal cermets have been developed; several are used industrially. Generally, they differ from oxide dispersion-strengthened alloys by having a ceramic component that is coarser by several orders of magnitude. Also, in most of these cermets, the volume fraction of the oxide is considerably larger than that in oxide dispersion-strengthened materials.

Silicon Oxide Cermets. The classic combination of ceramic and metal can be found in the metallic friction materials, in which the ceramic produces the hard phase. Industrial machinery clutches and heavy-duty brakes, including those for airplanes, are the major fields of application. The ceramic phase is a relatively coarse (for example, 200 mesh) granular SiO_2 to which Al_2O_3 sometimes is added; it amounts to about 2 to 7 vol% of the material. The metallic matrix consists of brass or bronze compositions, and it also can contain iron and lead. All materials have graphite dispersions to provide some degree of lubrication. Conventional P/M techniques, as well as pressure sintering, are employed to produce the friction materials in the form of disks that fit into special attachment cups or plates and strips that are bonded directly to the structural steel support.

Aluminum Oxide Cermets. In this type of cermet, the ceramic is the dominant phase and the metal serves only as a binder. Aluminum oxide cermets are used in cutting tool bits for very high-speed machining with light chip removal (Ref 34). The oxide is milled to great fineness (usually only 1 to 3 μm), then mixed and milled together with nickel powder. Because the binder phase rarely exceeds 5 to 10 vol%, the cermet is very brittle after pressing and sintering, and press lubricants and organic binders are required to facilitate handling. Sintering is carried out in dry hydrogen, in dry nitrogen, or, preferably, in vacuum at temperatures of about 1450 to 1550 °C (2640 to 2820 °F). Finishing is a delicate operation.

A different type of aluminum oxide cermet has been used in the past for high-temperature, heat-resistant applications, such as the furnace components, jet flame holders, pouring spouts, flame protection rods, and seals. These applications met with only limited commercial success over the years. These items were made from complex compositions with a small mass percentage of TiO_2 in the ceramic phase and with molybdenum replacing up to one-fifth of the metallic chromium as the bonding matrix.

However, a similar but less complex composition is used to produce thermocouple protection tubes, which enjoy a solid and expanding market (Ref 35). The tubes are made of a binary 77% Cr and 23% Al_2O_3 cermet. The standard tubular product has an outside diameter of 22 mm (0.876 in.) and an inside diameter of 16 mm (0.625 in.); it is closed at one end of the 910 mm (36 in.) long unit. Other fabricated tubes up to 75 mm (3 in.) in diameter and 600 mm (24 in.) long are on the market.

In the manufacture of these tubes, the powder mixture is ground to a particle size of about 10 μm. Consolidation is achieved by slip casting, cold pressing, or hydrostatic pressing, followed by high-temperature sintering at 1560 to 170 °C (2840 to 3090 °F). The furnace atmosphere is high-purity hydrogen that contains controlled amounts of water vapor to cause surface oxidation of the chromium particles. The chromium oxide diffuses into the alumina, forming a solid solution at the contact areas that results in strong bonds between the grains (Ref 36). Some typical properties of this type of cermet are listed in Table 4. Figure 19 shows the effect of temperature on the transverse rupture strength, the tensile strength, and the stress-rupture strength of aluminum-oxide cermets.

Table 4 Composition and properties of aluminum oxide cermets

Property	**Cermet**	
	Cr-Al_2O_3	**Cr-Al_2O_3**
Composition, wt%		
Chromium	72	77
Al_2O_3	28	23
Density, g/cm^3 (lb/$in.^3$)	5.9 (0.21)	5.9 (0.21)

Source: Ref 35, 36

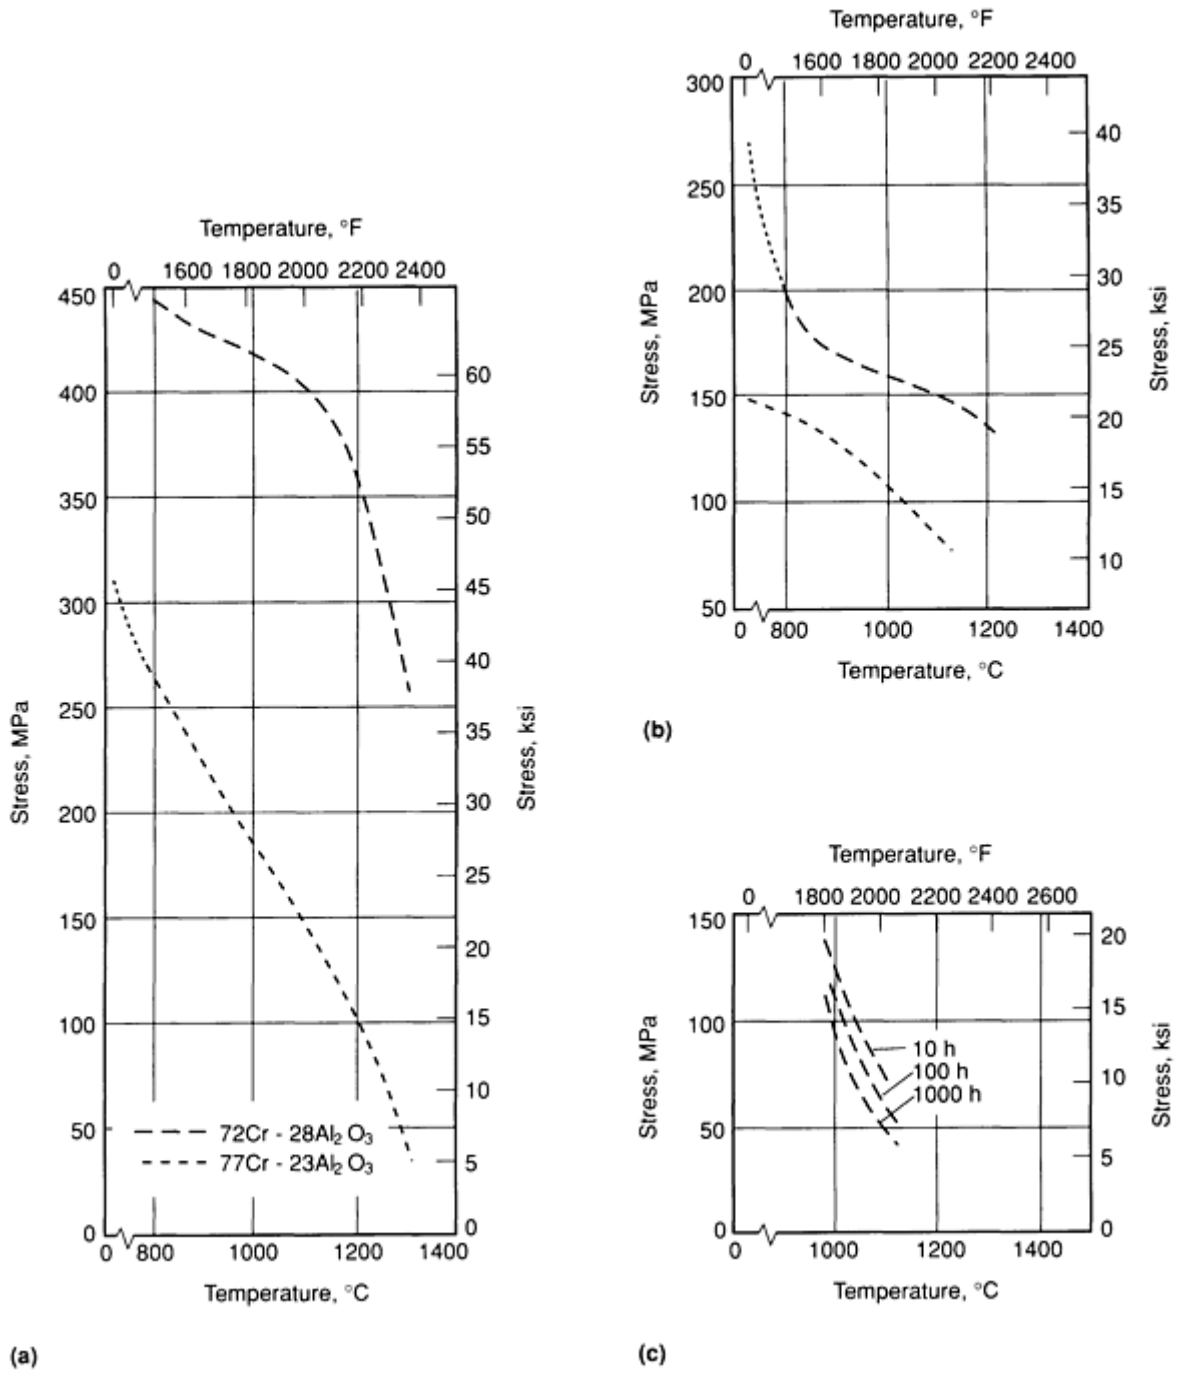

Fig. 19 Effect of temperature on the strength properties of aluminum oxide-chromium cermets. (a) Transverse rupture strength. (b) Tensile strength. (c) Stress-rupture strength. Source: Ref 35, 36

The chromium content has a significant bearing on the creep resistance of these cermets in the 1380 to 1530 °C (2515 to 2785 °F) temperature range (Ref 37). With up to about 25 vol% Cr, the Al_2O_3 forms a coherent matrix, and the chromium occurs mainly as a statistically distributed phase. For higher chromium concentrations, a network of the metal forms that is fairly continuous at 50 vol%. Consequently, the dominance of the creep strength of the Al_2O_3 is lost as the formation of the metallic network becomes complete.

Many other metals have been mated with Al_2O_3 on an experimental basis (Ref 38, 39, 40) with the objective of developing serviceable, high-temperature cermet materials that have acceptable engineering properties. Metals used in these studies include nickel, cobalt, iron, molybdenum, tungsten, copper, and silver; the main effort was directed at a better understanding of the bonding mechanism. None of these combinations, however, has achieved commercial realization.

Lately, considerable interest has been generated in aluminum as a matrix metal for Al_2O_3, and some ingenious fabrication methods, such as solid-state bonding and reaction infiltration (Ref 41), have been used to produce isometric and complex configurations as well as sheet structures. Because aluminum is the dominant phase, and the Al_2O_3 serves primarily as a reinforcement, these materials should be classified as metal-matrix composites.

Magnesium Oxide Cermets. Chromium also has been used as the metallic phase in magnesia-base cermets (Ref 36). Results of experiments with various metal-ceramic ratios have been reported in the literature, with the magnesium oxide (MgO) fraction ranging from 50 vol% (Ref 38) to as low as 6 vol% (Ref 42). None of these compositions has exhibited a combination of properties that is superior to that of the Al_2O_3-Cr cermets. However, in the MgO-Cr system, an intermediate reaction product (a $MgO{\cdot}Cr_2O_3$ spinel) was observed between the ceramic and metal phases (Ref 36).

The material containing 6% MgO is extrudable and exhibits elongation of 10% and more at room temperature after sintering of the extruded powder mixture (Ref 42). Yield and tensile strengths are about 200 and 350 MPa (30 and 50 ksi) at temperatures up to 600 °C (1110 °F), but they taper off at higher temperatures. These strength properties can be maintained at the higher level up to about 1000 °C (1800 °F) by alloying the chromium with a small amount (for example, 1%) of niobium; however, this degrades the ductility. A measurable degree of room-temperature elongation was also observed in a 30 vol% Cr material that was made by hydrostatically compressing a coarse powder mixture and sintering it at 1600 °C (2900 °F). Unfortunately, nitrides form in this highly refractory material if it is heated in air above 1100 to 1200 °C (2000 to 2200 °F); this causes the cermet to rapidly lose its ductility.

Nickel, iron, cobalt, and alloys of these metals with chromium have also been investigated for use in MgO-base cermets (Ref 38, 40). The MgO-Co cermets, in particular, exhibit interesting mechanical and electrical properties over a wide composition range (Ref 40). For example, the stress-rupture strength at 850 °C (1560 °F) for 100 h of a cermet with 50 wt% Co reaches a peak of 77 MPa (11.2 ksi). In spite of its almost continuous metal phase (~30 vol%), this cermet is an insulator. There is no abrupt change in strength as the material transits from high to low electrical resistance.

Beryllium Oxide Cermets. According to Ryshkewitch (Ref 43), beryllia cermets bonded with tungsten possess better thermal shock resistance and soften at a higher temperature than most of the chromium-alumina materials. They have been used successfully as crucibles, and at one time they were proposed for use in rocket nozzle throat inserts. Ryshkewitch has also proposed the use of combinations of beryllia with up to 50 vol% beryllium metal for high-temperature thermal insulators and nose cones for reentry bodies, despite the extreme brittleness and toxicity of these materials.

Zirconium Oxide Cermets. Zirconia is another ceramic that can be bonded with metal to give useful refractory products. Even when combined with only small amounts of metal, such as 5 to 15 at.% Ti, strong and thermal shock-resistant materials can be produced. These materials are suitable for such applications as crucibles for the melting of rare and reactive metals (Ref 44, 45). If the oxide is combined with molybdenum, the resulting cermet exhibits excellent corrosion resistance against molten steel, good high-temperature strength, and limited sensitivity to thermal shock (Ref 46), especially when the metal content is approximately 50 vol%. Applications include thermocouple sheaths for temperature measurements of metallic melts and extrusion dies used for forming nonferrous metals. Zirconium oxide cermets with a somewhat higher ceramic content, such as 60 vol%, are suitable for use in wear-resistant parts (Ref 46).

Thorium Oxide Cermets. Cronin (Ref 47, 48) discusses metal-ceramic materials in which finely divided thoria is combined with molybdenum or tungsten to form a number of products used in the electronics industry. The principal P/M operations performed on the oxide and metal powders include screening through 325 mesh screens, weighing, dry blending, compacting, sintering in a reducing atmosphere (at 2000 °C, or 3630 °F, for the molybdenum material; at a somewhat higher temperature for tungsten), and finish machining to specified sizes and tolerances.

These products take the form of cylinders and sleeves in high-power pulse magnetrons that can deliver up to several million watts. They are formed into simple disk shapes for use in evacuated electron beam tubes (klystrons), traveling wave tubes, and special-purpose guns. In some high-voltage operations, the thermionic emission cathodes operate over a wide temperature range (1000 to 1700 °C, or 1830 to 3100 °F), but the range is narrower (~1300 to 1500 °C, or 2370 to 2730 °F) for cathodes in the average tubes. Because the ThO_2 is present in the refractory metal as a well-dispersed, fine-particulate minor phase that rarely exceeds 4 to 5 vol%, the materials are usually referred to as a dispersion-type alloy rather than as a cermet in the literature (Ref 47, 48).

Uranium Oxide Cermets. These cermets are used in the fuel elements of nuclear reactor cores. They consist of a dispersion of the fissionable UO_2 in a sintered matrix of aluminum (Ref 49), stainless steel, or tungsten (Ref 50). Compared to plain

oxide fuel, these cermets have better retention of fission products and an increased thermal conductivity, which inhibits melting at high operating temperatures. Usually, to ensure a continuous and coherent metal matrix and to limit the radiation damage caused by the fissionable UO_2, the ceramic component is kept below 35 vol% of the cermet. The cermet is contained inside structural stainless steel supports, such as casings or frames.

Powder metallurgy fabrication details for uranium oxide cermets are given in Ref 51. The UO_2 may vary in purity, depending on its processing, and should be of stoichiometric composition. The ceramic particles are fairly coarse, and they must be strong enough to withstand subsequent working without fracturing. Typical particle sizes are 44 μm minimum (+325 mesh) for bicrystals, 35 to 44 μm for monocrystals, and 40 to 50 μm for the diameter of agglomerates of very fine (0.1 to 1 μm) irregular crystals. These UO_2 powders are fired at 1600 to 1700 °C (2900 to 3100 °F) in hydrogen to increase particle size, strength, and density (in the case of the agglomerates). Small additions of TiO_2 increase the sintering rate. Procedures used conventionally for mixing oxide and metal powder must be modified, that is, glovebox or other environmentally controlled operations must be used because of the strong radioactivity of the UO_2. Where large differences in density between the ceramic and metal exist, tumbling is inadequate to prevent segregation, and ball milling is required.

Table 5 lists the density and some physical and nuclear properties of the UO_2 and the various matrix metals in cermet fuels. Standard techniques are used to process the metal-ceramic powder mixture into consolidated cermet fuel. Cold pressing achieves higher densities when pressing lubricants are employed. Because high-temperature sintering usually is inadequate for meeting the high-density and dimensional specifications of the fuel element, either cold working and sizing or machining is required. Some oxide particle fragmentation and waste is unavoidable in this case. Alternate methods of consolidation that yield higher densities and minimize fragmentation, but increase production cost, include hot pressing and hot-working processes such as extrusion, swaging, rolling, and drawing.

Table 5 Properties of uranium dioxide and candidate matrix metals in nuclear reactor fuel cermets

Material	**Thermal absorption cross section, barns/atom**	**Density**		**Melting point**	
		g/cm^3	**lb/in.^{3}**	**°C**	**°F**
Uranium dioxide (0.53 uranium volume ratio)	0.002	10.96	0.397	2500	4530
Beryllium	0.01	1.848	0.067	1277	2330
Magnesium	0.06	1.738	0.063	650	1202

Cermets containing 50 vol% each of UO_2 and tungsten have been fabricated into fuel elements for gas-cooled reactor cores that have coolant temperatures of 1500 °C (2730 °F) and higher. This fabrication has been done by such methods as high-energy compaction, isostatic or vacuum hot pressing, powder rolling, and coextrusion (Ref 50).

Other Oxide-Containing Cermets. Recent high-technology developments have increased the demand for new materials with properties tailored to fit a particular application. A typical case in point is the need for cost-effective electronic packaging materials such as semiconductor substrates or heat sinks. These materials require unique combinations of electrical and thermal conductivities, adequate strength for assembly, and a strictly controlled thermal expansion coefficient that allows mating with silicon or other semiconductor substances. Particulate composites or cermets can best fulfill the requirements of the particular system because they offer flexibility in combining the properties of the respective metallic and ceramic components.

For example, a composite of iron and cordierite ($2Al_2O_3$-$2MgO$-$5SiO_2$) was developed to achieve a specific and controlled thermal expansion (Ref 52). When processed from powders by static cold pressing in a die and then sintering with the aid of a 0.2 vol% B addition, a fully dense cermet body results that exhibits good interfacial bonding. In compositions of up to 40 vol% cordierite, the ceramic phase dispersed in the iron matrix controls the thermal-expansion coefficient.

Metal-Matrix High-Temperature Superconductor. Another oxide-containing cermet has been developed for a high-temperature superconductor part. In this cermet, a ceramic-copper oxide complex is combined with an easily formable metal for the purpose of rendering the composite fabricative. Copper is a good choice for the metallic phase because it has good strength, ductility, and work-hardening characteristics combined with favorable electrical and thermal conductivities. These properties make copper an outstanding forming aid for the ceramic superconductor as a matrix, as encapsulation, or as both. For the severe working reductions required for bar and wire fabrication, intimate interfacial bonding between the ceramic and the metal is essential. One method of accomplishing this is grinding the $YBa_2Cu_3O_x$ and copper into ultrafine powders, mixing them intensively, and then subjecting the mix to shock wave consolidation inside copper tubing (Ref 53).

Carbide and Carbonitride Cermets

Metal-bonded carbide or carbonitride materials are probably the most important group of cermets at the present time. Logically, all metal-bonded tungsten carbide and titanium carbide materials should fall into the category of cermets. However, it has been customary in the industry to designate all cobalt-bonded tungsten carbide compositions as cemented carbides. This importance class of cermets is discussed in the article "Cemented Carbides" in this Volume. This section focuses on the other categories of metal-bonded carbide or carbonitride materials, such as:

- Titanium carbide cermets bonded with nickel of steel
- Titanium carbonitride cermets
- Steel-bonded tungsten carbide cermets
- Chromium carbide cermets
- Metalloid carbide-base cermets

Nickel-Bonded Titanium Carbide Cermets

This class of cermets has received a great deal of attention in recent years. The development of high-thrust turbojet engines for military aircraft, and the advent of commercial jet transports shortly thereafter, exposed the need for better materials for certain critical stationary and, in particular, moving parts in the power plants of these aircraft. A major effort has been mounted to develop TiC cermets for use in these applications.

The underlying motivation for the large development effort conducted in the United States and Europe throughout the 1950s was the desire to combine, on a microscale, the high strength, the relatively good oxidation resistance at elevated temperatures, and the low specific gravity of a ceramic with a metallic alloy phase that imparts good resistance to mechanical and thermal shock. In these TiC cermets, the metallic phase was varied over a broad range, that is, from about 30 to 72 wt%. The principal alloys were Ni-Mo, Ni-Mo-Al, Ni-Cr, and Ni-Co-Cr types (Ref 54, 55, 56). Some more-complex alloys similar to commercial superalloys were also used to bond the TiC. Where high-temperature oxidation resistance of the binder metal was inadequate, such as in Ni-Mo, this property was enhanced in the cermet by complexing the ceramic phases through prealloying a small amount of carbon and niobium, tantalum, or titanium in the solid-solution (Nb, Ta, Ti)C with the TiC (Ref 55).

Titanium carbide powder is produced industrially by a reaction that uses TiO_2 and carbon powders as starting materials. Carburization occurs through the gas phase (carbon monoxide) at a reaction temperature of 1600 to 1700 °C (2900 to 3100 °F). The reaction is terminated only when the free-carbon content of the product is below 0.8%. High-quality powder has only 0.1 to 0.2% free carbon and a minimum of 80.0% Ti.

Two manufacturing routes have been used to produce these cermets, conventional cemented-carbide production practices and infiltration. The first, still in use today, employs uniaxial or isostatic compaction of the ceramic and metal powder mixtures, presintering, shape generation by machining, high-temperature vacuum sintering, and finishing. With fastidious manipulations, particularly during the early processing steps, very complex shapes have been produced to a high degree of dimensional accuracy with this technique. Blades with different airfoil twists, and even completely integrated turbine rotor units with the individual blade foils hogged out of the disk have been made by these cemented-carbide practices.

If high stress-rupture strength and low creep strength at operating temperatures in the 1000 to 1100 °C (1830 to 2000 °F) range are to be derived from the TiC phase alone, the binder content must be low (comparable to that in cemented tungsten carbides). However, TiC cermets with low binder contents have insufficient toughness. Increasing the metal content improves toughness only slightly, and it degrades the strength properties of the material.

The brittle nature of the cemented TiC cermets affected their performance as gas turbine blades. In engine tests reported in Ref 57, blade failures occurred in the base of the fir tree roots, due to insufficient notch toughness; at the tips of the airfoil, due to low resistance to impact by hard carbon particles; and across the airfoil, due to an incapacity to accommodate dynamic interference with protrusions or bows of the stationary shroud by some degree of plastic deformation. Low fatigue resistance near the tip of the deeply scalloped foils was another shortcoming of the material.

Considerable progress was made toward production of an acceptable TiC cermet for these critical turbojet engine applications by increasing the amounts of cermet material and simultaneously strengthening the binder phase through alloying. The composition was varied in accordance with the strength and ductility requirements for different parts of the blades; this was accomplished by using the infiltration process for making graded products. Alloy accumulations were produced at the root and at the edges and tip of the airfoil (Ref 18, 31, 58, 59).

The goal of developing serviceable engine components made of infiltrated carbide cermets was stopped short by simultaneous developments in industrial vacuum metallurgy that produced advanced precipitation-strengthened superalloys capable of operating reliably and for sustained periods at increasingly higher gas temperatures. However, titanium carbide cermets have low density, and they have better high-temperature oxidation resistance than that of cobalt-cemented tungsten carbide; thus, they are still used in several less-sensitive applications, especially those in which such properties are advantageous. Examples are seals and bearings operating at elevated temperatures, sliding contacts, and, especially, wear-resistant parts.

A typical nickel-bonded titanium carbide grade for seal ring applications contains 25 wt% Ni, 8 wt% Mo, 6 wt% NbC, 3 wt% WC, and a balance of TiC. The physical and mechanical properties of this grade are:

Property	**Amount**
Density, g/cm^3 ($lb/in.^3$)	6.1 (0.221)
Thermal conductivity, W/m · K (Btu · in./ft^2 · h · °F)	17.99 (124.8)
Mean coefficient of thermal expansion, μm/m · °C (μin./in. · °F)	8.4 (4.67)
Hardness, HRA	89.0

Transverse rupture strength, GPa (ksi)	1.7 (247)
Ultimate compressive strength, GPa (ksi)	4.2 (610)
Compressive yield strength, GPa (ksi)	3.8 (550)
Compressive modulus of elasticity, GPa (10^6 psi)	394 (57.2)
Shear modulus, GPa (10^6 psi)	156 (22.6)
Poisson's ratio	0.264
Fracture toughness (K_{IC}), MPa $\cdot \sqrt{m}$ (ksi $\cdot \sqrt{in}$)	10.6 (9.64)

Steel-Bonded Titanium Carbide Cermets

Titanium carbide cermets with steel binders are a direct outgrowth of extensive development work on infiltrated TiC cermets with nickel-chromium and cobalt-molybdenum alloy binders. Development work in the 1950s was directed at solving the severe material problems encountered in the hot end of jet engines and gas turbines. Subsequent TiC-base cermet development efforts focused on the broad areas of tooling and wear.

A new cermet had to fulfill three main requirements to compete effectively in a crowded materials market for highly wear-resistant components and long-lasting tools. New cermets were expected to:

- Be machinable in the annealed condition with conventional cutting tools
- Be hardenable with conventional equipment, without decarburization and without experiencing an undue change in size
- Wear well after hardening on tough applications, giving a performance equivalent or superior to that of conventional cemented tungsten carbide.

Within a composition range of about 25 to 50 vol% TiC, a steel-bonded titanium carbide cermet fulfills all three of these requirements. Generally, the addition of titanium carbide by P/M methods alters the properties of a given steel in the direction of higher hardness, higher wear resistance, and higher modulus of elasticity; however, the addition is detrimental to elongation, impact, and fatigue properties.

The upper limits for TiC additions are reached when the cermet is no longer machinable or hardenable without quench cracking. The lower limits are not as well defined. Liquid-phase sintering becomes impractical when a compact with low titanium carbide content loses shape in the process. Figure 20 shows hardness as a function of heat-treating temperature in quench-hardened TiC cermets, and as a function of aging time in precipitation-hardened TiC cermets.

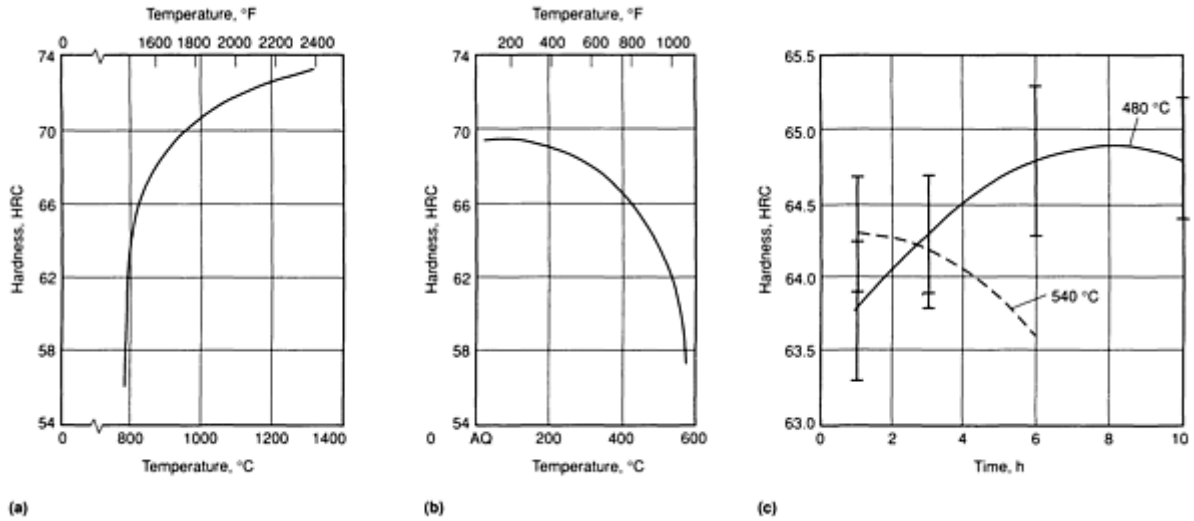

Fig. 20 Room-temperature hardness of heat-treated titanium carbide cermets with ferrous metal binders. (a) Effect of austenitizing temperature on a quench-hardenable material. (b) Effect of tempering temperature on a quench-hardened material. AQ, as-quenched. (c) Effect of aging time at temperature on two materials precipitation hardened at different temperatures

Depending on the choice of steel binders, some grades of steel-bonded titanium carbide have attractive oxidation-, corrosion-, and heat-resistant properties. The proportion of hard phase in the alloy governs the changes in physical and metallurgical properties, following the rule of mixtures.

Comparison of Heat-Treatable Steel-Bonded Carbides With Cobalt-Bonded Tungsten Carbide (Ref 60). In the general field of cemented carbides, the cobalt-bonded grades of tungsten carbide are the ones that have been developed to the greatest extent during the past three decades. The compositions, physical properties, methods of manufacture, and applications of this group of materials are reviewed in the article "Cemented Carbides" in this Volume.

In many applications, cobalt-bonded tungsten carbide has certain disadvantages. The properties or a steel-bonded titanium carbide can be compared with those of cobalt-bonded tungsten carbide:

- Steel-bonded titanium carbides respond to heat treatment and are machinable by conventional means when the binder is in the annealed condition. Cobalt-bonded tungsten carbide, on the other hand, does not respond to heat treatment and is not readily machinable by conventional means
- Fully hardened steel-bonded carbide can be tempered at varying temperatures, thereby obtaining greater toughness than the cobalt-bonded tungsten carbide. However, this gain in toughness is accompanied by some sacrifice in hardness
- Cemented tungsten carbides are high-modulus materials. Steel-bonded titanium carbides have moduli that are not much higher than those of steel
- The coefficients of thermal expansion of the steel-bonded carbides are nearer to those of steel than are those of the cemented tungsten carbides
- Both the tungsten carbide and titanium carbide products can be brazed. In the case of the latter, the braze must have a melting point higher than the austenitizing temperature. Hardening is performed after the brazing operation
- Steel-bonded carbides consisting of 45 vol% TiC have about one-half the density of the available grades of tungsten carbides. This is an important consideration when designing wear-resistant components for astronautical or aeronautical vehicles or for high-velocity rotating equipment
- The steel-bonded carbide compositions contain no cobalt. This is an advantage because cobalt has an exceedingly long half-life, and materials containing cobalt therefore retain radioactivity after exposure to nuclear radiation. Once irradiated, they are difficult to handle for long periods of time
- Most of the steel-bonded titanium carbides and all of the cobalt-bonded tungsten carbides are magnetic. The steel-bonded materials, however, have a much higher percentage of binder, which is generally

ferromagnetic. Thus, the steel-bonded materials can be held in a magnetic chuck during such operations as surface grinding

- Raw materials for steel-bonded titanium carbide are inexpensive and abundant in the United States. Tungsten and cobalt, on the other hand, are relatively high on the list of strategic materials
- Unlike the angular shape of tungsten carbide, the shape of titanium carbide particles, when sintered in a steel matrix, is rounded (Fig. 21). When these very hard and rounded titanium carbide particles are exposed at the surface, they resist cold welding and provide inherent lubricity and a low coefficient of friction
- Certain tungsten carbide compositions give better results in important applications involving severe abrasive wear and impact, such as coal mining bits, oil well drilling tools, and cold-heading dies. Cobalt-bonded tungsten carbide, with minor additions of titanium, tantalum, and niobium carbides, also dominates the large field of cutting tools

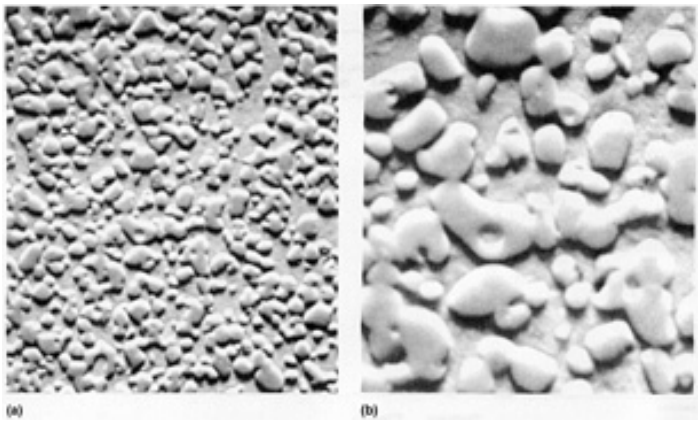

Fig. 21 Rounded shape of titanium carbide particles in a steel-bonded cermet. (a) 750×. (b) 2000×. Courtesy of Alloy Technology International, Inc.

Comparison of Steel-Bonded Titanium Carbide Cermets With Other Wear-Resistant Material. The wear resistance of steel-bonded carbides is far greater than that of even the highly wear-resistant machinable tool steels. In applications where tool steel blanking and forming tools have been replaced by steel-bonded carbide tools, 10- to 20-fold improvements in performance have been observed.

When compared with cast cobalt wear-resistant materials, the steel-bonded carbides have the advantage of machinability, hardenability, as well as wear resistance (Ref 60, 61, 62, 63).

Titanium Carbide Cermets With Various Steel Binder Compositions. The wetting and solubility characteristics of titanium carbide make it compatible with a great many alloy steels for formulating steel-bonded carbide (SBC) cermets. From the many possible combinations, a few significant ones have been developed into actual cermet grades. Table 6 gives the compositions, properties, and heat treatments of several quench- and precipitation-hardening SBC grades.

Table 6 Properties of steel-bonded titanium carbide cermets

Grade	Carbide content, vol%	Matrix alloy type	Heat-treating cycle, °C (°F)/h	Tempering cycle, °C (°F)/h	Hardness, HRC		Relative machinability[(a)]	Maximum working temperature		Density

(a) A rating of 1 indicates the greatest ease of machining.

(b) Unnotched specimen.

(c) Tested by heating the specimen to 1000 °C (1830 °F) and oil quenching; the cycle is repeated until a crack appears.

(d) Specimen did not fail.

Grade C is a general-purpose cermet with a low-chromium, low-molybdenum binder steel composition and 45 vol% TiC. It is comparatively tough and readily machinable in the annealed condition, and it quench hardens to a level of 70 HRC. It is well suited for tool and wear applications in which operating temperatures do not exceed 190 °C (375 °F). Beyond this temperature, the alloy steel binder will overtemper, with a resulting loss of hardness and wear resistance.

Grade CM has a high-chromium, low-molybdenum steel binder composition and contains 45 vol% TiC. This cermet is more heat resistant than grade C and has slightly lower toughness, good machinability, and reliable hardenability from 1080 °C (1975 °F). It will withstand maximum working temperatures of 525 °C (975 °F).

Other SBC grades have lower TiC contents in order to enhance their toughness and thermal shock resistance. Some grades with age-hardening characteristics allow for higher maximum operating temperatures and greater resistance to oxidation and corrosion. Table 7 gives a list of proven applications for TiC cermets.

Manufacturing Steel-Bonded Titanium Carbide Cermets. Two principal manufacturing processes are used for producing standard or special annealed blanks of steel-bonded cermets. The first process, shown in Fig. 1, includes these steps:

- Preparation of powder mixtures by ball milling titanium carbide, iron, carbon, and elemental alloying metals in powder form in the proportions needed for obtaining a specific alloy steel binder
- Static or hydrostatic cold compaction
- High sintering under vacuum in the presence of a liquid phase
- Hot isostatic re-pressing and annealing

The second process, which is used particularly for large pieces or special forms, includes these steps:

- Static or hydrostatic cold compaction
- Encapsulation in a steel can
- Hot isostatic pressing and annealing
- Decanning

Either process yields a product that is largely free from porosity, flaws, or other internal defects. The latter process is also used for bonding cermet pieces to a steel backup support or extension.

Hardening of steel-bonded cermets, such as those listed in Table 6, is accomplished by several processes that are usually selected in accordance with the availability of suitable equipment in the fabrication plant. Oxidation and decarburization should be avoided. Cracking, distortions, and size changes are minimal because only about one-half of the mass is transformed to martensite and the titanium carbide is permanently hard and does not participate in the process. Often, finish grinding after hardening can be avoided because the amount of size change is minimal.

Machining and Grinding. By purchasing suitable standard annealed blanks, a reasonably well-equipped machine or tool shop can produce complex tool or wear parts without nontraditional machining methods such as electric discharge machining. In the annealed condition, steel-bonded TiC cermets, such as those listed in Table 6, can be machined by conventional methods. Most machining operations work better dry than with lubricant. Taps, even when new, should be degreased before use.

Grinding the cermet in the annealed condition achieves a fine surface finish with rapid stock removal. For high-precision parts or tool components, finish grinding is usually accomplished with medium-grain aluminum oxide wheels operating at a relatively high transverse table speed without coolant. Heavy grinding equipment gives good results. Form grinding with form-dressed wheels in the annealed condition and regrinding, if necessary, after hardening together constitute a relatively inexpensive process for creating complex forms in die sections or forming rolls.

Titanium Carbonitride Cermets

Titanium carbonitride cermets, which are widely used as cutting tool materials, evolved from the development of titanium carbide cutting tools in the 1950s. The early cermet cutting tool materials contained 70% TiC, 12% Ni, and 18% Mo_2C. These sintered compositions had densities of 6.08 g/cm^2, Rockwell hardnesses of 92 HRA, and transverse rupture strengths of about 860 MPa (125 ksi). Because they combined high hardness, substantial strength, and low thermal conductivity, they were considered especially suitable for high-speed light-cut machining operations (Ref 4).

Subsequent development work in major industrial countries led to new complex cermet cutting tool compositions based on the titanium carbide and nickel-molybdenum cermet tool material. The titanium carbide cermets with nickel-molybdenum binders were promising high-speed tool materials, but they were inadequate in such areas as toughness the thermal shock resistance. This motivated research efforts such as the two-pronged approach to enhancing cutting performance by strengthening the binder phase and improving the carbide phase (Ref 33). For the former, aluminum seemed to be the most promising binder metal alloying element. Using 0.075 mm (0.003 in.) maximum nose deformation as the tool wear criterion, optimum cutting speeds were achieved with additions of about 7% Al to the matrix (Fig. 22). The maximum strength of the alloy appeared to peak with a content of about 7% (Al + Ti).

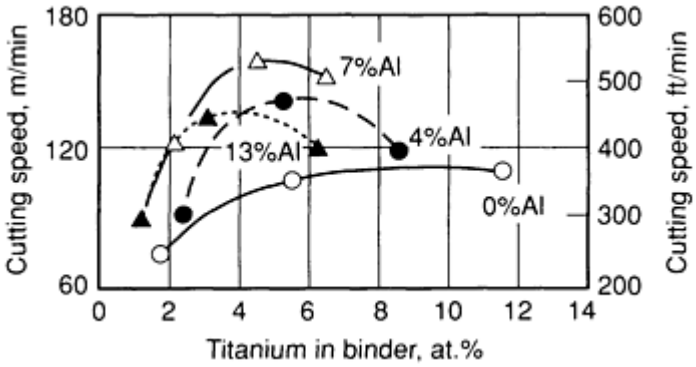

Fig. 22 Cutting speeds for 0.075 mm (0.003 in.) nose deformation versus atomic percent of binder titanium for materials containing four different levels of aluminum. Source: Ref 33

After reaching the optimum strengthening effect of the matrix by using an empirical approach to the problem, the research effort used the same approach in its investigation of ways to strengthen the carbide phase. Tool nose deformation resistance showed a clear increase with vanadium carbide (VC additions in solid solution with the TiC hard phase. At a level of 5% VC, the cutting speed for equivalent deformation was much higher than that of material with no addition. Higher VC additions had a negative effect (Fig. 23). However, further substantial improvements in deformation resistance were achieved by increasing TiN contents, probably because of the grain size refinement and solid-solution hardening effect of this material. Titanium nitride additions to a cermet alloy containing aluminum and vanadium carbide yielded greater improvements in deformation resistance than when each constituent was added individually. Along with increased deformation resistance, the TiN-modified cutting alloys also exhibited greater resistance to thermal cracking, an important factor for applications involving interrupted cuts, such as those which occur in milling operations.

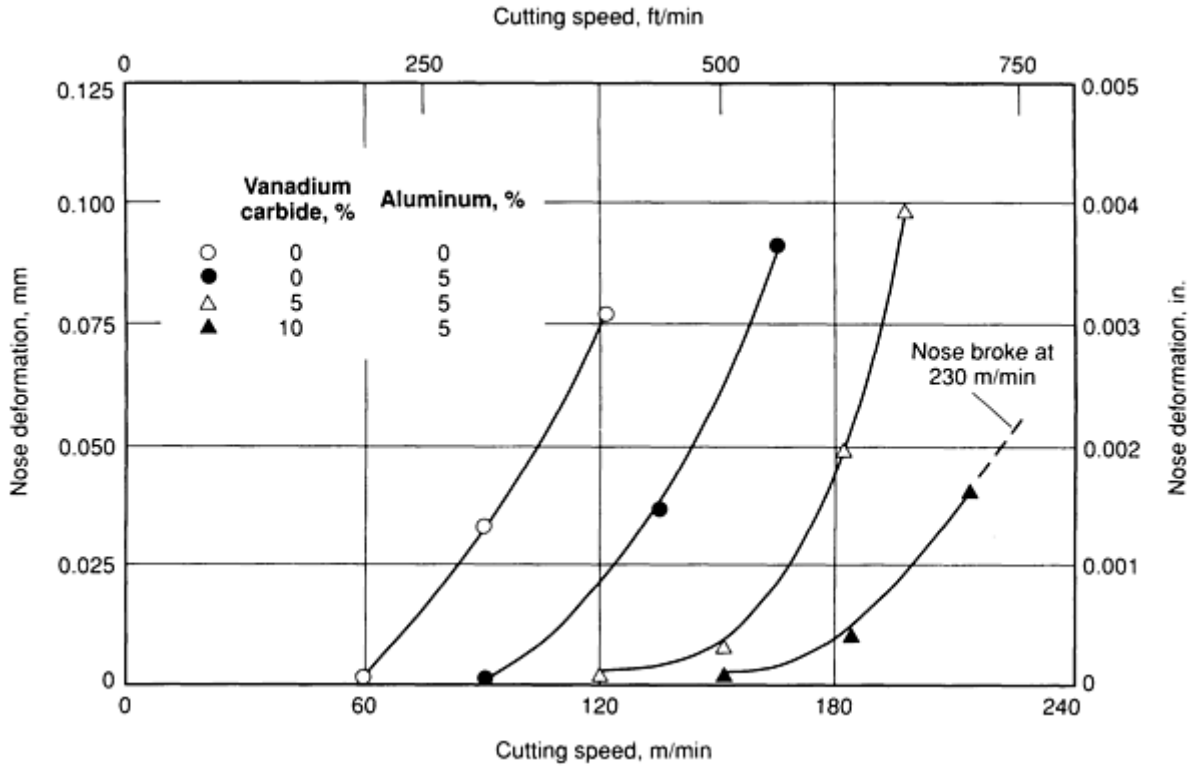

Fig. 23 Tool nose deformation versus vanadium carbide content of cutting tool materials containing 0 or 5% Al in the binder. Material cut was 4340 steel with a hardness of 300 HB. Source: Ref 33

It is interesting to note that in the final analysis, aluminum was no longer required for any of the improvements obtained by adding various strengthening elements to the original TiC-N-Mo composition. Compositions containing TiC-VC-TiN-Ni-Mo were optimized by adjusting the amount of each constituent to obtain the required properties for specific machining applications. With these complex cermets, harder workpieces can be machined at higher cutting speeds, even in applications with intermittent cutting, such as milling.

A somewhat more theoretical approach to the problem of improving on the original TiC-Ni-Mo cutting cermet was used to develop important alternative compositions of titanium carbonitride cermets. These materials were patented in 1976. According to the patent abstract, "The carbonitride alloys are based on selected compositions located within the spinodal range of the systems [that] [have] titanium and group VI metals M as [their] base metals and [have] a gross composition falling within the area ABDE of [Fig. 24]. The binder is selected from metals of the iron group and metals of the group VI refractory transition metals and comprises between 5 and 45 weight percent of the composition" (Ref 64).

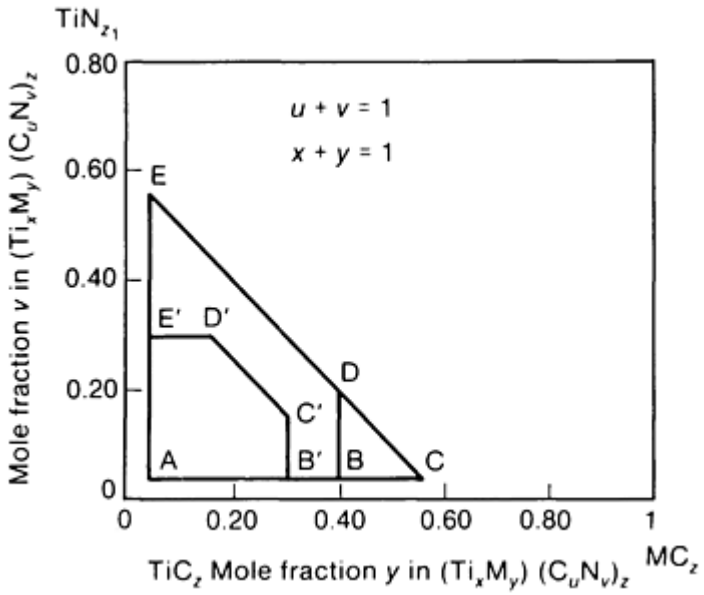

Fig. 24 Preferred compositions of titanium carbonitride cermets. M, molybdenum and/or tungsten; *z*, number of moles carbon and nitrogen divided by the number of moles titanium and M; *z* is variable between the limits 0.80 and 1.07. Source: Ref 64

Figure 24 shows the complex relationship between, and compositional limitations of, the TiN and CN factions that need to be accommodated to achieve desirable spinodal alloys with superior cutting properties. According to the patent abstract, this figure "defines the gross composition of the carbonitride solid solution $(Ti_x\ M_y)\ (C_u\ N_v)_z$ used as input material in the fabrication of the alloy composition" covered by the patent.

Properties. The microstructure of a typical spinodal titanium carbonitride at 1500× (Fig. 25) shows typical isolated angular carbides of much larger size than the surrounding carbides; they are more or less uniformly distributed throughout the field. Each larger carbide is separated from the next carbide of similar size by a distance of about 1 to 3× its size. Figure 26 shows schematically the α_1 core phase of the cermet, consisting of titanium carbonitride, and the α_2 rim phase, consisting of α_1 enriched with molybdenum carbide. The latter is the transition phase, which is responsible for the strength of the cermet. A typical composition has a hardness of 93 HRA, a density of 6.02 g/cm^3, and a transverse rupture strength of about 1550 MPa (225 ksi). A tougher grade of similar composition (produced by Teledyne-Firth-Sterling) has a hardness of 91.8 HRA, a density of 6.30 g/cm^3, and a transverse rupture strength of 2070 MPa (300 ksi).

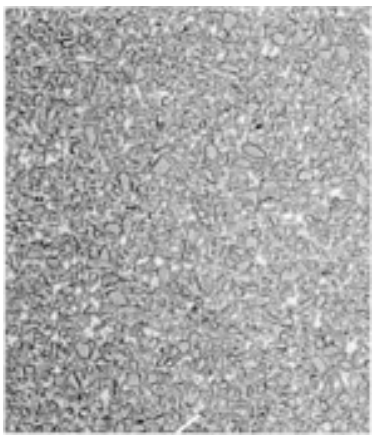

Fig. 25 Microstructure (at 1500×) of a typical spinodal titanium carbonitride cermet. The manufacturing process, called spinodal decomposition, minimizes grain growth and consistently produces nonporous material. Courtesy of Teledyne-Firth-Sterling

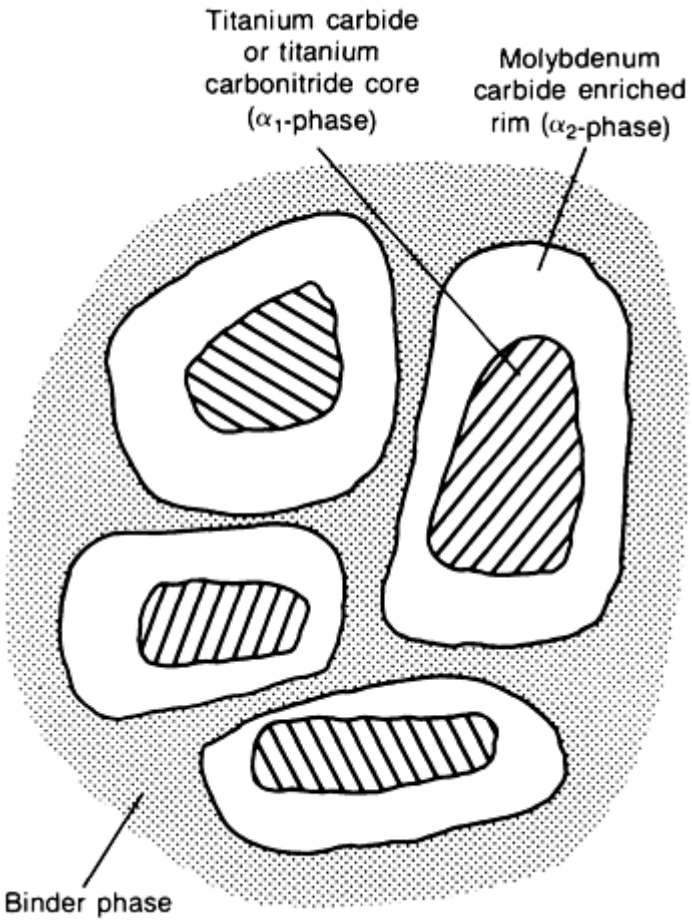

Fig. 26 Schematic of the microstructure of a titanium carbonitride cermet

Based on general experience with cemented carbides, the transverse rupture strength of the titanium carbonitride cermet would be expected to vary with the proportion of binder metal in the overall composition. Figure 27 shows this relationship in the range of 10 to 17.5% Ni and the dependency of this property on the weight fraction of molybdenum in nickel (Ref 64).

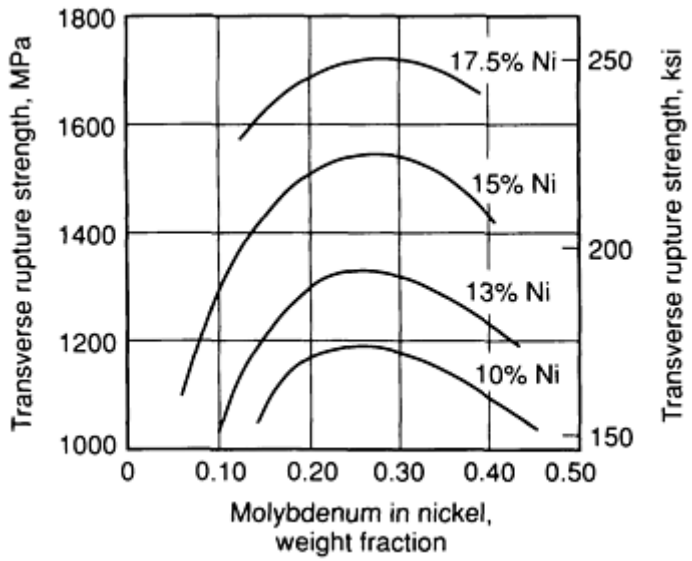

Fig. 27 Effect of binder metal composition on the transverse rupture strength of a titanium carbonitride cermet. Source: Ref 64

The hardnesses at room and elevated temperatures of these materials are comparable to those of conventional cemented carbides. Yet, the strength and toughness levels of the titanium carbonitride composition are somewhat lower than those of conventional cemented carbides; this would limit the feed rate and depth of cut in heavy roughing applications. On the other hand, Fig. 28 shows the low flank wear on a titanium carbonitride tool in comparison to that of a simple TiC-Mo-Ni cermet and that of a cemented tungsten carbide when turning 4340 steel at various speeds. The wear resistance of the cutting edge is related to the cutting temperature: Pressure welding results in a built-up edge at low temperatures, whereas diffusion and oxidation processes occur at high cutting temperatures. The relatively high free-formation enthalpy of titanium carbonitride increases its resistance to built-up edges, scaling, and crater formation. Favorable flank wear when cutting a tough steel at a relatively high cutting speed is the property of this cermet that enables it to prolong tool life and increase total chip removal between tool changes.

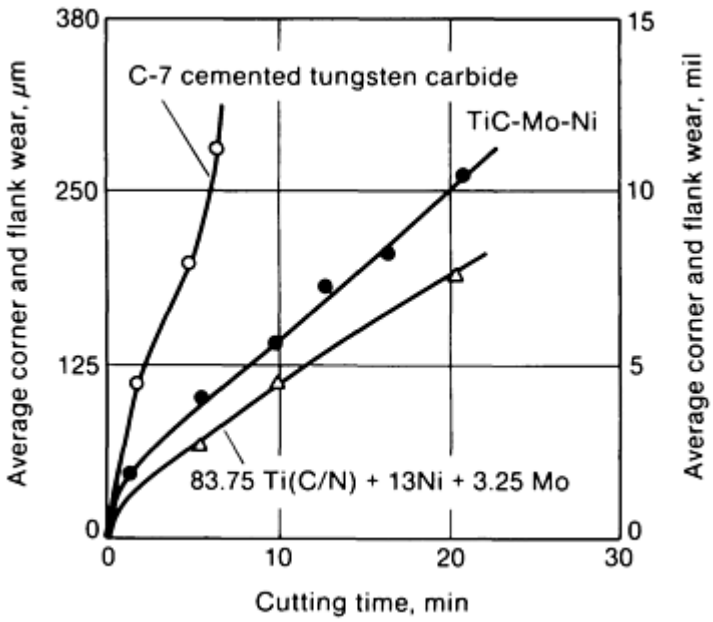

Fig. 28 Comparison of flank wear for two cermets and a cemented carbide when turning 4340 steel. Source: Ref 64

Applications. Titanium carbonitride cermet cutting tools are used for the high-speed milling, roughing, and semifinishing of carbon, alloy, and stainless steels. The resistance to cratering and flank wear exhibited by this material tends to preserve cutting edges; as a result, excellent surface finishes and close tolerances are obtained on longer production runs, even on superalloys and other difficult-to-machine materials. More detailed information on titanium carbonitride tool materials is given in the article "Cermets" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Steel-Bonded Tungsten Carbide Cermets

In an attempt to improved on the toughness of steel-bonded TiC cermets, Chinese research metallurgists directed their attention to tungsten carbide as a hard phase. The resulting steel-bonded tungsten carbide cermet tool retained the machinability and hardenability for which this class of materials became known (Ref 65). The higher toughness of the WC-base cermet was attributed to "a small wetting angle with steel under high temperature; even [when] sintering [this composition] in normal hydrogen, dense compacts can be obtained. The solubility of WC in iron group elements is much greater than that of TiC particle in the structure of the alloy maintained" (Ref 65). The physical properties of this new alloy are given in Table 8. The impact strength value of 7.35 J/cm^2 (35 ft · lbf/in.^{2}) is very high not only for steel-bonded cemented carbides but for any cemented-carbide material.

Table 8 Properties of steel-bonded tungsten carbide

Property	Amount
Density, g/cm^3 ($lb/in.^3$)	~10.2 (~0.37)
Hardness, HRC	
Annealed	33-40
Hardened and tempered	67-68
Transverse rupture strength, MPa (ksi)	2315 (336)
Impact toughness, J/cm^2 ($ft \cdot lbf/in.^2$	7.35 (35)
Modulus of elasticity, GPa ($psi \times 10^6$	295 (43)

Source: National Machining Carbide, Inc.

This cermet is used for heavy-impact applications such as cold upsetting or extrusion, heavy punching, cold forging, and ball heading. For example, on ball-heading tools, the performance of the WC steel-bonded cermet was 10 to 100 times superior to that of a previously used heading die.

Procedures for machining in the annealed condition and finish grinding in the hardened condition for these materials are similar to those prescribed for steel-bonded TiC cermets. The tungsten carbide cermets are supplied in the form of standard or special annealed blanks. Any reasonably well-equipped tool shop can fabricate and heat treat special parts in accordance with its needs.

Chromium Carbide Cermets

Cermets that contain chromium carbide as the major constituent possess some unique properties that make them useful for certain applications in the tool and chemical industries (Ref 66, 67). This class of material is essentially a cemented chromium carbide of the Cr_3C_2 modification that is bonded with nickel or a nickel-tungsten alloy. The Cr_3C_2 powder is produced by reacting Cr_2C_3 with carbon at a temperature of about 1600 °C (2900 °F). Minor additions of carbides of lower chromium content are added to control the carbon balance and keep the free-carbon content low. Standard cemented-carbide manufacturing practice is applied to the production of these cermets. Some interesting properties and specific applications of these Cr_3C_2 cermets are:

- Very low density, which makes the material useful in applications such as the production of valve balls in oil well valves
- Relatively high coefficient of thermal expansion, which permits direct brazing to steel, provided that boron-containing fluxes are used
- Bright and durable surfaces of high reflectivity, which permit finishing to optical flatness. These surfaces, together with the thermal expansion characteristics, make the material suitable for gage blocks, micrometer tips, and other measuring tools
- Virtually nonmagnetic nature, which eases measuring tasks, in spite of the nickel binder
- Excellent wear and corrosion resistance, for example, against salt water attack at temperatures up to 85 °C (185 °F), which makes the cermet suitable as a bearing and seal material or for fishing rod guide rings

- Abrasion resistance that is greatly superior to that of any normal corrosion-resistant alloy (Ref 12)
- Outstanding high-temperature erosion resistance at temperatures up to at least 1000 °C (1830 °F)

Applications and Properties. Applications for the chromium carbide cermets include high-temperature bearings and seals; various valve components, nozzles, and guides operating at elevated temperatures; and a multitude of gaging components. Typical physical, mechanical, and chemical properties of representative chromium carbide cermets are given in Table 9. Figure 29 shows the effect of temperature on the thermal conductivity, the expansion coefficient, and the transverse rupture strength of chromium carbide cermets (Ref 66, 67).

Although it has found moderate use in a number of the applications mentioned above, chromium carbide has recently fallen into disfavor and is no longer offered as a standard grade by the cemented-carbide industry. It should be noted, however, that chromium carbide has the potential of opening up an entirely new field of application for cermets in the area of coatings. For example, a coating developed for gas bearing journals blends chromium carbide for wear resistance, nickel alloy for bonding, silver for lubrication up to 500 °C (930 °F), and calcium fluoride-barium fluoride eutectic for lubrication in the 500 to 900 °C (930 to 1650 °F) temperature range (Ref 68). The cermet coatings are plasma sprayed from powder blends and finished by diamond grinding. A typical composition of such a blend is 32% Ni alloy, 10% Ag, 10% BaF_2-CaF_2 eutectic, with the balance consisting of Cr_3C_2.

Other Carbide-Base Cermets

Carbides of other refractory metals, such as zirconium carbide (ZrC), hafnium carbide (HfC), tantalum carbide (TaC), and niobium carbide (NbC), have been produced experimentally and investigated for high-temperature applications. They have the highest melting points of all compounds known (Ref 69). Hafnium carbide melts at 3890 °C (7030 °F), tantalum carbide at 3800 °C (6870 °F), zirconium carbide at 3530 °C (6380 °F), and niobium carbide at 3500 °C (6330 °F). All of these carbides exhibit poor oxidation resistance at high temperatures and are extremely brittle. Cementing these carbides with ductile binder metals does not improve these properties sufficiently to make the resulting cermets competitive with the industrial carbides available for high-temperature structural and tool applications (Ref 70). The use of small amounts of tantalum and niobium carbides as additions to titanium carbide to produce cermets of enhanced high-temperature oxidation resistance has been cited before.

Uranium carbide cermets are of some interest in nuclear reactor technology (Ref 51). Because carbon has a low neutron cross section, uranium carbide would be desirable as a fuel element for neutron economy. The compound has higher thermal conductivity than uranium dioxide; also, it has a high melting point (2300 °C, or 4170 °F) and is creep resistant to 1000 °C (1830 °F). The major disadvantages of uranium carbide are brittleness, poor thermal shock resistance, and susceptibility to corrosion in aqueous environments at elevated temperatures. Binder matrix metals chosen for their low thermal-absorption cross section, such as beryllium, zirconium, niobium, molybdenum, or iron, do not alleviate the disadvantages of the UC ceramic phase. Therefore, this type of cermet has not found industrial applications beyond experimental reactor technology in the United States and abroad.

The carbides of the metalloids boron and silicon, B^4C and SiC, are of considerable industrial significance and enjoy such diverse applications as superhard tools and electrical resistor heating elements. These compounds often are processed and used without metallic binder phases, which results in a product outside the material classification for cermets. An important exception, however, involves cermets in which the metalloidal carbide is combined with a metallic matrix

phase of major proportion. Some of these have been of long-standing importance to aerospace and nuclear reactor technology; others have more recently come to the fore in avionics and automotive engine manufacturing. The materials are commonly categorized as ceramic-reinforced metal-matrix composites, but those containing a relatively high volume fraction of particulate metalloidal carbide and a discontinuous aluminum matrix are relevant to this article and are discussed below.

Aluminum-Silicon Carbide Cermets. The recently publicized Lanxide process (Ref 26, 41), whereby ceramic-reinforced aluminum-matrix composites are produced by a chemically controlled capillary infiltration process, has produced some very interesting property data (Ref 71). For a cermet containing as reinforcement about 45 vol% of SiC particles ranging in size from about 8 to 25 μm, the following approximate data were established:

Property	**Amount**
Bending strength, MPa (ksi)	475 (70)
Tensile strength, MPa (ksi)	350 (50)
Modulus of elasticity in tension, GPa (10^6 psi)	180 (26)
Fracture toughness (K_{IC}), MPa $\sqrt{m}$ (ksi $\sqrt{in}$)	13 (11.8)
Thermal expansion coefficient, μm/m · °C (μin./in. · °F)	14 (7.8)

As the silicon carbide to aluminum ratio is varied either up or down in metal-matrix volume fraction, the property values change accordingly. The material is believed to be of particular interest for structures subjected to sliding abrasion and similar wear conditions.

Aluminum-Boron Carbide Cermets. Natural boron contains 18.8% of an isotope B-10, which has a high neutron cross section (that is, it shows a high capacity for absorbing neutrons). Thus, boron and boron-containing alloys or intermetallic compounds are useful for controlling a nuclear reactor. This makes boron carbide (B_4C) a desirable neutron absorber because of its commercial availability in powder form, its high purity, and its consistent quality. Low density and high chemical stability are other favorable characteristics of this powder. Boron carbide has been included in most aluminum cermets used for neutron absorption elements in nuclear reactors. In some cases, oxides of europium, dysprosium, and samarium are also considered desirable (Table 10).

Table 10 Properties of selected neutron-absorbing materials

Material	**Melting temperature**		**Density**		**Neutron absorption cross-section, Barns**
	°C	**°F**	**g/m^3**	**lb/in.^{3}**	
Boron-10	2000	3630	2.3	0.083	4,000
Boron	2000	3630	2.3	0.083	715

Hafnium	2130	3865	13.4	0.484	115
Samarium	1070	1958	6.9	0.25	8,900

Source: Ref 15

Cermet components of the Al-B_4C composition have found repeated and diversified applications in certain sectors of the nuclear industry, particularly for those water-cooled reactors that operate within the useful temperature range of aluminum. Some typical components are flat plates with dimensions of 2.5 × 20 × 1370 mm (0.1 × $\frac{3}{4}$ × 54 in.). Other more complicated shapes include 11 m (36 ft) long reactor control rods with a 43 mm (1.7 in.) outside diameter and a 0.5 mm (0.020 in.) wall thickness. Special P/M processes are required to produce components of this type in accordance with rigid dimensional tolerances and a high degree of critical chemical consistency from end to end.

Successful processes for the manufacture of Al-B_4C cermets include these steps (see Fig. 1):

- Thorough mixing of ingredient powders
- Cold compaction of powders into billets
- Sintering
- Hot consolidation of billets
- Hot extrusion
- Cold rolling

Special multiple-step blending techniques are needed when producing mixtures with very low concentration of the neutron absorber (that is, less than 1%). It has been found that uniform powder blends invariably yield control rods with highly uniform distributions of the neutron absorber over their entire length. The P/M process ensures higher levels of compositional accuracy from end to end than can be verified by chemical analysis. To avoid undesirable contamination, extreme cleanliness is required when switching mixing equipment from one composition to another.

Hot billet densification prior to extrusion is a necessary step. This may involve the expensive step of encapsulation (that is, extruding with a can as shown earlier in Fig. 13). When the hard phase in the cermet exceeds about 15 to 20 vol%, the composition is no longer malleable and hot extrusion becomes more difficult.

Direct roll compaction of Al-B_4C mixtures in the range of 15 to 20 vol% hard phase at room temperature has not produced acceptable results. It is interesting to note, however, that other groups have been successful in producing nuclear control rods by the direct powder-rolling technique. Copper-boron-carbide strip, for example, has been produced by a continuous direct powder-rolling process. The compositions contained as much as 20 wt% (about 50 vol%) boron carbide. The precompacted strip was sintered and brought to full density by a sequence of rerolling and annealing steps (Ref 72). The processing and microstructural characterization of Al-B_4C cermets and their fabrication into a variety of structural elements has been described (Ref 27, 73) and patented (Ref 74) by Halverson and co-workers.

Boride Cermets

Because metal borides generally are more refractory than titanium carbide, cermets based on borides are of interest for applications that require a material of extreme heat and corrosion resistance, such as materials in contact with reactive hot gases or molten metals. The diborides of the transition metals hafnium, tantalum, zirconium, and titanium have extremely high melting points, descending in the order given from 3250 to 2800 °C (5880 to 5070 °F). Molybdenum boride (MoB) and chromium boride (CrB) melt at considerably lower temperatures (2180 and 1550 °C, or 3960 and 2820 °F, respectively). The oxidation resistance of the transition metal diborides above a temperature of 1100 °C (2000 °F) is considerably better than that of TiC and roughly follows the descending order of the melting point (Ref 75). The oxidation resistance and strength properties at high temperatures can be further enhanced by reacting the boride crystals with small amounts of other thermally stable compounds, such as SiC or molybdenum disilicide ($MoSi_2$), prior to processing the powder into solid bodies.

Because these metal borides have relatively high thermal conductivity and high-temperature stability, they do not depend on a supportive metallic binder matrix for thermal shock resistance and strength as do the Ni-Cr alloys in TiC cermets. The boride phases alone in their highly purified state are extremely hard and abrasive; however, their consolidated bodies pose problems in fabrication to useful products, as well as in service, especially in environments involving dynamic gas or liquid metal flow. This shortcoming can be alleviated in some instances by a metallic binder phase. For thermodynamic reasons, this binder phase generally is limited to 2 to 5 at.% up to a maximum of 10 at.%.

The principal candidate metals for cementing the boride grains are iron, nickel, cobalt, chromium, molybdenum, tungsten, and boron, or some of the alloys of these metals. Low-melting eutectics in the systems boron-iron (1161 °C, or 2122 °F), boron-cobalt (1102 °C, or 2015 °F), and especially boron-nickel (990 °C, or 1814 °F) restrict the amount of the respective binder metals to a small percentage. The effectiveness of iron and cobalt, especially as binders for titanium diboride (TiB_2) and zirconium diboride (ZrB_2), is further diminished by the formation of very brittle intermetallic compounds; whereas chromium and boron, singly or combined, produce tougher, higher-melting eutectics with these borides (Ref 76). Additions of up to 5 wt% B and 10 wt% Mo or W can be successfully used as a binder (of ZrB_2, for example) without forming low-melting phases (Ref 77, 78).

The transition metal borides are produced as pure crystals by such processes as the solid-state reaction of metal boron, the reaction of the metal or its oxide with boron carbide, the reduction of boron and metal oxides with carbon or reactive metals, or fused-salt electrolysis. Mixtures of these borides and binder metal powder are processed into cermet products by ceramic or P/M techniques, such as hydrostatic pressing or slip casting followed by vacuum sintering, or by hot uniaxial or isostatic pressing. The high costs of producing the borides and handling the brittle products with the necessary care have limited applications to those cases in which the unusual properties of these materials are an essential requirement. In addition to the high cost, these materials generally have poor mechanical properties, and thus few boride-base cermets have been able to hold on to practical uses in industry. Table 11 lists the physical and mechanical properties of metal borides and boride-base cermets.

Table 11 Properties of metal borides and boride-base cermets

Property	Cermet grades

Zirconium Boride Cermets. A comprehensive study of the properties of this transition metal boride was reported some 25 years ago (Ref 81). The very high melting point and good high-temperature mechanical properties, as well as a noticeable reduction in brittleness with rising temperature, make it one of the few borides that have attracted considerable attention. The addition of 2 to 5 wt% B binder to ZrB_2 renders the material suitable for extremely high-temperature applications, including high-performance burner, rocket, and jet reaction systems (Ref 77).

The oxidation resistance of zirconium boride can be further enhanced by reacting it with up to 15% SiC, and the consolidated cermet bodies can successfully withstand oxidizing environments in the 1900 to 2500 °C (3450 to 4530 °F) temperature range (Ref 82, 83). These materials have been the object of an extensive investigation for use as nozzle throat inserts for liquid propellant rockets (Ref 84). Probably the most outstanding characteristics of zirconium boride are its high-temperature corrosion resistance and non-wetting properties when in contact with molten aluminum, brass, zinc, and lead. As a result, applications for this cermet opened up in systems handling molten metals. Typical examples include impellers and bearings in pumps for liquid die casting alloys, spray nozzles for atomizing metal powders, and furnace parts that come in contact with molten reactive metals or vapors.

Titanium Boride Cermets. The physical and mechanical properties at low and high temperatures of titanium boride do not vary greatly from those of zirconium boride (Ref 81). As a single boride or in solid solution with chromium boride (CrB_2), titanium boride has been considered by some to be the most promising of the transition metal borides (Ref 76). Successful applications have included evaporation vessels for reactive metals, electrodes for aluminum refining, and, in general, parts that are exposed to molten zinc and brass. The addition of TiB_2 to TiC in a composite structure has been successfully used for cutting tools, and complex cermets of TiC-TiB_2 with a Co-Si alloy binder (Ref 85, 86) or a TiB-MoSi with a graphite binder (Ref 84) have been experimented with for use as nozzles.

A gradient-type cermet of titanium boride and copper has been produced recently in the form of intermediate ceramic-metal layers that link TiB_2 to pure copper (Ref 87). The composite is the product of a self-propagating high-temperature synthesis. Careful determination of the respective blending ratios of the boride and copper powders for each layer ensures that the reaction proceeds from one layer to the next.

Chromium Boride Cermets. Of the generally excellent corrosion- and oxidation-resistant boride materials, chromium boride was one of the first to be in investigated for its high-temperature potential. The compound can be successfully bonded with cobalt, nickel, nickel-chromium, and nickel-copper (Ref 88). A composition containing as much as 15 wt% Ni can be hot pressed without exuding much liquid phase. The cermet is oxidation resistant up to 950 °C (1740 °F) and has a high hot hardness and a transverse rupture strength of about 890 MPa (130 ksi). These properties can be further improved by using Cr_2B crystals and cementing them with up to 10 wt% of an 80Cr-20Mo alloy (Ref 76, 89). These cermets have good stress-to-rupture properties and mechanical shock resistance and at one time were considered as candidate materials for steam and gas turbine blades, valve seats and inserts for internal combustion engines, and exhaust nozzles and tubes for jet engines. Although compositions much higher in nickel (for example, cermets containing the compound Cr_2NiB_4) suffer from the low-melting eutectics, this is used as an advantage for wear- and erosion-resistant overlay coatings and hardfacing applications.

Molybdenum Boride Cermets. The molybdenum borides MoB and Mo_2B have less thermal stability than the previously discussed metal borides, but their electrical properties, hardness, and wear resistance are very good. When cemented with nickel, these cermets have excellent corrosion resistance, for example, to dilute sulfuric acid (Ref 79). Nickel-bonded molybdenum boride exhibits interesting behavior in two areas: First, if the composition corresponds to the compound molybdenum-nickel boride (Mo_2NiB_2), if the cermet contains Mo_2B in addition to Mo_2NiB_2, or if a low-melting, intermetallic binder containing chromium boride and nickel is used, cutting tool materials can be produced from the composition that are comparable to commercial WC tool tips for machining brass, aluminum, and cast iron (Ref 90, 91). Second, the Mo_2NiB_2-type composition has thermal expansion characteristics that closely match those of the refractory metals and a favorable melting temperature; these properties make it ideal for use as a high-temperature braze for molybdenum and tungsten, without risk of excessive grain growth or embrittlement of the primary metal structure (Ref 79, 92). When used in rod form with shielded arc welding equipment, this cermet is suitable for brazing electronic components in applications such as vacuum tubes and magnetrons.

Recently, a molybdenum boride cemented with an iron-base binder phase alloyed with nickel and chromium has shown promise as a cutting tool material (Ref 93). This cermet exhibits good mechanical properties coupled with excellent wear and corrosion resistance. In specific tool applications, such as extrusion dies for hot copper and tools for can making, this boride cermet has performed better than cemented carbides. The role of nickel in the Mo_2FeB_2 cermet and the effect of varying its content up to 10 wt% in the Fe-5B-44.4Mo composition have also been investigated, mainly as part of a study of the corrosion resistance potential of the material (Ref 94). The nickel enters only into the iron-base binder phase, which changes with increasing nickel content from ferritic to martensitic to austenitic. The martensitic binder phase at 2.5% Ni gives the cermet a transverse rupture strength of 2.24 GPa (325 ksi) and a hardness of 86.9 HRA.

Other Refractory Cermets

The nitrides, carbonitrides, and silicides of certain transition metals have gained importance for specific uses in operations involving high temperatures. The main mode of application for these refractory cermets, however, is in the form of coatings, such as TiN and TiC-TiN in various ratios for high-speed cutting tools or $MoSi_2$ for surface protection of molybdenum against high-temperature oxidation. In a very few cases, these compounds are used as solids, either in the pure state or cemented with a lower-melting metallic phase.

Carbonitride- and Nitride-Based Cermets. Titanium nitrides and titanium carbonitrides have been found suitable for use as the hard phase for tool materials (Ref 95). The best binder is an alloy of 70Ni-30Mo, and optimum hardness, in the 1000 to 2000 HV range, is obtained with 10 wt% binder. The hardness increases progressively with the TiC component of the solid solution. The same trend prevails for the hardness of a cermet containing 14 wt% binder: The values increase from about 1400 to 1900 HV for the straight cemented TiC composition. Transverse rupture strength does not follow any trend; the best values reach about 1300 MPa (188 ksi) for a 10 wt% binder composition with a 72-to-18 TiN-TiC ratio and a 14 wt% binder material with a 69-to-17 TiN-TiC ratio. This compares with 1070 and 1275 MPa (155 ksi and 185 ksi), respectively, for the straight TiC cermets with 10 and 14 wt% binder. The hardness of titanium nitride alone cemented with 10% of the 70Ni-30Mo alloy has a hardness level of about 1050 HV and a transverse rupture strength of about 785 MPa (115 ksi). Titanium carbonitride cermets for tool applications are discussed in greater detail in the section "Titanium Carbonitride Cermets" in this article.

Combinations of nitrides and borides, with or without metallic binder, can also be fabricated into tools. A mixture of 60 wt% tantalum nitride (TaN) and 40 wt% ZrB_2 has been hot pressed into tool bits that have performed very well at very high cutting speeds (Ref 96).

Nitride products based on the metalloids boron and silicon, like their carbide counterparts, have gained some significant commercial uses since their early development in the 1950s and 1970s, respectively. The normal hexagonal crystal lattice of boron nitride (BN) can be converted to a cubic crystal form by reacting boron powder with nitrogen at a minimum temperature of 1650 °C (3000 °F) while simultaneously applying pressure in excess of 7000 MPa (1000 ksi) with the aid of special press tools adopted from the manufacture of synthetic diamond. The product is extremely hard and is considered to be one of the best electrical insulators known, especially at high temperatures up to about two-thirds of its melting point, that is, in the vicinity of 2730 °C (4950 °F) (Ref 45, 97).

Cermets exhibiting excellent cutting performance have been achieved by bonding carefully graded particles of the superhard cubic boron nitride with cobalt or similar hard metal binders. Hot pressing is the preferred method of powder consolidation, and tool bits made in this manner outperform tungsten carbide tips by a factor of two-to-one and better (Ref 98).

The nitride of silicon and its combination with different oxides, notably Al_2O_3 (known as the SiAlONs), as well as the different silicon ceramics based on silicon carbide, belong to the increasingly important new class of refractory materials known as structural ceramics. Additives of these cermets are nonmetallic and serve mainly to control the sintering mechanism. They do not contribute to a strengthening of the hard particle structure in the sense of a metallic binder. In fact, they cause a weakening of the grain-boundary network at high temperature in many systems. Therefore, these silicon ceramics are considered to lie outside the material classification for cermets.

Silicide Cermets. The metallic silicides have found commercial use only in isolated instances. This is due chiefly to the extreme brittleness of these compounds and to the concomitant problems encountered when they are fabricated into solid objects. Because of its outstanding high-temperature oxidation resistance, and its favorable coefficients of thermal expansion and electrical resistance, molybdenum disilicide ($MoSi_2$) is an important material for heating elements. Poor resistance to mechanical and thermal shock is the major deficiency of molybdenum disilicide and limits the applications of this material to simple cylindrical or rectangular shapes. Additions of metallic elements to remedy this handicap have been only partially successful, and $MoSi_2$ cermets with nickel, cobalt, and platinum binder metals are still too brittle for fabrication into complex shapes (Ref 99). High-temperature bearings have been made experimentally by infiltrating molten silver into hard matrices containing $MoSi_2$, tungsten disilicide (WSi_2), or vanadium disilicide (VSi_2); these bearings have shown good antifriction behavior against steels at elevated temperatures (Ref 100).

Graphite- and Diamond-Containing Cermets. Materials that contain a combination of carbon in the form of graphite or diamond with metals constitute a border region for cermets and are usually not designated as such. However, because the carbon and metallic components are most often intimately mixed and uniformly distributed in the microstructure, they are pertinent to this discussion.

Graphite-metal combinations for electrical contact applications basically fall into two types of materials. For metallic brushes used in motors and generators, the metallic phase consists of copper or bronze; in the case of sliding contacts involving relatively low rubbing speeds and light contact pressure, the metallic phase is silver. In brushes, the graphite particle content may spread over a wider range, from 5 to 70 wt%. A typical binary composition contains 70% Cu and 30% graphite. To improve wear and bearing properties, many brushes also contain up to 10% Sn and/or Pb and up to 12% Zn (Ref 101). The graphite content in the silver contact composition generally ranges between 2 and 50 wt%.

Graphite-containing metallic friction materials for brake linings and clutch facings have a predominantly metallic matrix to utilize a high thermal conductivity. This property permits rapid energy absorption, making this type of material suitable for service under a more severe wear and temperature environment than that which is possible for organic, resin-bonded asbestos friction elements. The most important contribution of a cermet-type lining material in aircraft brakes probably has been an increased energy capacity without additional weight or the use of a larger unit (Ref 102). The friction coefficient of these cermets is tailored to the requirements of the particular application, principally by varying the ratio of a friction-producing ceramic to the graphite, which acts as a solid lubricant. The metallic matrix phase is essentially a bearing alloy containing 60 to 75 wt% Cu and 5 to 10% each of tin, lead, zinc, and/or iron. Graphite content falls within the 5 to 10% range, and the ceramic, mainly SiO_2 with the possibility of some Al_2O_3 additions, amounts to 2 to 7% (Ref 103).

Cermets composed of diamond, varying in size from coarse splinters to fine dust inside a metal matrix, are used for grinding, lapping, sawing, cutting, dressing, and trueing tools. The size of the diamond is important for the efficiency of the tool; although finish improves as the grain or grit size becomes finer, the cutting speed is slower. For dressing tools, 5 to 35 diamond splinters are embedded per carat with a size of approximately 1 to 2.5 mm (0.04 to 0.1 in.). For rough grinding, the grit size is in the range of 0.15 to 0.5 mm (0.006 to 0.02 in,); for fine polishing, it falls between 0.05 and 0.15 mm (0.002 and 0.006 in.). Even finer diamond powder is used in combination with tungsten carbide for specialized applications such as polishing plane surfaces of hard metal tools or finishing the rolls for Sendzimir-type mills. Typical compositions of these tools contain 12 to 16 wt% diamond dust embedded in a tungsten carbide matrix cemented with 13% Co (Ref 104).

Other metallic bonding substances are based on copper, iron, nickel, molybdenum, or tungsten. Examples for copper matrices are bronzes with 10 to 20% Sn or 2 to 4% Be, which can be strengthened by precipitation hardening, and a 47Cu-47Ag-6Co alloy. Bonding metals suitable for somewhat higher-temperature service include iron-nickel, iron-nickel-chromium, and iron-tin-antimony-lead alloys; Permalloy; and nickel alloys containing 2 to 8% Be. Refractory metal-base matrices are alloys of the molybdenum-copper, molybdenum-cobalt, or tungsten-nickel-copper types and tungsten-nickel-iron heavy alloys (Ref 104). In general, the bond materials must be selected with consideration of lowest possible processing temperatures to avoid the possible transformation of the diamond to graphite.

Superabrasives and Ultrahard Tool Materials

T.J. Clark, G.E. Superabrasives; and R.C. DeVries, G.E. Corporate Research and Development Center (Retired)

Introduction

THE PRINCIPAL superhard materials are found as phases in the boron-carbon-nitrogen-silicon family of elements (Fig. 1). Of these, the superhard materials of commercial interest include silicon nitride (Si_3N_4), silicon carbide (SiC), boron carbide (B_4C), diamond, and cubic boron nitride (CBN). Silicon nitride provides the base composition for the important category of SiAlON ceramics, which are used in structural applications (see the article "Structural Ceramics" in this Volume) and as high-speed cutting tool materials (see the article "Ceramics" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook*).

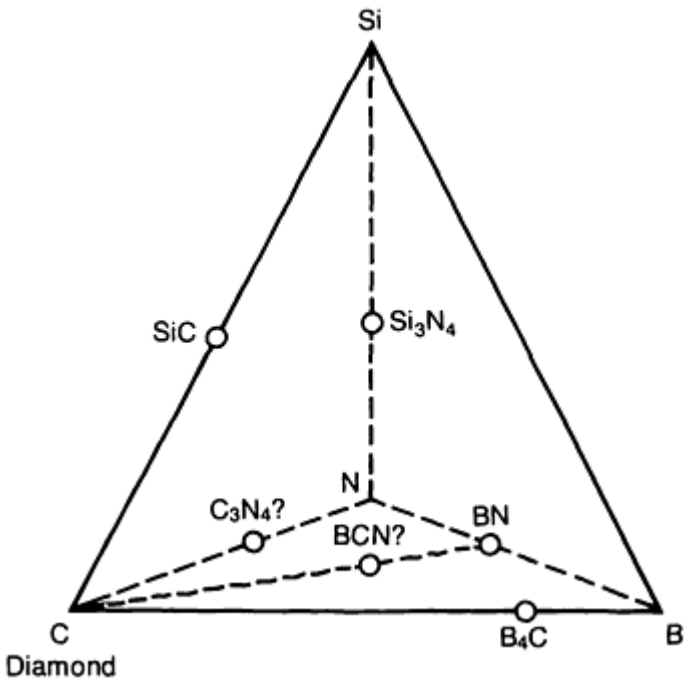

Fig. 1 The carbon-boron-nitrogen-silicon composition tetrahedron showing the principal known superhard materials: the diamond form of carbon, cubic BN, SiC, and B_4C. Polycrystalline aggregates of diamond and SiC as well as Si_3N_4 are also commercially available.

The carbides of the metalloids boron and silicon (B_4C and SiC in Fig. 1) are also of considerable industrial significance and enjoy such diverse applications as superhard tools and electrical resistor heating elements. These compounds are processed and used both with or without metallic binder phases. When these two metalloid carbides are used without a metallic binder phase, the resultant material most likely falls within the material group of ceramics. If silicon carbide (SiC) and boron carbide (B_4C) are used with a metallic binder phase, then the resultant material is considered a cermet (see the article "Cermets" in this Volume).

This article focuses exclusively on the superhard materials consisting of either diamond or CBN. The other commercially significant materials in Fig. 1 are discussed in the above-mentioned articles of *ASM Handbook.* Additional information on the superhard nitrides and carbides can be found in Ref 1 and 2. Information on possible new hard materials is available in Ref 3.

The focus of this article is further restricted to synthesized diamond and CBN. The latter does not occur in nature, and the former commands 90% of the industrial diamond market. These materials will be treated in terms of the forms in common use: diamond or CBN grains (looser or bonded) and sintered polycrystalline diamond or CBN tools.

Synthesis of Diamond and Cubic Boron Nitride

The basic objective in the synthesis of diamond and CBN is to transform a crystal structure from a soft hexagonal form to a hard cubic form. In the case of carbon, for example, hexagonal carbon (graphite) would be transformed into cubic carbon (diamond). Synthetic CBN and diamond are produced either as crystalline grains or as sintered polycrystalline products.

The synthesis of CBN or diamond grit can be achieved by static high-pressure high-temperature (HPHT) processing or by dynamic (explosive) techniques. The HPHT method, despite high equipment investment costs, is the predominant technique for producing synthetic diamond and CBN. In addition, diamond is also synthesized under metastable conditions (see the section "Low-Pressure Synthesis of Superhard Coatings" in this article).

High-Pressure High-Temperature Synthesis. The bulk of synthetic CBN and diamond is made by subjecting hexagonal carbon or boron nitride to high temperatures and high pressures with large special-purpose presses or with the commonly used mechanical device known as the uniaxial belt (Ref 4). By the simultaneous application of heat and pressure, hexagonal carbon or boron nitride can be transformed into a hard cubic form. This requires strenuous pressures and temperatures, as illustrated in the graphite-diamond and hexagonal BN-cubic carbon nitride equilibrium diagrams (Fig. 2, 3).

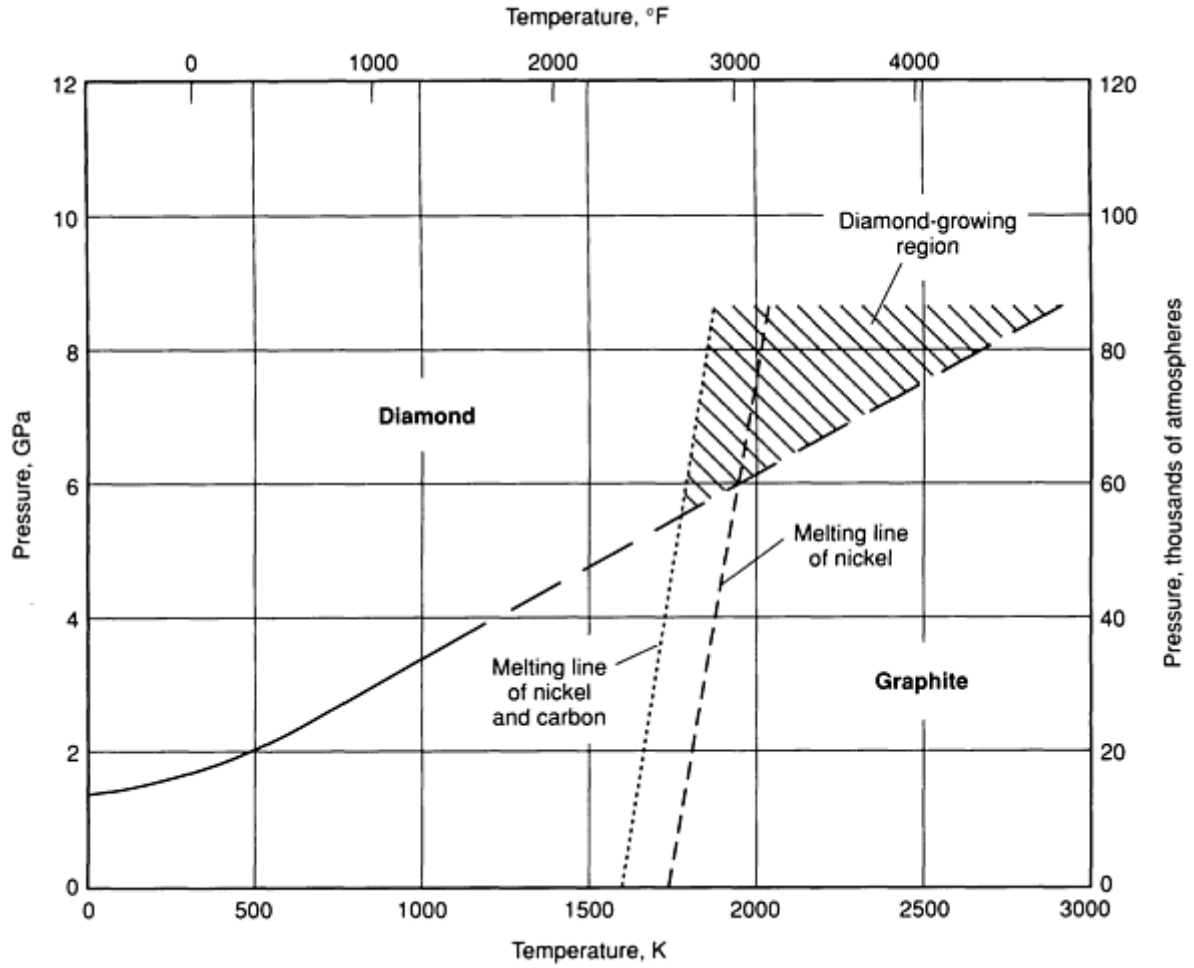

Fig. 2 Pressure-temperature diagram showing the stability regions of diamond and graphite and the role of the solvent/catalyst in lowering the synthesis conditions

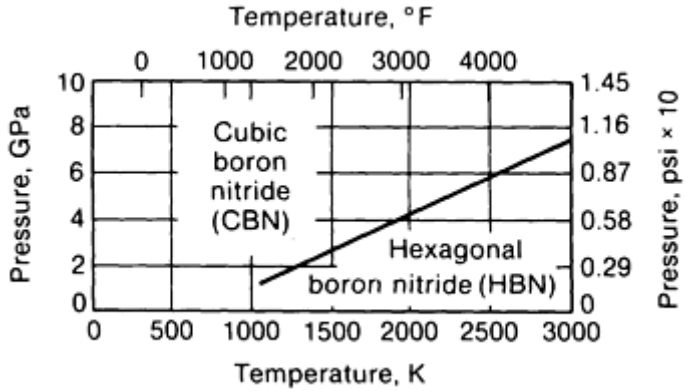

Fig. 3 Equilibrium diagram for HBN and CBN

It is possible to directly convert graphite to diamond, but very high pressures are required, and the properties of the resultant product are difficult to control. In commercial practice, the required conditions for diamond synthesis can be reduced by the use of solvent/catalysts such as nickel, iron, cobalt, and manganese or alloys of these metals (Ref 5, 6). Figure 4 shows an example of a metal-carbon system at 5.7 GPa (57 kb), where a stable diamond plus liquid region exists. Even with solvent/catalysts it is necessary to simultaneously sustain a pressure of about 5 GPa (50 kb)and a temperature

of about 1500 °C (2700 °F), for periods ranging from minutes to hours, to make the variety of products in common use today.

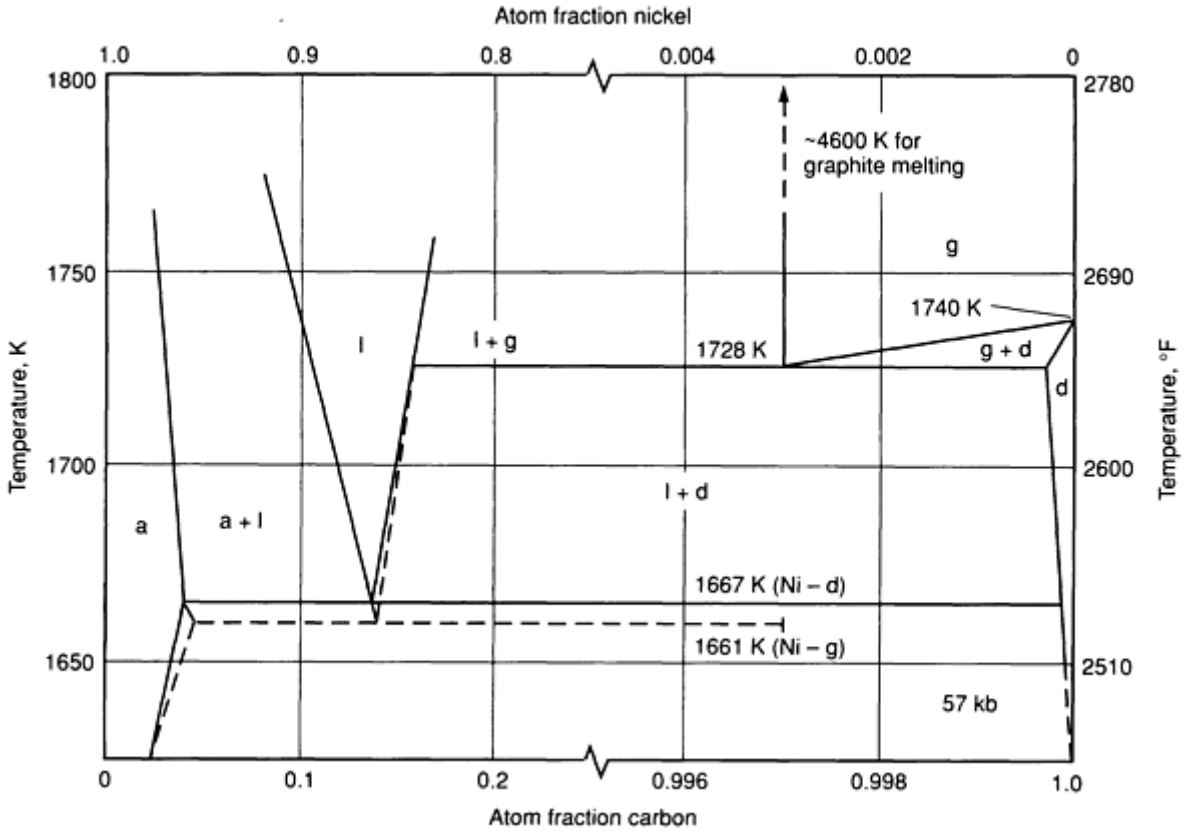

Fig. 4 Nickel-carbon system at 5.7 GPa (57 kb) showing the stability regions of diamond (d) and graphite (g) in equilibrium with liquid (l + d, l + g). a, austenite. Source: Ref 7

Conditions are similar for the synthesis of CBN, but the reactants are usually alkali, alkaline earth metals, or compounds. Cubic boron nitride can be grown from a variety of solvent/catalysts, including metal systems similar to those used for diamond synthesis (Ref 8). Because the pressure-temperature conditions for the conversion of hexagonal boron nitride (HBN) to CBN are less severe than those for the conversion of graphite to diamond, some sintered polycrystalline products are synthesized by the direct process under static conditions; however, most commercial monocrystalline CBN is made by a solvent/catalyst process.

Explosive Shock Synthesis. The direct conversion of graphite to diamond, or HBN to CBN, can be done on a commercial scale using explosive shock techniques (Ref 9). The process is relatively simple but produces only fine-grain materials, which are principally used as polishing powders or as possible source materials for sintering into polycrystalline products.

Low-Pressure Synthesis of Superhard Coatings. The history of diamond synthesis under metastable conditions (plasma-assisted, chemical vapor deposition, or physical vapor deposition coating processes) goes back at least to the late 1950s and perhaps even earlier. The efforts of Russian (Ref 10) and Japanese (Ref 11) scientists in the period from 1975 to 1985 made this technique feasible for limited commercial applications. The potential exists to make films or sheets of polycrystalline and single-crystal diamond at temperatures of about 900 °C (1650 °F) and at pressures of less than 1 atmosphere (0.1 MPa). A limited amount of information exists (Ref 12) on grinding or machining applications of these materials. Some films have been made for x-ray windows, speaker diaphragms, and wear surfaces.

Synthesis of Polycrystalline Diamond and Polycrystalline Cubic Boron Nitride. It is possible also to produce polycrystalline diamond (PCD) or polycrystalline cubic boron nitride (PCBN) by sintering (or binding) many individual crystals of diamond or CBN together to produce a larger polycrystalline mass. It is commercial practice to enhance the rate of sintering by the addition of a metal second phase (Ref 13). In addition, the whole mass must again be maintained in the cubic region of the respective temperature-pressure phase diagram to prevent the hard cubic crystals from reverting to the

soft hexagonal form. By such high-temperature high-pressure sintering techniques, it is possible to obtain a mass of diamond or CBN in which randomly oriented crystals are combined to produce a large isotropic mass.

An immense range of polycrystalline products can be made of diamond or CBN. Changes in grain size, the second phase employed, the degree of sintering, the particle size distribution, and the presence or absence of inert ceramic, metallic, or non-metallic fillers are examples of factors that have profound effects on the mechanical, physical, and thermal properties of the final product. By careful formulation it is possible to tailor material properties for particular applications.

Properties of Diamond

The crystal structure of diamond and the lattice structure of graphite are shown in Fig. 5. The conversion from graphite to diamond is accompanied by a 26% decrease in volume. For diamond, all the lattice sites are occupied nominally by carbon, but boron and nitrogen can be substituted for carbon in amounts in the parts-per-million range. Synthesized diamond usually has metal, metal carbide, and graphite inclusions; however, some of the metal may be on defect or interstitial sites and thus may not be visible.

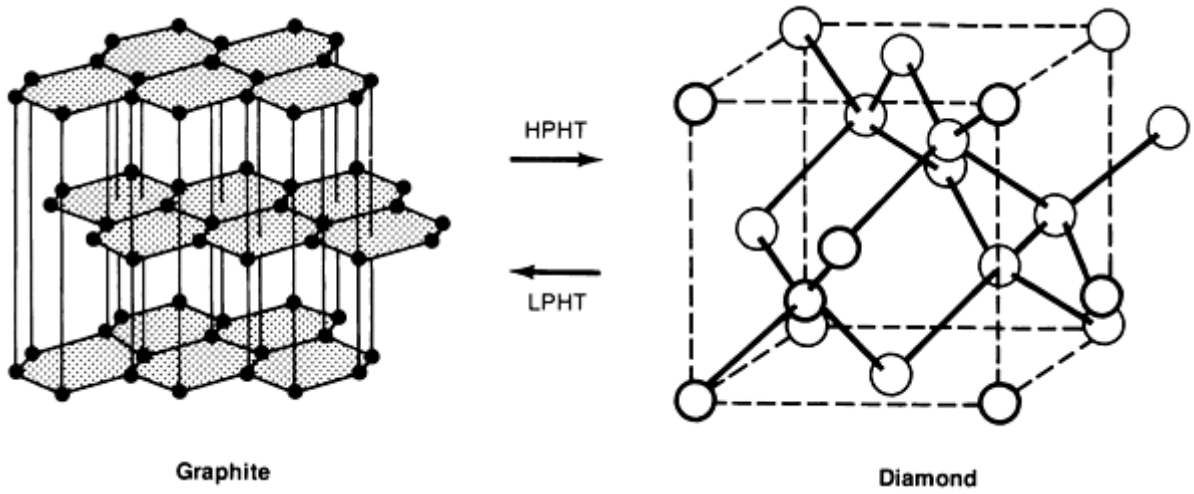

Fig. 5 Arrangement of carbon atoms in diamond and graphite. The arrows indicate the transformation of graphite to diamond at HPHT conditions and the reverse transformation at low pressures and high temperatures (LPHT).

Diamond oxidizes in air above about 600 °C (1100 °F) and back converts into a poorly graphitized form (as indicated by the reverse arrow in Fig. 5) upon heating in the absence of air. The reaction rate for the transformation back into graphite is dependent on conditions, but it is a significant factor at temperatures about 750 °C (1400 °F) in many practical applications. These phenomena impose critical limitations on the use and fabrication of bonded-abrasive tools.

Diamond is chemically inert to inorganic acids, but upon heating it reacts readily with carbide-forming elements such as iron, nickel, cobalt, tantalum, tungsten, titanium, vanadium, boron, chromium, zirconium, and hafnium. Controlled reactivity is important in forming metal bonds, but that same reactivity can limit the use of diamonds in cutting and grinding applications.

The thermal conductivity of some near-perfect diamond crystals can be as high as 5× that of copper at room temperature. Less-perfect materials still have a high conductivity, and this has to be taken into consideration before use in many applications. In terms of electrical conductivity, diamond is an electrical insulator unless doped with boron or, as in some commercial materials, mixed with a metal phase.

Diamond is the hardest practical material known (Table 1). The hardness of single-crystal diamond varies as a function of orientation, but this is important only in single-point tools and in the polishing of gemstones, diamond microtome blades, and diamond surgical knives.

Table 1 Properties of selected hard materials

	Density		**Hardness, HK**	**Compressive strength**		**Coefficient of thermal expansion**		**Thermal conductivity**	
	g/cm^3	**lb/in.^{3}**		**GPa**	**10^6 psi**	**mm/mm/°C × 10^{-6}**	**in./in./°F × 10^{-6}**	**W/m · K**	**cal/°C · cm · s**
Diamond (C)	3.52	0.127	7000-10000	10	1.5	4.8	2.7	2100	5.0
Cubic boron nitride	3.48	0.126	4500	7	1	5.6	3.1	1400	3.3

Alumina oxide (Al_2O_3)	3.92	0.142	2100	3	0.435	8.6	4.8	33	0.08
Tungsten carbide (WC-Co, 6%)	15.0	0.542	1700	5.4	0.78	4.5	2.5	105	0.25

Although hard, diamond is a brittle material and breaks on impact, primarily by cleavage on the four (111) planes. Toughness or friability can be varied considerably for synthesized grains. Thus, it is possible to make a very friable material for some grinding operations and a very tough material for stonecutting. The presence of defects and second phases can be manipulated to influence the fracture properties of synthesized diamond. This control is not available from most natural stones.

Most natural diamonds are essentially octahedral in shape as grown. Irregularly shaped fragments can be obtained by crushing and selection. Synthesized diamond can be reproducibly grown as cubes, cubooctahedrons, and octahedrons (Fig. 6). The cubooctahedral shapes are generally preferred for stone sawing, but they are not always appropriate for grinding.

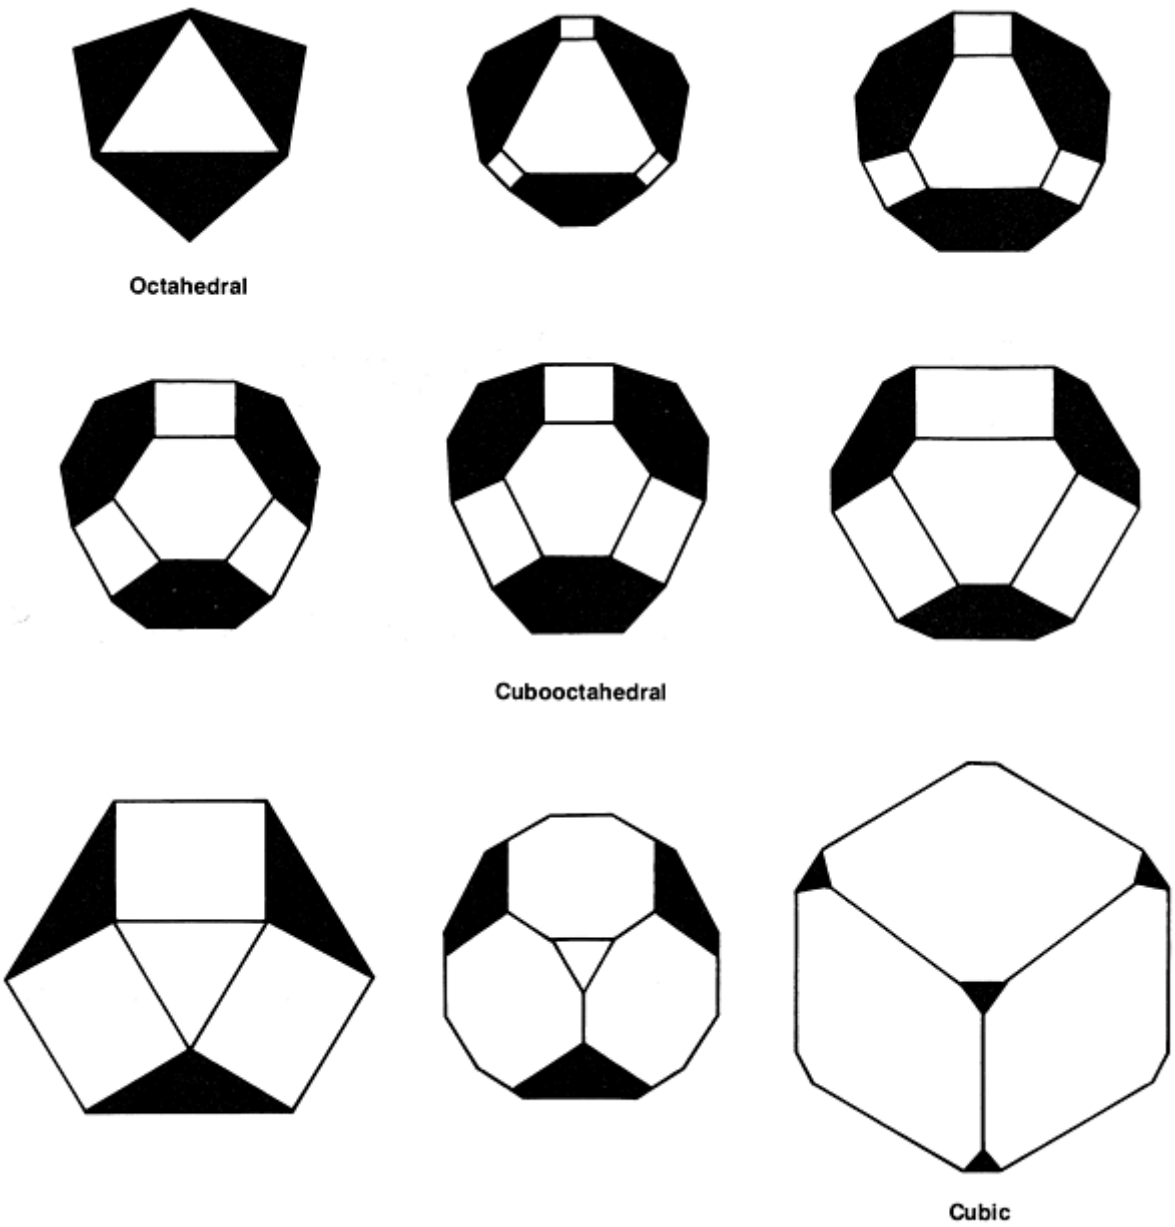

Fig. 6 Shapes of synthesized diamond abrasive grains. Varying proportions of cube (100) and octahedral faces (111) predominate, but (110) and (113) shapes are often present as well.

Synthesized diamond is available in the size range from submicron to about one centimeter. The latter are specialty items for single-point tools; heat sinks, microtomes, surgical blades, and other applications. Table 2 shows the most popular sizes for many applications. For still larger sizes it is more practical to use sintered polycrystalline materials.

Table 2 Sizes of diamond and CBN grains for grinding applications

Superabrasive	Bond	U.S. mesh size ranges													
		20-30	30-40	40-50	50-60	60-80	80-100	100-120	120-140	140-170	170-200	200-230	230-270	270-325	325-400
Diamond	Resin/vitreous						X	X	X	X	X	X	X	X	X
Diamond	Metal						X	X	X	X	X	X	X	X	X
CBN	Resin/vitreous						X	X	X	X	X	X	X	X	X
CBN (microcrystalline)	Metal/vitreous	X	X	X	X	X	X	X	X	X	X	X	X	X	X

Properties of Cubic Boron Nitride

The crystal structure of CBN can be derived from that of diamond (Fig. 5) by substituting boron and nitrogen for carbon on alternate sites in the diamond lattice. The resulting zinc blende structure differs from diamond in having no center of symmetry and a different cleavage plane (110). The soft hexagonal form of boron nitride (HBN) has the same relationship to graphite that CBN has to diamond. Cubic boron nitride may also exhibit a back conversion to a hexagonal structure that is analogous to the back conversion of diamond into graphite.

Cubic boron nitride is nominally boron nitride (that is, B:N = 1:1), with a band gap of about 6.6 eV, and thus should be colorless. However, it is usually amber in color and behaves like an extrinsic semiconductor. Cubic boron nitride can be doped as both p- and n-type. It is most likely to be boron-rich when obtained from conventional processes. A black form is also commercially available. Cubic boron nitride can include solvent/catalyst materials and HBN from the synthesis process. An extremely tough microcrystalline form is also available that is useful in metal and vitreous bonds for heavy-duty applications.

Cubic boron nitride is more resistant both to oxidation and to back conversion into a graphitelike form than is diamond. It can be heated to 1300 to 1400 °C (2350 to 2550 °F) before its protective oxide layer no longer prevents further degradation. Back conversion is not significant until temperatures reach about 1700 °C (3100 °F).

Because the reactivity of CBN with iron-, cobalt-, and nickel-base alloys is much less than that of diamond, CBN fills an important gap in the use of ultrahard materials for the machining of these metals. Cubic boron nitride reacts with strong nitride and boride formers such as titanium, tantalum, zirconium, hafnium, chromium, tungsten, silicon, and aluminum. Under controlled conditions some of these elements can be used as bonding materials. The reactivity of the oxidized surface of boron nitride with alkalis and alkaline earths can be used in making vitreous bonds, but it also can lead to degradation by borate formation in the presence of these reactants.

Theoretically, the thermal conductivity of CBN is slightly more than half that of diamond. Cubic boron nitride also is about half as hard as diamond, but it is about twice as hard as any other material. In contrast to the four (111) cleavage

planes of diamond, CBN cleaves on six (110) planes and therefore is intrinsically more friable than diamond on a single-grain basis.

The preferred growth form for CBN from most solvent systems is a (111) truncated tetrahedron, with some development of cube forms. The size range for CBN grains is from the submicron level to about $\frac{1}{2}$ mm (0.02 in.). Grains larger than 1 mm (0.04 in.) are not usually grown.

Properties of Sintered Polycrystalline Diamond

Sintered PCD, which was developed in 1970 (Ref 13), is a unique material produced by liquid-phase sintering at HPHT conditions. It is characterized by diamond-to-diamond bonding. This sintering process made possible the production of pieces much larger than 1 mm (0.04 in.) with isotropic properties. The commercial product is useful for cutting tools, drill bits, wear surfaces, and wire dies.

Compared to a single crystal, a sintered polycrystalline material is essentially isotropic with respect to wear and cleavage; therefore, its practical toughness in use is improved. Whereas a single crystal is fragile with respect to catastrophic failure by cleavage, a polycrystalline material may chip locally but has no extensive cleavage plane. Wire-drawing dies of sintered PCD outlast single crystals because they do not cleave in hoop tension and because they maintain roundness and dimensions.

Sintered polycrystalline diamond blanks are made *in situ* in an HPHT apparatus, which imparts some limitations to size and shape. Round tool shapes are most common, but squares, triangles, and other shapes are also available. The sintered diamond blanks are produced in both supported and unsupported configurations. In supported structures, cemented tungsten carbide (WC-Co) provides additional strength and a brazeable surface for tool fabrication. A combination of chemical and mechanical bonding exists between the diamond and the substrate by virtue of the transport of cobalt through the diamond layer during HPHT production. Unsupported polycrystalline diamond can be mounted in tools by more conventional diamond-bonding techniques. Subsequent finishing operations are involved in all cases to make tools with tight dimensional and angular tolerances from the blanks. Finishing operations, depending on the tools, can include laser cutting, electrodischarge machine cutting, grinding, lapping, and polishing steps.

Polycrystalline diamond with a metallic second phase has a microstructure of diamond grains with the metallic phase mostly at the grain boundaries (Fig. 7). Both phases are continuous, and the metal phase can be removed chemically. Within the grains it is very common to see deformation twin bands that were produced during the HPHT sintering. These bands are visible in a polished section because they are more wear resistant than the surrounding material.

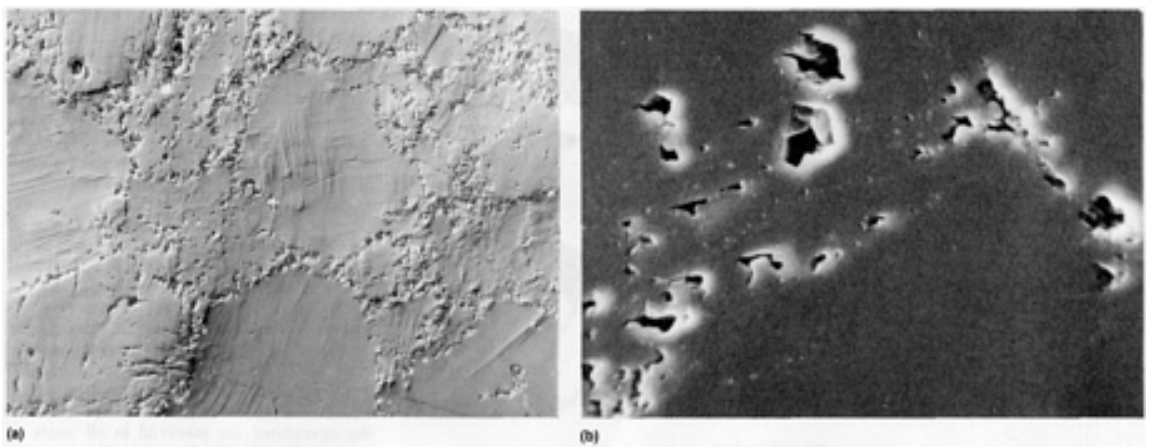

Fig. 7 Microstructure of sintered polycrystalline diamond. (a) Diamond with second phase at the grain boundaries. 225×. (b) Detailed structure of diamond-to-diamond bonding at grain boundary

The sintered diamond contains about 5 to 10 vol% of metal phase and, when made of synthetic diamonds, also may include metals and graphite from the original crystal growth process. Because diamond predominates, the chemical

reactivity and stability for oxidation, back conversion, and wetting/bonding will be similar to those for synthetic diamond alone. The metal phase is an added complication, however, with respect to thermal stability. It can enhance graphitization (back conversion), and it can also contribute to degradation above about 700 °C (1300 °F) by thermal stresses that are due to the large differences in the thermal expansion coefficients of diamond and metals. It is advisable not to overheat these tools during bonding and brazing. Without the metal phase, the material is more thermally stable. Some sintered material is made with better thermal expansion matching of the bonding phase (such as silicon carbide) with diamond to minimize thermal degradation at the expense of strength.

Properties of Sintered Polycrystalline Cubic Boron Nitride

The microstructure of sintered PCBN is shown in Fig. 8. The major phase is CBN with a metallic second phase from the liquid sintering process. With respect to chemical composition and chemical reactivity (oxidation, back conversion, and wetting/bonding), CBN is the predominant material.

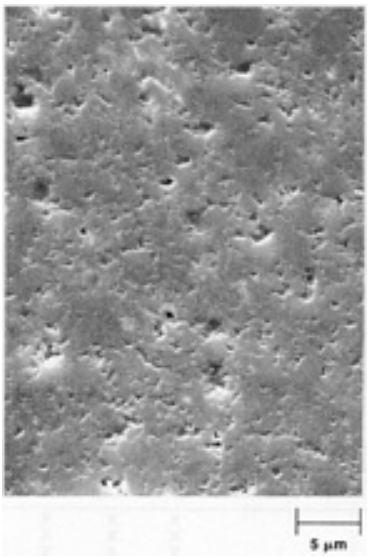

Fig. 8 Microstructure of sintered PCBN

Sintered PCBN can be heated to at least 700 °C (1300 °F) before thermal degradation occurs. The maximum thermal conductivity of sintered PCBN lies in the range of 2.5 to 9.0 W/cm · °C, depending on the processing conditions used to make the samples (Ref 14).

Sintered PCBN is less tough than sintered polycrystalline diamond. As with the diamond version, it has the advantage of isotropic wear and hardness rather than the catastrophic cracking and cleavage that characterize the single crystals in heavy-duty applications. The sizes and shapes available are similar to those for diamond.

Superabrasive Grains

Superabrasive grains are commercially available in a range of sizes, shapes, and qualities (Table 2). Diamond or CBN grains can be used as loose abrasives, as bonded abrasives in grinding wheels and hones, and as bonded abrasives in single-point applications such as turning tools, dressers, and scribes.

Loose Abrasive Grains

Lapping and polishing constitute two major applications of both natural and synthetic loose abrasive grains. Of the synthetic abrasive powders, alumina and silicon carbide are the most widely used in lapping and polishing operations. Silicon carbide is harder than alumina (Table 1) and fractures more easily, thereby providing new cutting edges and extending the useful life of the abrasive.

Synthetic Lapping Abrasive. Silicon carbide, which has sharp edges for cutting, is used for lapping hardened steel or cast iron, particularly when an appreciable amount of stock is to be removed. Fused alumina is also sharp, but it is tougher than silicon carbide and breaks down less readily. Fused alumina is generally more suitable than silicon carbide for lapping soft steels or nonferrous metals.

Boron carbide (B_4C), one of the superhard materials shown in Fig. 1, has a hardness of about 2800 HV and is an excellent abrasive for lapping. However, because it costs 10 to 25 times as much as silicon carbide or fused alumina, boron carbide is usually used only for lapping dies and gages, which is often done by hand and in small quantities, using little abrasive. An example of such a use of boron carbide is in the production of synthetic sapphire for electronic applications. The raw material cost is expensive, justifying a high abrasive-processing cost.

Diamond is also used as an abrasive for lapping metals. It is available as a paste or a slurry. Table 3 lists typical sizes of powders used for lapping applications. Fine-mesh diamond and diamond micron powders are the abrasives most often used in lapping. Depending on the needs of the purchaser, these powders can be provided in several types that differ in aggressiveness (the sharpness of cutting points and edges), shape, and toughness.

Table 3 Size ranges of micron diamond powders for grinding and polishing

Size ranges, μm							
$\frac{1}{10}$	0-1	1-3	4-8	10-15	15-20	22-36	40-60
0-$\frac{1}{4}$	0-2	2-4	5-10	10-20	15-25	30-40	54-80
0-$\frac{1}{2}$	1-2	3-6	6-12	12-22	20-30	36-54	60-100

In a typical lapping machine, the abrasive is applied in a slurry with a water-soluble glycol solution to the surface of a cast iron lap. A continuous feed system ensures that fresh abrasive is always available. To provide uniform lapping on each tool, the workpieces are held under pressure on the lap face and are rotated in a fixture while the lap is turning. When the desired surface is achieved, the tools are replaced with the next set, allowing an efficient semicontinuous operation.

Polishing. As with lapping, aluminum oxide and silicon carbide are widely used synthetic abrasives for polishing. They are harder, more uniform, longer lasting, and easier to control than most natural abrasives. Aluminum oxide grains are very angular and are particularly useful in polishing tougher metals, such as alloy steels, high-speed steels, and malleable and wrought iron. Silicon carbide is usually used in polishing low-strength metals, such as aluminum and copper. It is also applied in polishing hard, brittle materials, such as carbide tools, high-strength steels, and chilled and gray irons. Polishing with loose-grain diamond is more common for nonmetallic workpieces (like granite) than it is for metals. When done on metals, however, the same fine mesh size diamond and diamond micron powders that are used for lapping are employed.

Bonded-Abrasive Grains

The principal use of bonded-abrasive grains is in grinding wheels. The primary metals commonly ground with diamond or CBN are shown in Table 4. Of these applications, the most important worldwide is the grinding of cemented tungsten carbide for producing machine tools, wear surfaces, and dimensioned parts and for resharpening tool blanks. Resin-bonded diamond grinding wheels have become the accepted standard for this application. Cemented tungsten carbide, made by sintering compacted mixtures of tungsten carbide particles with cobalt powders, is a hard, tough, wear-resistant material suitable for use in metal-cutting tools. These same characteristics make it difficult to grind but an ideal workpiece for resin-bonded diamond grinding wheels. Generally, a more friable diamond is best suited for these applications because friable diamond is capable of regenerating cutting edges and points.

Table 4 Metals typically ground or machined with superabrasives and ultrahard tool materials

Metal types	Hardness	Examples of designations or applications	Principal alloying elements	Grind with		Machine with	
				CBN	Diamond	PCBN	PCD

(a) Can be machined or ground if the equipment and operating conditions are suitable for superabrasives

One limitation to the economical use of diamond as the superabrasive of choice is its solubility in iron, nickel, cobalt, and alloys based on these metals. Cubic boron nitride is preferred for the grinding of these metals (Table 4), and CBN grains for grinding iron, nickel, cobalt, and their alloys are generally in the 60 to 400 mesh size range (250 to 38 μm).

Grinding wheels are available in a wide variety of sizes and shapes. Selection of the proper wheel for a given application is critical. The grinding wheel manufacturers have years of experience and can provide help as needed. Krar and Ratterman (Ref 15) also give guidelines that can be of help. They indicate that one should first choose the best bond for the application, then specify, in order, wheel diameters and widths, superabrasive mesh size, and concentrations. If properly done, this procedure will ensure good wheel life, good material removal rates, and the required workpiece surface finish.

Once the grinding wheels have been fabricated, it is good practice to true them to establish the desired shape; they should then be dressed to ensure good protrusion of the abrasive grains. These operations are covered in detail in Ref 16 and in the article "Superabrasives" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Bonds. Several commercial bonds are available for grinding wheels. The most common are resin systems, vitreous systems, metal systems, and electroplated systems. All are suitable for use with superabrasive.

Resin Bonds. The diamond types synthesized for use in resin bond grinding wheels are shown in Fig. 9(a). This type of diamond is friable and thus is capable of regenerating cutting edges and points. It is also well suited to the scratching action required for material removal in the grinding of hard materials such as cemented tungsten carbide. Depending on the application, diamond concentrations can range from 50 to 150 (12.5 to 37.5 vol% of superabrasive). Most commercially available wheels have a 75 to 100 concentration (18.75 to 25 vol% of superabrasive).

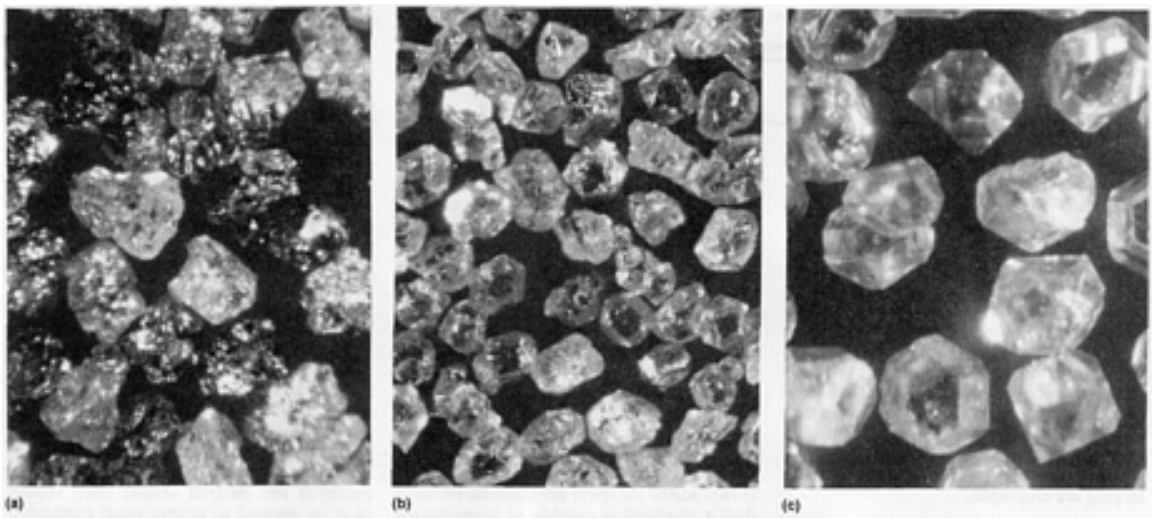

Fig. 9 Commercially available diamond grains used in various applications. (a) Friable diamond grains especially tailored for resin bond grinding wheels. (b) Diamond grains tailored for use in metal bond grinding wheels. These grains are typically in the 80 to 400 mesh size (350 to 38 μm) range. (c) Synthesized diamond grains for use in diamond saw blade applications, such as for the sawing of marble, granite, and concrete. These grains are in the 20 to 60 mesh size (850 to 250 μm) range.

Nearly all of the common resin bonds are thermosetting resins, and most of the thermosetting resins are phenolic resins. Resin powders and a solvent, such as furfural, are mixed with superabrasive particles and a filler, such as silicon carbide, and then placed in a mold containing the metal core. The resin mixture is cured in the hot press mold at pressures of 35 to 105 MPa (5 to 15 ksi) temperatures of at least 150 °C (300 °F) for times ranging from 30 min to 2 h. Before use, the wheels are trued to eliminate chatter and to ensure the proper form. After trueing, it is necessary to dress the wheels to ensure abrasive protrusion for free cutting. Resin bond wheels are commercially available in a large range of sizes. The wheels can be used wet or dry and are free cutting, but they have relatively short life and poor form-holding characteristics.

Phenol-Aralkyl Bonds. Recently, work has been made public concerning new phenol-aralkyl bond systems for diamond abrasives (Ref 17). This class of resins can be used for making grinding wheels in the same equipment used for ordinary phenolic resin wheels. The new formulations are claimed to provide significantly improved wear life, cooler cutting, and a superior workpiece surface finish.

Thermoplastic resins, such as polyimides, are of interest as bond systems for heavy-duty grinding wheels. They are characterized by higher temperature stability limits than those of the phenolic resins. However, these resins do soften at high temperature; this can allow the superabrasive particles to move within the softened bond, and grains may be lost prematurely from the wheels. Special rough coatings have been devised to anchor the abrasive grains in such bonds (Fig. 10), and these coatings have proved effective.

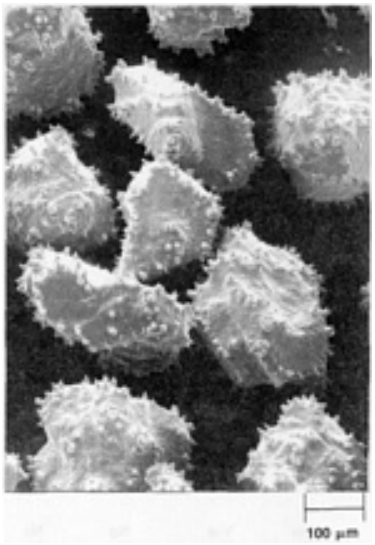

Fig. 10 Diamond of the type shown in Fig. 9(a), but with a special spiked nickel coating. Cubic boron nitride can be coated in a similar fashion.

Vitreous bond systems are generally tailored from glass or ceramic formulations. Vitreous bonds are finding increasing application with CBN abrasive grains; they are also useful for diamond grain wheels. Most vitreous bond systems are proprietary materials used for the production grinding of steel, cast iron, and superalloys. To be suitable for use with superabrasives, the bonds must have the proper wear characteristics, be formable at moderate temperatures and pressures, and be chemically compatible with the superabrasive grains. Some vitreous bonds meet these criteria with diamond but are too reactive with CBN; these applications require the use of protective metal coatings on the CBN. A significant reaction between the bond and the CBN abrasive can produce gaseous by-products that cause excessive porosity in the bond; this can lead to a loss of abrasive particle material and a weakening of the bond. Properly made vitreous bonds have several advantages: ease of conditioning, free-cutting characteristics, reduced frictional heat, excellent surface finish capabilities, consistently accurate geometry, and long wheel life (Ref 16).

Metal bond systems are used with superabrasive grinding wheels in applications such as glass and ceramic grinding. Figure 9(b) shows typical diamond grains used in metal bonds for grinding. The grains are stronger than those used in resin bonds (Fig. 9a), but they are not, as strong as the grains used in saw blade applications for stone and concrete (Fig. 9c). It is common practice to use softer metals such as bronze for metal bond grinding wheels. These metals wear away during use at a rate that ensures both crystal protrusion at the wear surface and free-cutting action. The two basic processes for the fabrication of metal bond wheels are hot pressing and cold pressing followed by sintering. Processing temperatures range from 600 °C (1100 °F) to greater than 1100 °C (2000 °F), pressures from about 14 to 140 MPa (2 to 20 ksi), and times at temperature from about 15 min to over 1 h. Superabrasive concentrations generally vary from 50 to 100 (12.5 or 25 vol% of superabrasive). These bonds are relatively tough, and they have long life and good form-holding characteristics. For glass and ceramic grinding, the mesh size ranges from 60 to 400 (250 to 38 μm).

Electroplated bond systems are available for grinding wheel fabrication. Superabrasive grains are bonded to wheel cores by electrodeposition of nickel or a nickel alloy. Normally, the layer of superabrasive is tacked down by immersing the core as a cathode into a bed of the superabrasive crystals in a plating solution; the wheel is then removed to a fresh bath for final plating. The final product has a single layer of superabrasive crystals with good particle exposure. Such wheels can be fabricated into complex forms and will hold those forms well for the life of the wheel. The wheels are free cutting but have a relatively short life because they possess only a monolayer of crystals.

Coatings. Superabrasive grains are often coated before being incorporated into the bond systems. The coatings are generally of metals, specifically nickel, cobalt, copper, and titanium. The coatings serve several purposes, depending on the superabrasive and the bond. Many of the resin bonds wet metals better than they wet superabrasives. A good example of this is a phenolic bond with nickel-coated synthetic diamond as compared with the same bond with uncoated synthetic diamond. The bond with the nickel-coated diamond is stronger aiding retention of the protruding grains. In addition, metal coatings can slow the transfer of heat from the cutting points of the grains to the resin bond delaying the onset of charring and degradation of the bond and extending the life of the grinding wheel. Coatings can also act as barriers to

chemical reactions, such as those that occur between some vitreous bonds and CBN. Detrimental reactions can be eliminated by thin coatings of titanium on the superabrasive surfaces.

While a number of processes can be used for coating superabrasives (for example, chemical vapor deposition, physical vapor deposition, plasma spraying, and sputter), most commercial coatings are prepared by electroplating techniques. Electrolytic coatings can be applied using a standard or modified Watts bath (Ref 18). Autocatalytic (electroless) coatings are also common and can be applied with baths that require no passage of electric current from external power sources (Ref 19). Autocatalytic coatings can generally be distinguished by the presence of phosphorus from the hypophosphites used as reducing agents. This phosphorus can slightly embrittle the coating, which often improves its performance.

Copper coatings have been designed for superabrasives in resin bond wheels that are used for dry grinding, and the copper-coated wheels are more effective for these applications that those with nickel coatings or uncoated crystals. Copper coatings are normally applied at a 60 wt% concentration. Nickel coatings are more effective in wet grinding with resin bond grinding wheels; they are commercially available at 30 and 56 wt% concentrations. To simplify inventories, some shops prefer to use nickel coatings for all applications, wet or dry. The dry grinding performance of wheels with nickel-coated superabrasives is definitely not as good as that of wheels with copper coatings, but it may be acceptable. The reverse situation, that is, using copper-coated grains in wet grinding applications, gives poor results and is not recommended.

Coated grains are not commonly found in metal bond grinding wheels or in electro-plated wheels. There is nothing to restrict their use for special applications, however.

Ultrahard Tool Materials

Ultrahard tool materials of sintered polycrystalline diamond (PCD) or PCBN are commercially available in many shapes, sizes, and compositions. Depending on their type, they are used for cutting, drilling, milling, dressing, and as wear surfaces.

The PCD or PCBN in ultrahard tool blanks often is bonded to a cemented carbide substrate (Fig. 11), which allows brazing to tool shanks or to indexable inserts for use in standard toolholders. Solid PCD and PCBN can also be used as inserts.

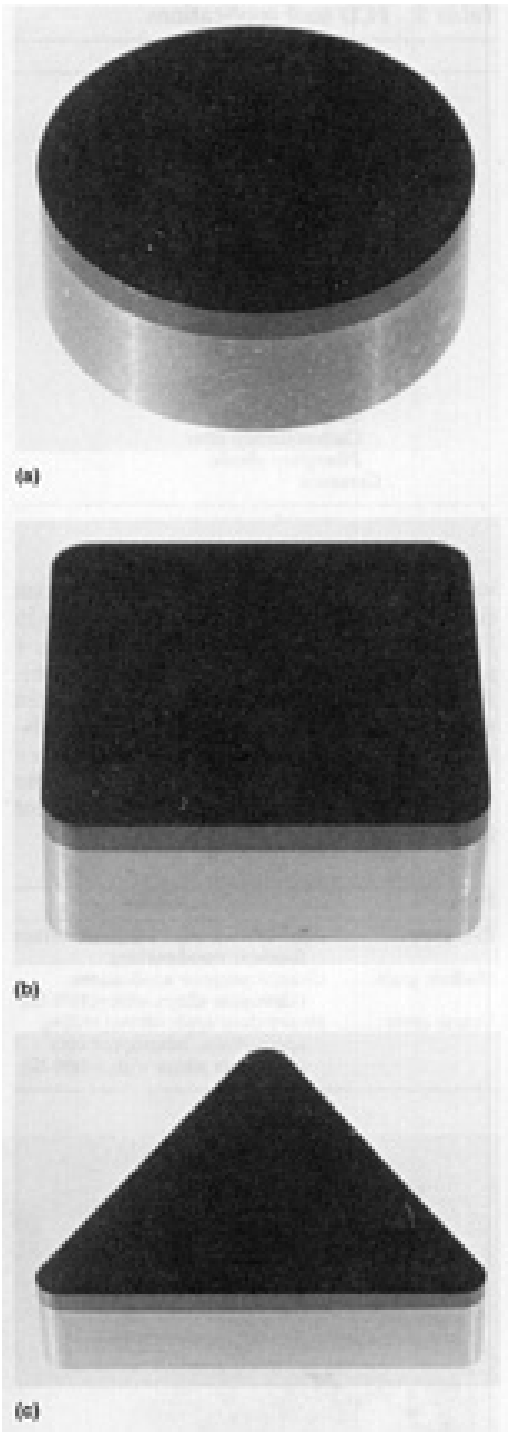

Fig. 11 Polycrystalline diamond with substrates. (a) Typical fully round PCD tool blank. This type of blank is brazed or mechanically clamped to extend the usable cutting edge. (b) Typical square PCD tool blank with a long straight cutting edge that is ideal for many applications. (c) Typical triangular PCD tool blank that is useful in single-point turning applications, either as tools or as brazed-in tips on carbide tools

The types of metals typically machined with ultrahard tool materials are summarized in Table 4. More detailed information on tool fabrication and applications is available in the article "Ultrahard Tool Materials" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Polycrystalline diamond tool blanks are useful in the machining of nonferrous and nonmetallic materials (Tables 4 and 5) and are commercially available in a variety of shapes and sizes (Fig. 12). An important variable for the end user is the average grain size, which is separated into three grades in Fig. 13: fine (average diamond grain size, 4 μm), medium (5 μm), and coarse (25 μm). As shown in Fig. 13, differences in grain size can cause variations in abrasion resistance,

grindability, and workpiece surface finish. As a result of these differences, the areas of preferred application are different for the three grades:

PCD grade	Application
Fine grain	Applications requiring good surface finishes; woodworking
Medium grain	General purpose applications (aluminum alloys with <16% Si)
Coarse grain	Heavy-duty applications; milling applications, interrupted cuts (aluminum alloys with >16% Si)

Table 5 PCD tool applications

Application

Ceramics

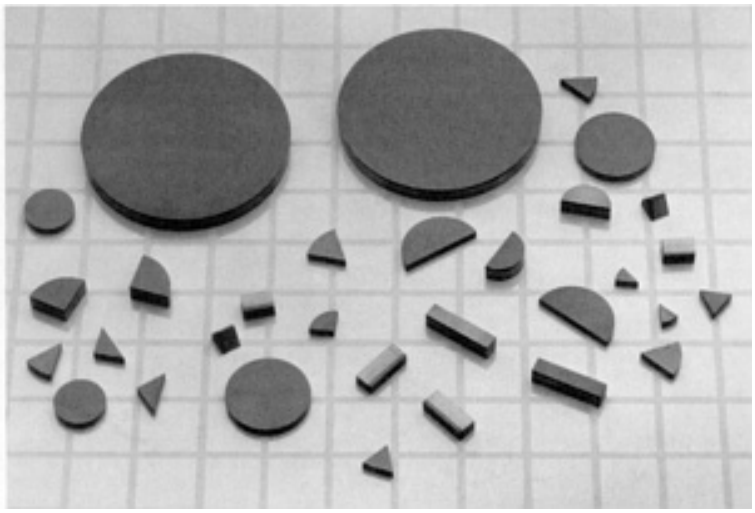

Fig. 12 Various configurations and sizes of PCD tool blanks. Round shapes are available in standard sizes up to about 34 mm (1.34 in.) in diameter.

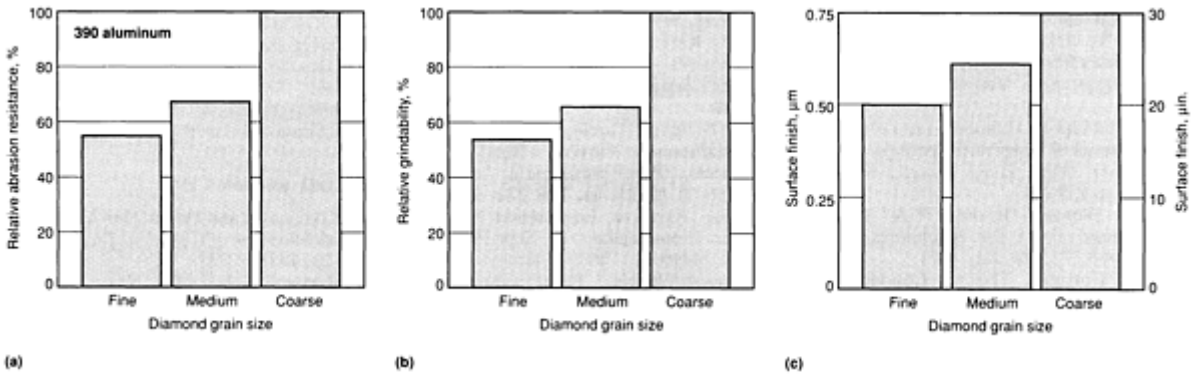

Fig. 13 Variation in tool performance with average grain size in PCD tool blanks. (a) Abrasion resistance. (b) Grindability. (c) Surface finish. Surface finish is also dependent on other factors such as feed rate, tool geometry, and workpiece condition.

The techniques for using PCD tool blanks are not very different from those for using conventional ceramic blanks. Where possible, these guidelines should be followed:

- Use a positive rake
- Maintain a sharp cutting edge
- Use the largest nose radius possible
- Use a rigid machine set-up
- Minimize tool overhang
- Use a flood coolant whenever possible

When first machining a new material, the starting conditions suggested in Table 6 can be used. Slight modifications may give improved results, depending on the particular configuration. Polycrystalline diamond tool blanks can be used dry; the high thermal conductivity of the diamond layer removes and distributes heat generated at the cutting edge. However, tool performance is generally improved by the use of coolants (Ref 15). Water-soluble oil emulsions, such as those used in conventional machining with cemented tungsten carbide tools, are adequate if properly applied to the rake surface. They reduce frictional heating and the formation of built-up edges while providing good chip flow.

Table 6 General starting conditions for PCD cutting tools

Workpiece material	Speed		Feed	
	m/min	ft/min	mm/rev	in./rev
Aluminum alloys				
4-8% Si	1280-1980	4200-6500	0.1-0.65	0.004-0.025
9-14% Si	1005-1585	3300-5200	0.1-0.5	0.004-0.020
16-18% Si	305-700	1000-2300	0.1-0.4	0.004-0.015
Copper alloys	610-1005	2000-3300	0.05-0.2	0.002-0.008
Plastics and composites	300-1005	1000-3300	0.1-0.3	0.004-0.012
Sintered tungsten carbide	20-40	65-130	0.15-0.25	0.006-0.010

Polycrystalline cubic boron nitride (PCBN) tool blanks are useful in the machining of iron, steel, and cobalt- and nickel-base alloys (Tables 4 and 7). This makes them complementary to rather than competitive with the PCD tool blanks. They are generally not recommended for use with superalloys or steels that have hardness of less than 35 and 45 HRC, respectively. The causes and solutions of common problems encountered when using PCBN tools are listed in Table 8.

Table 7 PCBN tool applications

Application
Hard cast iron Ni-Hard Alloy cast iron Chilled cast iron Nodular cast iron
Soft cast iron Gray cast iron
Sintered iron Powder metallurgy products
Hardened steel Tool steels Die steels Case-hardened steels A, D, and M series steels

Bearing steels
Superalloys Inconel 600, 718, and 901 René 77 and 95 Hastelloy Waspaloy Stellite

Table 8 Common problems encountered with PCBN tool blanks

Problem	Cause	Solution
Edge chippage	Improper edge preparation	Chamfer the cutting edge by 15° and 0.2 mm (0.008 in.); ensure a rigid toolholding system
Rapid tool flank wear	Cutting speed too slow (insufficient to soften ahead of tool); or cutting speed too fast (excessive heat generated)	Change speed to recommended rates: For hardened ferrous materials (>45 HRC), 70-130 m/min (230-430 ft/min) For soft gray cast iron (200 HB), 450-915 m/min (1500-3000 ft/min)
	Feed rate too light (thin chip cannot dissipate heat; tool rubbing)	Use a minimum feed rate of 0.1 mm/rev (0.004 in./rev)
	Depth of cut too light (excessive tool rubbing)	Use a minimum depth of cut of 0.125 mm (0.005 in.)
Rapid tool crater wear	Soft tool steel; cutting speed too high (excessive heat)	Use only for steels with a minimum hardness of 45 HRC (see above for speed recommendations)

Polycrystalline CBN blanks are available in a variety of shapes and sizes similar to those of polycrystalline diamond (Fig. 12). Polycrystalline CBN tool blanks can consist of a basic CBN layer (either solid or on a cemented carbide substrate) or a composite abrasive layer (about half CBN and half ceramic). The composite blanks have excellent thermal and wear resistance but lower impact resistance; therefore, they are less applicable to interrupted-cut machining. For milling applications, basic PCBN blanks are preferred.

Tool Geometry. The general guidelines for the use of PCBN tools (Ref 15) are similar but not identical to those for PCD tools. Negative-rake PCBN tools should be used wherever possible because they can withstand high cutting forces.

The lead or side cutting-edge angle should be as large as possible when using PCBN tools; it should only rarely be less than 15°. A large lead angle spreads the cut over a wide section of the cutting edge, resulting in a thinner chip, which in turn reduces loading on the tool blank or insert. The reduced loading allows the feed per revolution to be increased without increasing the chances of cutting edge chippage. In addition, a large lead angle helps reduce notching at the depth-of-cut line; notching can occur in an overly hard workpiece, or as the presence of scale on a workpiece.

Sharp corners on cutting tools concentrate stresses and can cause premature load failures. Honing a radius on the edge and chamfering the cutting edge are two available methods for overcoming this problem. A chamfer of 15° with a width of 0.2 mm (0.008 in.) is recommended for most roughing operations. Honing the edge is slightly is suggested for finishing operations (Ref 15).

Starting Feeds and Speeds. Good starting conditions are listed in Table 9 for several materials commonly machined with PCBN tools. While feeds and speeds are dependent on workpiece properties, the conditions given in Table 9 generally

produce satisfactory result. In the speed ranges shown, the higher speeds are for finishing operations. It is recommended that cutting fluids be used whenever possible.

Table 9 General starting conditions for PCBN cutting tools

Classification	Material Type	Speed		Feed	
		m/min	ft/min	mm/rev	in./rev
Hardened ferrous materials (>45 HRC)	Hardened steels (4340, 8620, M2, T15); hard cast irons (chilled iron, Ni-Hard)	70-130	230-430	0.1-0.5	0.004-0.020
Superalloys (>35 HRC)	Nickel- and cobalt-base alloys (Inconel, René, Stellite, Colmonoy)	200-245	650-800	0.1-0.25	0.004-0.010
Soft cast irons (typically 180-240 HB)	Pearlitic gray iron, Ni-Resist	460-915	1500-3000	0.1-0.65	0.004-0.025
Flame-sprayed materials	Hardfacing materials	60-105	200-350	0.1-0.3	0.004-0.012
Cold-sprayed materials	Hardfacing materials	105-	350-500	0.1-0.33	0.004-

Structural Ceramics

Gerald L. DePoorter, Colorado Center for Advanced Ceramics, Department of Metallurgical and Materials Engineering, Colorado School of Mines; Terrence K. Brog and Michael J. Readey, Coors Ceramics Company

Introduction

CERAMICS are nonmetallic, inorganic engineering materials processed at a high temperature. The general term "structural ceramics" refers to a large family of ceramic materials used in an extensive range of applications. Included are both monolithic ceramics and ceramic-ceramic composites. Chemically, structural ceramics include oxides, nitrides, borides, and carbides. Many processing routes are possible for structural ceramics and are important because the microstructure, and therefore the properties, are developed during processing.

General properties and uses of structural ceramics are reviewed first. Ceramic processing is described and the relationship of processing, microstructure, and properties presented. Specific structural ceramic materials, including composites, are presented. This article concludes with a discussion of future direction and problems with structural ceramics.

Uses and General Properties of Structural Ceramics

Industrial uses, required properties, and examples of specific applications for structural ceramics are summarized in Table 1. These applications take advantage of the temperature resistance, corrosion resistance, hardness, chemical inertness, thermal and electrical insulating properties, wear resistance, and mechanical properties of the structural ceramic materials. Combinations of properties for specific applications are summarized in Table 1. Ceramics offer advantages for structural

applications because their density is about one-half the density of steel, and they provide very high stiffness-to-weight ratios over a broad temperature range. The high hardness of structural ceramics can be utilized in applications where mechanical abrasion or erosion is encountered. The ability to maintain mechanical strength and dimensional tolerances at high temperature makes them suitable for high-temperature use. For electrical applications, ceramics have high resistivity, low dielectric constant, and low loss factors that when combined with their mechanical strength and high-temperature stability make them suitable for extreme electrical insulating applications.

Table 1 Industry, use, properties, and applications for structural ceramics

Industry	Use	Property	Application
Fluid handling	Transport and control of aggressive fluids	Resistance to corrosion, mechanical erosion, and abrasion	Mechanical seal faces, meter bearings, faucet valve plates, spray nozzles, micro-filtration membranes
Mineral processing power generation	Handling ores, slurries, pulverized coal, cement clinker, and flue gas neutralizing compounds	Hardness, corrosion resistance, and electrical insulation	Pipe linings, cyclone linings, grinding media, pump components, electrostatic precipitator insulators
Wire manufacturing	Wear applications and surface finish	Hardness, toughness	Capstans and draw blocks, pulleys and sheaves, guides, rolls, dies
Pulp and paper	High-speed paper manufacturing	Abrasion and corrosion resistance	Slitting and sizing knives, stock-preparation equipment
Machine tool and process tooling	Machine components and process tooling	Hardness, high stiffness-to-weight ratio, low inertial mass, and low thermal expansion	Bearings and bushings, close tolerance fittings, extrusion and forming dies, spindles, metal-forming rolls and tools, coordinate-measuring machine structures
Thermal processing	Heat recovery, hot-gas cleanup, general thermal processing	Thermal stress resistance, corrosion resistance, and dimensional stability at extreme temperatures	Compact heat exchanges, heat exchanger tubes, radiant tubes, furnace components, insulators, thermocouple protection tubes, kiln furniture
Internal combustion engine components	Engine components	High-Temperature resistance, wear resistance, and corrosion resistance	Exhaust port liners, valve guides, head faceplates, wear surface inserts, piston caps, bearings, bushing, intake manifold liners
Medical and scientific products	Medical devices	Inertness in aggressive environments	Blood centrifuge, pacemaker components, surgical instruments, implant components, lab ware

Specific properties of ceramics compared with other materials are discussed in the section "Properties and Applications of Structural Ceramics" in this article. The text by Kingery (Ref 1) should be consulted for a general discussion of the properties as related to composition and microstructure.

Processing of Structural Ceramics

The processing steps for producing structural ceramics are shown in the flow chart given in Fig. 1. These steps can be grouped into four general categories:

- Raw material preparation
- Forming and fabrication
- Thermal processing
- Finishing

These categories are also indicated on Fig. 1. Only a brief overview of ceramic processing can be included here. For specific details see the text by Reed (Ref 2).

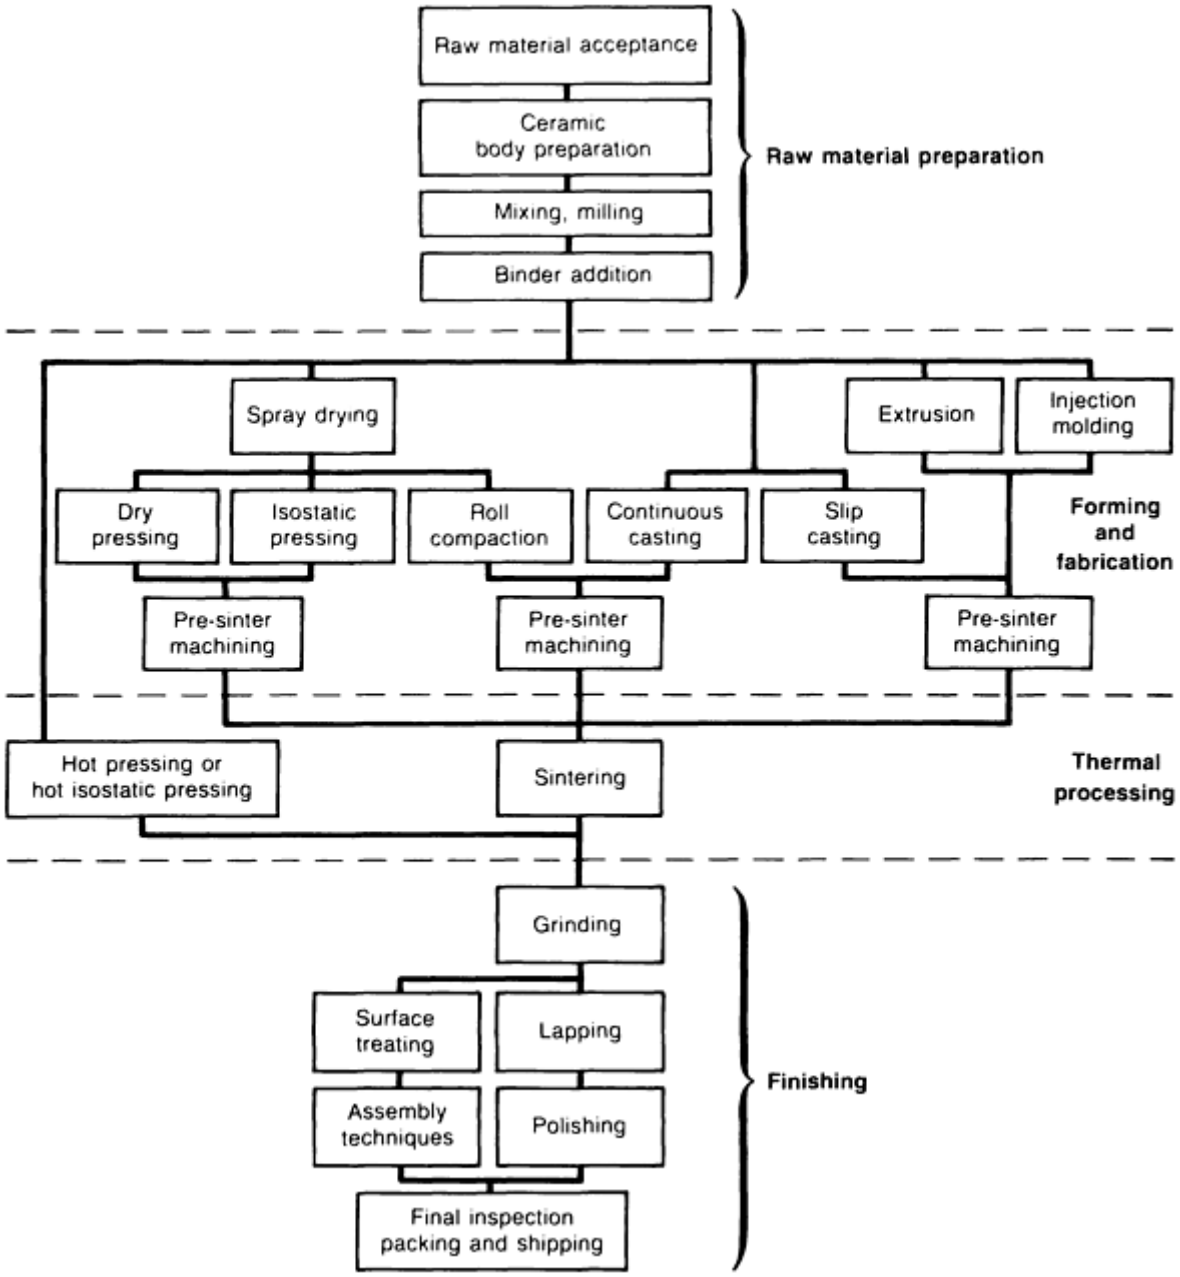

Fig. 1 Flow chart for ceramic processing

Raw material preparation includes material selection, ceramic-body preparation, mixing and milling, and the addition of processing additives such as binders. Material selection is important because structural ceramics require high-quality starting materials that can be described as industrial inorganic chemicals. For example, the Al_2O_3 powder for alumina ceramics is usually obtained as calcined alumina from the Bayer process, which uses bauxite as the starting material. Zirconia is obtained from industrial sources that process zircon ($ZrSiO_4$) to produce ZrO_2 of 99% purity. Silicon carbide, SiC, is produced by the Acheson process in which silica, SiO_2, and coke are placed in an arc furnace and reacted at 2200 to 2500 °C (4000 to 4500 °F). Silicon nitride, Si_3N_4, is produced by reacting silicon with nitrogen. Chemical techniques are used to produce powders where extremely high purity and very fine particle sizes are required. A detailed description of material selection for structural ceramics is included in the reference text edited by Somiya (Ref 3). The assurance of final product quality starts with well-defined and strict material acceptance criteria.

Ceramic body preparation consists of combining the collection of materials necessary for the final body composition. For oxide systems, the starting materials are generally mixed in aqueous systems and milled to obtain the specified particle-size distribution for the body. If necessary, organic binders are added after the milling and mixing. This results in a slurry or slip, which is the starting material for forming and fabrication of the component.

Forming and Fabrication. Structural ceramics are formed from either powders, stiff pasters, or slurries. The slurry from the preparation procedures is converted to an agglomerated flowable powder by spray drying or to a stiff paste by filter pressing. Structural components are formed by pressing of powders, extrusion of stiff pastes, or by slip casting of slurries. In some cases, pre-sinter machining (green machining) is required.

Forming Structural Ceramics From Powders. Pressing operations are used to make consolidated ceramics starting from a powder. Complex shapes are made to net shape in large volumes by dry pressing in uniaxial double-acting presses using specific tooling made for each part. No further shaping of these components is usually required prior to the thermal processing step. Faucet valve plates, pipe linings, and grinding media are made by pressing.

Isostatic pressing is used for larger components and where extensive pre-sinter machining is required. Powders are placed in flexible tooling and pressure is hydraulically applied in all directions forming a part that is machined to net shape prior to sintering. Electrostatic precipitator insulators, sodium-vapor lamp tubes, and spark plugs are examples of products formed by isopressing.

Forming Structural Ceramics From Stiff Pastes. Stiff pastes are used to form structural ceramics by extrusion. In extrusion the plastic mass is forced through a die at high pressure, which determines the shape of the component. Rods and tubes are usually formed by extrusion.

Forming Structural Ceramics From Slurries or Slips. Slurries, or slips, are used to form structural components by slip casting. In slip casting a porous mold, usually plaster, is filled with slip. Capillary action draws the water from the slip into the mold, which forms a solid layer at the slip-mold interface. When the required wall thickness is reached, the remaining slip is poured from the mold. Thermocouple protection tubes are made by slip casting.

Pre-Sinter Machining. Structural components, when required, are machined to final unfired dimensions after the forming operations described above. Conventional machining techniques such as turning, milling, and drilling are used, and in many cases the machining is done on numerically controlled machines.

Thermal processing for structural ceramics is done either at ambient pressure or with added pressure in the case of hot pressing or hot isostatic pressing (HIP). The final microstructure is developed during thermal processing by sintering, vitrification, or reaction bonding.

Sintering takes place by volume, surface, or grain-boundary diffusion and is a solid-state process. During sintering the pores are removed, the piece is densified, and grain growth occurs if desired for the particular ceramic being processed. Sintering is used for high-purity oxide systems.

Vitrification involves the presence of a liquid phase during thermal processing. The liquid phase provides faster diffusion paths and holds the piece together by capillary action during processing. This results in an amorphous or glassy phase

being present in the final microstructure. The final microstructure is created by vitrification for system with less than 99% pure oxide, porcelains, and Si_3Ni_4 with sintering additives.

In some cases the thermal processing is aided by adding external pressure during sintering. The pressure can be applied uniaxially in hot pressing or isostatically in hot isostatic pressing. Covalent materials such as silicon carbide and silicon nitride, and composite systems usually undergo hot pressing. Pressure can also be used to suppress the decomposition of materials (such as in the gas-pressure sintering of Si_3Ni_4). Hot pressing is also used in the processing of spinels.

The microstructure is developed by reaction bonding for some covalent structural ceramics such as silicon carbide and silicon nitride. For example, silicon carbide components are formed by mixing together very fine SiC coated with fine carbon, which is exposed to silicon above its melting point. The molten silicon and the carbon react to form silicon carbide in place which bonds the SiC grains together.

Finishing. Additional processing is required where tolerances are tighter than can be achieved by sintering or where a surface must be extremely flat or polished. Diamond grinding is used to provide tight dimensional tolerances. Lapping using abrasive slurries, extremely flat surfaces, and polishing by slurry abrasion will achieve a fine surface finish.

Properties and Applications of Structural Ceramics

Alumina Ceramics. Aluminum oxide, Al_2O_3 (often referred to as alumina), is perhaps the material most commonly used in the production of technical ceramics. The reasons for its wide acceptance are many; alumina has a high hardness, excellent wear and corrosion resistance, and low electrical conductivity. It is also fairly economical to manufacture, involving low-cost alumina powders.

Alumina ceramics actually include a family of materials, typically having alumina contents from 85 to ≥99% Al_2O_3, the remainder being a grain-boundary phase. The different varieties of alumina stem from diverse application requirements. For example, 85% alumina ceramics such as milling media are used in applications requiring high hardness, yet they are economical. Aluminas having purities in the 90 to 97% range are often found in electronic applications as substrate materials, due to the low electrical conductivity. The grain-boundary phase in these materials also allows for a strong bond between the ceramic and the metal conduction paths for integrated circuits. High-purity alumina (>99%) is often used in the production of translucent envelopes for sodium-vapor lamps.

The microstructure and resulting properties of alumina ceramics greatly depend on the percentage of alumina present. For example, high-purity aluminas typically have a fairly simple microstructure of equiaxed alumina grains (Fig. 2), whereas as 96% alumina ceramic will have a more complicated microstructure consisting of alumina grains (often elongated in shape) surrounded by a grain-boundary phase (Fig. 3). Depending on processing, this grain-boundary phase may be amorphous, crystalline, or both. The properties of this family of materials vary widely, as shown in Table 2.

Table 2 Properties of various alumina ceramics

Alumina content, %	Bulk density, g/cm^3	Flexure strength, MPa (ksi)	Fracture toughness, MPa $\sqrt{m}$ (ksi $\sqrt{in}$)	Hardness, GPa (10^6 psi)	Elastic modulus, GPa (10^6 psi)	Thermal conductivity, W/m · K (Btu/ft · h · °F)	Linear coefficient of thermal expansion, ppm/°C (ppm/°F)
85	3.41	317 (46)	3-4 (2.8-3.7)	9 (1.3)	221 (32)	16.0 (9.24)	7.2 (4)
90	3.60	338	3-4	10	276	16.7	8.1

		(49)	(2.8-3.7)	(1.5)	(40)	(9.65)	(4.5)
94	3.70	352 (51)	3-4 (2.8-3.7)	12 (1.7)	296 (43)	22.4 (12.9)	8.2 (12.9)
96	3.72	358 (52)	3-4 (2.8-3.7)	11 (1.6)	303 (44)	24.7 (14.3)	8.2 (4.6)
99.5	3.89	379 (55)	3-4 (2.8-3.7)	14 (2.0)	372 (54)	35.6 (20.6)	8.0 (4.4)

Aluminum titanate, Al_2TiO_5, is a ceramic material that has recently received much attention because of its good thermal shock resistance. Aluminum titanate has an orthorhombic crystal structure, which results in a very anisotropic thermal expansion. The coefficient of thermal expansion (CTE) normal to the *c*-axis of the orthorhombic crystal is -2.6×10^{-6}/°C (-1.4×10^{-6}/°F) whereas the CTE parallel to the *c*-axis is about 11×10^{-6}/°C (6.1×10^{-6}/°F). The resulting thermal expansion coefficient for a polycrystalline material is very low (0.7×10^{-6}/°C, or 0.4×10^{-6}/°F) as shown in Table 3.

Table 3 Physical properties of various ceramics

Material	Bulk density, g/cm^3	Flexure strength, MPa (ksi)	Fracture toughness, MPa $\sqrt{m}$ (ksi $\sqrt{in}$)	Hardness, GPa (10^6 psi)	Elastic modulus, GPa	Thermal conductivity, W/m · K (Btu/ft · h · °F)	Linear coefficient of thermal expansion, ppm/°C (ppm/°F)
Aluminum titanate	3.10	25 (3.6)	. . . . . .	. . . . . .	5 (0.7)	1.0 (0.6)	0.7 (0.4)
Sintered SiC	3.10	550 (80)	4 (3.6)	29 (4.2)	400 (58)	110.0 (63.6)	4.4 (2.4)
Reaction-bond SiC	3.10	462 (67)	3-4 (2.7-3.6)	25 (3.6)	393 (57)	125.0 (72.2)	4.3 (2.4)
Silicon nitride	3.31	906 (131)	6 (5.5)	15 (2.2)	311 (45)	15.0 (8.7)	3.0 (1.7)
Boron carbide	2.50	350 (51)	3-4 (2.7-3.6)	29 (4.2)	350 (51)	. . . . . .	. . . . . .

The excellent thermal shock resistance of aluminum titanate derives from this considerable thermal expansion anisotropy. During cooling from the densification temperature, the aluminum titanate grains shrink more in one direction than the other, which results in small microcracks developing in the microstructure as the grains actually pull away from each other. Subsequent thermal stresses (either by fast cooling or heating) are thereby dissipated by the opening and closing of the microcracks. Unfortunately, a consequence of the microcracks is that aluminum titanate does not have particularly high strength (25 MPa, or 3 ksi). However, the microcracks do impart very low thermal conductivity, making it an excellent candidate for thermal insulation devices.

The excellent thermal shock resistance of aluminum titanate offers the potential for many applications. For example, aluminum titanate has found uses as funnels and ladles in the foundry industry (aluminum, magnesium, zinc, and iron do not wet aluminum titanate). The automotive industry is also investigating aluminum titanate for exhaust port liners and exhaust manifolds.

Silicon carbide, SiC, is ceramic material that has been in existence for decades but has recently found many applications in advanced ceramics. There are actually two families of silicon carbide, one known as direct-sintered SiC, and the other known as reaction-bonded SiC (also referred to as silconized SiC). In direct-sintered SiC, submicrometer SiC powder is compacted and sintered at temperatures in excess of 2000 °C (3600 °F), resulting in a high-purity product. Reaction-bonded SiC, on the other hand, is processed by forming a porous shape comprised of SiC and carbon-powder particles. The shape is then infiltrated with silicon metal; the silicon metal acts to bond the SiC particles.

The properties of the two families of SiC are similar in some ways and quite different in others. Both materials have very high hardnesses (27 GPa, or 3.9×10^6 psi), high thermal conductivities (typically 110 W/m · K), and high strengths (500 MPa, or 73 ksi). However, the fracture toughness of both materials is generally low, of the order of 3 to 4 MPa $\sqrt{m}$ (2.7 to 3.6 ksi $\sqrt{in}$). The major differences are found in wear and corrosion resistance. While both are very good in each

category, direct-sintered SiC has a greater ability to withstand severely corrosive and erosive environments (the limiting factor for reaction-bonded SiC is the silicon metal).

Applications for SiC ceramics are typically in the areas where wear and corrosion are problems. For example, SiC is often found as pump seal rings and automotive water-pump seals. Silicon carbide's high thermal conductivity also allows them to be used as radiant heating tubes in metallurgical heat-treatment furnaces.

Silicon Nitride. An intense interest in silicon nitride (Si_3N_4) ceramics has emerged over the past few decades. The motivation for such interest lies in the automotive industry, where use of ceramic components in engines would greatly improve operating efficiency. Silicon nitride offers great potential in these applications because of its excellent high-temperature strength of 900 MPa (130 ksi) at 1000 °C (1830 °F), high fracture toughness of 6 to 10 MPa $\sqrt{m}$ (5.5 to 9 ksi $\sqrt{in}$), and good thermal shock resistance. It also has very good oxidation resistance, a property of particular importance in automotive applications.

The automotive components of interest are turbocharger rotors, pistons, piston liners, and valves. The greatest application of Si_3N_4, however, is as a cutting-tool material in metal-machining applications, where machining rates can be dramatically increased due to the high-temperature strength of Si_3N_4.

Boron carbide, B_4C, is another material that is just now finding applications. The chief advantages of B_4C are its exceptionally high hardness (29 GPa, or 4.2×10^6 psi) and low density (2.50 g/cm^3, or 0.09 lb/in.^{3}). However manufacturing B_4C is difficult because of the high temperatures necessary to effect densification (>>2000 °C, or 3600 °F). Thus in most cases B_4C is densified with pressure, as in hot pressing. This limits the complexity of shapes possible without excessive grinding and machining.

A disadvantage of B_4C is the high cost of the powders and subsequent processing. As such, B_4C has found use only in applications that demand the unique properties of B_4C, namely military armor.

SiAlON is an acronym for silicon-aluminum-oxynitride. SiAlON is fabricated in several ways, but is typically made by reacting Si_3N_4 with Al_2O_3 and AIN at high temperatures. SiAlON is a generic term for the family of compositions that can be obtained by varying the quantities of the original constituents. The advantages of SiAlONs are their low thermal expansion coefficient (2 to 3×10^{-6}/°C, or 1 to 1.7×10^{-6}/°F) and good oxidation resistance.

The array of potential applications is similar to that of Si_3N_4, namely automotive components and machine tool bits. However, the chemistry of SiAlON is complex, and reproducibility is a major to becoming more commercially successful. The processing of SiAlONs and their use as cutting-tool materials are discussed in more detail in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Zirconia. Pure zirconia cannot be fabricated into a fully dense ceramic body using existing conventional processing techniques. The 3 to 5% volume increase associated with the tetragonal-to-monoclinic phase transformation causes any pure ZrO_2 body to completely destruct upon cooling from the sintering temperature. Additives such as calcia (CaO), magnesia (MgO), yttria (Y_2O_3, or ceria (CeO_2) must be mixed with ZrO_2 to stabilize the material in either the tetragonal or cubic phase. Applications for cubic-stabilized ZrO_2 (CSZ) include various oxygen-sensor devices (cubic ZrO_2 has excellent ionic conductivity), induction heating elements for the production of optical fibers, resistance heating elements in new high-temperature oxidizing kilns, and inexpensive diamond-like gemstones. Partially-stabilized or tetragonal-stabilized ZrO_2 systems will be discussed below.

Toughened Ceramics. Decades ago, ceramics were characterized as hard, high-strength materials with excellent corrosion and electrical resistance in addition to high-temperature capability. However, low fracture toughness limited its use in structural applications. The birth of toughened ceramics coincided with industrial applications requiring high-temperature capability, high strength, and an improvement in fracture resistance over existing ceramic materials. The primary driving force toward developing toughened ceramics was the promise of an all-ceramic engine. Several of the materials discussed in this section were or are being considered as ceramic-engine component materials.

Zirconia-toughened alumina (ZTA) is the generic term applied to alumina-zirconia systems where alumina is considered the primary or continuous (70 to 95%) phase. Zirconia particulate additions (either as pure ZrO_2 or as stabilized ZrO_2 from 5 to 30% represent the second phase (Fig. 4). The solubility of ZrO_2 in Al_2O_3 and Al_2O_3 in ZrO_2 is negligible. The ZrO_2 is present either in the tetragonal or monoclinic symmetry. ZTA is a material of interest primarily because it has a significant higher strength and fracture toughness than alumina.

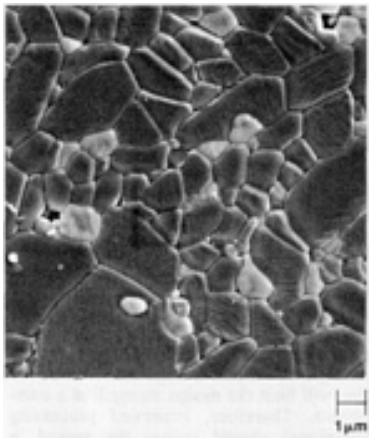

Fig. 4 Scanning electron micrograph of high-purity, zirconia-toughened alumina showing dispersed zirconia phase (white) within an alumina matrix

The microstructure and subsequent mechanical properties can be tailored to specific applications. Higher ZrO_2 contents lead to increased fracture toughness and strength values, with little reduction in hardness and elastic modulus, provided most of the ZrO_2 can be retained in the tetragonal phase. Strengths up to 1050 MPa (152 ksi) and fracture toughness values as high as 7.5 MPa $\sqrt{m}$ (6.8 ksi $\sqrt{in}$) have been measured (Table 4). Wear properties in some applications may also improve due to mechanical property enhancement compared to alumina. These types of ZTA compositions have been used in some cutting-tool applications.

Table 4 Typical physical properties of various ceramics

Material	**Bulk density, g/cm^3**	**Flexure strength**		**Fracture toughness**		**Hardness,**		**Elastic modulus**	
		MPa	**ksi**	**MPa $\sqrt{m}$**	**ksi $\sqrt{in}$**	**GPa**	**10^6 psi**	**GPa**	**10^6 psi**
ZTA	4.1-4.3	600-700	87-101	5-8	4.6-7.3	15-16	2-2.3	330-360	48-52
Mg-PSZ	5.7-5.8	600-700	87-101	11-14	10-13	12	1.7	210	30
Y-TZP	6.1	900-1200	130-174	8-9	7.3-8.2	12	1.7	210	30
Alumina-SiC	3.7-3.9	600-700	87-101	5-8	4.6-7.3	15-16	2-2.3	430-380	62-55
Silicon nitride-SiC	3.2-3.3	800-1000	116-145	6-8	5.5-7.3	15-16	2-2.3	300-380	43-55

Zirconia-toughened alumina has also seen some use in thermal shock applications. Extensive use of monoclinic ZrO_2 can result in a severely microcracked ceramic body. This microstructure allows thermal stresses to be distributed throughout a network of microcracks where energy is expended opening and/or extending microcracks, leaving the bulk ceramic body intact.

Zirconia-toughened alumina was invented almost 15 years ago. However, commercial success has been limited, partly due to the failure of industry to produce a low-cost ZTA with improved properties and its failure to identify markets allowing immediate penetration. One exception has been the use of ZTA in some cutting-tool applications.

Transformation-toughened zirconia is a generic term applied to stabilized zirconia systems in which the tetragonal symmetry is retained as the primary zirconia phase. The four most popular tetragonal phase stabilizers are CeO_2, Y_2O_3, CaO, and MgO. The use of these four additives results in two distinct microstructures. MgO- and CaO-stabilized ZrO_2 consist of 0.1 to 0.25 μm tetragonal precipitates within 50 to 100 μm cubic grains. Firing usually occurs within the single cubic-phase field, and phase assemblage is controlled during cooling.

Interest in CaO-stabilized ZrO_2 has waned in recent years. MgO-stabilized ZrO_2 (Mg-PSZ), on the other hand, has enjoyed immense commercial success. Its combination of moderate-high strength of 600 to 700 MPa (87 to 100 ksi), high fracture toughness of 11 to 14 MPa $\sqrt{m}$ (10 to 13 ksi $\sqrt{in}$, and flaw tolerance enables the use of Mg-PSZ in the most demanding structural ceramic applications. The elastic modulus is approximately 210 GPa (30×10^6 psi), and the hardness is approximately 12 to 13 GPa (1.7 to 1.9×10^6 psi). Among the applications for this material are extrusion nozzles in steel production, wire-drawing cap stands, foils for the paper-making industry, and compacting dies. Among the toughened or high-technology ceramic materials, Mg-PSZ exhibits the best combination of mechanical properties and cost, for room- and moderate-temperature structural applications.

Yttria-stabilized ZrO_2 (Y-TZP) is a fine-grain, high-strength, and moderate-high fracture toughness material. High-strength Y-TZPs are manufactured by sintering at relatively low sintering temperatures (1400 °C, or 2550 °F). Nearly 100% of the zirconia is in the tetragonal symmetry and the average grain size is approximately 0.6 to 0.8 μm. The tetragonal phase in this microstructure is very stable. Higher firing temperatures (1550 °C, or 2800 °F) result in a high-strength (1000 MPa, or 145 ksi), high fracture toughness (8.5 MPa $\sqrt{m}$, or 7.7 ksi $\sqrt{in}$), fine-grain material with excellent wear resistance. The microstructure (Fig. 5) consists of a mixture of 1 to 2 μm tetragonal grains (90 to 95%) and 4 to 8 μm cubic grains (5 to 10%). The tetragonal phase in this microstructure is more readily transformable than above due to the larger tetragonal grain size and a lower yttria content in the tetragonal phase, resulting in a tougher material.

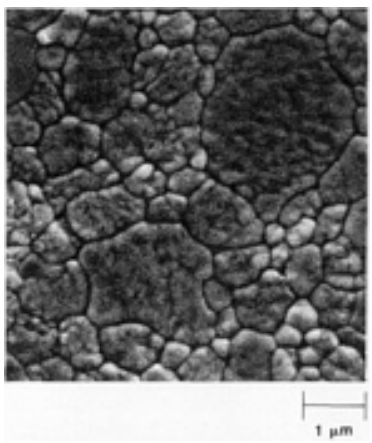

Fig. 5 Scanning electron micrograph of a Y-TZP sample. The larger 3 to 5 μm grains are cubic (~5%); the smaller 1 to 2 μm grains are tetragonal (~95%).

Among the applications for Y-TZP are ferrules for fiber-optic assemblies. Materials requirements include a very fine-grain microstructure, grain-size control, dimensional control, excellent wear properties, and high strength. The fine-grain microstructure and good mechanical properties lend the Y-TZP as a candidate material for knife-edge applications, including scissors, slitter blades, knife blades, scalpels, and so forth. However, compared to Mg-PSZ, Y-TZP is more expensive, has a lower fracture toughness, and is not nearly as flaw tolerant.

There are some temperature limitations in these materials. Mechanical strength of both Mg-PSZ and Y-TZP may start to deteriorate at temperatures as low as 500 °C (930 °F). Also, the Y-TZP ceramic is susceptible to severe degradation at temperatures between 200 to 300 °C (400 to 570 °F).

Composite Ceramics. The early success of ZTA and partially-stabilized zirconia systems provided the impetus to include toughened ceramics as a candidate for structural applications. However, due to the limited maximum-temperature use of these materials, intense research was generated to determined other toughening mechanisms (besides transformation toughening and dispersed-phase toughening) and alternative toughened-ceramic systems.

Silicon carbide whisker (SiC_w)-reinforced alumina surfaced in the last decade as a potential ceramic-engine component material. Composed of fine equiaxed alumina grains and needlelike SiC whiskers, this material exhibited promising fracture toughness (6.5 MPa $\sqrt{m}$, or 5.9 ksi $\sqrt{in}$) and strength (600 MPa, or 87 ksi) properties. Al_2O_3-SiC_w composites have been used quite successfully in cutting-tool applications. These composites may also overcome the severe obstacles that currently prevent the use of ceramic materials in some aluminum can tooling applications.

Conventional processing methods can be employed provided the whisker loading is less than approximately 8 vol%. Composites with higher whisker loadings must be hot pressed, or sufficient liquid-glass-phase sintering must occur to fabricate fully dense bodies. The former limits the fired billet size and requires extensive grinding after sintering. The latter limits its high-temperature use.

Silicon Nitride Matrix Composites. High-temperature degradation of the mechanical properties of Al_2O_3-SiC_w composites and the excellent high-temperature strength, oxidation resistance, thermal shock resistance and fracture toughness of Si_3N_4 caused a recent thrust of interest in fabricating SiC_w-reinforced Si_3N_4. The major phase, Si_3N_4, offers many favorable properties and the SiC whiskers provide significant improvement in the fracture toughness of the composite. Whisker-reinforced Si_3N_4 is now being touted as the material of choice for hot-section ceramic-engine components, although production is currently limited to laboratory or pilot plant-size fabrication. Processing difficulties, health issues, and raw material costs of all of the SiC whisker-reinforced composites have lessened the industrial impact of these materials and may prevent widespread acceptance and use in the near future.

Future Directions and Problems

One of the primary disadvantages of ceramic materials is their brittle nature, characterized by a low fracture toughness. Although significant improvements have been made to increase the fracture toughness, brittleness continues to keep ceramics from more widespread use.

Ceramic Composites. One direction that shows promise is that of composite materials. For example, silicon carbide whiskers have been incorporated into an aluminum oxide matrix, resulting in a composite with greatly improved toughness. The toughening mechanism is probably a combination of whisker pullout and crack bridging, whereby SiC whisker effectively resists crack propagation. Other types of ceramic-ceramic composites would include adding a transforming phase such as zirconia to a host matrix, allowing transformation toughening to improve the fracture toughness of ceramics.

Metal-Ceramic Composites (Cermets). Another class of composites is metal-ceramic composites (cermets). In this case, a ductile metal phase is incorporated into the brittle ceramic. In the event of a propagating crack, the crack interacts with the metal phase, and the metal then begins to plastically deform. This deformation absorbs energy, acting to increase the toughness of the composite. The development and commercial use of various metal-ceramic composites are the subject of the article "Cermets" in this Volume.

Processing. Another area of importance is the science and technology of ceramic processing, both from an economic and performance sense. Currently manufacturing ceramics is a labor- and capital-intensive industry, where products are often custom-made for customers. Manufacturers are continually striving to increase productivity and reduce costs, very often through intense process engineering and optimization

Improved processing techniques should also enhance the performance of structural ceramic components, particularly with respect to reliability. Currently ceramics tend to be very flaw sensitive, in that the strength depends on the size of flaw in the microstructure. The flaw size in turn is usually determined by processing conditions. In most ceramics, conventional processing results in a fairly broad flaw size distribution, which yields a broad strength distribution. Since design engineers often need to know the average strength and strength deviation, a large standard deviation will limit the design strength of a component. Therefore, improved processing techniques should reduce the spread in strengths and allow greater opportunities for ceramics in structural applications.

Introduction

D.C. Larbalestier, L.V. Shubnikov Professor of Superconducting Materials in the Applied Superconductivity Center, and the Department of Materials Science and Engineering, University of Wisconsin-Madison

Introduction

SINCE THE DISCOVERY of high-temperature superconductivity in 1986, pictures of the levitation of a magnet above a superconducting sheet have been widely published in both scientific and popular journals. Owing to the widespread distribution of levitation kits to high schools, many students have been able to play with this almost magical property of superconductors. In the six articles that follow, some of the details of how the superconducting state manifests itself in important classes of superconducting materials are described. Following a contribution entitled "Principles of Superconductivity," the manufacture, properties, and applications of various superconducting materials are addressed in the following articles:

- "Niobium-Titanium Superconductors" (the most widely used superconductor)
- "A15 Superconductors" (in which class the important material Nb_3Sn lies)
- "Ternary Molybdenum Chalcogenides (Chevrel Phases)"
- "Thin-Film Materials"
- "High-Temperature Superconductors for Wires and Tapes"

Even with this broad view, however, only a brief flavor of the breadth of the superconducting state and its applications can be given here.

At the beginning of the 1990s, the science and applications of superconductivity find themselves in an interesting state. A vigorous industry has grown up around the applications of low-temperature niobium-base superconductors. This includes a superconducting electronics industry and a substantial industry producing superconducting magnets. Few large laboratories are now without a superconducting magnet, whether used for physical property measurements, nuclear magnetic resonance (NMR) and other resonance experiments, or for investigations of superconductivity itself. Magnetic resonance imaging (MRI) magnets for the NMR imaging of the whole human body are installed in thousands of hospitals worldwide, and enormous magnet assemblies for particle accelerators and plasma fusion experiments have been built.

At present the largest superconducting device is the Tevatron, the 4.8 km (3 mile) circumference 1000 GeV proton accelerator at Fermilab near Chicago. This consists of about 1000 6 m (20 ft) long superconducting magnets. The proven success of this device was vital to the decision to construct the Superconducting Super Collider (SSC). The SSC, now beginning its construction phase near Dallas, will be about 80 km (50 miles) in circumference and contain about 10,000 20 m (65 ft) long superconducting magnets.

The great vitality of the superconducting community has been enormously enhanced by the amazing and very unexpected discovery in early 1986 by Bednorz and Muller of high-temperature superconductivity in the rare earth cuprates (Ref 1). A rapid phase of new discovery quickly produced several new classes of high-temperature superconductors (Ref 2). Enormously important issues of basic physics are posed by the existence of superconductivity at temperatures as high as 125 K and magnetic fields of greater than 50 T (500 kG). At the same time, the potential for applications is enormous. Before considering these issues further, however, it is instructive to go back to the beginning at superconductivity and trace the development of its technology. This overview will provide a foundation for understanding the basic science and potential applications of superconductivity.

Historical Development

The superconducting state was an unexpected outcome of the low-temperature researches of a group led by Kamerlingh Onnes at the University of Leiden (Holland) in 1911. Onnes discovered that mercury lost all resistance when cooled to about 4 K. Two years later, he came to Chicago to report to the third International Conference of Refrigeration (1913). At this time he reviewed the recent research of the Leiden group (Ref 3). This article is quite astonishing, and only extensive quotations can convey the breadth of Onnes's conception of the possibilities of the superconducting state. Onnes commences by describing his initial 1911 experiments on mercury and then proceeds to rapidly sketch whole segments of the technology of superconducting magnets:

Mercury has passed into a new state, which on account of its extraordinary electrical properties may be called the superconductive state. . . . The behavior of metals in this state gives rise to new fundamental questions as to the mechanism of electrical conductivity.

It is therefore of great importance that tin and lead were found to become superconductive also. Tin has its step-down point at 3.8° K, a somewhat lower temperature than that of the vanishing point of mercury. The vanishing point of lead may be put at 6° K. Tin and lead being easily workable metals, we can now contemplate all kinds of electrical experiments with apparatus without resistance. . . .

The extraordinary character of this state can be well elucidated by its bearing on the problem of producing intense magnetic fields with the aid of coils without iron cores. . . . Theoretically it will be possible to obtain a field as intense as we wish by arranging a sufficient number of amperewindings round the space where the field has to be established. This is the idea of Perrin, who made the suggestion of a field of 100,000 gauss being produced over a fairly large space in this way. He pointed out that by cooling the coil by liquid air the resistance of the coil and therefore the electric work to maintain the field could be diminished. . . . In order to get a field of 100,000 gauss in a coil with an internal space of 1 cm radius, with copper as metal, and cooled by liquid air 100 kilowatt would be necessary. . . . The electric supply, as Fabry remarks, would give no real difficulty, but it would arise from the development of Joule-heat in the small volume of coil, the dimensions of which are measured by centimeters, to the amount of 25 kilogram-calories per second, which in order to be carried off by evaporation of liquid air would require about 0.4 liter of liquid air per second, let us say about 1500 liters of liquid air per hour. . . .

But greatest difficulty, as Fabry points out, resides in the impossibility of making the small coil give off the relatively enormous quantity of Joule-heat to be liquefied gas. The dimensions of the coil to make the cooling possible must be much larger, by which at the same time the electric work and the amount of liquefied gas required becomes greater in the same proportion. The cost of carrying out Perrin's plan even with liquid air might be about comparable to that of building a cruiser. . . .

We should no more get a solution by cooling with liquid helium as long as the coil doest not become superconductive.

The problem which seems hopeless in this way enters a quite new phase when a superconductive wire can be used. Joule-heat comes not more into play, not even at very high current densities, and an exceedingly great number of amperewindings can be located in a very small space without in such a coil heat being developed. A current of 1000 amp/mm^2 density was sent through a mercury wire, and of 460 amp/mm^2 density through a lead wire, without appreciable heat being developed in either. . . .

There remains of course the possibility that a resistance is developed in the superconductor by the magnetic field. If this were the case, the Joule-heat depending on this resistance would have been withdrawn. One of the first things to be investigated as soon as the appliances, which are arranged for making the projected researches on magnetism at helium-temperatures, will be ready, will be this magnetic resistance. We shall see that this plays no role for fields below say 1000 gauss.

The insulation of the wire was obtained by putting silk between the windings, which being soaked by the liquid helium brought the windings as much as possible into contact with the bath. The coil proved to bear a current of 0.8 ampere without losing its superconductivity. There may have been bad places in the wire, where heat was developed which could not be withdrawn and which locally warmed the wire above the vanishing point of resistance. . . .

I think it will be possible to come to a higher current density . . . if we secure a better heat conduction from the bad places in the wire to the liquid helium . . . in a coil of bare lead wire wound on a copper tube the current will take its way, when the whole is cooled to 1.5° K, practically exclusively through the windings of the superconductor. If the projected contrivance succeeds and the current through the coil can be brought to 8 amperes . . . we shall approach to a field of 10,000 gauss. The solution of the problem of obtaining a field of 100,000 gauss could then be obtained by a coil of say 30 centimeters in diameter and the cooling with helium would require a plant which could be realized in Leiden with a relatively modest financial support. . . . When all outstanding questions will have been studied and all difficulties overcome, the miniature coil referred to may prove to be the prototype of magnetic coils without iron, by which in future much stronger and at the same time much more extensive fields may be realized then are at present reached in the interferrum of the strongest electromagnets. As we may trust in an accelerated development of experimental science this

future ought not to be far away.

What a description! Many of the points essential to the development of a proper magnet technology were sketched out by Onnes already in 1913. His vision of powerful magnets, the problem of heat removal from compact windings, the attractive economic feasibility of superconducting as opposed to resistive magnets, operation at current densities of 1000 A/mm^2 and temperatures down t 1.5 K--all of these are crucial aspects of our present superconducting magnet technology. Elsewhere in the same article he describes the melting of superconducting wires following an abrupt transition from the superconducting to the normal state and perhaps prefigures modern composite conductor manufacture by considering the properties of a resistive constantan wire coated with a superconducting layer of tin.

Returning to Onnes's own words, it is only the last sentence that strike a false note. An accelerated progress to applications was reasonable to dream about--but it did not happen. The reason is clearly delineated in a footnote to Onnes's paper: The passage of the electric current through the superconducting wire easily produced a magnetic field of about 0.05 T (500 G), which though weak was sufficiently strong to quench the superconducting state of a type I superconductor such as lead, tin, or mercury. Sadly, more than 20 years passed before there was much understanding of this issue.

In the early 1930s the thermodynamic aspects of the superconducting-to-normal transition were established by Meissner and Ochsenfeld by Gorter and Casimir (Ref 4). As we know now, the crucial step to applications would have been to identify how to make the transition from a (low-field) type I superconductor to a (high-field) type II superconductor (see the article "Principles of Superconductivity" in this Section for an explanation of these terms). This work was in fact underway.

The systematic effects of alloying lead with indium, tellurium, and similar solutes were carried out by Shubnikov's group in Kharkov (Ukrainian Republic) in the period 1935 to 1937, and the basic thermodynamic aspects of the transition--the appearance of a lower (H_{c1}) and an upper critical field (H_{c2}) in the alloys in place of the single small critical field (H_c) of pure lead--were all identified. These were crucial observations. Tragically, Shubnikov's work remained unappreciated by the scientific community as a whole. In 1937 Shubnikov was falsely denounced and sent to a labor camp, dying in prison in 1945. As a political prisoner his work could not be cited by his fellow Soviet scientists, and the scanty accounts of his early researches that had appeared in the Western literature were ignored. An alternative erroneous hypothesis--the filamentary sponge model, which inherently regarded the high-field superconducting properties as being associated with microscopic metallurgical inhomogeneities--was then used to explain the occasional reports of high-field superconductivity (Ref 4).

Further advances had to wait until the 1950s when Soviet theoreticians Ginzburg a Landau addressed the phenomenology of the superconducting-to-normal transition in a magnetic field. It is very striking to recall that event then, Ginzburg and Landau rejected as unphysical those solutions that predicted type II superconductivity. It was left to a persistent student of Landau's (Abrikosov) to explore the "unphysical" type II state. This work was published only in 1957 (Ref 5).

It took the serendipitous experiments of Kunzler *et al.* in late 1960 (Ref 6) to convince the experimentalists that type II superconductivity could indeed realize Onnes's 1913 dreams. Kunzler's experiment showed that a prototype wire of Nb_3Sn could carry a supercurrent of more than 10^5 A/cm^2 in a field of 8.8 T (88.8 kG). Compared to copper, which might operate (resistively) at 10^3 A/cm^2, the advantages of superconductors for high-field magnets became widely appreciated. A rapid advance to applications proceeded during the 1960s, culminating in a wide range of applications in both high-magnetic-field and electronic devices (Ref 7, 8, 9).

During the 1960s, 1970s, and 1980s there was a continued interest in the search for new superconductors. However, higher T_c materials were hard to find. The A15 compound Nb_3Sn held the record of 18 K in 1960, and no advance beyond the 23 K of Nb_3Ge was obtained after 1973. In extensive reviews of the field in 1986 (75 years after the discovery of Onnes), virtually no attention was paid to the prospect of developing materials having higher T_c (Ref 7, 8, 9). The community had run out of collective ideas.

Fortunately, however, one group at least, that of Muller in Switzerland, was still pursuing higher T_c materials. After several years of unsuccessful efforts, their researches were crowned with success. A mixed-phase ceramic of La-Ba-Cu-O exhibited a T_c onset of about 40 K (Ref 1). Within a very short time T_c had been raised to 92 K ($YBa_2Cu_3O_{7-x}$), 110 K ($Bi_2Sr_2Ca_2Cu_3O_x$), and 125 K ($Tl_2Ba_2Ca_2Cu_3O_x$) (Ref 2). Because major expectations for exciting new physics and applications lie with these materials, we confidently expect that the next edition of *Metals Handbook* will require a comprehensive rewrite of the present introduction.

Introduction

SINCE ITS DISCOVERY in the early 1900s, superconductivity has been found in a wide range of materials, including pure metals, alloys, compounds, oxides, and organic materials (see Fig. 1 and Table 1). Superconductivity is by no means a rare phenomenon, as there are several hundred superconducting materials known today (Ref 1). The following sections will provide a basic introduction to the principles of superconductivity. Due to the necessarily limited nature of this article, the reader is referred for more information to the large number of excellent texts available in the field:

- References 2 and 3 for a general overview of superconductivity and its applications
- Reference 4 for a midlevel introduction to the theory of superconductivity
- Reference 5 for a comprehensive survey of filamentary superconductors in magnet applications
- References 6 and 7 for technical information on superconducting materials and applications
- References 8 and 9 for an advanced treatment of superconductivity theory

The breadth of this article is further restricted to focus primarily on the principles of superconductivity as they relate to applications. As a result, details of the quantum theory and thermodynamics of superconductivity will be largely left to the references. The few equations that are described use the International System of Units (SI).

Table 1 Approximate superconducting properties of selected superconducting materials

Material	Type	Critical temperature, T_c at 0 T	Parameters at 4.2 K					
			Thermodynamic critical field, T, at			Magnetic penetration depth (λ), nm	Coherence length (x) nm	Critical current density (J_c), kA · mm^{-2}
			$\mu_0 H_c$	$\mu_0 H_{c1}$	$\mu_0 H_{c2}$

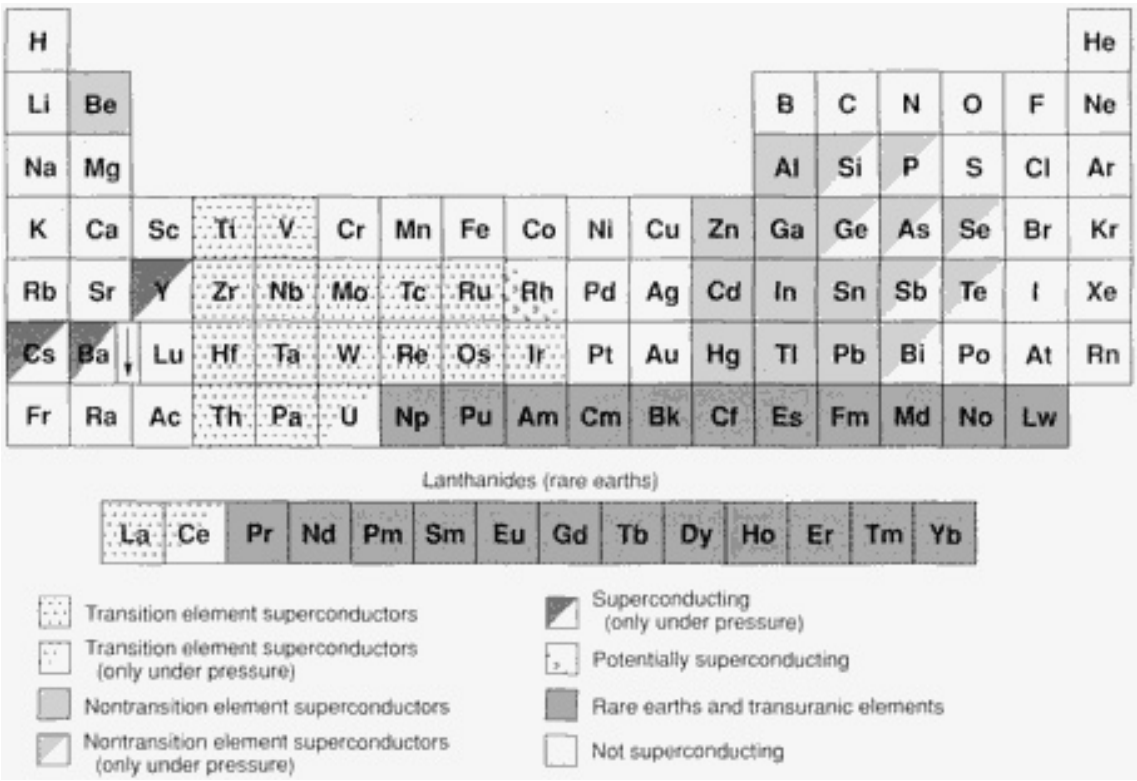

Fig. 1 Periodic table of the elements showing the large number of elements known to have superconducting transitions

The primary physical property of the superconducting state is the complete disappearance of electrical resistance (see Fig. 2(a) and 2(b)) on lowering the temperature below a critical temperature (T_c) (see Table 1). For all superconductors presently known, the critical temperatures are well below room temperature, and they are usually attained by cooling with liquified gases, either at or below atmospheric pressure. The two most common of these coolants are liquid helium and liquid nitrogen (see Table 2).

Table 2 Properties of selected cryogenic cooling fluids

Fluid	T_b at 760 mm Hg, K	Heat of vaporization, J/L × 10^3	Enthalpy at various temperatures, J/L, at				Cost, ($/L)
			4.2 K	20.3 K	77.4 K	273 K

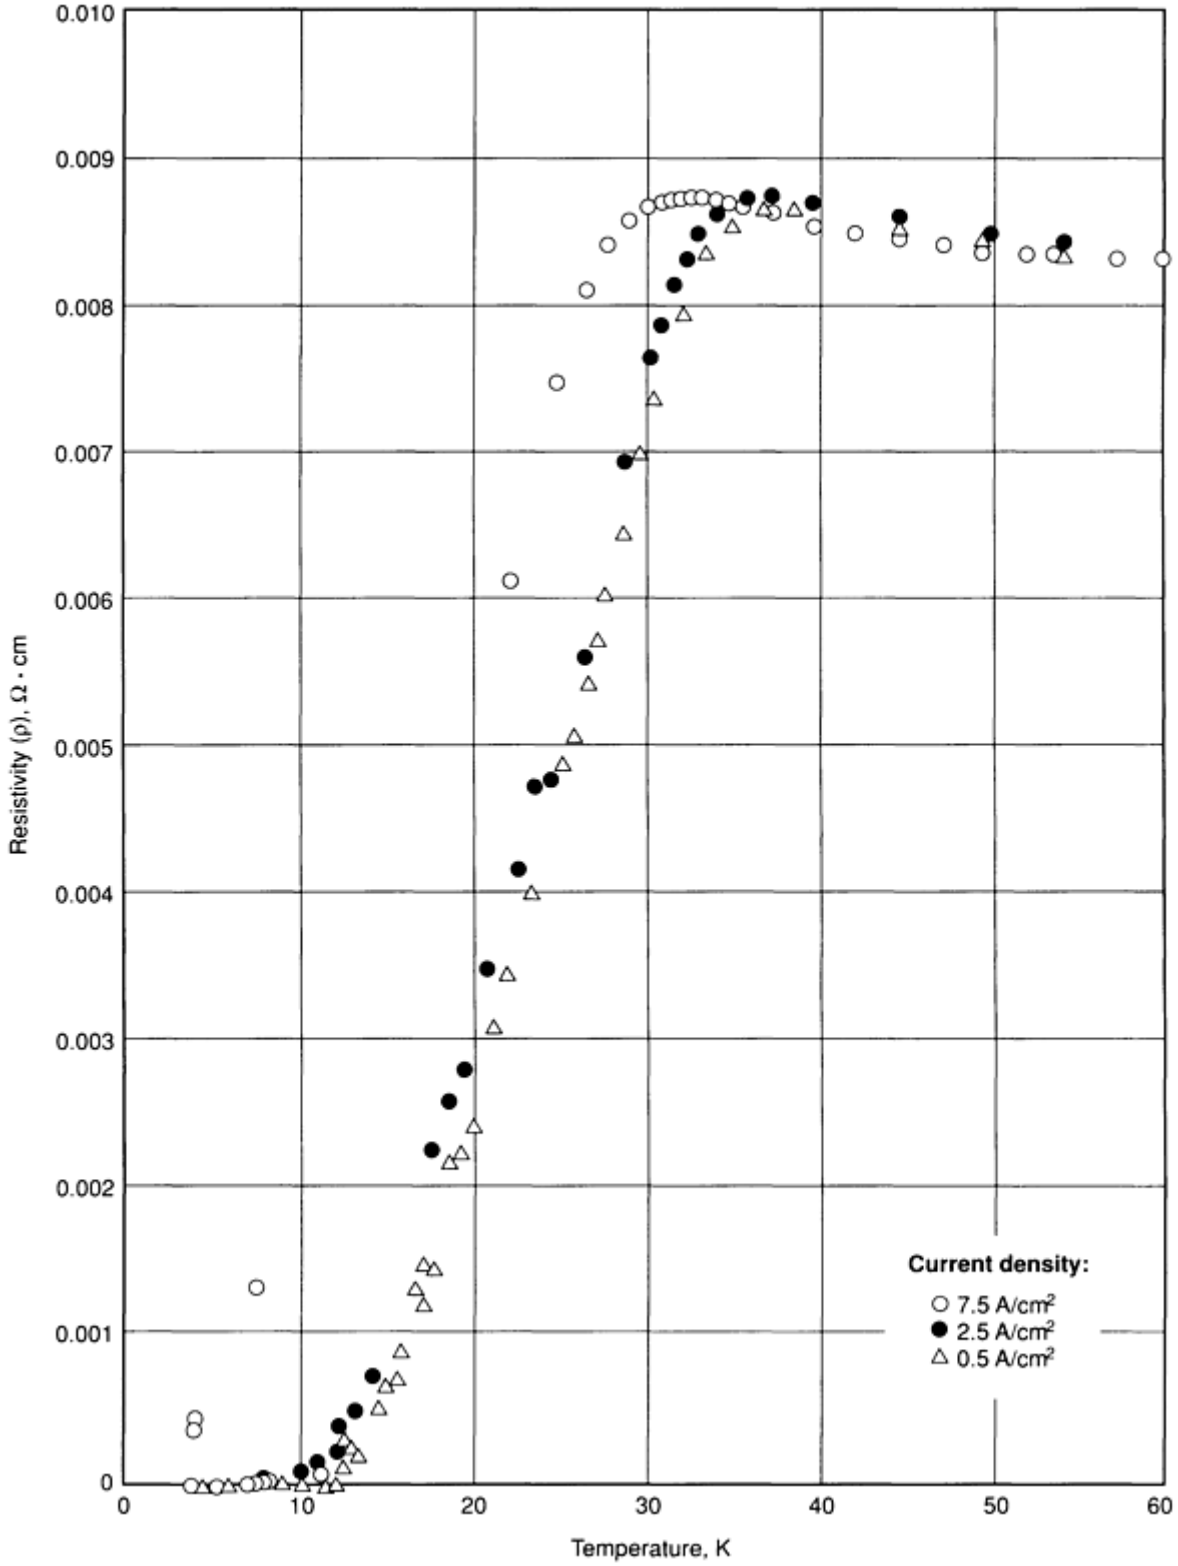

Fig. 2(b) Electrical resistance as a function of temperature for the first high-temperature ceramic (oxide-containing barium) superconductors discovered by Bednorz and Muller in 1986. Source: Ref 10

That the resistance of superconducting materials is (within experimental resolution) zero has been shown by measurements of electrical currents flowing in superconducting loops (Ref 11). Sensitive measurements of the continuously circulating electrical currents after periods of several weeks have shown no measurable decay of the supercurrents, yielding a resistive decay time scale of greater than 10^5 years.

Zero electrical resistance is not the only hallmark of superconductivity. A superconducting material must also exhibit perfect diamagnetism, that is, complete exclusion of an applied magnetic field from the bulk of the superconductor (see Fig. 3). The Meissner effect (also known as Meissner-Ochsenfeld effect) (Ref 12) occurs because circulating supercurrents are induced to flow in a thin sheath at the surface of the superconductor. These currents generate a magnetic field opposing the external field and summing to zero field inside the superconductor. Because these surface currents do not have infinite current density, the external field penetrates the superconductor over the thickness of the sheath. This characteristic distance is called the magnetic penetration depth, $\lambda(T)$ (see Fig. 4), and is a function of temperature. Values of $\lambda(T)$ for several materials at 4.2 K are given in Table 1.

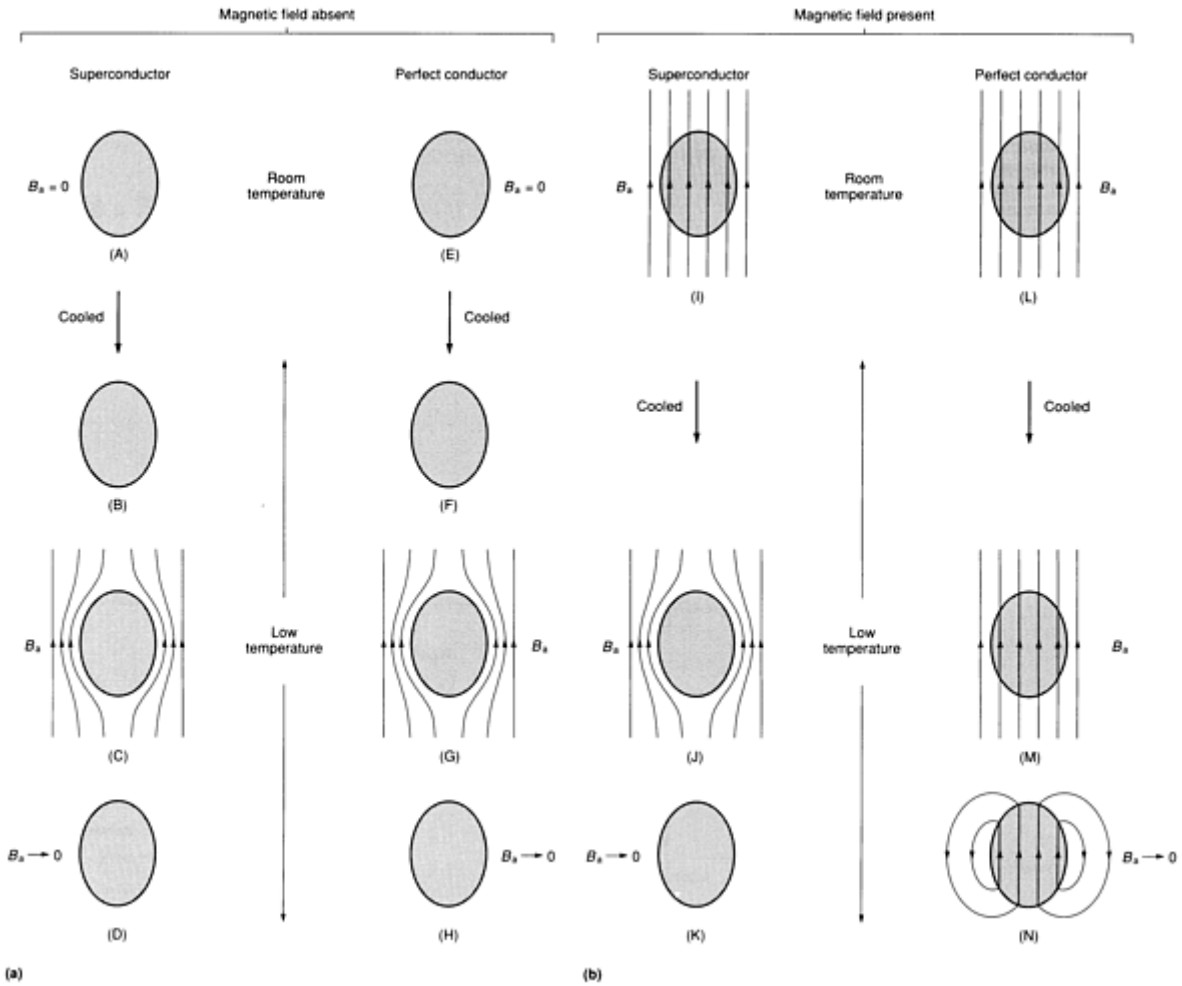

Fig. 3 Comparison of the magnetic behavior of a superconductor to that of a perfect conductor in the presence or absence of an external magnetic field (B_a) when cooled to below the transition temperature. (a) When cooled without being subjected to the magnetic field (A and B) and (E and F), both conductors exhibit exclusion of an applied magnetic field (C and D) and (G and H). (b) When cooled in the presence of a magnetic field (I) and (L), the superconductor excludes the magnetic field, called the Meissner effect (J and K), Whereas the perfect conductor traps the field (M and N).

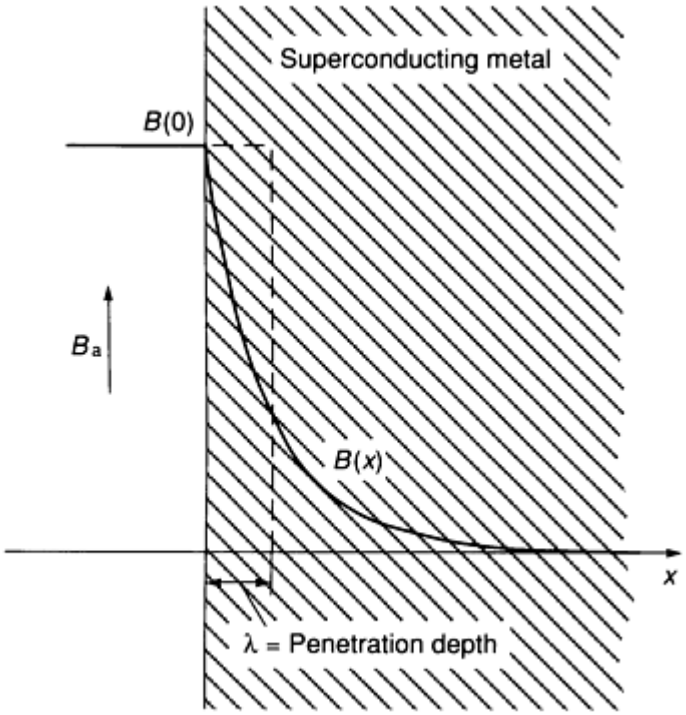

Fig. 4 Currents flowing within a thin sheath at the surface of a superconductor preventing the external applied magnetic field from entering the bulk. The thickness of the current sheath, and the distance over which the magnetic field decays is called the penetration length (λ).

The perfect diamagnetism of superconducting materials implies that the superconducting state will cease to be thermodynamically stable when the magnetic field is large enough. The thermodynamic critical field (H_c) is therefore defined by the difference in the volumetric Gibbs free energies of the normal and superconducting states. This difference is called the condensation energy, and it equals the energy density of the excluded field:

$$G_n(T) - G_s(T) = \mu_0[H_c(T)]^2/2 \qquad \textbf{(Eq 1)}$$

Application of a magnetic field larger than H_c will destroy the superconducting state.

Theoretical Background of Superconductivity

In 1950, Ginzburg and Landau developed a phenomenological theory of superconductivity (Ref 13) invoking a macroscopic quantum mechanical wave function or order parameter (ψ) for which $|\psi(x)|^2 = n_s$, where n_s is the density of superconducting electrons. The minimum distance over which n_s may change significantly (for example, at a normal metal/ superconductor boundary, n_s changes from 0 to 1) defines the temperature-dependent coherence length, $\xi(T)$ (see Table 1). In addition, the spatial extent of ψ suggests that superconductivity is a cooperative phenomenon between the conduction electrons extending over significant distances, comparable to the sample dimensions. The long-range ordering of electrons is responsible for the Josephson effects discussed below.

Theoretical work by Bardeen, Cooper, and Schrieffer (BCS) in 1957 (Ref 14) showed that superconductivity could be well described by pairs of conduction electrons of opposite momenta coupling together through a weak attractive interaction. The pair interaction produces a gap in the energy levels of the electrons and allows a net reduction in the free energy of the superconductor by forming electron pairs. The Frohlich electron-phonon interaction (Ref 15) provides a mechanism for attractive interaction between the electrons by coupling them through the exchange of virtual phonons. BCS theory and the electron-phono mechanism have been very successful in describing many of the experimental results of superconductivity, including the size of the energy gap (Ref 16) and the isotope effect (Ref 17, 18).

Type I and Type II Superconductors. Abrikosov, also in 1957 (Ref 19), showed that the Ginzburg-Landau theory predicted two distinct behaviors for superconductors in an applied magnetic field (see Fig. 5), depending on the value of the dimensionless Ginzburg-Landau parameter, $\kappa(T)$. The $\kappa(T)$ is defined as the ratio of the two characteristic lengths, $\lambda(T)/\xi(T)$, and is only weakly dependent on temperature (see Table 1). When $\kappa(T)$ is small ($<1/\sqrt{2}$), there is a positive surface energy between regions of superconducting and normal phases. This positive surface energy is responsible for the exclusion of magnetic flux from the bulk superconductor because bulk penetration of the magnetic field would produce a normal phase region containing the magnetic field within the superconductor. This would require an increase in the free energy equal to the surface energy of the normal-superconducting boundary and therefore is not thermodynamically stable. Materials with $\kappa(T) < 1/\sqrt{2}$, comprising most of the elemental superconductors, are called type I superconductors.

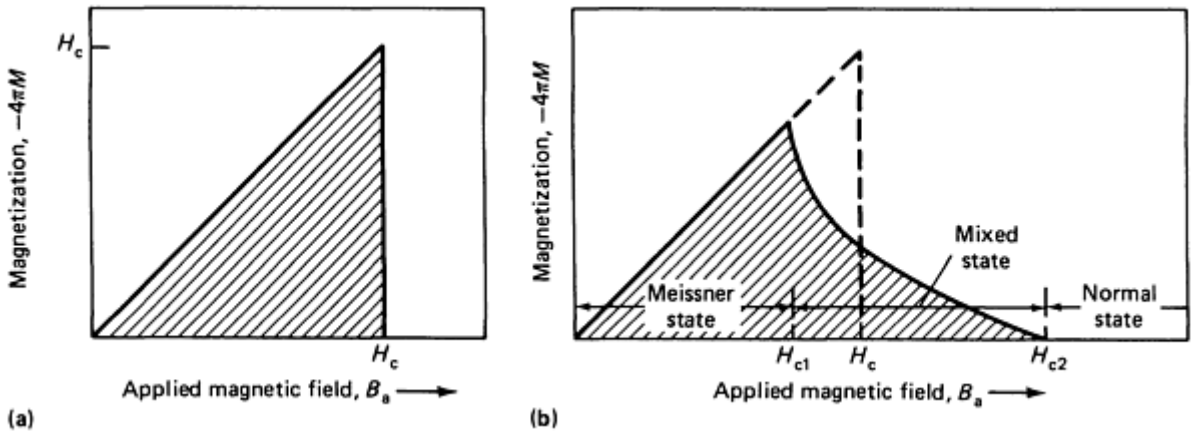

Fig. 5 Plot of magnetization versus applied magnetic field for two classifications of bulk superconductors. (a) Type I. This type exhibits a complete Meissner effect (perfect diamagnetism). The internal field (given by $B = H - 4\pi M$) is zero. Above H_c the material is a normal conductor, and the magnetization is too small to be seen on this scale. (b) Type II. The applied field begins to enter the sample at a field H_{c1} that is lower than H_c. Superconductivity persists in the mixed state up to a high field of H_{c2}, above which the material is a normal conductor. For a given value of H_c, the area under the magnetization curves is the same for both conductors.

Type II superconductors, for which $\kappa(T) > 1/\sqrt{2}$, have a negative surface energy between normal and superconducting phases. Type II superconductors, consisting of the alloy superconductors, exhibit perfect diamagnetism up to a lower critical magnetic field (H_{c1}, which is smaller than H_c. Below H_{c1}, type II materials show identical magnetic behavior to type I materials. As the magnetic field is increased above H_{c1}, the overall free energy is reduced by creating superconducting/normal phase boundaries, allowing the magnetic field to enter the bulk of the superconductor. The field

enters as flux quanta (Φ_0), the smallest unit of magnetic flux, creating a large superconducting/normal phase boundary area (see Fig. 6). The overall reduction in free energy allows type II superconductors to maintain the superconducting state to much larger values of the applied magnetic field before the free-energy balance favors the normal state. Stability of the superconducting state in magnetic fields up to the upper critical magnetic field (H_{c2}) allows type II materials to be exploited for high-magnetic-field applications.

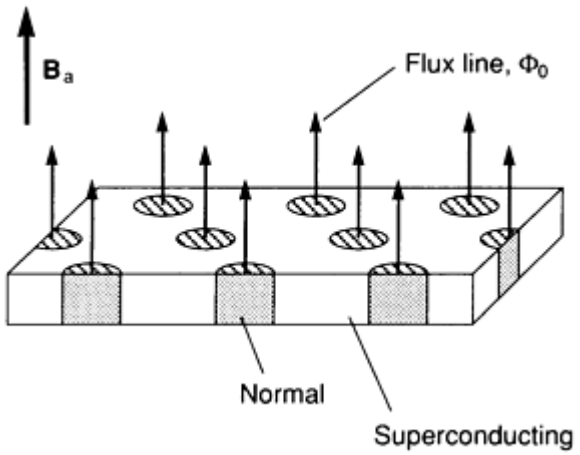

Fig. 6 The magnetic flux line lattice predicted by Abrikosov for type II supeconductors in the mixed state. The field enters as individual units of magnetic flux (the flux quantum, Φ_0) in a triangular array. The areal density of the flux lines is equal to the internal magnetic field.

When the applied magnetic field is between H_{c1} and H_{c2}, the superconductor is said to be in the mixed state. The number density of magnetic flux quanta within the superconductor is then determined by the internal field, $B_i = n\Phi_0$, where $n$is the number per unit area.

Critical Parameters of Superconductivity

Superconductivity can be destroyed not only by large magnetic fields or high temperatures, but also by passing an electric current through the superconductor that is larger per unit cross sectional area than the critical current density (J_c). The J_c is measured in units of A/mm^2. A current density less than J_c will flow in the superconductor with no resistance and thereby result in no power loss or ohmic heating. Current densities larger than J_c produce a voltage loss in the superconductor, generating heat and eventually raising the temperature above T_c. The critical temperature (T_c) and the critical magnetic fields (H_c, H_{c1}, and H_{c2}) are material properties for a given material or composition; they are not affected to any large extent by changes in processing or microstructure. However, within a single material the J_c may vary over several orders of magnitude, and it is very strongly affected by metallurgical microstructure and defect distribution. This provides an opportunity for control of the J_c through appropriate materials processing (Ref 20, 21).

Applications of superconductivity may be broken into two categories: high-magnetic-field and low-magnetic-field applications (Ref 22). High-field applications require that superconductivity carry large critical current densities. This is especially true for superconducting magnets and generators (Ref 23). The applied research effort in high-field

superconductivity is therefore primarily focused on increasing the J_c. Low-field applications include flux shields, transmission lines, Josephson devices, and resonant cavities; these are primarily limited by T_c and H_c.

The three critical parameters of temperature, magnetic field, and current density are closely interdependent. For example, the H_{c2} decreases with increasing temperature or current. These three parameters define a three-dimensional thermodynamic phase field, within which the superconducting state is stable (see Fig. 7). Design and operation of superconducting devices must keep in mind the overall shape of the phase surface, in order to provide margins of safety in all parameters. Operating conditions for superconducting magnets are often at temperatures of $T \leq 0.5\ T_c$.

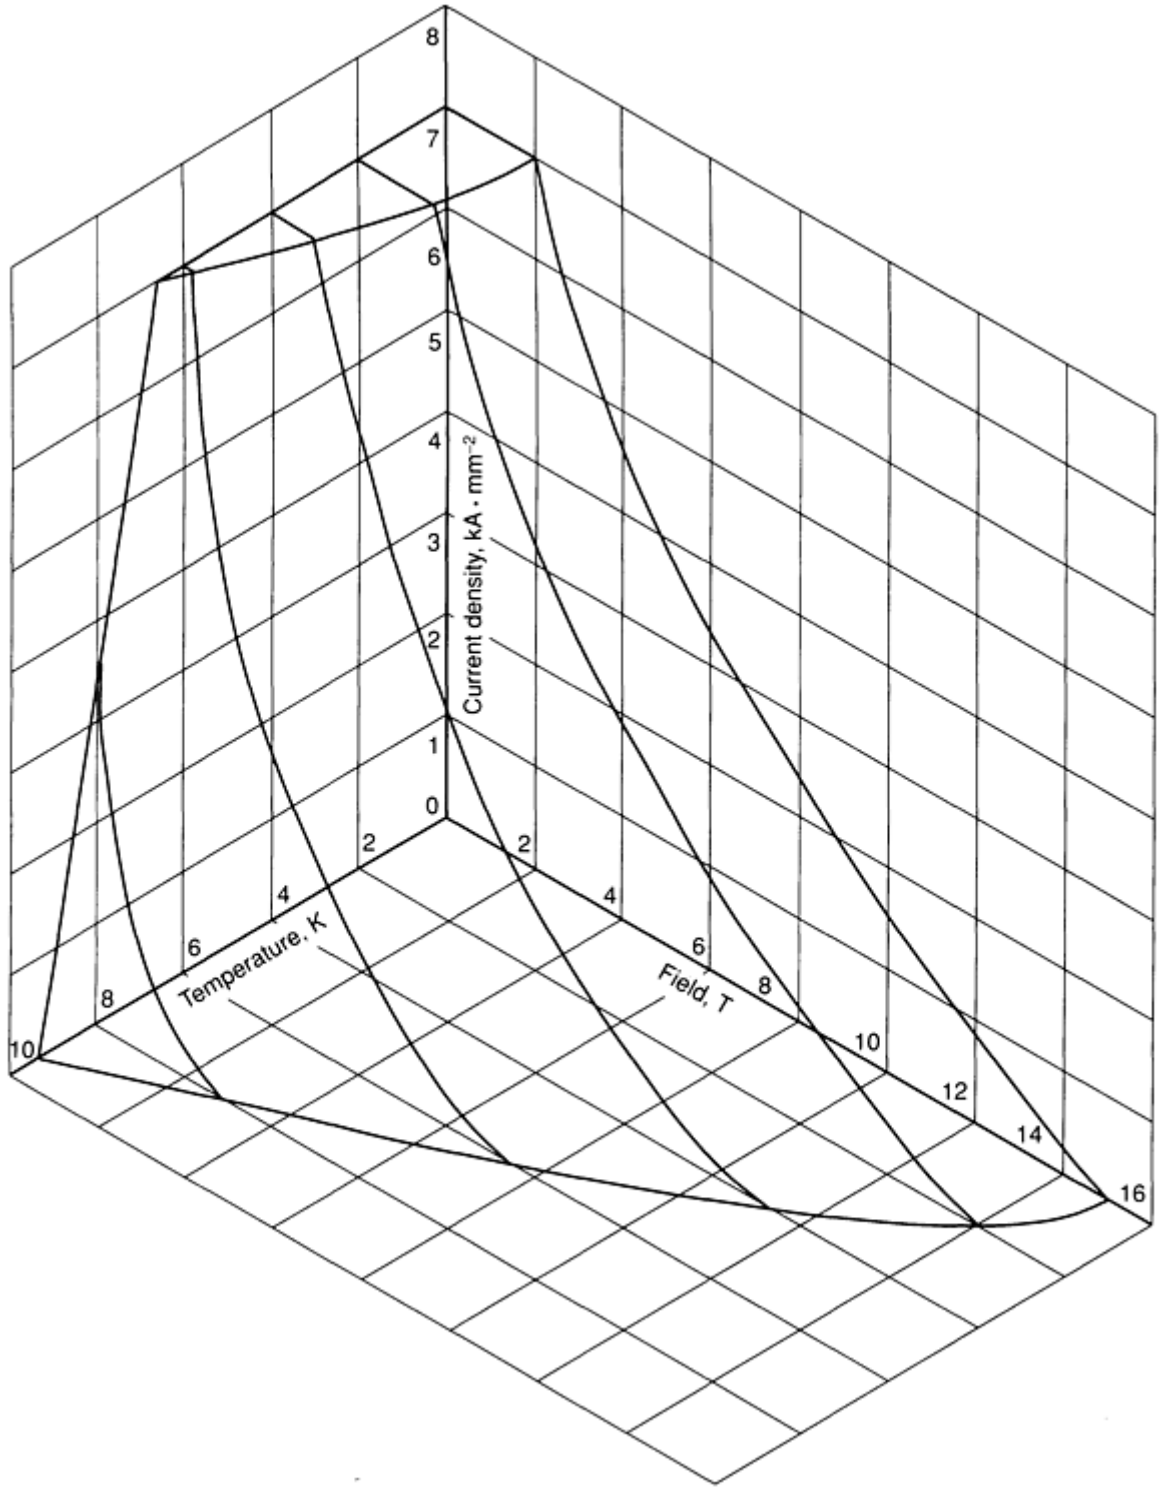

Fig. 7 The critical surface for a niobium-titanium alloy. As long as the state of the superconductor remains within the critical surface, it will

be superconducting. The strong interdependence of the three critical parameters (T_c, H_{c2}, and J_c) is clearly seen.

Many high-field materials have been found to obey a scaling law behavior (Ref 24), with:

$$J_c(T,H) = C[H_{c2}(T)]^n f(h) \qquad \textbf{(Eq 2)}$$

where C is a materials dependent constant and $h = H_a/H_{c2}$ (see Fig. 8). The parameter n varies between 1.5 and 2.5 at low temperatures, while the function $f(h)$ is found to be approximately $h(1 - h)$ for Nb-Ti materials (Ref 25, 26), and $h^{1/2}(1 - h)^2$ for Nb_3Sn (Ref 27).

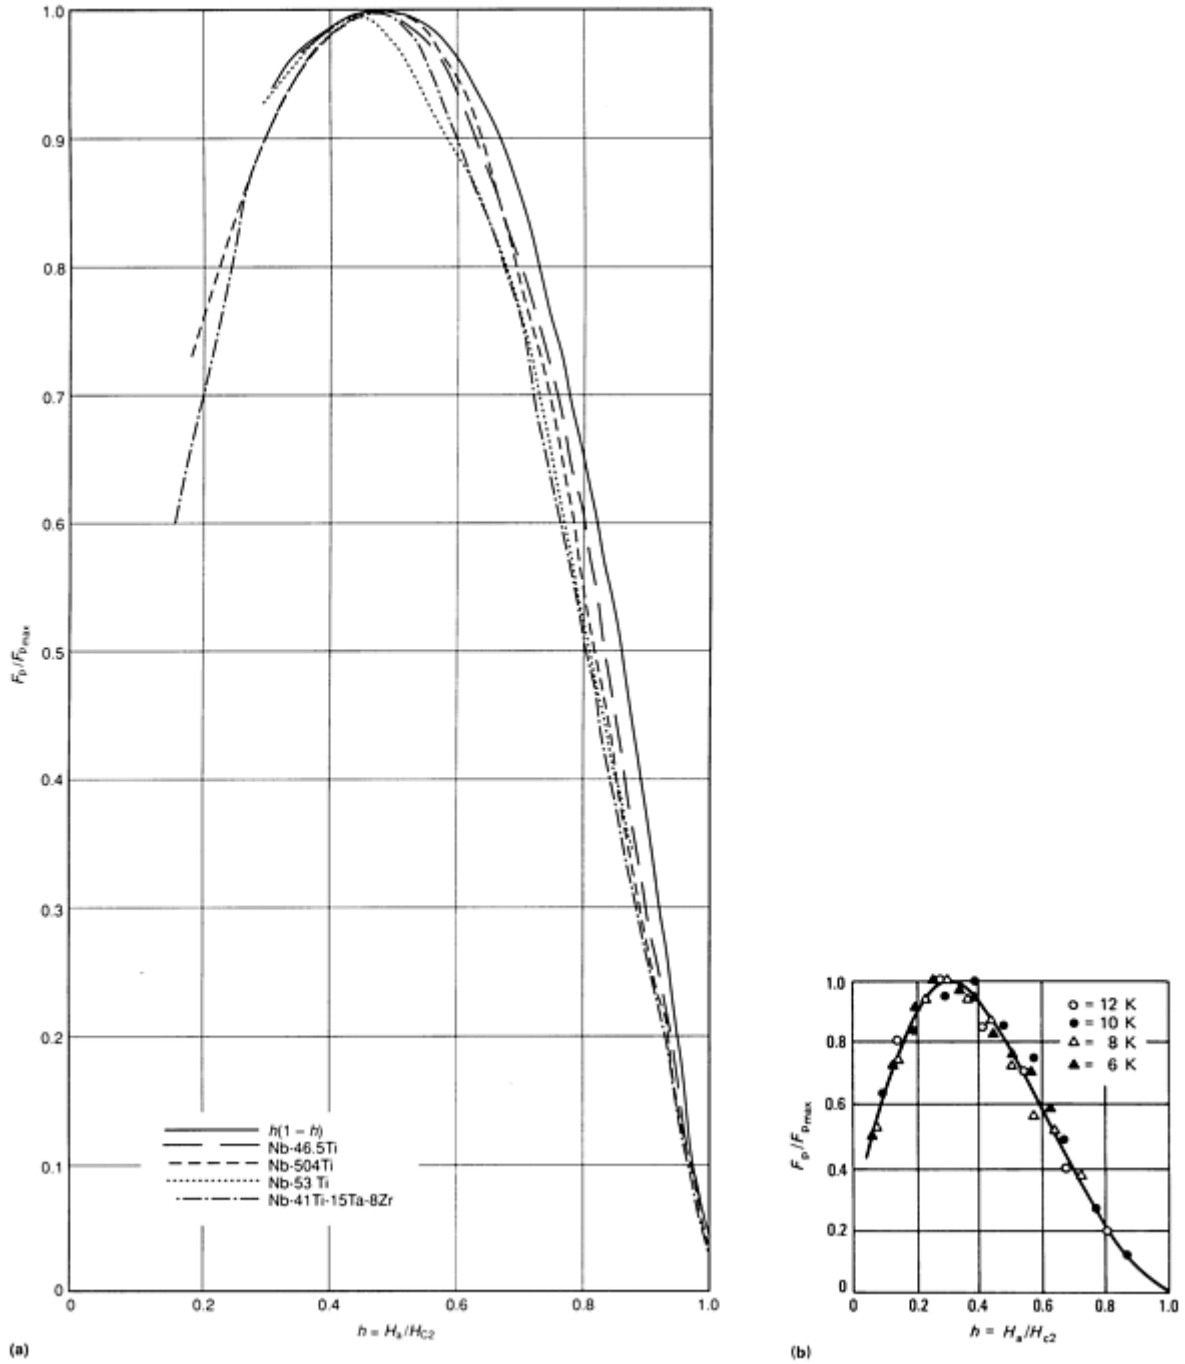

Fig. 8 Scaling law behavior of the critical current density (J_c) for (a) several niobium-titanium alloys (Ref 25) and (b) a Nb_3Sn conductor (Ref 26). In both cases, $F_p = J_cB$ is plotted, scaled by the maximum value versus the reduced applied magnetic field, $h = H_a/H_{c2}$. The

niobium-titanium alloys show an $h(1 - h)$ dependence, whereas the Nb_3Sn exhibits an $h^{1/2}(1 - h)^2$ dependence.

Measurements of T_c, H_{c2} and J_c can be made by either resistive or magnetic methods (Ref 28). A typical resistive measurement involves passing a small measuring current through the superconductor and recording the voltage along the superconductor as a function of temperature, magnetic field, or current density. The transition from the normal to the superconducting state can occur over a very small range of temperatures, fields, or current densities in ideal samples (for example, $\Delta T_c < 10^{-5}$ K for a carefully prepared niobium standard (Ref 29). However, in many type II materials the phase transitions are much broader, and thus the location of the superconducting phase boundary is not precise (see Fig. 2(a), 2(b), and 9).

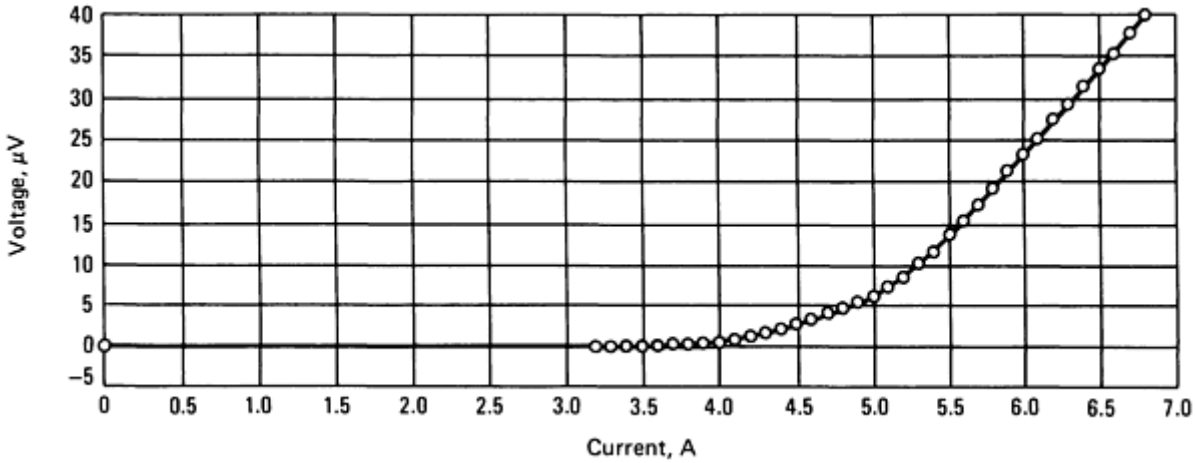

Fig. 9 Broadened critical current transition measured resistively for a niobium-titanium wire. Source: Ref 30

Flux Pinning

Abrikosov (Ref 19) was the first to show that the Ginzburg-Landau theory predicted type II superconductivity. He showed that the flux quanta would be arranged in a periodic triangular lattice when the applied magnetic field is $H_{c1} \leq H_a \leq H_{c2}$. This periodic magnetic structure is called the Abrikosov, or flux line, lattice (see Fig. 10). An isolated flux line can be modeled as a cylindrical core of normal-phase material of radius ξ containing a single unit of magnetic flux (Φ_0) surrounded by a circulating shielding supercurrent of extent λ(see Fig. 11).

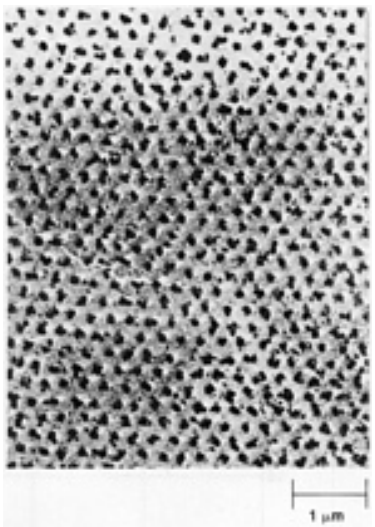

Fig. 10 Triangular flux line lattice in a lead-indium alloy type II superconductor. Small ferromagnetic particles are attracted to the points of high-field density in the core of the flux lines. The flux line positions are seen using a replica in the transmission electron microscopy (TEM).

Source: Ref 31

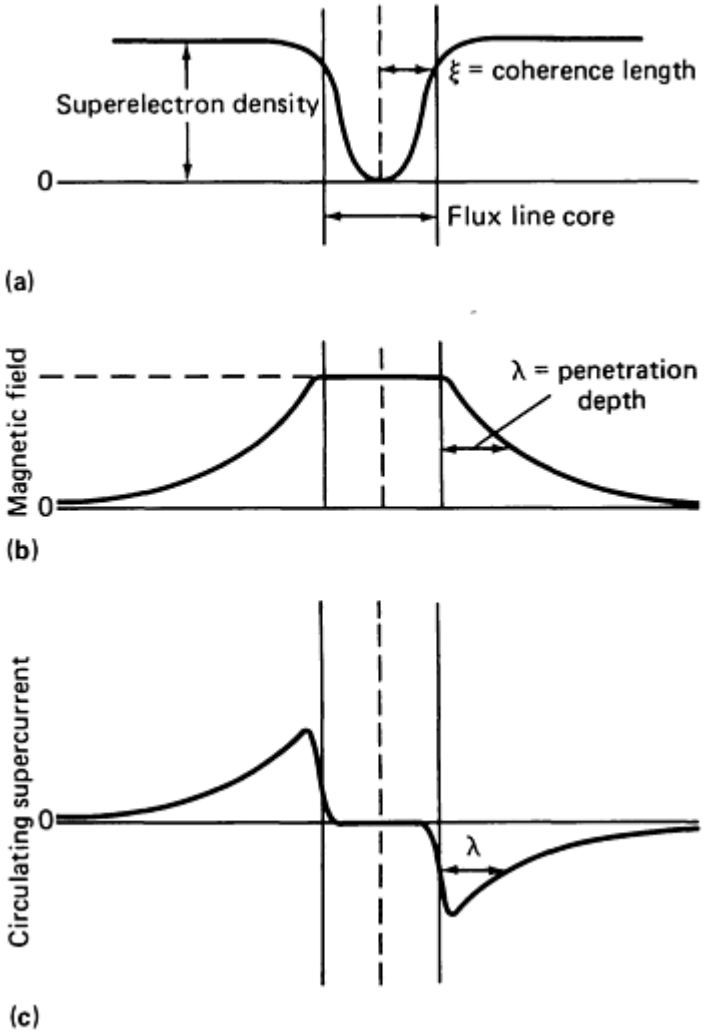

Fig. 11 Model of a single flux line considered as a single unit of magnetic flux, $\Phi_0 = 2 \times 10^{-15}$ Wb, filling a cylindrical volume of radius ξ, the coherence length. (a) The superelectron density rises to its maximum value within about ξ of the core of the flux line. (b) The magnetic field falls off over the distance of the penetration depth (λ). (c) The magnetic field in the core ($\Phi_0/\pi x^2$) is generated by circulating supercurrents flowing within λof the core.

The passage of an electric transport current through the superconductor produces a Lorentz force between the current and the flux lines:

$$\mathbf{F}_L = \mathbf{J} \times \mathbf{B} \qquad \textbf{(Eq 3)}$$

(see Fig. 12). In an ideal homogeneous superconductor, the flux lines will move in the direction of the Lorentz force, causing a dissipation of energy due to their viscous flow. The dissipation appears as a voltage in the direction of the current flow, producing a power loss in the superconductor and an accompanying heating. This flux motion is called flux flow, and the resistivity measured during flux flow is found to be proportional to $\rho_n H_a/H_{c2}$, where ρ_n is the normal state resistivity and H_a is the applied field (Ref 32).

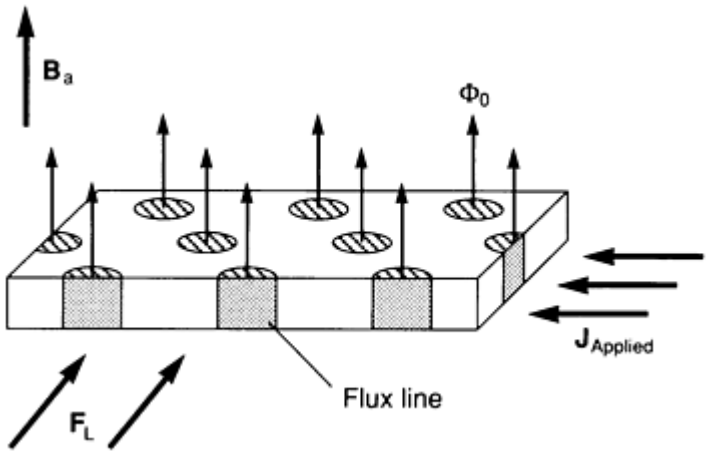

Fig. 12 Transport current density (**J**) flowing through the superconductor. The flux lines experience a reactive force given by the Lorentz force equation, $\mathbf{F}_L = \mathbf{J} \times \mathbf{B}$. In the absence of flux pinning, the Lorentz force will cause the flux lines to flow in a direction perpendicular to both the transport current and the applied field, creating a voltage dissipation in the direction of the current.

By introducing microstructural inhomogeneities to the superconductor (for example, second-phase precipitates, inclusions, voids, dislocation tangles, or grain boundaries), the flux lines can be effectively pinned against the Lorentz force (Ref 33). The basic interaction force between a single flux line and a single pinning center can be viewed as follows: Although the negative surface energy of the superconducting/normal boundary allows the flux line to enter the superconductor, there is still an energy penalty paid to create a flux line equal to the condensation energy times the flux line volume. This increased energy is needed to convert the core of the flux line to the normal state.

If the flux line were positioned on a nonsuperconducting volume defect, such as a void or normal precipitate, the energy necessary to turn the core normal would be saved, and a lower free energy would result. This type of flux pinning, called the core interaction, is the primary source of pinning in two-phase alloys such as niobium-titanium (Ref 34). Grain-boundary pinning described in the model by Zerweck (Ref 35) is thought to be responsible for the high critical currents in Nb_3Sn and other single-phase type II superconductors. Other basic pinning forces include pinning by minority superconducting phases, by magnetic interactions, and by elastic interactions with the strain field surrounding inclusions and precipitates (Ref 36).

By including pinning centers in the microstructure, the superconductor is capable of carrying substantial currents in an applied magnetic field with no voltage loss or power dissipation. The critical current density is given by equating the maximum Lorentz force to the maximum pinning force:

$$\mathbf{F}^{L_{max}} = \mathbf{J}_c \times \mathbf{B} \qquad \textbf{(Eq 4)}$$

Flux pinning theory provides and insight into the scale of inhomogeneities required to produce large critical current densities. Volume pinning centers should be about $2x$ in diameter to optimally match the flux line size. In addition, there should be a large number density of pinning centers, spaced by approximately the flux line lattice spacing:

$$a_0 = 1.075(\Phi_0/B)^{1/2} \qquad \textbf{(Eq 5)}$$

Within an order of magnitude, these dimensions are obtainable and have been observed in high-current-density materials (see Fig. 13).

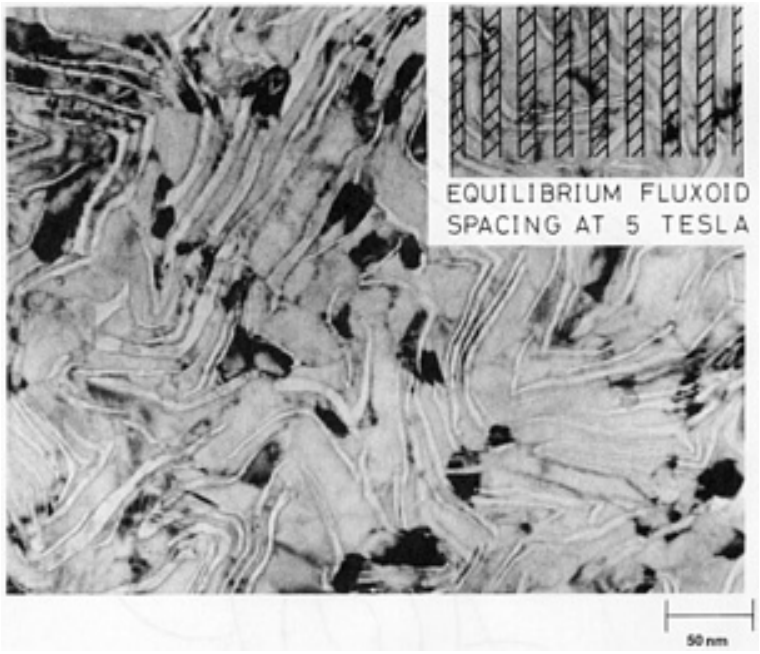

Fig. 13 Transverse cross section TEM photomicrograph of a portion of one filament of a Nb-46.5Ti composite wire. The light streaks are the α-Ti precipitates that are responsible for flux pinning through the core interaction. This wire has a large pinning force, with J_c = 3150 A/mm$_2$ at 5 T and 4.2 K. The scale of the α-Ti precipitates can be compared to the flux line lattice size and spacing in the inset. Courtesy of Peter Lee, University of Wisconsin, Applied Superconductivity Center

Flux line motion of any kind produces resistive-type losses in the superconductor. In addition to flux flow losses, which occur at high Lorentz forces, flux lines can be thermally activated to move out of the pinning potential of the pinning centers at current densities appreciably below J_c. This thermally activated flux motion is called flux creep; it was originally proposed by Anderson (Ref 37). For high-field materials at low temperatures, flux creep is not generally a significant problem. However, as the $T_c$increases (for example, in high- temperature ceramic materials), the thermal energy available to promote flux creep becomes important, producing resistive losses at current densities well below J_c (Ref 38).

Magnetic Properties

The field region below H_c for type I and below H_{c1} for type II materials is called the Meissner state and exists because of the surface-energy barrier to flux entry. The exclusion of magnetic flux from the superconductor (except within λof the surface) in this field range suggests the possibility of using superconductors as flux shields to provide magnetic-field free volumes. Both type I (Ref 39) and type II (Ref 40) superconductors have been used for this purpose. These applications are somewhat limited, however, owing to the generally low values of H_c and H_{c1}.

In type II materials, the critical current density plays an important role in determining the magnetization behavior. The reversible magnetization curve of Fig. 5 is seldom approached in real materials; a hysteretic behavior is more generally found (Fig. 14). Irreversibility of the magnetization as a function of the field is caused by metallurgical defects pinning the flux lines and restricting their movement in and out of the sample. The magnetic hysteresis (ΔM) is therefore proportional to the J_c (Ref 41). The relationship between J_c and magnetization hysteresis may be given as:

$$\Delta M(H) = \mu_0 J_c(H) d \qquad \textbf{(Eq 6)}$$

where d is the diameter of the superconductor. The magnetization of type II superconductors is analogous to the magnetization behavior of magnetic materials such as iron, with the exception that in superconductors it is a diamagnetic rather than a paramagnetic effect. Measurements of ΔM have been used extensively as a means of determining the J_c (Ref 42), especially with samples with a size or shape that renders transport measurements difficult.

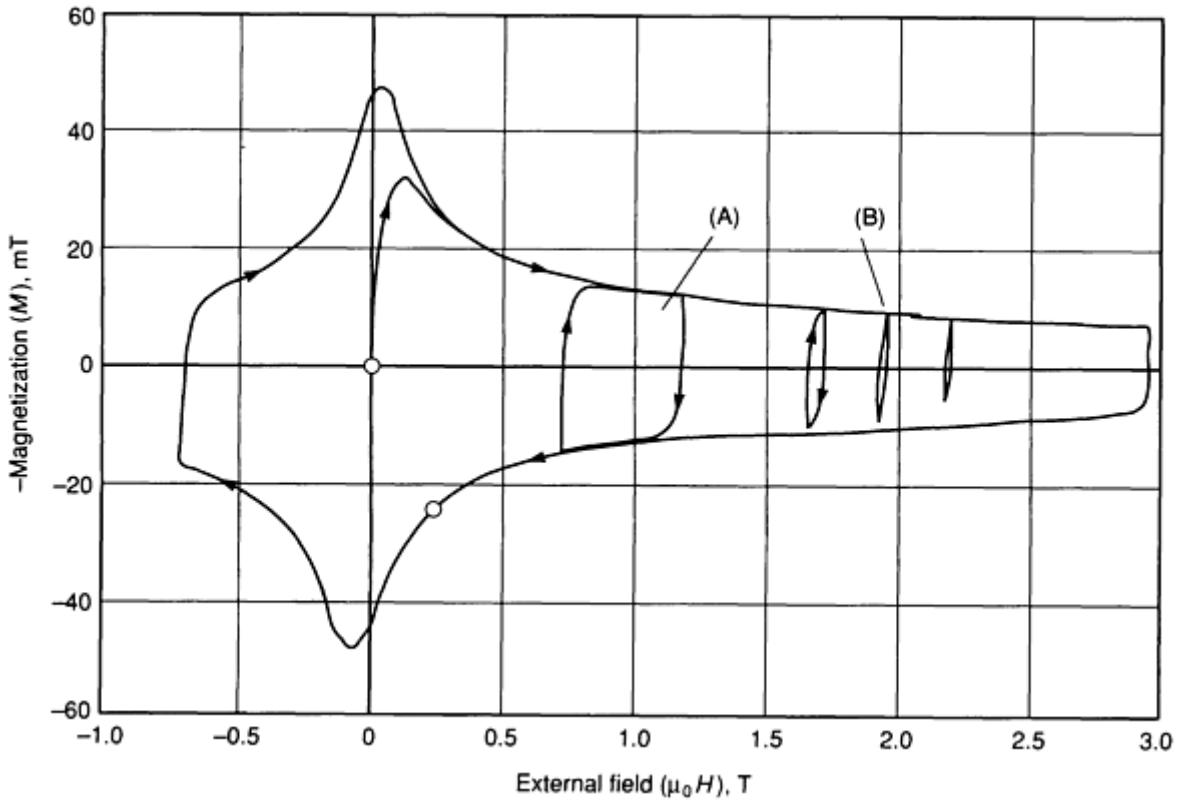

Fig. 14 Hysteretic magnetization of a multifilament niobium-titanium composite wire due to the trapping of magnetic flux by flux pinning centers. At low fields (A) where the J_c is highest, the hysteresis loops are larger than at high fields (B).

Performing a field cycle of 0-*H*-0 will leave a magnetic field trapped inside type II superconductors that depends on the value of *H*, *d*, and the J_c. The magnetic field caused by the magnetization of the superconductor produces a distortion in the transport-current-generated magnetic fields and is a significant problem in designing superconducting magnets of high-field quality, for example, accelerator and magnetic resonance imaging (MRI) magnets (Ref 43).

Since the discovery of high-temperature superconductors in 1986 (Ref 10), the demonstration of magnetic flux exclusion causing a small magnet to levitate above a liquid nitrogen superconductor has become commonplace (see Fig. 15). This experiment was originally performed at 4.2 K using superconducting lead (Ref 44), but is now more commonly performed at liquid nitrogen temperatures with ceramic superconductors. The flux expulsion responsible for levitation with the liquid nitrogen superconductors is not only due to the Meissner effect (because the material is in the mixed state), but is also due to the effect of the flux pinning and the critical current density (Ref 45). Any application involving diamagnetic flux expulsion for levitation (for example, levitated bearing surfaces) will require materials with large J_c values.

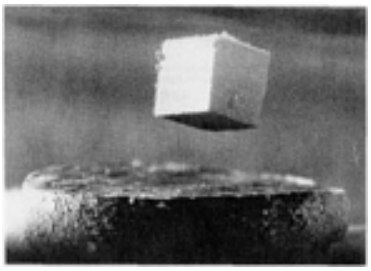

Fig. 15 Levitation of a high-field permanent magnet above a high-T_c superconductor at liquid nitrogen temperatures. The exclusion of magnetic flux by the superconductor due to flux pinning defects creates a magnetic pressure between the magnet and the superconductor that

opposes the gravitational force.

Stabilization

A major consideration in operating superconducting devices near their critical surface is stability of the superconducting state to small disturbances. The primary problem is that at the low temperatures necessary for superconductivity, the specific heat of materials is quite small (see Table 3). Even a small energy input will therefore cause a large increase in the temperature of the superconductor. The temperature increase lowers the critical current density, which changes the magnetic field profile in the superconductor.The flux motion provides a heat input, leading to a further temperature increase and a run-away transition to the normal state. Two major sources of transient-energy input in high-field magnets are mechanical disturbances (for example, due to wire movement under the magnetic hoop stresses) (Ref 46), and flux jumping (Ref 47).

Table 3 Specific heats of selected materials at various temperatures for an applied field of 0 T

Material	Specific heat, J/g · K, at		
	4.2 K	77 K	300 K
Nb-Ti	6.3×10^{-4}	0.14	. . .
Cu	1.1×10^{-4}	0.19	0.38
Al	3.0×10^{-4}	0.34	0.90

The goal in stabilization of superconductors is to prevent a localized disturbance from growing. This can be accomplished in several ways. The simplest, and least satisfactory, is operating the device with enough margin to avoid crossing the critical surface. In this case, the superconductor will be stable if the heat is conducted away from the localized disturbance more quickly than it is generated.

Cryogenic Stability. For larger disturbances, which generate larger heat inputs, it becomes necessary to put the coolant in intimate contact with the superconductor. The criterion for cryogenic stability was determined by Stekly and Zar (Ref 48) and, simply stated, requires the cooling power available in the cryogen to be larger than the heat generated by the disturbance (see Fig. 16). To assist in transporting the heat to the cryogen, the superconductor is generally surrounded by a high-thermal-conductivity normal metal such as copper or aluminum

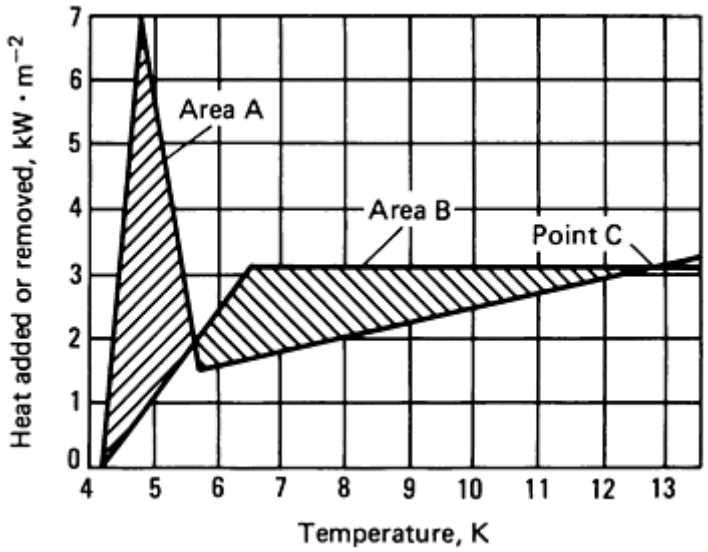

Fig. 16 Equal-area condition for cryogenic stability of a superconductor. (A) is the heat transfer from the superconductor to liquid helium, and (B) is the heat generated in the superconductor by a local disturbance. As long as the area under the cooling curve (A) is greater than the area under the generation curve (B), the superconductor will recover. For this case, the superconductor will be stable for disturbances producing temperature increases as high as Point C, 13 K above ambient temperature.

In addition to higher thermal conductivity, the normal metal matrices provide a high-electrical-conductivity parallel current path. Because the normal-state resistivity (ρ_n) of the superconductor is quite high, the resistive heat input during the disturbance is greatly reduced, allowing recovery from a larger disturbance.

The primary drawback to designing devices that are cryogenically stable is that surrounding the superconductor with coolant significantly dilutes the block current density, thereby reducing the achievable magnetic field. Most large-scale magnets rely heavily on cryogenic stability, however, and designs incorporating normal liquid helium (Ref 49), superfluid helium (Ref 50), and forced-flow liquid helium (Ref 51) have been tested.

Adiabatic Stability. A different stability issue is raised with the problem of flux jumps. A flux jump is the sudden movement of magnetic flux in the superconductor, causing a voltage and generating a local heating. The flux motion can come about in many ways. A slight temperature increase (due to mechanical motion, for example), or an increase in the applied magnetic field causes the local J_c to be reduced. Because the J_c is related to the flux gradient in the superconductor by Maxwell's equations ($\partial B/\partial x = \mu_0 J_c$), the flux must redistribute to match the new gradient. The flux movement generates, heat, increasing the temperature, which in turn reduces the J_c still further. The temperature continues to rise, quickly leading to a normal zone in the superconductor.

The heat generated locally by a flux jump is given roughly by $\mu_0 J_c^2 a^2$ where a is the half thickness of the conductor. The condittion' for a adiabatic stability against flux jumps is established by equating the heat generated during the flux jump to the heat capacity of the superconductor. If the superconductor size (a) can be made small enough (typically <50 μm, or 0.002 in.), the temperature will not rise above T_c and the superconductor will recover.

Dynamic Stability. The condition for stability against flux jumping is eased by allowing the heat to be carried away by the coolant. However, in the superconductor the thermal-diffusion time constant (τ_t) is much larger than the magnetic-diffusion time constant (τ_m) and the heat cannot be extracted from the superconductor during the flux jump. For copper and aluminum, (τ_m) is much larger than (τ_t) and the flux motion is slowed enough that, for superconductors of small size, the heat can be conducted away safely. This dynamic stability criterion yields a maximum size for the superconductor similar to that determined by the adiabatic criterion, although they arise from quite different mechanisms. In both cases, the stability is ensured if the superconductor is made small enough. This is one of the reasons for producing multifilamentary wires with fine superconducting filaments as discussed in the sections "Alternating Current Losses and RF Effects" and "Josephson Effects" in this article.

A third aspect of superconductor stability relates to the interfilament coupling of multifilamentary composites. Because the filaments are very close together in the composite (commonly <5 μm, or 200 μin.), a varying magnetic field will induce eddy currents to flow across the resistive matrix (see Fig. 17). The coupling causes the individual filaments to behave as a single large filament with a diameter that is nearly as large as that of the wire. The increased effective diameter exceeds the flux jump stability criteria, leading to degraded performance of the composite wire. By introducing a twist-pitch to the filament bundle during wire processing, the induced eddy currents can be made to cancel one another, effectively decoupling the filaments and restoring flux jump stability.

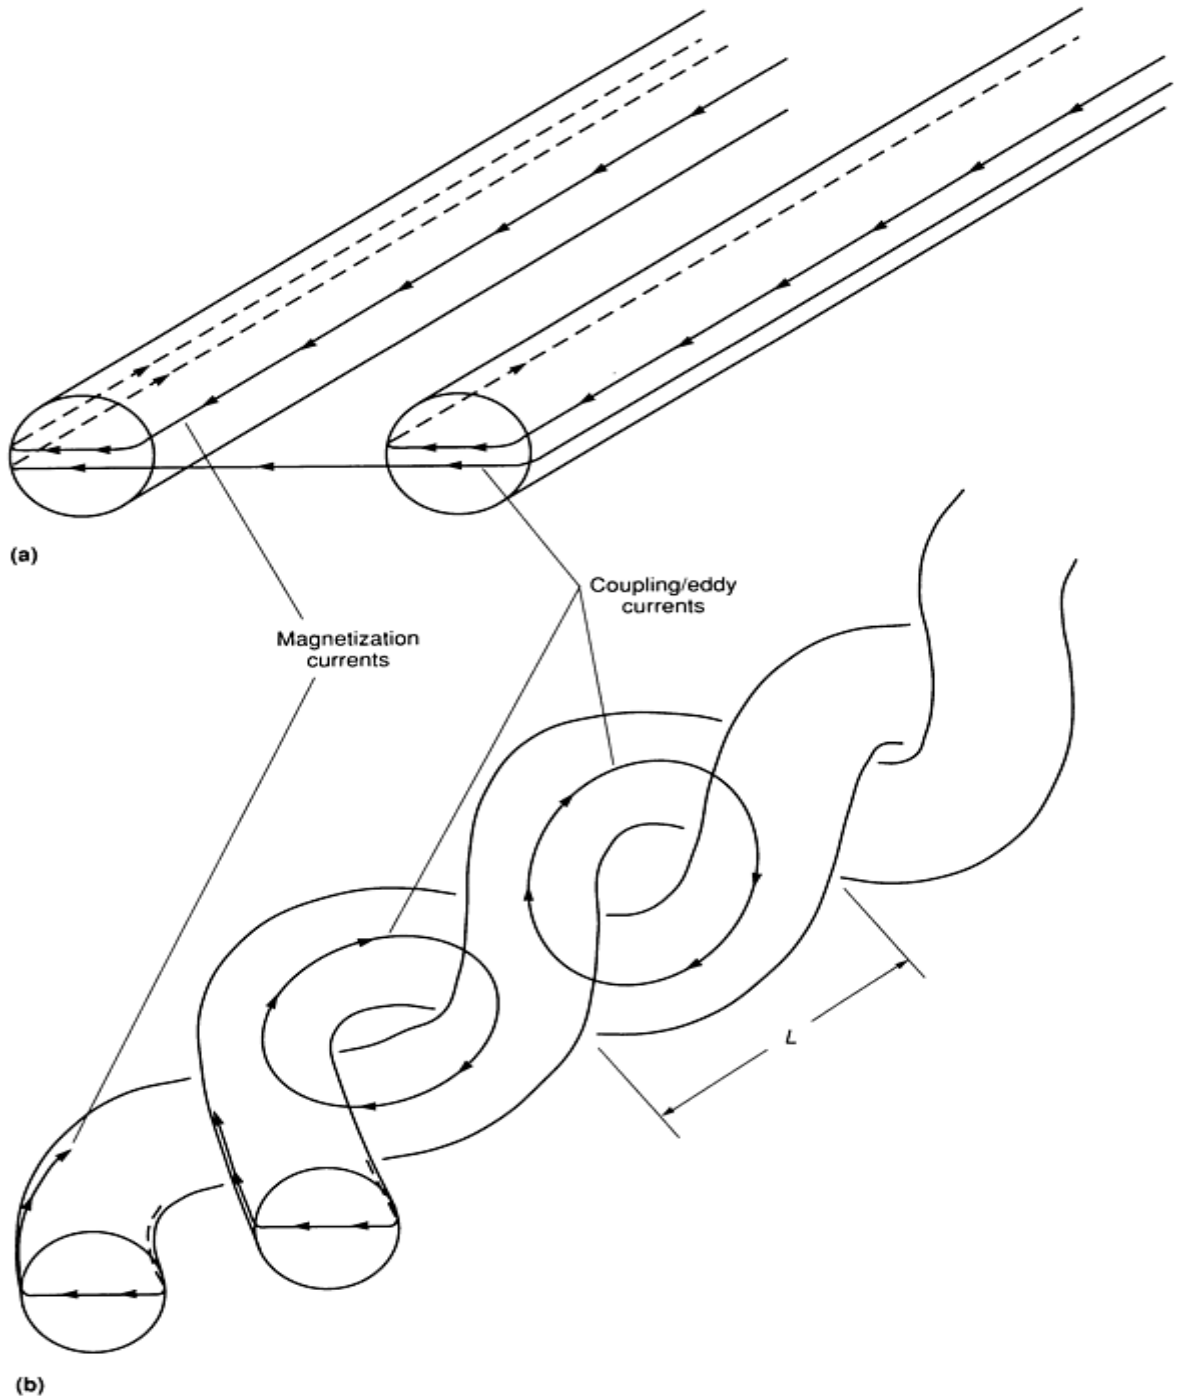

Fig. 17 Comparison of coupling eddy currents in two parallel filaments with those in two twisted filaments. (a) Untwisted filaments couple together in a varying magnetic field by the large eddy currents flowing in the matrix. (b) By twisting the filaments, the inductive area is diminished and the eddy currents are reduced. In both cases the filaments still carry a magnetization current. *L* is the twist pitch distance of the composite.

These stability criteria were originally developed for superconductors at liquid helium temperatures, but the basic phenomenon is not expected to be different in superconductors at liquid nitrogen temperatures. The primary difference will be in the beneficial effect of the larger specific heats of the device components (see Table 3) and the increased cooling capacity of liquid nitrogen. On the other hand, the increased resistivity and slower thermal diffusion of the normal metals at these higher temperatures will lower the stability margins. The probable effect will be an increase in the stability margins over those of superconductors at liquid helium temperatures (Ref 52).

Alternating Current Losses and RF Effects

Superconductors subjected to time-varying magnetic fields can experience significant losses and therefore power dissipation. Even magnets constructed for constant-field use must be ramped up and down during operation and are thus subject to ac losses. The time-varying magnetic field generates an electromotive force (emf) in the superconductor and therefore results in a resistive loss.

Alternating Current Losses

The power loss associated with time-varying fields can be broken into three components (see Fig. 18 and Ref 23):

- Hysteresis
- Penetration
- Eddy currents

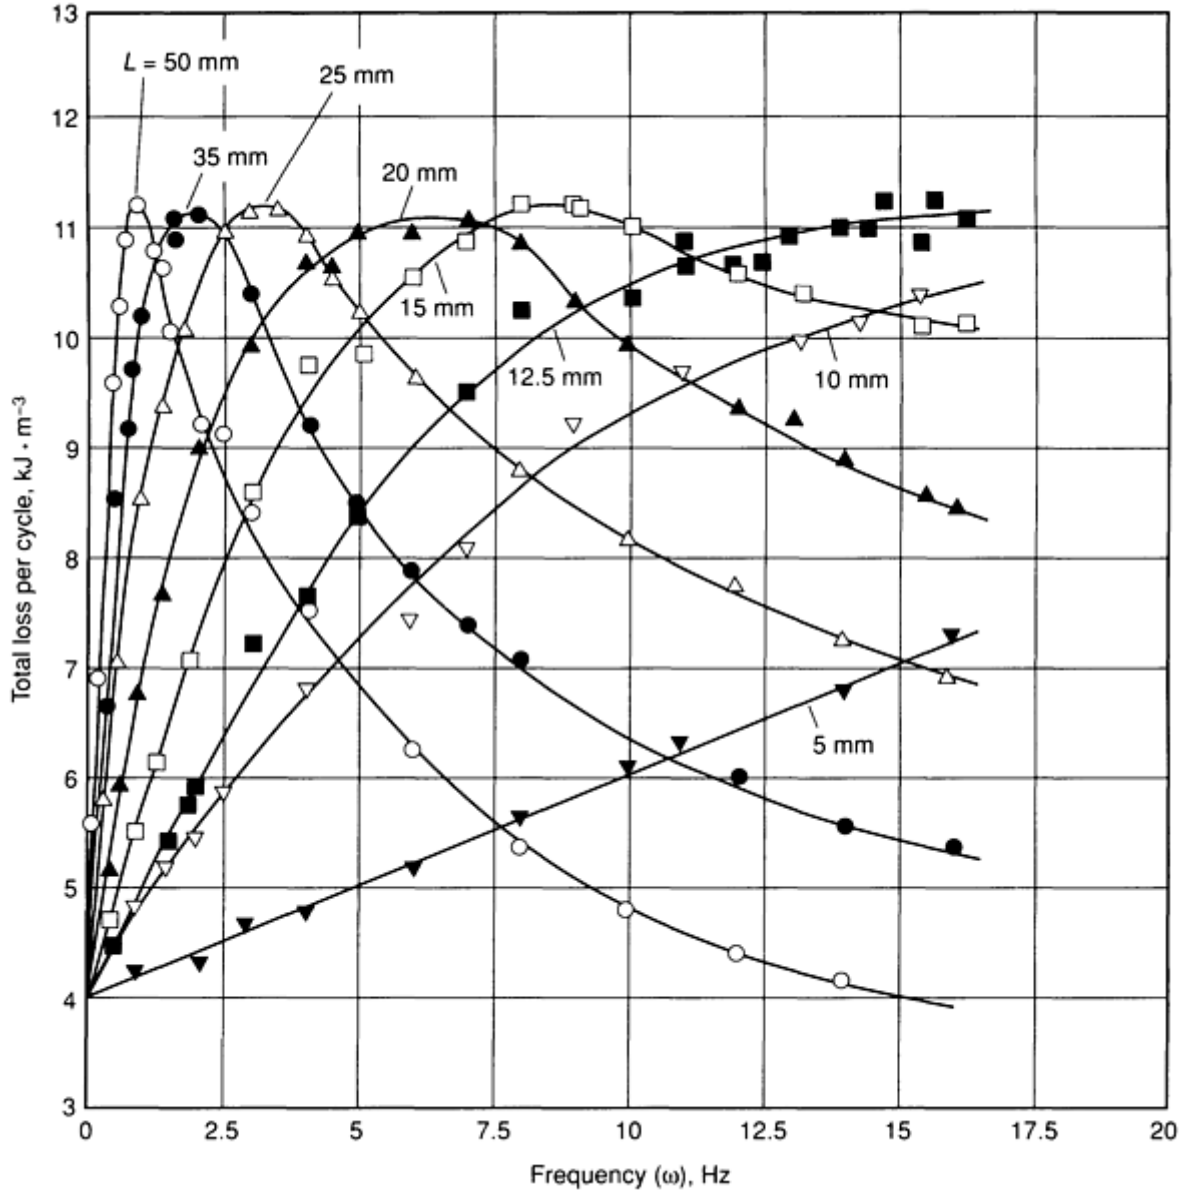

Fig. 18 Measurements of the ac loss in a twisted multifilamentary composite in a dc magnetic field with a small ac ripple. As L decreases, the magnitude of the ac losses decreases dramatically. At low frequencies, the only loss is due to the hysteresis loss. As the frequency increases, the eddy current losses go through a maximum. At high frequencies, the penetration losses become most important.

Hysteresis losses occur because the movement of the applied magnetic field into and out of the superconducting filament must overcome the flux pinning, and the loss is therefore dependent on J_c. A change in the applied field of approximately $B_p = \mu_0 J_c d$ will penetrate fully to the center of a superconductor of a diameter d (see Fig. 19). For magnetic field changes less than B_p, the flux penetrates only an outer layer of the superconductor of thickness p, and the bulk of the superconductor is shielded from the changing field. Because flux motion takes place in only a small volume near the surface, the losses per cycle are small. As the applied field change increases, the volume swept by the flux in each cycle increases to a maximum at B_p, at which $p = d/2$. For field changes much larger than B_p, the flux fully penetrates the superconductor. Because the J_c falls as the applied field increases, the size of the magnetization hysteresis is reduced, and the losses are again small.

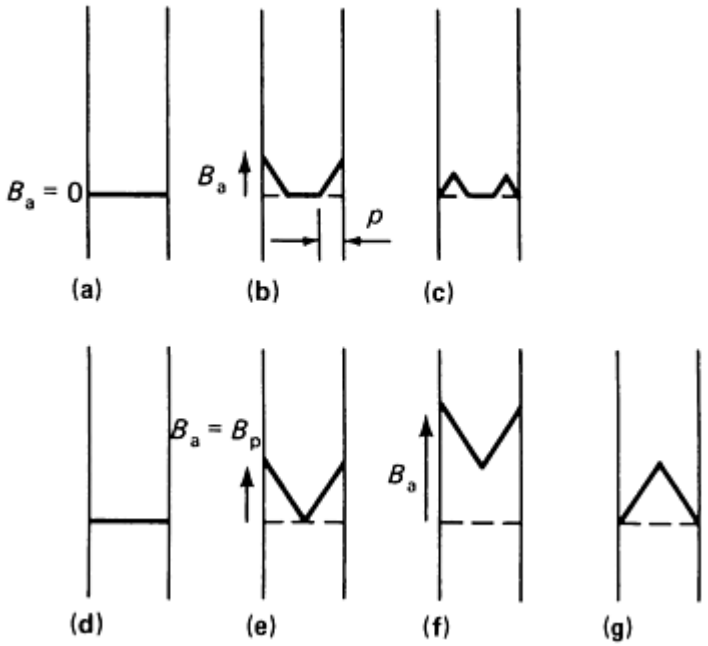

Fig. 19 The critical state model of flux penetration into a superconducting slab. As the applied field is raised from zero (a and b), the field penetrates the surface of the superconductor to a depth p The gradient of the field ($\partial B/\partial x$ is equal to the critical current density (J_c. When the field is reduced to zero (c), magnetic flux remains trapped inside the superconductor. When a large magnetic field is applied from zero (d and f), the field fully penetrates the sample at the field $B_p = \mu_0 J_c d$. As the field is raised above B_p, the field profile changes across the entire sample (f). When the field is removed (g), the maximum trapped flux is left in the sample.

The picture is somewhat more complicated when a transport current is introduced into the superconductor, but the behavior for field changes larger than B_p is not very different. The hysteresis losses are independent of the frequency of the field variation and are proportional to $B_m J_c d$ where B_m is the amplitude of the field change. This suggests that hysteresis losses can be minimized by reducing the diameter of the superconductor. The partitioning of the superconductor into many small filaments in composite wires has been discussed above for the purpose of stability. Reduction of ac losses is another reason to design composites in this way.

Penetration losses are similar to hysteresis losses, in that they come from the restricted movement of flux, in this case, into and out of the composite as a whole. When the J_c is large, the outer filaments of a conductor may shield the inner filaments from the field change. The outer filaments couple together to act as a single filament with a diameter equal to that of the wire diameter; these losses become more important as the spacing between filaments is reduced. Unlike the hysteresis losses, the penetration losses are frequency dependent, similar to the dependence of skin depth on frequency in normal conductors. The penetration losses per cycle are proportional to $B_m^2(\omega^2\tau^2)/\omega^2\tau^2 + 1)$, where τ is the natural decay time for the induced currents; these losses become important only or large values of $\omega\tau$(that is, high frequency) (see Fig. 20 and Ref 23).

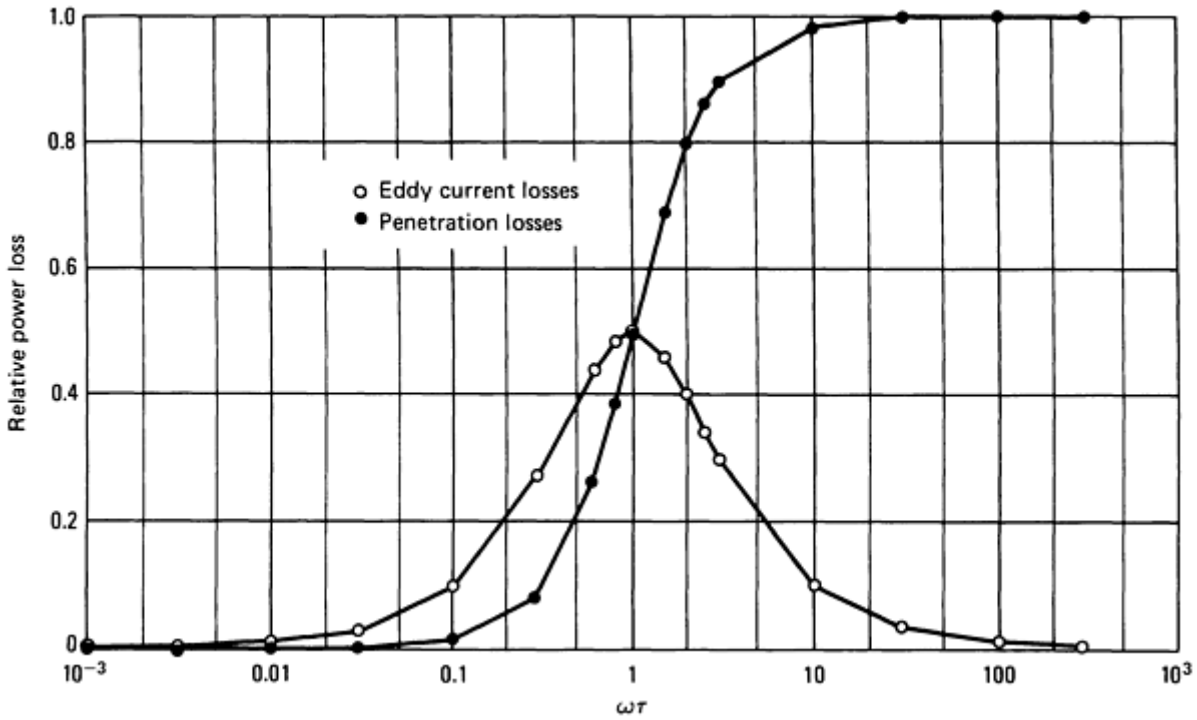

Fig. 20 The behavior of the penetration and eddy current losses as a function of ωτ where ω is the frequency of the ac magnetic field and τ is the natural decay time constant of the induced eddy currents

Eddy current losses in multifilamentary composites can significantly increase the ac losses because currents are induced to flow in the resistive matrix surrounding the superconducting filaments. The induced eddy current will be proportional to the rate of change of the magnetic field, the resistivity of the matrix, and the effective size of the inductive loop formed by the superconducting filaments. The eddy current losses can be reduced by introducing a twist pitch to the filament bundle, which reduces the area of the loop coupling with the changing magnetic field. Once the filaments have been twisted, the eddy current loss per cycle is roughly $B_m^2 \omega\tau/(\omega^2\tau^2 + 1)$. The only effective way to further reduce the eddy current losses at a given frequency is to reduce θby increasing the matrix resistivity. This has been done for many ac applications (for example, by using copper-nickel alloys for the matrix material) (Ref 53).

Radio Frequency losses

For high-frequency application (ω > 10 MHz), superconductors are attractive because of the very low values of surface resistance that they provide (Ref 54). The surface resistance of superconductors was studied by London (Ref 55), who developed the two-fluid model in which the total current at high frequencies is made up of a normal-electron current and a superelectron current. The normal current is concentrated within the classical skin depth of the surface, whereas the supercurrent flows within the penetration depth (λ). At low temperatures, the normal-electron mean free path can become quite large and the surface resistance becomes limited by the residual surface resistance, which is caused by the presence of impurities and detects in the superconductor. The superconducting surface resistance varies as ω^2, whereas the residual surface resistance varies as ω^n, where *n* varies between 1.5 and 2.0.

The exact source of all the residual resistance losses is still under investigation. However, the surface resistance of superconducting materials at frequencies of 1 GHz is a factor of 10^6 lower than conventional copper at room temperature. The small value of the surface resistance is what makes superconductors attractive for high-frequency applications. In particular, the *Q* value of a resonant circuit, which depends inversely on the resistance, can be extremely high for a superconducting circuit. Superconductors haves found many applications in stable oscillators (with frequency stability of better than 1 part in 10^{12}), microwave generators and detectors, resonant cavities for particle accelerators, filters, tuners, and high-frequency transmission lines and field guides (Ref 56).

Josephson Effects

As mentioned above, the superconducting state can be described as a macroscopic order parameter, or wave function of electron pairs:

$$\psi(x,t) = |\psi(x,t)| \exp[i f(x,t)] \qquad \textbf{(Eq 7)}$$

where $|\psi|^2 = n_s$ the density of superconducting electron pairs, $i = \sqrt{-1}$, and $f(x,t)$ is the phase of the wave function, which is dependent on position and time. Because superconductivity is a cooperative phenomenon involving many of the conduction electrons in the superconductor, the phase $f(x,t)$ is coherent everywhere: The is, if at an instant in time the value of $f(x,t)$ is known at one position and the wavelength of the wavefunction is known, then the phase is known everywhere in the sample. The wavelength of the wave function is determined by the momentum of the superelectron pairs, and it is therefore dependent on the current density and the applied magnetic field.

The wave function, $\psi(x,t)$, can only have one value at each position in the sample at any given time. This means that for a current flowing in a superconducting loop, the phase $f(x,t)$ have to change by $2\pi n$ (where n is an integer) on going once around the loop. The consequence of this is that the magnetic flux contained in the loop will be quantized in units of the flux quantum (Φ_0) (Ref 57).

When a thick nonsuperconducting barrier interrupts the current path, the supercurrent through the barrier is zero and the phases on either side of the barrier act independently. If the barrier thickness is reduced to allow some superconducting electron pairs to tunnel through the barrier, then their wave functions overlap and begin to couple together, producing a fixed phase difference across gap (Ref 58). The phase difference between the two superconductors (Δf) is given by:

$$\sin(\Delta f) = I/I_{cj} \qquad \textbf{(Eq 8)}$$

where I is the transport current through the junction, I_{cj} is the critical current of the junction; this current is much smaller than the critical current of the bulk material. This is the dc Josephson effect (Fig. 21).

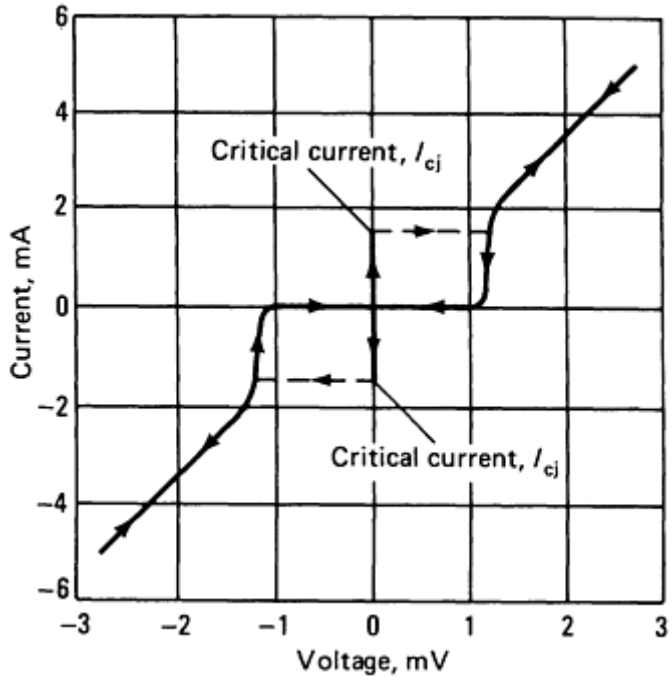

Fig. 21 Current-voltage characteristic produced by the dc Josephson effect. As long as the current through the junction is less than the critical junction current (I_{cj}), the voltage is zero. Note the hysteretic behavior on cycling the current.

If the current through the junction is made to vary as a function of time, then the phase difference Δf will also be a function of time. The changing phase produces a voltage across the junction, which is given by:

$$2\ \mathrm{eV} = (h/2\pi)d(\Delta f)/dt \qquad \textbf{(Eq 9)}$$

These two equations, which relate the phase differences across a weak link or tunneling junction to the junction voltage and current, are descriptive of most of the properties of a Josephson junction (Ref 59).

In a junction in which the supercurrent through the junction (I_s) is changing as a function of time, a voltage appears across the junction and normal electrons may tunnel through the weak link, producing a resistive current (I_r). Because the junction is made of two pieces of metal close together, the junction has a capacitance (C) (see Fig. 22). The total current through the junction, consisting of both the supercurrent and the normal current, can now be written as:

$$I = \frac{ch}{4\pi e}\frac{d^2(\Delta\phi)}{dt^2} + \frac{h}{4\pi eR}\frac{d(\Delta\phi)}{dt} + I_c\sin(\Delta\phi) \qquad \textbf{(Eq 10)}$$

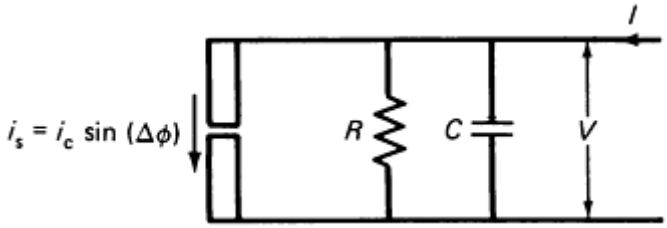

Fig. 22 The effective circuit of a Josephson junction, including a self-capacitance and a normal resistance parallel with the junction. This effective circuit is used to develop $I(\Delta f)$ (see Eq 10).

Examination of Eq 10 that for small currents the voltage across the junction will be zero and Δf will increase as the current increases. There is, however, a critical current above which a dc voltage appears across the junction. Associated with the appearance of the dc voltage, the super-electron current begins flowing back and forth across the junction with a frequency of $v = 2eV_{dc}/h$, where e is the charge of an electron. The superelectron current produces an ac ripple voltage on top of the dc voltage. This is known as the ac Josephson effect, and it is the basis for applications involving tunable oscillators and radiation bolometers (Ref 60).

If a magnetic field is applied to the junction, the change in Δf due to the field is negligible, but there is a large change in the critical current of the junction. By applying a very small magnetic field to a junction carrying a bias current, the junction will develop a resistive voltage that persists until the current is lowered below the critical current. The switching of the junction on (resistive) and off (superconducting) can be extremely fast (on the order of a few picoseconds), and is one of the motivations behind using Josephson junctions as elements in computer devices (Ref 61).

When a loop of superconductor consisting of two junctions carrying a current is put in a magnetic field, the applied field lowers the I_c of the junctions (see Fig. 23). Because the total phase change of the wave function traveling once around the loop must equal $n2\pi$, the change of phase across the two junctions becomes a strong function of the applied magnetic field. The critical current of the total loop will oscillate as a function of the applied field with a period equal to the flux quantum (Φ_0). This oscillation is due to the interference of the wave functions at the two junctions, and this device is called a dc superconducting quantum interference device (SQUID). By measuring the voltage across the loop, the number of flux quanta contained in the loop can be accurately determined, and the SQUID can therefore be used as a very sensitive magnetic flux detector (Ref 60).

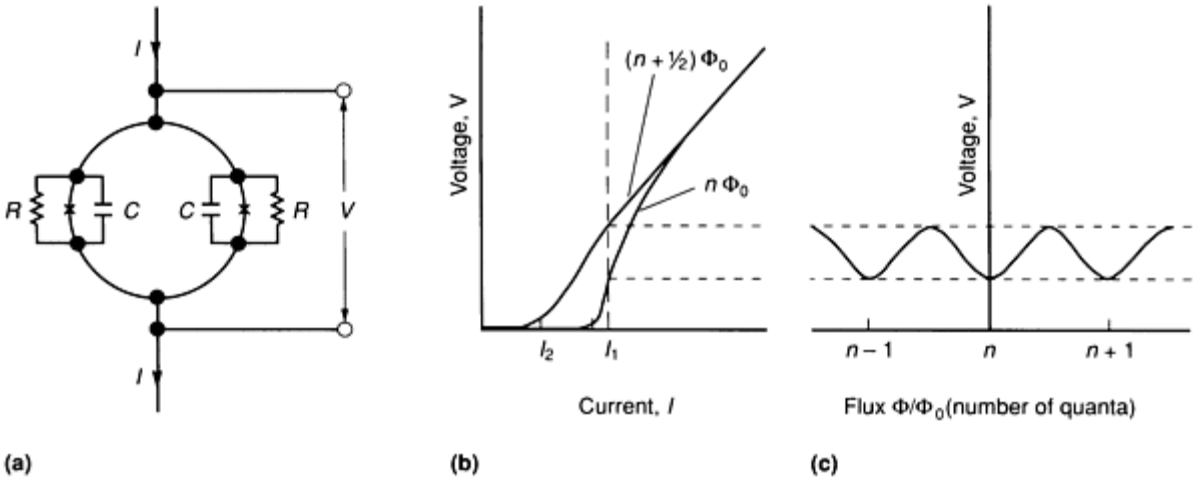

Fig. 23 Effect of applied magnetic field on the critical current of the total loop in a two-junction superconductor. (a) The dc SQUID consists of two junctions carrying a bias current (I). The voltage (V) is measured as a function of the magnetic field. (b) In the presence of a magnetic field, the critical currents of the junctions are lowered from I_1 to I_2. (c) The change in critical current produces a change in the voltage across the SQUID that oscillates with the frequency of the flux quantum (Φ_0).

Niobium-Titanium Superconductors

T. Scott Kreilick, Hudson International Conductors

Introduction

NIOBIUM-TITANIUM ALLOYS became the superconductors of choice in the early 1960s, providing a viable alternative to the A-15 compounds and less ductile alloys of niobium-zirconium. The first NbTi alloys were titanium-rich with a composition of Nb-65Ti (Ref 1). The relative ease with which were could be fabricated, better electrical properties, and greater compatibility with copper stabilizing materials were the primary forces behind this shift.

The monofilamentary wire utilized in the first magnets was subject to flux jumps or magnetic instabilities (Ref 2). By subdividing the superconducting core into individual fine filaments, adiabatic flux-jump stability was achieved. In addition, the incorporation of copper, or another conductive metal, as the interfilamentary matrix material provided not only dynamic flux-jump stability but also cryostability (Ref 3). Finer filaments also helped minimize hysteresis loss and inherent magnetization.

Multifilamentary composite wires, when subjected to a time-varying external magnetic field, exhibit coupling of the filaments by circulating currents. As a result, the effective filament diameter is larger than the actual filament diameter, thus negating the benefits of individual fine filaments. To counter the problem, multifilamentary wire must be twisted. Twisting of the strand reduces eddy-current losses in time-varying applied fields as does the incorporation of a resistive matrix.

In this article, the ramifications of the design requirements delineated above will be discussed in the context of multifilamentary NbTi superconducting composite fabrication.

Alloy Selection

As conductor instabilities became better understood, the titanium-rich NbTi alloy composition evolved into a more ductile, niobium-rich material. Historically, high-energy physics (HEP) pulsed accelerator-magnet applications have provided the impetus for alloy development. The alloy most widely used today is Nb-46.5Ti, although in some areas Nb-50Ti is preferred (Ref 4, 5). Binary NbTi compositions in the range of 45 to 50% Ti exhibit upper critical field ($\mu_0 H_{c2}$) values of 11.5 to 12.2 T at the boiling point of helium (4.2 K), combined with critical temperature (T_c) values of 9.0 to 9.3 K. For HEP applications this combination of operating parameters has provided sufficient operating margin, but for other applications (notably plasma fusion confinement), higher fields and larger temperature fluctuations are anticipated. For lower field applications, such as superconducting magnetic energy storage (SMES) and magnetic resonance imaging (MRI), there is a renewed interest in the higher-titanium-containing alloys (52 to 65% Ti) due to enhanced flux pinning characteristics (Ref 6). The trade-off, however, for higher current-carrying capacity and lower alloy cost (by replacing niobium with titanium) is decreased ductility.

Theory predicts an upper critical field (H_{c2}) of 17 to 18 T for binary NbTi. As indicated above, experimental values are somewhat lower. The origin of the diminished H_{c2} lies in the appreciable orbital paramagnetism of NbTi, which makes a significant contribution to the free energy of the normal state. Spin-orbit scattering can relax this paramagnetic limitation, and it has been demonstrated that heavy element additions of tantalum (Z = 73) and hafnium (Z = 72) are very effective in this regard. The relative effects of adding tantalum or hafnium to the NbTi system have intrigued researchers for many years (Ref 7, 8, 9), and tantalum additions seem to be the concensus choice (Ref 10, 11, 12, 13). While T_c is reduced for both additions, there is a small enhancement (0.3 T) of the upper critical field for the NbTiTa system at 4.2 K. At this temperature, no enhancement is observed for NbTiHf, whereas at 2 K a small increase of 0.3 T is noted. This rise in $\mu_0 H_{c2}$

is small compared to the 1.3 T enhancement at 2 K in the NbTiTa system. Experiments have shown that some quaternary alloys (for example, NbTiTaZr) can also extend the upper critical field (Ref 10).

Once the values for $\mu_0 H_{c2}$ and T_c are fixed during the alloy melting process, there is little the wire manufacturer can do to alter them. It is the critical current density (J_c) that is most affected by the processing from cast ingot to final wire and cable. The superconducting properties, therefore, are highly dependent on the cooling rate following melting or heat treatment and the degree of cold work. At high temperatures, the NbTi system forms a βsolid solution.

The fine-scale dislocation cell structure achieved by cold working combined with the α-titanium precipitates produced in heat treatment yields an inhomogeneous microstructure. These defects are the flux pinning centers (see the article "Principles of Superconductivity" in this Volume) responsible for large critical current. The diameter of the fluxline (~11 nm in NbTi) and the distance between fluxlines dictate the size and spacing of the defect required to achieve the best current-carrying capacities at a given magnetic field. The process of heat treatment and cold working needed to develop these microstructures will be discussed in greater detail below.

Alloy Preparation

Niobium. High-purity niobium for superconducting applications comes from two primary sources: columbite-tantalite and pyrochlore (Ref 14). Columbite-tantalite contains Nb_2O_5 and Ta_2O_5 in ratios of 10:1 to 5:1 (depending on the specific geology) together with oxides of iron and manganese. After the recovery of the niobium pentoxide from the columbite concentrate by digestion in HF followed by solvent extraction, it is then processed in a manner identical to that used for the pyrochlore ores. Pyrochlore ore is mined at three principle locations:

- Araxa, in Minas Gerais, Brazil (3.0% Nb_2O_5)
- Catalao I, in Goias, Brazil (1 to 2% Nb_2O_5)

- Niobec, in Quebec, Canada (0.25 to 0.66% Nb_2O_5)

The niobium pentoxide is mixed with iron powder and reduced to ferrocolumbium, by the aluminothermic reaction. The specialty steel industry is the largest consumer of the material in this form (see the section "Niobium" in the article "Properties of Pure Metals" in this Volume). $NbCl_5$ is then produced by chlorination and converted by hydrolysis to the oxide. The aluminothermic reaction is again used to reduce the oxide, now mixed with aluminum powder, to niobium. The metal is electron-beam (EB) melted under high vacuum for added purification.

Titanium. Most producers of commercially pure titanium utilize the Kroll process, which involves the chlorination of a mixture of carbon and the minerals rutile and ilmenite (found in beach sand). Liquid $TiCl_4$ is then mixed with liquid magnesium under an inert atmosphere in a closed heated reactor vessel. $MgCl_2$ is drained off and recycled electrolytically, leaving titanium sponge. The sponge is then consolidated by arc melting in a water-cooled copper crucible. Titanium cannot be effectively purified by melting because its vapor pressure is too high and its melting point too low for selective evaporation of most impurities. It is the purity of the niobium, therefore, that dictates the overall purity of the NbTi ingot. The allowable limits for metallic impurities and interstitials in NbTi alloy produced for the superconducting supercollider (SSC) program are listed below:

Impurity element	**Allowable limit**
Ti	45, 46.5, 48, 55 wt%, ± 1.5 wt%[(a)]
O	1000 ppm max
H	35 ppm max
C	200 ppm max
Fe	200 ppm max
Ta	1000 or 2500 ppm max[(a)]
N	150 ppm max
Ni	100 ppm max
Si	100 ppm max
Cu	100 ppm max
Al	100 ppm max
Cr	60 ppm max

Nb	Bal

(a) As specified by purchase order

Tantalum and oxygen are the principal impurities, and as was pointed out earlier, small additions of tantalum serve to enhance the high field properties. Furthermore, some impurities seem to be necessary for nucleation of pinning sites.

Melting of Composite. Consumable electrode vacuum arc remelting (VAR) or plasma arc melting techniques are employed to combine niobium and titanium ingots into the alloy composition of choice. Typically, two or three melts are required to yield a product with the desired homogeneity. Figure 1 shows an electrode ready for its final melt. The diameter of the cast product ranges from 203 to 584 mm (8 to 23 in.) in diameter, with weights exceeding 2000 kg (4000 lb) for the larger diameters. After sidewall machining (Fig. 2), the ingot undergoes bulk-chemical and electron-beam analysis to determine the exact alloy composition, in addition to metallographic examination.

Fig. 1 Consumable NbTi electrode being prepared for its final vacuum-arc remelt. Courtesy of Teledyne Wah Chang Albany

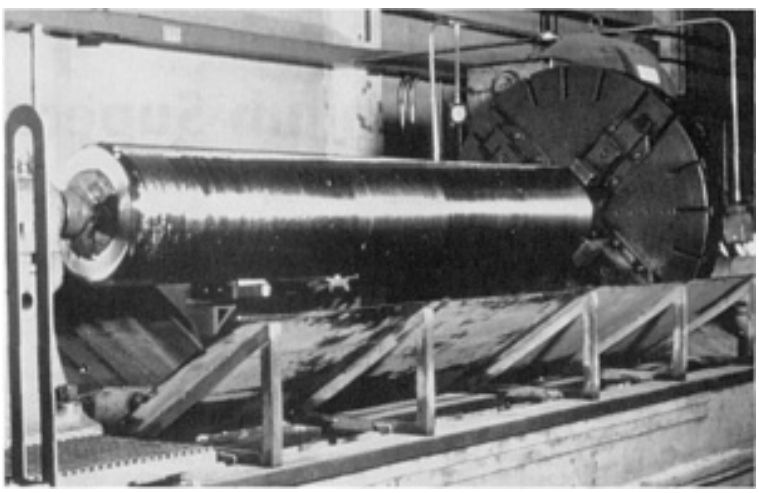

Fig. 2 NbTi ingot ready for sidewall machining prior to forging. Courtesy of Teledyne Wah Chang Albany

Forging of NbTi Ingot. The NbTi ingot is then hot forged to a diameter of 152 mm (6 in.) followed by an anneal in air. The temperature of the anneal is approximately 870 °C (1600 °F). At this temperature the ingot is fully β-recrystallized. The time at temperature is typically 2 h, followed by a water quench. The ingot is then machined to a diameter of 146 mm

(5.75 in.) and inspected. Further processing techniques will be described in the section "Assembly Techniques" in this article.

Ingot Inspection. Homogeneity of the ingot is determined by means of a high-resolution radiograph taken from a cross section of the material, which is compared to a series of standard radiographs. The importance of alloy homogeneity has been identified and discussed (Ref 15, 16, 17), and it is generally believed that the availability of more homogeneous alloys has led to the significant improvements in conductor performance observed in recent years. Mechanical properties testing includes tensile and hardness (less than 170 DPH is typically required). The internal structure is determined nondestructively by liquid penetrant examination and 100% ultrasonic inspection (see the articles "Liquid Penetrant Inspection" and "Ultrasonic Inspection" in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*) performed in three stages. The ultrasonic inspection techniques utilized are:

- Comparison with a flat bottom hole standard
- Longitudinal wave
- Circumferential angle-beam examination

Average grain size is determined using the applicable provisions of ASTM Standard E 112. Grain size 6 or smaller is typically specified. Large grain sizes lead to better workability but also to lower current densities.

Matrix Materials

Adequate stability has been identified as being of first-order importance in the operation of electromagnetic systems incorporating NbTi superconducting materials. The properties required in a successful stabilizing material are:

- High electrical and thermal conductivity
- High heat capacity
- Good mechanical strength at cryogenic temperature
- Good adherence to the superconductor
- Good ductility for forming and winding

Copper

High-purity copper satisfies *all* of these requirements to a high degree and is, therefore, the most frequently utilized stabilizing material.

Resistivity. The conductive metal surrounding a resistive spot in a superconductor stabilizes the coil by providing an alternative path to shunt the current around the spot until it has cooled down. The ability of a metal to conduct electricity at liquid helium temperatures is dependent on three factors. The resistivity of a metal will be the rough sum of:

- Resistivity of the pure metal
- Resistivity caused by impurities in solution in the metal and dislocations in the metal's crystal structure caused by stress
- Magnetoresistance of the metal

The residual resistance ratio (RRR) is often used as a figure of merit when comparing the relative purity of potential stabilizers. The residual resistance ratio is the ratio of the electrical resistivity at room temperature (293 K) divided by the resistivity at liquid helium temperature (4.2 K). In copper of nominal purity or better, the numerator depends essentially on the thermal vibrations of the copper lattice and not the impurities; the denominator depends only on the impurities. Resistance-at-field dictates the volume of stabilizer required to achieve a given stability criterion.

Magnetoresistance is the relative increase in resistivity of a metal in the presence of an external magnetic field. Copper tends to obey Kohler's rule, unlike most high-purity metals including aluminum. Kohler's rule is a mathematical statement of the fact that the magnetoresistance is observed to be an increasing function of the applied magnetic field per unit change in the electrical resistivity. With this information, it has been shown for different copper samples with RRR values of 150 or more and an applied field strength in excess of 4 MA $\cdot$ m^{-1} (50 kOe) that the at-field residual resistivities are nearly equal (Ref 18). In other words, higher-purity coppers, yielding higher RRR values have a diminishing return on investment in terms of magnetoresistance. Copper Development Association (CDA) alloy 10100 (ASTM designation B 170), oxygen-free copper is available from several commercial sources with RRR values ranging from 180 to over 500, depending on the quality of the cathode used in the continuous casting process.

Aluminum

High-purity aluminum, as mentioned above, does not obey Kohler's rule. Saturation occurs in the 800 to 1600 kA $\cdot$ m^{-1} (10 to 20 kOe) range after a very fast rise in the lower field region, the result being that in strong magnetic fields the resistivity of aluminum will be much less than that of copper. Thermal conductivity mimics electrical conductivity in the presence of a magnetic field. When RRR is used as the basis for comparison, any aluminum with an RRR greater than 1.57 times that of copper will have a higher thermal conductivity (at 4.2 K) and a higher electrical conductivity than the copper.

Aluminum offers improved flux-jump stability over copper due to its lower heat capacity. This, combined with a high thermal conductivity, reduces the time required to dissipate the heat generated during a flux jump. Aluminum offers several other advantages as a stabilizer of superconducting composites. Aluminum is one-third as dense as copper enabling the construction of lighter weight machines. In addition, aluminum has a high degree of transparency to many types of particles, thus radiation damage can be greatly reduced in environments where this is a factor.

One of the few areas that aluminum is not superior to copper as a stabilizer material is that of mechanical compatibility with the NbTi alloy during the reduction process. Attempts to coprocess aluminum and NbTi alloys have taken several directions. The three most common methods are:

- Strengthening of the aluminum by alloying or other metallurgical techniques
- Low-temperature hydrostatic extrusion that minimizes the mechanical dissimilarities
- Addition of the aluminum stabilizer, by extrusion cladding or soldering, after the NbTi alloy has been coprocessed in a copper matrix

Extrusion and cladding techniques will be discussed in the section "Processing of Superconductor Composites" in this article.

Higher-strength aluminum-base materials have been investigated with varied results. NbTi filaments embedded in commercial-purity aluminum (alloy 1100, 99.0% Al min) show signs of filament nonuniformities during extrusion or after relatively small strains (Ref 19, 20). Dispersion-hardened and heat-treatable aluminum alloys, such as those mentioned in Ref 20, offer higher strengths, but at the expense of ductility and conductivity. Some directionally solidified eutectic alloys containing randomly dispersed intermetallic whiskers reinforce the α-Al matrix without significantly reducing conductivity (Ref 21), but these materials have not been routinely used.

A great deal of effort has gone into producing aluminum alloys with good strength retention at high operating temperatures, such as those experienced by rotating engine components (Ref 22). Powder metallurgy, rapidly solidified, dynamically recrystallized aluminum alloys show promise in this area, in addition to use as a high-strength aluminum matrix material for cryo-conducting and superconducting applications (Ref 23). Al-8.4Fe-3.6Ce (Alcoa's alloy CU78) has demonstrated the best combination of properties and is the most completely characterized composition of this type (Ref 24, 25, 26, 27).

The diffusionless alloying elements, iron and cerium, enable the retention of high conductivity in the aluminum of the final composite. Figure 3 shows a prototype conductor incorporating AlFeCe as the matrix, designed for MRI applications.

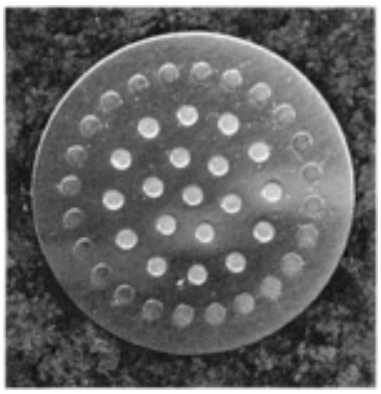

Fig. 3 Cross section of a prototype aluminum-stabilized composite for MRI applications fabricated using drilled-billet techniques. Outer ring of filaments are NbTi, inner filaments are high-purity aluminum, matrix is high-strength AlFeCe. Courtesy of Supercon, Inc.

Copper-Nickel

Most applications of NbTi superconducting materials have been dc systems with relatively large filaments, and for these, copper and aluminum have been suitable matrix materials. For ac and pulsed-field environments, however, finer filaments are desired. The minimization of eddy current loss in the normal-metal matrix and hysteretic loss in the filaments must be considered. For these applications, the introduction of nickel into copper in the form of a high-resistivity solid-solution alloy matrix has found wide acceptable (Ref 28, 29, 30, 31, 32).

The copper-nickel alloy, typically in concentrations of 90:10 or 70:30, is used to isolate individual filaments or groups of filaments as a means of reducing intrafilament coupling leading to losses. Figure 4 shows a partial cross section of a composite in which a portion of the copper matrix (which remains in close contact with the NbTi core) is replaced by a web of copper-nickel. Figure 5 shows the cross section of a conductor designed for ac applications in which the stabilizing core area is subdivided with copper-nickel, as are the NbTi filaments themselves. Two limitations arise in the use of copper-nickel matrix materials. The first is a decreased fabricability and the second is the increase of resistivity and loss of thermal diffusivity resulting in a loss of stability.

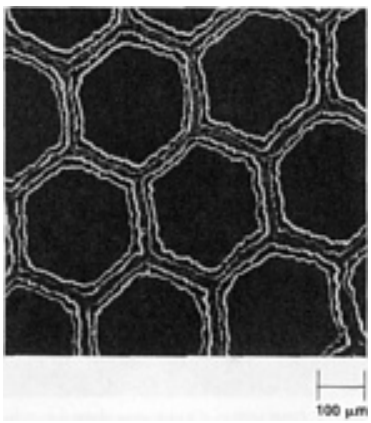

Fig. 4 Partial cross section of a mixed-matrix composite for ac applications. High-purity copper surrounds each NbTi filament for stability, and a web of resistive CuNi maintains the electrical integrity of each filament. Courtesy of Supercon, Inc.

Copper-Manganese

When the interfilamentary matrix material is pure copper, close spacing of the NbTi filaments will exhibit the proximity-effect coupling at lower fields, for as soon as the filament spacing and the superconducting coherence length become comparable, the wire will tend to behave as a monofilament (Ref 33). Several methods of reducing this coupling have been suggested. The first, mentioned above, operates by suppression of the mean free path of the electrons (that is, CuNi), but as also mentioned, this has an adverse effect on the stability of the composite. The second method employs electron-spin-flip scattering by solute ions carrying localized magnetic moments (for example, manganese, iron, or chromium) (Ref 34).

Several large billets have been fabricated to investigate the benefits (and limitations) of manganese additions to the copper matrix (Ref 35, 36). The evaluation has included mechanical, electrical, thermal, and magnetic properties, and to date no significant limitations appear to exist for composites containing 0.5% Mn additions to the copper (Ref 32, 35, 36, 37, 38, 39, 40, 41). This percentage of manganese is as effective as 30% Ni additions to the matrix in reducing proximity-effect coupling of the filaments, but without the added transverse resistivity. Susceptibility and magnetization measurements show that filaments as fine as 1.5 μm (60 μin.) in diameter with interfilament spacings of ≥280 nm are effectively decoupled.

Figure 6 shows the cross section of a prototype billet fabricated for the SSC strand-development program. The core and the outer can are high-purity copper. The interfilamentary region is Cu-0.5 % Mn. This composite (Ref 36), containing 22,900 NbTi filaments, was designed to yield 2.5 μm (100 μin.) diam filaments when the overall conductor diameter was 0.65 mm (0.0255 in.).

Processing of Superconductor Composites

There are several methods used to fabricate NbTi superconducting composites depending primarily on the proposed application. The conditions of operation dictate the number and size of the superconducting filaments, as well as the volume of stabilizer necessary to adequately protect the magnet in the event of a flux jump. Minimum current density, piece length requirements, and cost considerations influence the size of the initial billet.

Assembly Techniques

The quality of the starting materials was emphasized in the section "Alloy Preparation" in this article. Well-characterized, homogeneous alloys and matrix materials are two of the prerequisites in the production of reliable wire products. NbTi alloy is usually procured in the β-recrystallized state, although the use of cold-worked alloy has been considered. When the stabilizing material is high-purity copper, special attention must be given to the size of the grains. Copper in the as-cast condition is not suitable for most applications of NbTi superconductors. The coarse grains of high-purity copper in the as-cast and/or insufficiently forged condition have been known to compromise the integrity of the superconducting composite during isostatic pressing and extrusion operations. The copper should have a fine-grain microstructure obtained by cross-grain forging or extrusion.

Billet Cleanliness. All billet components should be free of oxide, inclusions, or other surface defects prior to assembly. A nonductile inclusion at the time of assembly could become a significant fraction of a wire's cross section at final size resulting in breakage. Because O_2 has significant solubility in copper, diffusion from unclean surfaces can readily occur at temperatures encountered during processing. If the oxide is not completely removed by the cleaning procedures, such contamination can affect the entire copper cross section and even penetrate to the NbTi core. Some etching agents leave an oxide layer a few hundred angstroms in thickness, and calculations show that the total amount of oxygen that can be introduced into a fine filament material this way is enough to convert oxygen-free copper into a relatively high O_2 tough-pitch copper. The significance of this condition on the drawability of fine copper cross sections is well known to the copper industry (Ref 42, 43).

All cleaning procedures are not the same, but there are general similarities. All components are degreased, acid etched, rinsed in water, then in acetone and/or a drying agent, such as methanol. The parts are then blown dry and stored in a N_2 atmosphere until they are assembled. Assembly takes place in a low-level clean-room environment.

Monofilamentary conductors are used in small, low-field magnets (for example, nuclear magnetic resonance, NMR, applications) where persistent joints are required. Fewer filaments expedite the joining of superconducting wires with low resistance, enabling persistent mode operation. In other words, the power supply can be removed after current excitation and the current will continue to flow without significant degradation for long periods of time. Techniques employed to fabricate joints include resistance welding, spot welding, ultrasonic welding, pressure contacts, and soldered lap joints, among others. When a superconductor-superconductor joint becomes necessary, attempts are made to remove the joint from close proximity of the operating field of the magnet in order to maintain field uniformity. When these factors are considered it soon becomes clear why long lengths of conductor are requested from the wire manufacturer.

Monofilaments are made by coextruding a large ingot of NbTi alloy within a copper can. Billets of this type are frequently 200 mm (8 in.) in diameter, with a 120 mm ($4\frac{3}{4}$ in.) diam core. The maximum billet length is dictated by the length of the extrusion press liner. Once extruded, the composite is reduced in diameter by rod reduction and wire-drawing techniques to final size, which is typically 0.5 to 1.0 mm (0.02 to 0.04 in.) in diameter. During the reduction process the wire is subjected to a series of intermediate heat treatments designed to precipitate the α-phase titanium of the alloy. The ratio of copper stabilizer to superconductor volume is approximately 1.8:1 but may vary depending on the application.

Multifilamentary Conductors. Conductors incorporating less than 200 NbTi filaments can utilize gun-drilling techniques. A solid copper billet is deep-hole drilled with either concentric circles or a hexagonal close-pack array to facilitate symmetry within the wire. Sufficient margin must be left between holes to allow for drift during the drilling operation. Longer lengths and smaller diameters make a difficult procedure self-limiting in terms of the number of holes that can be accommodated. NbTi rods are inserted and the billets processed to final wire. The copper-to-superconductor ratio (Cu:Sc) varies depending on the number and size of the filaments. Billet diameters are typically 250 to 280 mm (9.8 to 11 in.). Figure 7 shows the cross section of a 54-filament conductor with a Cu:Sc ratio of 1.35:1. Figure 8 shows the cross section of a 24-filament conductor with a Cu:Sc ratio of 7:1. It is this type of 24-filament conductor which is widely used in low field (0.6 T, or 6 kG) whole-body MRI magnets.

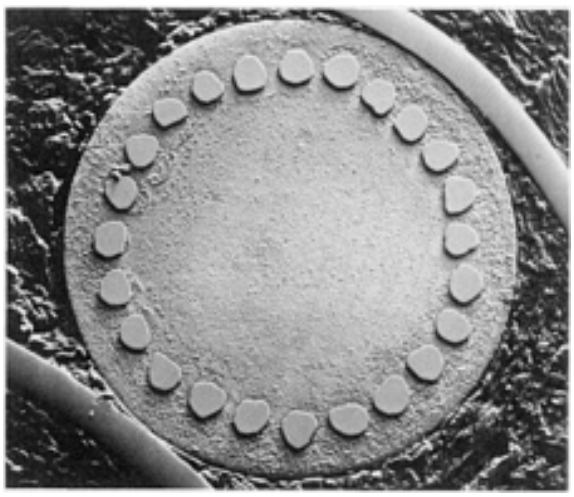

Fig. 8 Cross section of a 24-filament composite fabricated using gun-drilled billets. The Cu:Sc ratio is 7:1. Courtesy of Supercon, Inc.

Composite conductors with more than 200 filaments are assembled using one of three basic techniques:

- Kit method
- Restacked monofilaments method
- Restacked drilled billets

Kit Method. The first approach is referred to as the CBA/Fermi kit method and is so named because it was used to manufacture the strand for the Fermilab Tevatron magnets. It was also considered for use in the Brookhaven National Laboratory colliding beam accelerator (CBA), a machine that was never built. Although it is a relatively simple and inexpensive method of assembly, it has significant drawbacks when the highest current-carrying capacity or long piece lengths are required.

Small-diameter NbTi rods (3.18 to 7.11 mm, or 0.125 to 0.280 in.) are inserted into copper hexagonal tubes with round inside diameters. Several hundred to 2000 of these tubes are stacked into a hexagonal close-pack array. A copper can, with an outside diameter of approximately 250 mm (10 in.), is lowered over the assembled filaments, the ends sealed, and the billet processed to final wire. Figure 9 is a schematic illustration of the kit approach to billet assembly. Figure 10 is a cross section of a 2070-filament conductor fabricated to the CBA specifications.

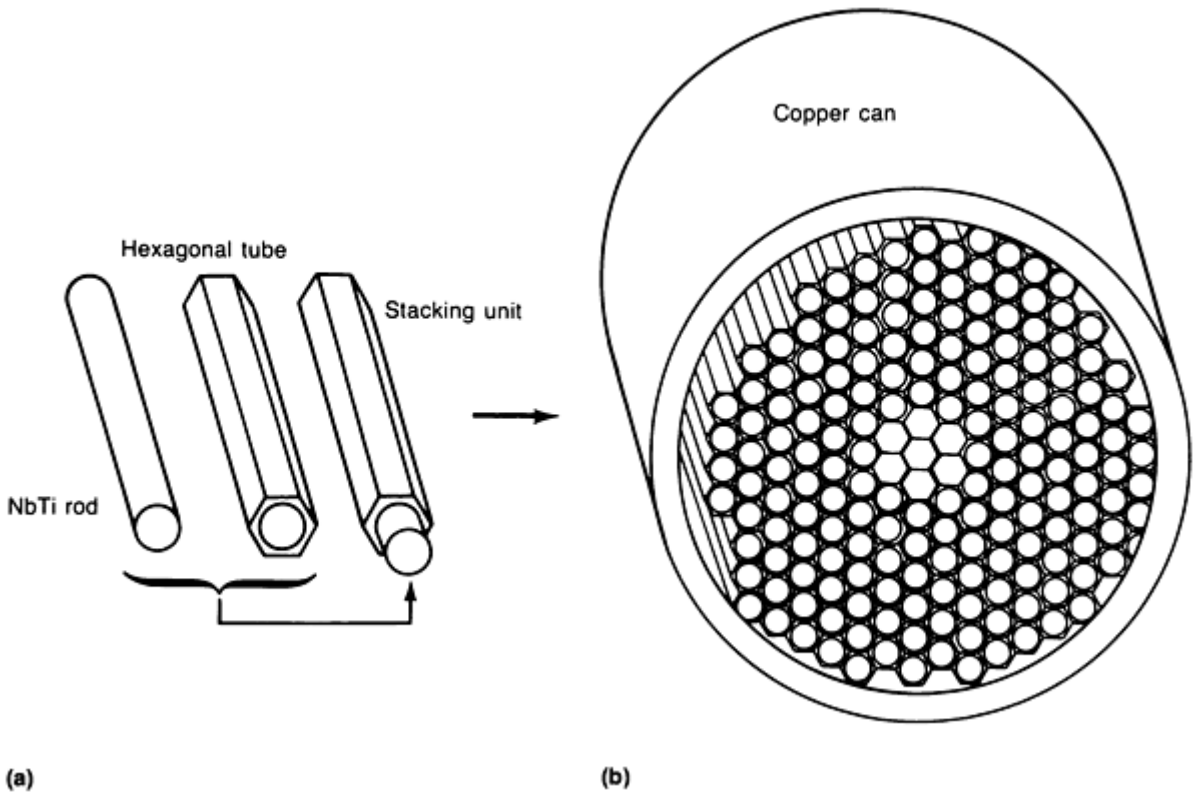

Fig. 9 Schematic illustration of the CBA/Fermi kit approach to billet fabrication. (a) NbTi rod is inserted into a copper tube with hexagonal OD and circular ID to yield an individual stacking unit. (b) Individual stacking units arranged in a hexagonal close-packed (hcp) array in a 250 mm (10 in.) diam copper can

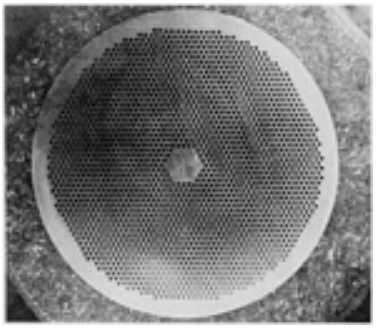

Fig. 10 Cross section of a 2070-filament composite assembled using a kit. Courtesy of Supercon, Inc.

Restacked Monofilament Method. Inherent factors limit the quality of strand produced with the kit technique. The amount of exposed surface area that must be oxide-free prior to assembly is approximately twice that of a similar composite (with the same number of filaments) fabricated using the restacked monofilament method. Any remnant oxide, now in close proximity to the NbTi core, can lead to embrittlement problems, not only of the core but also of the copper matrix. Furthermore, the presence of oxide impurities in the copper reduces its effectiveness as a stabilizer, although this is probably a secondary effect.

Figure 11 is a micrograph of the NbTi filaments extracted from a composite, fabricated using a kit, at final size after undergoing several intermediate precipitation heat treatments. The nodules on the filament surfaces are a brittle intermetallic compound of titanium-copper. As the wire is drawn, the nonductile particles become a significant fraction of the filament cross section. Although the exact composition is not clear (Ti_2Cu, $TiCu_4$, Ti_2Cu_7 from Ref 15, 44, and 45 respectively), the effect on filament quality is to locally reduce the cross section and to eventually cause filament and wire failure.

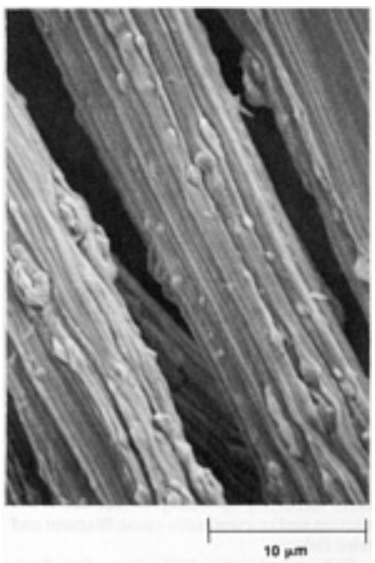

Fig. 11 NbTi filaments extracted from a composite at final size after several intermediate precipitation heat treatments. The nodules are an intermetallic compound of Cu-Ti. 2500×. Courtesy of Supercon, Inc.

Diffusion barrier technology has been employed to inhibit the growth of unwanted intermetallic compounds (Ref 46, 47, 48).

The most commonly used method of fabrication is to wrap one or more sheets of niobium foil around a large NbTi ingot and then to encase the whole assembly in a copper or copper-manganese can. Bonding is achieved during a high-

temperature, large reduction extrusion process. Figure 12 shows niobium diffusion barriers in high relief around NbTi filaments within a deeply etched copper matrix. Figure 13 shows niobium barrier-protected NbTi filaments extracted from a composite in which the filaments were very closely spaced within a copper matrix.

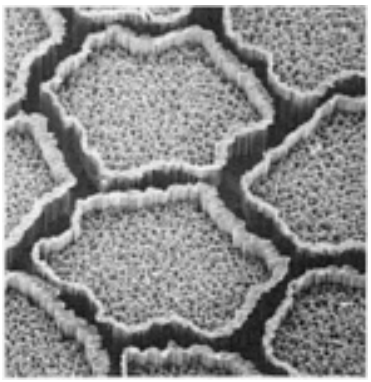

Fig. 12 Partial cross section of a multifilamentary NbTi composite with a niobium diffusion barrier (in high relief) around each filament. The copper interfilamentary matrix is deeply etched. Courtesy of Supercon, Inc.

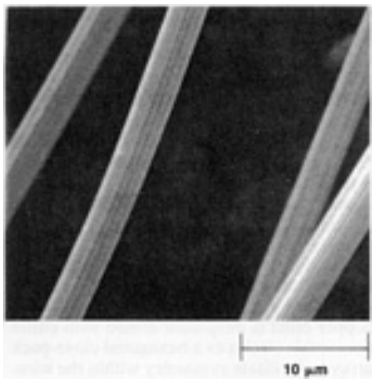

Fig. 13 Niobium diffusion barrier-clad NbTi filaments extracted from the copper matrix of a composite designed for the superconducting supercollider. Courtesy of Supercon, Inc.

The preparation of NbTi monofilament incorporating a diffusion barrier is shown schematically in Fig. 14. The NbTi ingot is procured at a diameter of 146 mm (5.75 in.) and a length of 610 mm (24 in.). Once extruded, the monofilament is drawn to the proper diameter, shaped by drawing through a hexagonal cross-sectional die, cut to the appropriate length, and restacked into the desired multifilamentary array. An alternative to this approach is to forego the hexagonal shaping step and to restack round monofilamentary subelements. Figure 15 shows a partial cross section of a conductor composed of hexagonal subelements, and Fig. 16 shows the result of restacked round subelements. The uniformity of the array obtained from restacking hexagonal subelements is evident. The voids and dislocations associated with the round subelement restack result in areas of the array in which filament spacing is not uniform.

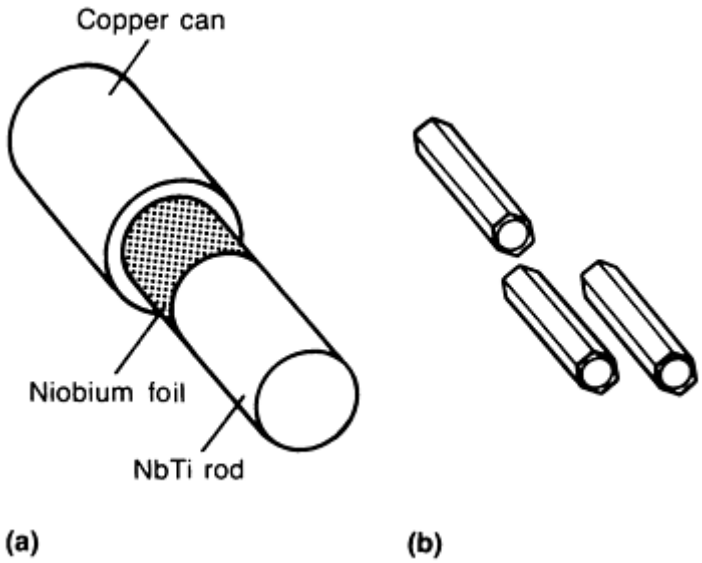

Fig. 14 Schematic illustration of diffusion barrier-clad monofilament assembly. (a) Diffusion barrier is obtained by wrapping an NbTi rod with niobium foil and placing foil-wrapped rod in a copper can. (b) Extruding and drawing of copper can assembly yields monofilamentary hexagonal rods with diffusion barrier.

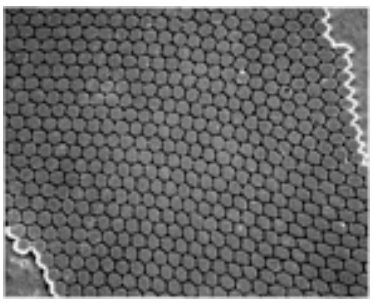

Fig. 15 Partial cross section of a multifilamentary NbTi composite assembled using hexagonal monofilaments. Courtesy of Supercon, Inc.

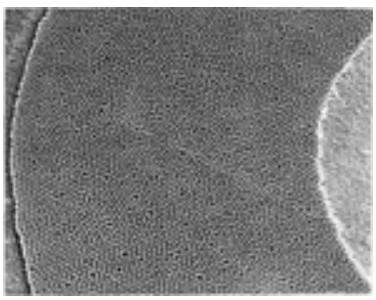

Fig. 16 Partial cross section of a multifilamentary NbTi composite assembled using round monofilaments. Courtesy of Supercon, Inc.

Restacked Drilled Billets. The third method of billet assembly is to restack drilled billets. This approach is commonly used when many thousands of very fine filaments are required, as is the case for ac applications. A variation of this technique is to produce a monofilament and restack it twice, technically a triple extrusion. Figure 5 shows such a composite. The limitation to multiple restacks is, again, nonuniform filament spacing. The outermost filaments in each subbundle are mechanically unsupported. This instability is exemplified in Fig. 17.

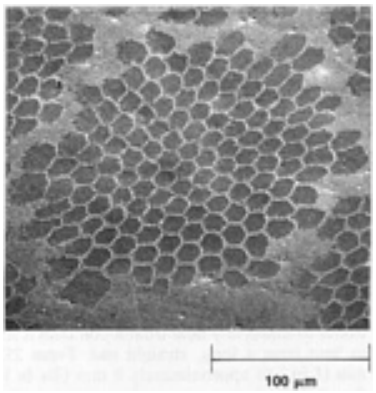

Fig. 17 Partial cross section of a multifilamentary NbTi composite assembled using a double restack of hexagonal monofilaments. Mechanically unsupported outermost filaments display erratic filament cross sections. Courtesy of Supercon, Inc.

It would seem, therefore, that the lowest percentage of unsupported filaments would be produced in a billet comprised of a single restack of hexagonal subelements. Unfortunately, there are limits to the number of hexed rods that can be practicably restacked. The cross section shown in Fig. 6 contains 22,900 NbTi filaments *plus* 11,200 copper hexes (which make up the core and part of the outer can). Each hexagonal subelement was 1.42 mm, or 0.056 in. (flat-to-flat). The can used to fabricate this composite had an outside diameter of 316 mm (12.4 in.). It is conceivable that with a larger can, and thus larger hexed rods, more filaments could be incorporated into a single restack, but this remains unexplored. In addition, automation of the billet assembly process has yet to be undertaken.

Welding

Upon assembly, billets must be sealed to prevent oxidation of the freshly etched surfaces. The surface area increases as the inverse square of the filament size. Electron-beam (EB) welding and tungsten-inert-gas (TIG) welding are the two techniques most widely used. Trapped gases and contaminants will inhibit proper bonding of the components. It is, therefore, essential that a vacuum exist within the enclosed can.

Compared to TIG welding, EB welding provides a much deeper heat-affected zone (HAZ). This is a distinct advantage during the rigorous processing to follow. Furthermore, TIG welding requires an evacuation port, usually in the form of a copper tube protruding from the front or rear of the billet. After evacuation, this tube is sealed, but this site remains a point of weakness. Should a rupture occur during isostatic pressing or extrusion and go undetected, air can be forced into the composite during extrusion.

EB welding is not without its drawbacks. The lengthy residence time required in the EB vacuum chamber is significant. Good use of this time can be made by welding one end of the billet at the end of the work day, then allowing the heated billet to pump-down overnight and welding the other end in the morning. The slower cooling rate associated with EB welding yields larger grains in the HAZ. As mentioned in the section "Assembly Techniques" in this article, large copper grains are to be avoided.

Isostatic Compaction

The void space in a drilled billet as assembled is relatively small, and the upset experienced during extrusion is insignificant as long as the billet fits snugly in the liner. For composites containing larger numbers of filaments, the void space is much greater. For a billet containing several thousand hexagonal subelements the void space is on the order of 6%, and for the same number of round subelements the void space is approximately twice as much (Ref 49). To densify multifilamentary composites, isostatic compaction techniques have been employed prior to extrusion. The billets fabricated for the Fermilab Tevatron were isostatically pressed at ambient temperature (cold isostatic pressing, CIP), and sufficient bonding of the components was achieved during hot conventional extrusion.

Experience has shown that, by reducing the temperature of extrusion, higher current densities can be achieved. When reducing the extrusion temperature too much, however, complete bonding is not achieved (Ref 50). The use of hot isostatic pressing (HIP) as a means of densifying and prebonding extrusion components is not new (Ref 51), but from the

perspective of achieving a complete bond followed by very low-temperature extrusion as a means of retaining cold work, it is relatively unexploited (Ref 52, 53). *In situ* billet consolidation is possible if hydrostatic extrusion techniques are used, due to the extremely high temperatures involved (Ref 54). By compensating for void fraction in the billet design, a uniform circular cross section is obtained prior to extrusion.

HIP parameters, when applied to NbTi/Cu superconducting materials, include temperatures that mimic those of extrusion (500 to 650 °C, or 930 to 1200 °F), pressures in the range of 103 to 206 MPa (15 to 30 ksi), and residence times of several hours in an argon atmosphere.

Extrusion

Extrusion is utilized to transform the assembled array of components into a true composite structure. High area reduction in a single step and a homogeneous plastic flow are distinct advantages. The principles of conventional and hydrostatic extrusion have been discussed in the section "Processing of Superconductor Composites" in this article (Ref 15, 55, and 56). As mentioned earlier, NbTi alloys are sensitive to the temperatures encountered during processing. For this reason the temperature of extrusion is kept far below the recrystallization temperature of the superconductor. Those materials without diffusion barriers are also subject to intermetallic compound formation during preheating and extrusion.

Billet heating prior to extrusion can be accomplished several ways. Electric furnaces with forced convection, gas-fired furnaces, induction coils, and molten salt baths have all been used successfully. Manufacturers have their individual preferences. Conventional extrusion temperatures are usually in the range 500 to 650 °C (930 to 1200 °F). Hydrostatic extrusion temperatures range from ambient temperature for aluminum matrix composites to 200 to 400 °C (390 to 750 °F) for copper matrix composites (Ref 50, 52, and 53). The length of time required is determined by the heating method employed and is considered sufficient once the billet is uniformly heated. In addition to preheating the billet, the liner, cone, and die are often heated prior to extrusion.

The extrusion ratio is determined after considering a number of factors. Among these are: the available tonnage of the press, the equipment available to process the extrudate, and the deformation resistance of the billet. The deformation resistance is composition dependent and varies as a function of the temperature. Typical extrusion ratios range from 10:1 to 20:1. Too small a reduction can lead to a phenomenon referred to as center burst, in which the soft copper shell tends to flow faster than the harder NbTi core elements, causing an internal tensile tear. Billet diameters range from 178 to 203 mm (7 to 8 in.) for monofilaments, 203 to 280 mm (8 to 11 in.) for drilled billets, and 250 to 356 mm (9.8 to 14 in.) for restacked monofilaments.

The temperature dependence of the NbTi alloy again comes into play when one considers the speed of extrusion. As the extrusion proceeds, friction between the billet and the liner heats the billet. To facilitate a smooth extrusion, the billet and the extrusion tooling are coated with MoS_2 or graphite to reduce friction. Furthermore, if the deformation energy is transferred to the work piece and not the liner, the extrudate is subject to a significant heat differential from front to rear. These considerations necessitate relatively slow extrusion speeds. Stem speeds range from 3 to 7 mm/s (0.12 to 0.28 in./s). Upon complete extrusion the composite rods are water quenched to avoid coarsening of the grains.

Some benefits of low-temperature hydrostatic extrusion have been alluded to, that is, maximization of retained cold work, reduced intermetallic compound formation, and reduced friction during extrusion. Other advantages include:

- Ability to coextrude widely dissimilar metals such as aluminum-stabilized NbTi superconductors (Fig. 18)
- Larger length/diameter (l/d) ratios that translate into reduced extrusion end-effect losses and higher yields

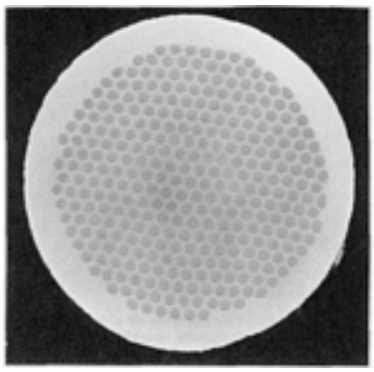

Fig. 18 Cross section of an aluminum-stabilized composite containing 294 NbTi filaments in a 6063-T6 aluminum alloy matrix. The 19 filaments in the center of the array are high-purity (99.999%) aluminum. This composite was assembled using kit technology and was hydrostatically extruded at ambient temperature in a conventional extrusion press converted for dual hydrostatic/conventional use. Courtesy of Supercon, Inc.

The largest production hydrostatic extrusion presses have maximum capacities of 39.1 MN (4400 tonf) and are located in Europe and Japan. The feasibility of modifying an existing midsize (11.1 MN, or 1250 tonf) conventional extrusion press to permit, with a reversible tooling change, hydrostatic extrusion of superconducting materials, has been demonstrated (Ref 53).

Wire Drawing

Standard nonferrous rod and wire-drawing techniques are used to reduce the extruded rod to final wire diameter (see the article "Wire, Rod, and Tube Drawing" in *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). As-extruded superconducting composites are 50 to 90 mm (2 to $3\frac{1}{2}$ in.) in diameter. The reduction in area per pass is 15 to 25%. Again, as with extrusion, center-bursting must be avoided. Rod is drawn straight, on a draw bench (Fig. 19), to 20 to 25 mm ($\frac{25}{32}$ to 1 in.) diameter. At this size the rod is coiled. The coil diameter should be large enough to prevent plastic straining of the filaments outside the neutral axis during bending. Coiling the material at this time serves a second purpose. It is at this size, 20 to 25 mm ($\frac{25}{32}$ to 1 in.), that the first of several intermediate precipitation heat treatments is administered, and it is much easier to uniformly heat treat a coil than it is to heat treat a long, straight rod. From 25 mm (1 in.) to approximately 8 mm ($\frac{5}{16}$ in.) the rod is drawn on single-capstan bull-blocks. Below this diameter, multiple die machines are used. Final wire diameters can range from 0.05 to 2.8 mm (0.002 to 0.11 in.) depending on the application.

Twisting and Final Sizing

All multifilamentary superconducting composites must be twisted in order to:

- Minimize flux-jump instability in the presence of a time-varying external field
- Reduce eddy-current losses
- Eliminate self-field instabilities

The amount of twist required depends on the conditions of operation. Most applications envisioned for NbTi superconducting magnets operate in a steady-state mode, with minimal applied-field ramping, and therefore, require relatively little twist. For instance, the present SSC specification calls for 2 twists/inch, or 15.7 times the wire diameter (0.808 mm, or 0.0318 in.). When large applied-field ramp rates are required, as is the case for ac motors and generators, the twist pitch must be very small. Four to eight times the wire diameter is the norm.

Twisting is usually the second-to-last step in the mechanical processing of NbTi superconductors. The last step is final sizing or shaping. In this way, the twist is locked in. In some twisting machines where there is an external take-up the final sizing operation is performed in tandem with the twisting. If the take-up is an internal arrangement, the final drawing pass must be performed in a separate operation. Some magnet wire is shaped into a square or rectangular cross section. This can be accomplished with a Turk's head comprised of four independently adjusted rolls. The rolls can be passive or powered.

Additional Stabilizer

For those applications where greater stability is required, it is often easier and more economical to supplement the stabilizing matrix of a standard product than it is to design and fabricate a monolith with a large cross section with the necessary stabilizer-to-superconductor ratio. To reiterate a point made in the "Extrusion" section of the article, the length of a monolith is limited by the volume of the starting billet and the size of the extrusion press. Figure 20 shows the cross section of a 54-filament composite (see Fig. 7) that has been continuously soldered into the channel of a high-purity copper strip. The resulting Cu:Sc ratio is 15:1. Wire-in-channel conductors of this type are used in high field (1 to 2 T, or 10 to 20 kG) MRI magnets.

The advantages of aluminum stabilization have been outlined previously in the "Matrix Materials" section of this article. One of several techniques available to the wire manufacturer as a means of incorporating high-purity aluminum is to process a copper matrix composite to final wire and then to add the aluminum in a continuous coextrusion process (Ref 57). Figure 21 shows the cross section of a hybrid aluminum-clad Cu/NbTi conductor. Cables and aspected monoliths have also been clad with high-purity aluminum (Ref 57, 58, 59). Applications for aluminum-stabilized materials include mobile MRI units, particle detector magnets, isotope separation, magnetic energy storage, and fusion containment devices.

Cabling

For many large-scale applications, the required current-carrying capacity exceeds the capabilities of monolithic strand. For these situations, magnet designers have resorted to cabling or braiding many individual strands together to obtain a larger cross section. This assemblage must be fully transposed for the same reasons that individual strands must be twisted. Several methods have been employed including litz configurations and flat braid produced by rotary or maypole techniques. Both techniques have low filling factors, and flat braid has the added disadvantage that crossed wires can lead to filament degradation, especially when compacted.

The favored approach is the fabrication of a two-layer Rutherford cable. Strands run parallel over the entire length of the cable and suffer minimal damage during compaction. The early dipole magnets for the superconducting supercollider were designed to incorporate 23- and 30-strand keystoned cables of this type (Ref 60). Figure 22 shows a schematic illustration of an SSC cable. Figure 23 shows both inner and outer SSC cables in cross section. A unique cabling machine was designed and constructed for the SSC project (Ref 61). Special features include:

- Planetary motion on the payoff spools to facilitate over- or under-twisting of the cable
- High rates of production (10.6 m/min, or 34.8 sfm)
- Power Turk's head for compaction/shaping and reduction of cable tension
- Broken-strand detectors
- In-line measurement capability and data acquisition

Figure 24 gives one perspective of the cabling-line arrangement. The cable produced on this machine shows little degradation of the strand due to cabling. Average values are 1 to 2% for 23-strand inner cable and 4 to 5% for 30-strand outer cable (Ref 62).

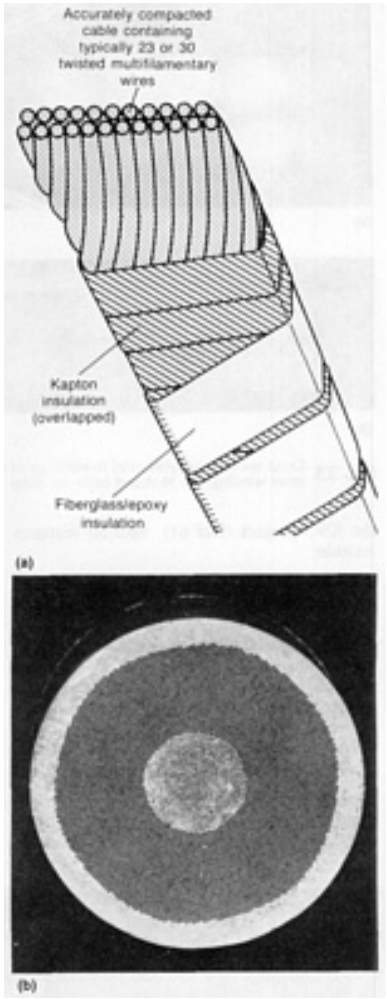

Fig. 22 Schematic representation and close-up photo of a 23-strand transposed Rutherford cable for the superconducting supercollider. Polyamide (Kapton) film wrap allows slippage with low friction as the coils are energized, reducing thermal transients in the conductor. Widely spaced fiberglass insulation promotes better cryogenic cooling. Courtesy of the SSC Laboratory. Superconductor Filament Properties

A number of factors are directly related to the ability to produce fine filaments of NbTi with very high current-carrying capacities. High-homogeneity NbTi alloy is frequently cited as a major factor. Of equal importance is the use of a diffusion barrier and its success in preventing the formation of brittle intermetallic compounds that degrade the filaments and impede the wire-drawing process. These considerations were discussed in the section "Assembly Techniques" in this article.

Other equally significant factors are:

- Uniformity of the array
- Filament spacing
- Employment of a carefully controlled strain-heat treatment cycle

It is insufficient to address one and not all of the design and process considerations mentioned when endeavoring to produce high-quality filaments.

Geometric Uniformity

One of the primary causes of filament nonuniformity is the differential hardness of the filaments relative to that of the matrix. As nonheat-treated filaments are drawn down, both they and the matrix harden progressively and little sausaging (variation in cross-sectional area) occurs. When heat treatments are superimposed on the reduction process, hardening of the filaments and softening of the matrix takes place at each heat-treatment stage. During the reduction pass immediately following each heat treatment, the differential hardness is at its greatest, and this increases with each successive treatment until a point is reached where instability occurs and the filaments begin to reduce in cross section locally. This is known as sausaging. Less sausaging takes place if the average filament spacing (*S*) to filament diameter (*D*) ratio is small as more closely spaced filaments tend to mechanically support one another (Ref 63, 64).

This observation is a logical progression from the work described earlier for subbundles of filaments doubly stacked in which filaments on the outer edge of each subbundle tend to deform more readily than those in the center of the subbundle. By arranging hexagonally-shaped monofilaments in a single-stack array, the number of unsupported filaments is greatly reduced. Furthermore, the hexagonal subelements yield more uniform spacing between individual filaments. A qualitative examination of a wide range of superconducting materials produced by different manufacturers has shown that when the filaments are closer together they tend to sausage less than under otherwise similar conditions.

Sausaging results in low *n* values, where *n* is a measure of the broadening of the superconducting normal-state transition. This is frequently used as an indicator of the average filament quality (Ref 65) and can be represented by the equation:

$$\rho = VA/I = \text{Constant} \times I^n \qquad \textbf{(Eq 1)}$$

where ρ is the resistivity, *V* is the voltage per unit length, *A* is the total wire cross section, and *I* is the measured current in the sample. The *n* value is inversely related to the width of the *V-I* transition. The influence of *n* on J_c was clearly shown for CBA wires in earlier work (Ref 66).

It is now generally agreed that more closely spaced filaments yield higher-quality filaments and are, therefore, able to carry higher currents. *S*/*D* ratios of 0.2 or less are now common in the fine-filament NbTi composites exhibiting the highest current-carrying capacities. Conversely, if the filaments are too closely spaced, proximity-effect coupling of the filaments can take place. The advent of copper-manganese alloys (see the section "Matrix Materials" in this article) offers a solution to proximity couplings. The present SSC specification calls for 6 μm (240 μin.) filaments with a minimum interfilamentary spacing of 1 μm (40 μin.) when the matrix is pure copper. This yields an *S*/*D* ratio of 0.167.

Heat-Treatment and Strain Cycles

The critical current density of Cu/NbTi composite conductors depends on two microstructure-related factors:

- Flux pinning by the cold-work-induced elongated grain boundaries
- Flux pinning by α-phase precipitates that are also the product of extreme cold work plus heat treatment

Manipulation of these precipitates by appropriate thermomechanical processing is responsible for J_c optimization.

The strand diameter required for the inner cable of an SSC dipole magnet is 0.81 mm (0.0319 in.). If one starts with a 305 mm (12 in.) diam billet, the total strain to which the material is subjected is approximately 12. Strain is defined as the true strain, ε:

$$\epsilon = \ln\left[\frac{A_0}{A}\right] \qquad \textbf{(Eq 2)}$$

where A_0 and A are the initial and final cross-sectional areas, respectively. If the first precipitation heat treatment is delayed until a strain of 6, and the strain after the last heat treatment is 4, then there is room for only three heat treatments (Ref 67, 68). The exact prestrain depends on heat-treatment temperature, alloy composition, and alloy homogeneity (Ref 69). It has been shown that the prestrain can be reduced to 4 if high-homogeneity Nb-46.5Ti alloy is used with a 420 °C (790 °F) heat treatment (Ref 70). Reduction of the prestrain to lower values can form Widmanstätten α-Ti and/or ω-phase precipitates that could lead to ductility problems (Ref 67).

An available strain of 12 assumes that hot extrusion has the same strain effect as cold drawing. If cold work is not retained throughout conventional extrusion, the total strain available is significantly reduced from the calculations referenced above. It has been demonstrated that employing HIP techniques (to densify and bond the composite) followed by hydrostatic extrusion allows one to retain significant amounts of cold work, as discussed previously (Ref 53).

The stored energy, achieved after sufficient prestrain, enables the precipitation of α-Ti in the β-NbTi structure after relatively low-temperature (375 to 420 °C, or 705 to 790 °F) heat treatments. Nucleation of the α-Ti precipitate takes place at the NbTi grain-boundary triple points, in addition to the formation of a thin titanium-rich film at the grain

boundaries. The time-at-temperature ranges from 10 to 80 h, and varies from manufacturer to manufacturer. From an economic perspective, long residence times in a heat treat furnace increase cost and slow production. Although it is usually consistent within a single processing cycle (that is, three 40-h heat treatments at 375 °C, or 705 °F), recent work has shown that the first heat treatment or two need not be as long as subsequent heat treatments in order to maximize the volume percentage of α-Ti (Ref 71). Optimized composites contain approximately 20 vol% α-Ti.

A heat-treatment/strain sequence incorporating three intermediate precipitation heat treatments is represented in Fig. 25. As illustrated, the first heat treatment (section C) produces equiaxed precipitates approximately 50 to 100 nm in size. Figure 26(a) is a transmission electron microscopy (TEM) micrograph of a NbTi composite, in transverse cross section, after its first precipitation heat treatment (corresponding to section C of Fig. 25). Figure 26(b) is a longitudinal (parallel to the drawing axis) cross section of the same composite at the same stage of processing.

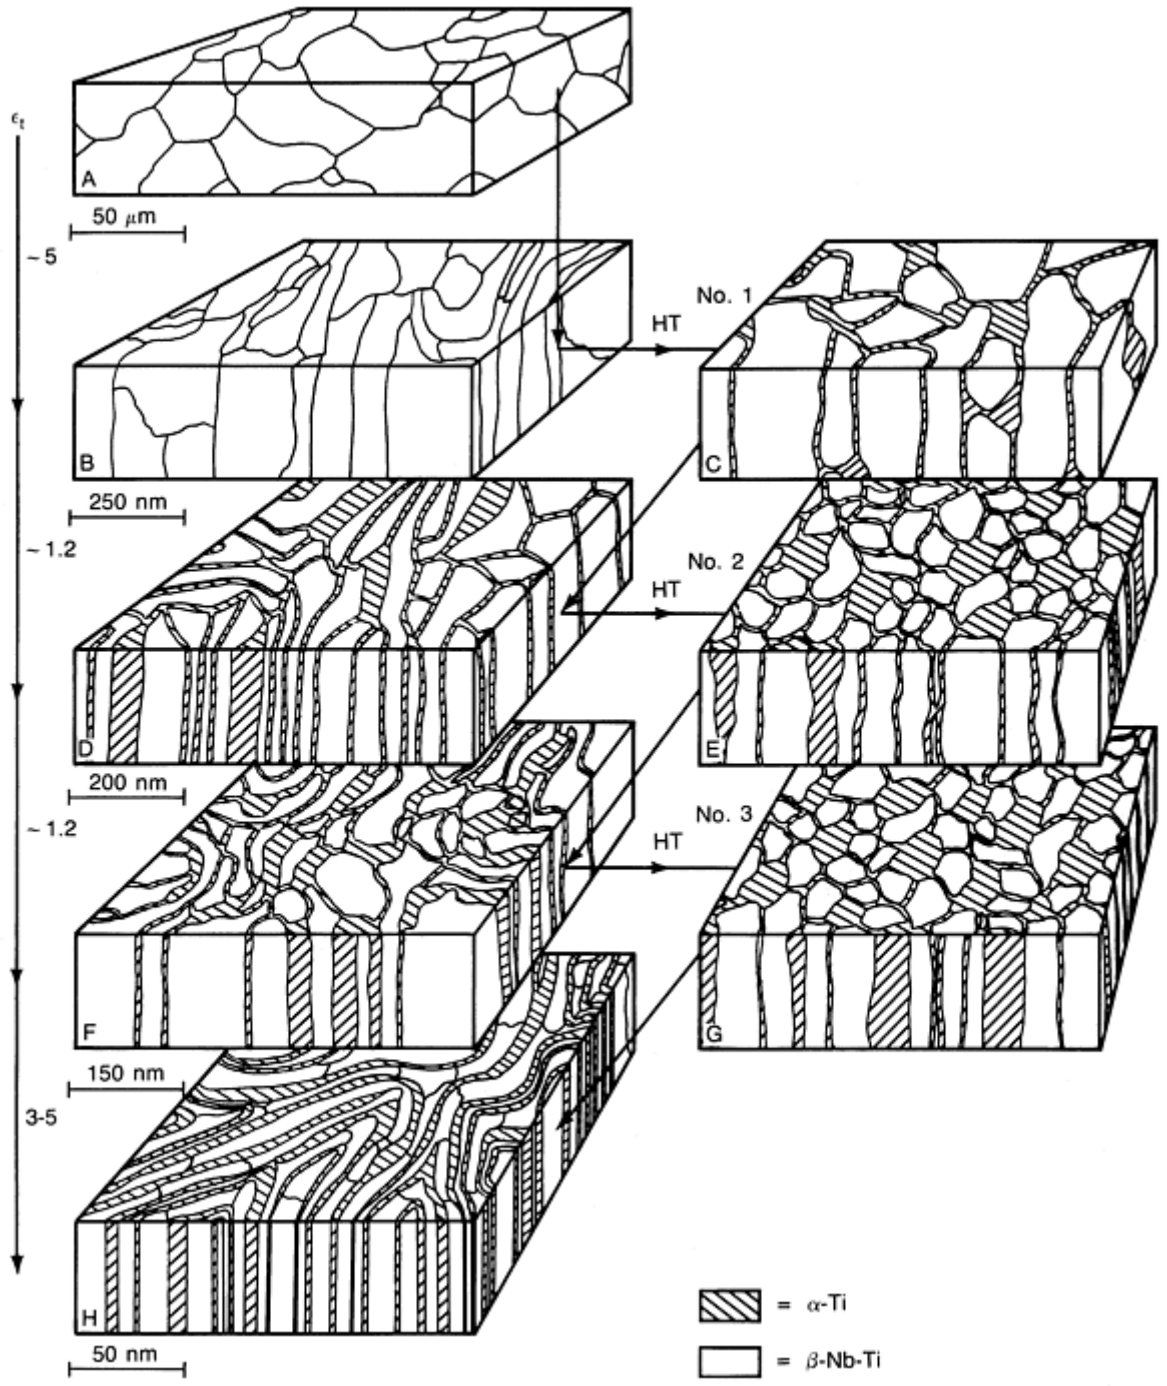

Fig. 25 Heat-treatment/strain sequence incorporating three intermediate precipitation heat treatments to illustrate the development of

nanometer scale structures in composites of NbTi. Courtesy of the Applied Superconductivity Center, University of Wisconsin-Madison

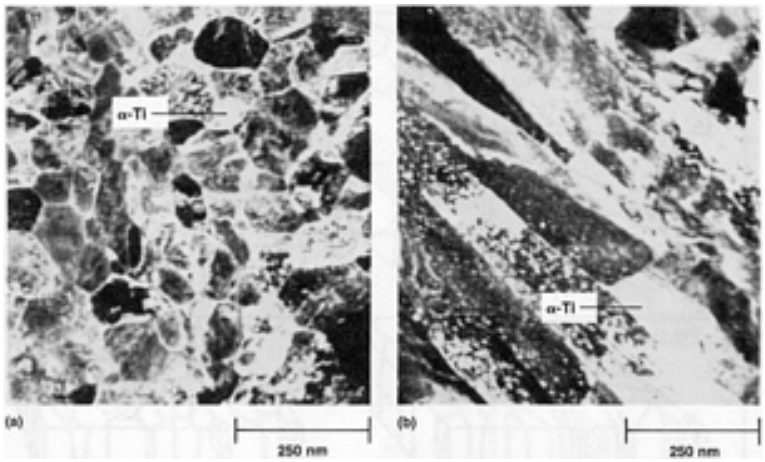

Fig. 26 TEM micrographs of NbTi composite in cross sections after first precipitation heat treatment. (a) Transverse (corresponding to section C of Fig. 25). (b) Longitudinal. Courtesy of the Applied Superconductivity Center, University of Wisconsin-Madison

Further cold work and heat treatment deform the precipitates into ribbons with large aspect ratios, as depicted in section H of Fig. 25. Typical ribbons are 1 to 2 nm thick, 10 to 300 nm in length, and spaced approximately 4 to 8 nm apart (Ref 72). It is this uniform ribbon morphology that acts to pin flux so efficiently. Figure 27(a) is a TEM micrograph showing a transverse cross section of the same composite that received two additional heat treatments followed by a drawing strain of 4.13 (corresponding to section H of Fig. 25). Figure 27(b) shows the same sample in longitudinal cross section.

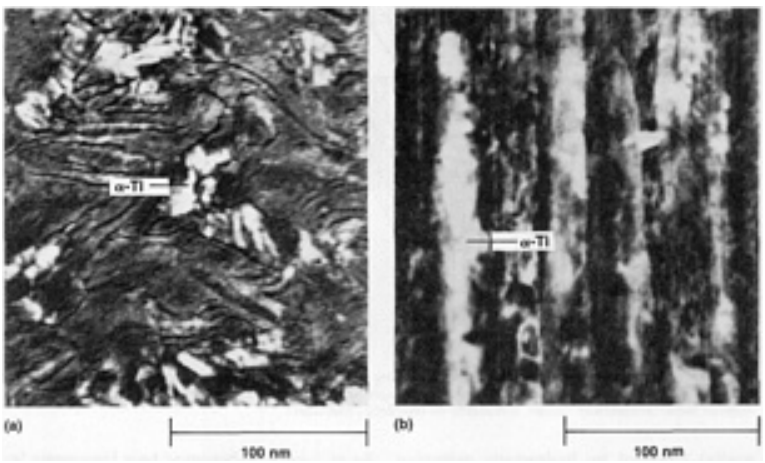

Fig. 27 TEM micrographs of NbTi composite cross sections, after third precipitation heat treatment and a final strain of 4.13. (a) Transverse (corresponding to section H of Fig. 25). (b) Longitudinal. Courtesy of the Applied Superconductivity Center, University of Wisconsin-Madison

Additional heat treatments (>3) yield higher current-carrying capacities, but overall ductility and piece length can be compromised (Ref 73). Furthermore, large final diameters do not have the requisite strain space to achieve the very high J_c values, unless hydrostatic extrusion is utilized. Figure 28 plots J_c versus strain (since the last precipitation heat treatment) for a multifilamentary composite that received 4, 5, 6, 7, and 8 heat treatments. Three observations can be made as follows:

- J_c increases with the number of heat treatments until saturation
- A saturation limit is reached for seven heat treatments

- Strain required to obtain the peak J_c decreases with more heat treatments

This work did not benefit from microstructural analysis using TEM techniques; therefore, the amount of α-Ti present is unknown and the observations general in nature.

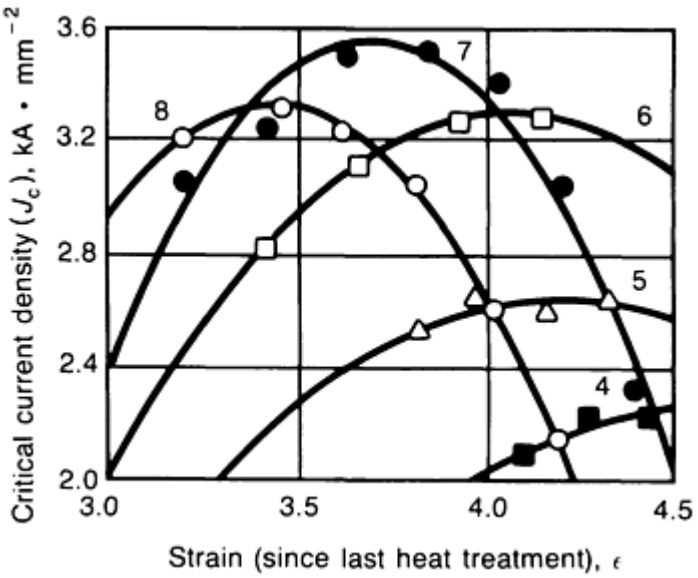

Fig. 28 Plot of critical current density versus strain (since the last precipitation heat treatment) for a multifilamentary composite that received 4, 5, 6, 7, and 8 heat treatments. Courtesy of Supercon, Inc.

When standard three-heat-treatment processing is applied to NbTi alloys with higher percentages of Ti, Widmanstätten α-Ti and/or ω-phase precipitates can be produced (Ref 74). Higher-temperature heat treatments tend to suppress the ω-phase precipitation (Ref 69). It has been demonstrated that when titanium content increases by 1 wt%, the prestrain should be increased 0.74 to inhibit the precipitation of the hardening phases (Ref 69). Furthermore, the rate of precipitation increases markedly with increasing Ti content (Ref 69). It may, therefore, be possible to compensate for larger required prestrains with fewer intermediate heat treatments.

Superconductor Applications

Magnetic Resonance Imaging (MRI) is the first large-scale application of superconductivity and has now achieved the status of a mature industry with an annual turnover in excess of $150,000,000 (Ref 75). There are more than 1700 superconducting MRI units installed worldwide.

When the human body is exposed to a magnetic field, the protons in water and other molecules align themselves relative to this field. When a burst of radiofrequency energy having the correct resonant frequency is applied these protons are excited, and when the pulse decays they return to their former state with a release of energy. This energy is detected in several different ways and used to create an image, which in turn gives significant information about tissue that is frequently lacking in x-ray computerized axial tomography (CAT) scans. In addition, little patient preparation is required and there is no exposure to ionizing radiation.

Magnetic resonance imaging is particularly good for studies of the brain, liver, and kidneys. Figure 29 shows an MRI image of the brain. Higher fields for imaging produce better images faster. Higher fields are required for biochemistry where elements other than hydrogen (that is, ^{31}P, ^{23}Na, ^{39}K, ^{43}Ca, and ^{14}N) could be used to obtain additional information. Lower-field superconducting magnets with large homogeneous volumes and 1 m (3 ft) bores are available in a range of field strengths up to 2 T (20 kG) (Fig. 30).

High-energy physics (HEP) has for many years been concerned with obtaining an understanding of the nature of elementary particles of which all matter is composed and the forces through which matter interacts. The machines required to investigate these particles and forces have grown in size over the years and begun to consume more energy, primarily in the magnets required to confine the particles and control their behavior. The only way known to achieve the particle energies now required for further investigations at an acceptable cost is to employ superconducting magnets. High-energy physics has been the largest consumer of NbTi superconducting materials and has provided the impetus for much of the improved performance observed in recent years.

The world's first high-energy superconducting accelerator, Fermilab's Tevatron, was successfully tested in July 1983. The 6 km (3.7 mi) ring contains 774 superconducting dipoles and 216 quadrupoles, like those shown in Fig. 31. Other superconducting accelerators now in operation or under construction are the hadron-electron ring anordnung (HERA) at Deutsche Electronen Syncrotron (DESY) in Hamburg, FRG; the accelerating and storage complex (UNK) in Serpukhov, USSR; the TRISTAN facility at the Japanese atomic energy facility (KEK); the relativistic heavy ion collider (RHIC) at Brookhaven National Laboratory; the continuous electron beam accelerator facility (CEBAF); the large hadron collider (LHC) at Center for European Research (CERN); and the superconducting supercollider (SSC) in Texas.

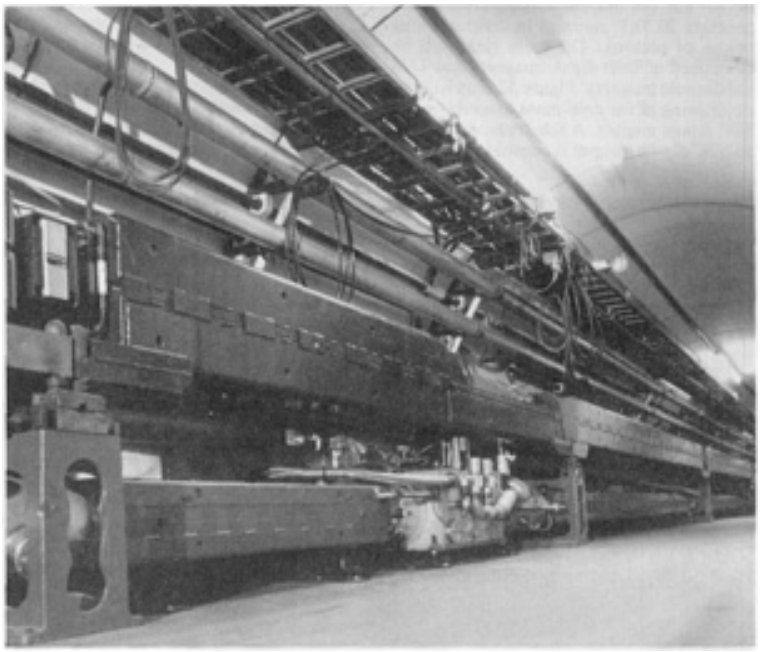

Fig. 31 Portion of the Fermilab Tevatron main 6 km (3.7 mi) ring. Courtesy of Fermi National Accelerator Laboratory

The superconducting supercollider will be 83 km (51 mi) in circumference and generate 20 TeV energies in contrarotating beams of protons. The main rings will be composed of 7680 dipole magnets and 1776 quadrupole magnets. Figure 32 is an isometric drawing of the cold-mass assembly of an SSC dipole magnet. A schematic drawing of an SSC dipole magnet is shown in Fig. 33. It is estimated that more than 1.8 Gg of NbTi superconducting cable will be required. Construction is scheduled for completion at the end of this decade at a cost exceeding $6,000,000,000.

Magnetic Confinement for Thermonuclear Fusion. If thermonuclear fusion is to become a viable energy source, the plasma produced must be confined. The most highly developed fusion-containment machines are tokamaks, which operate on the principle of toroidal confinement by magnetic fields. Superconducting magnets are preferred over copper magnets, otherwise it is possible that more electrical energy will be used to confine the plasma than the machine produces.

The principal effort for the development of superconducting coils incorporating NbTi materials for tokamaks was the large coil test (LCT) at the Oak Ridge National Laboratory (ORNL) (Ref 76). Of the six coils in this array, five were fabricated using NbTi superconductors. All the coils have a peak field of 8 T (80 kG) with conductor currents in the range of 10 to 19 kA. Figure 34 shows the LCT test stand during magnet installation.

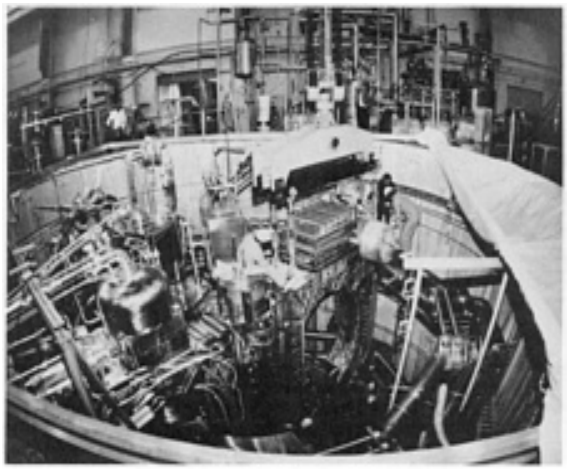

Fig. 34 LCT facility during magnet installation with four of six coils shown. Courtesy of Oak Ridge National Laboratory

The alternative method of confinement is to restrict the plasma to a straight tube by means of plugs (or mirrors) at the end of the vessel. The Axicell Mirror Fusion Test Facility (Axicell MFTF-B) at Lawrence Livermore National Laboratory is an example of this approach. The configuration of the magnets is shown schematically in Fig. 35. The solenoids used in the central cell, the transition cell, and the Yin-yang cell use NbTi superconducting materials, and the Axicell magnets are made with Nb_3Sn.

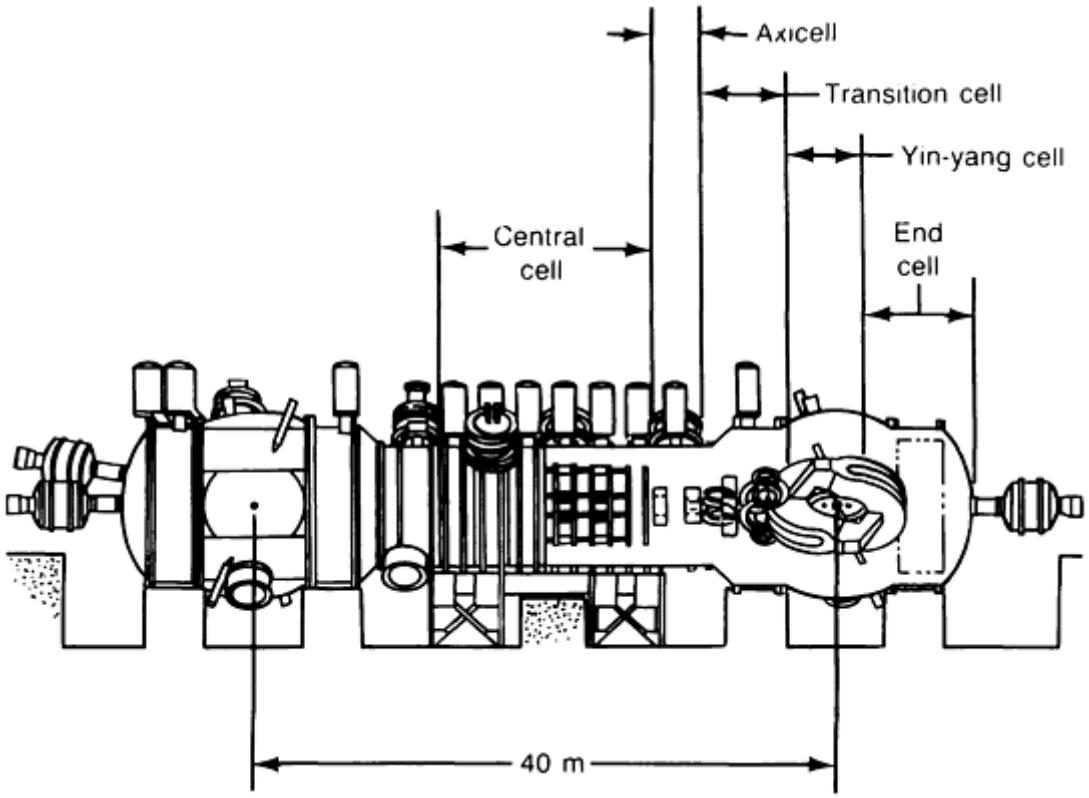

Fig. 35 Schematic configuration of magnets for Axicell MFTF-B. Courtesy of Lawrence Livermore National Laboratory

Superconducting Magnetic Energy Storage. All electric utilities experience fluctuations in demand. Excess electrical energy, generated during off-peak periods, can be stored for use during the periods of highest demand. It is estimated that 5 to 15% of the total generating capacity could be in the form of stored energy. Superconducting magnetic energy storage

(SMES) offers an efficient (~95%) method for storage and retrieval of the excess electric power. Presently, there is a joint program between the Electric Power Research Institute (EPRI) and the strategic defense initiative (SDI) to design and build an engineering test model (ETM), with an energy storage capacity of 20 MW · h (Ref 77).

Power Applications. Thus far, superconducting electric power generators have had only a superconducting rotor winding. The feasibility of fabricating low-loss 50 to 60 Hz conductors, as described above, leads to ac generators with superconducting armature windings. Making both the motor and the armature superconducting will allow a large reduction in the size of the device and simplify the cryogenic cooling requirement. Potentially 50% smaller and 1% more efficient than other types of generators with the same power output, superconducting motors and generators should find application not only in the utility industry but in aerospace and shipboard environments as well.

More efficient transformers with improved steady-state and transient stability, which when integrated over their life cycle result in appreciable cost savings, are possible with superconducting windings. The proposed application would eliminate the need for step-up transformers on a primary distribution system.

Additional Applications. Other NbTi applications of interest include nuclear magnetic resonance (NMR) for chemical spectroscopy, magnetic separation, magnetohydrodynamic (MHD) power generation, power transmission, magnetic levitation, and proton beam therapy.

A15 Superconductors

David B. Smathers, Teledyne Wah Chang Albany

Introduction

THE TERM A15 refers to a cubic crystal type in the Strukturbericht System represented by the example Cr_3Si. The intermetallic A_3B compound is formed by a body-centered cubic (bcc) arrangement of B atoms with two A atoms centered in every face yielding orthogonal chain structures running through the crystal (Fig. 1). Of 76 known A15 compounds, 46 are known to be superconducting (Fig. 2 and Table 1). The A atoms are from the groups IVA, VA, and VIA transition metals, whereas the B atoms are from groups IIIB, IVB, and VB and some transition metals including osmium, iridium, platinum, gold, and technetium.

Table 1 Critical temperature of all A15 compounds known to be superconducting

Compound	T_c, K
Ti_3Ir	4.6
Ti_3Pt	0.49
Ti_3Sb	5.8

Zr_3Au	0.92
Zr_4Sn	0.92
Zr_3Pb	0.76
V_3Os	5.15
V_3Rh	0.38
V_3Ir	1.39
V_3Ni	0.57
V_3Pd	0.08
V_3Pb	3.7
V_3Au	3.2
V_3Al	9.6
V_3Ga	15.4
V_3In	13.9
V_3Si	17.1
V_3Ge	7
V_3Sn	4.3
V_3Sb	0.8
Nb_3Os	0.94
Nb_3Rh	2.5
Nb_3Ir	1.76
Nb_3Pt	10

Nb_3Au	11
Nb_3Al	18.9
Nb_3Ga	20.3
Nb_3In	8
Nb_3Ge	23
Nb_3Sn	18.3

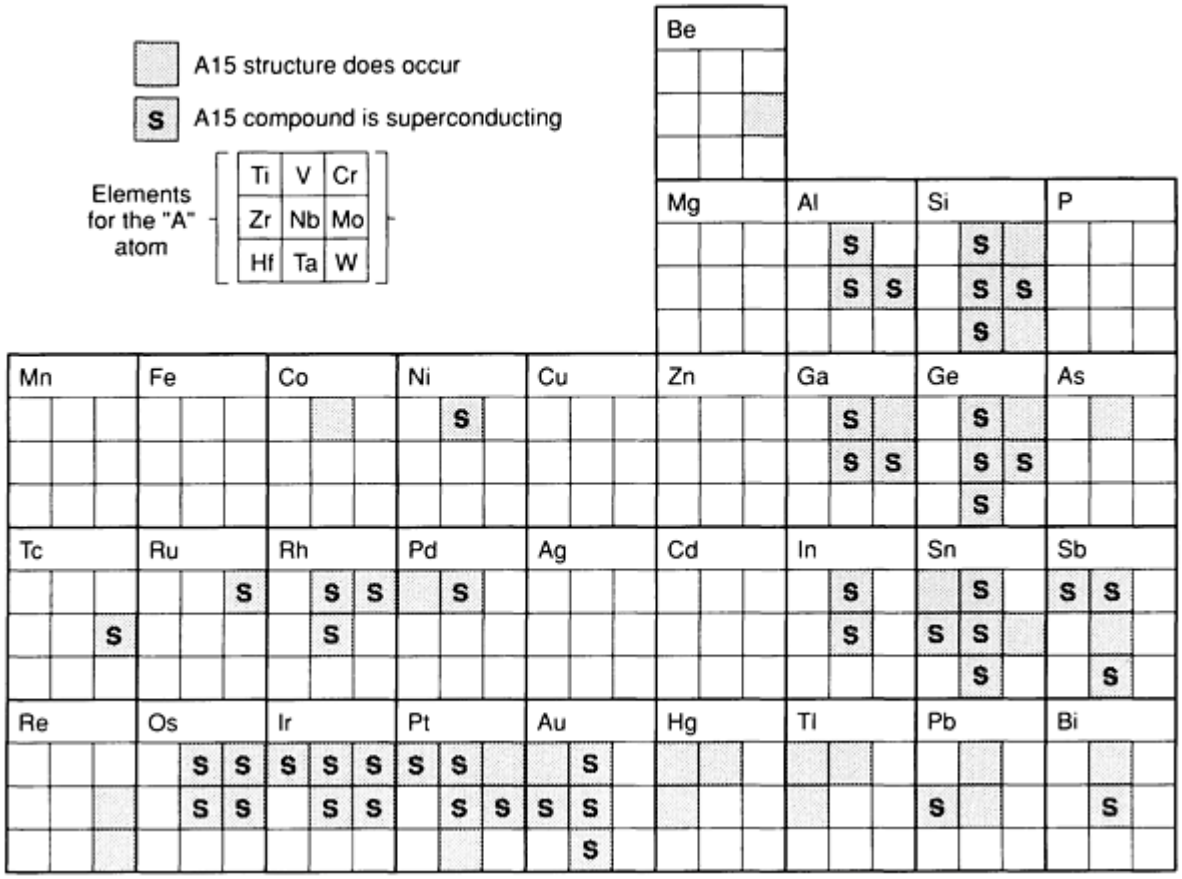

Fig. 2 Occurrence of the A15 (A_3B) crystal structure. Source: Ref 1

V_3Si was the first A15 compound discovered to be superconducting. The compounds formed with niobium or vanadium have the best superconducting properties (3(a) and Fig. 3(b)). Nb_3Ge held the high critical temperature (T_c) record for 20 years at 23 K and has the highest critical temperature of the metal, or so-called low-temperature, superconductors. The high-T_c properties of this structure are related to its atomic arrangement. When niobium or vanadium (valence 5) are the A atoms, there are many choices for the B atom with valence 4 to give the compound an average electron-to-atom ratio of 4.75. The A atoms are spaced 10 to 15% closer together on the chains than in pure A metal, and this produces an enhanced *d*-band density of states near the Fermi level (also known as Fermi energy). This correlation between superconductivity and the *d*-band density of states was deduced from Knight Shift measurements on V_3X compounds (Ref 3).

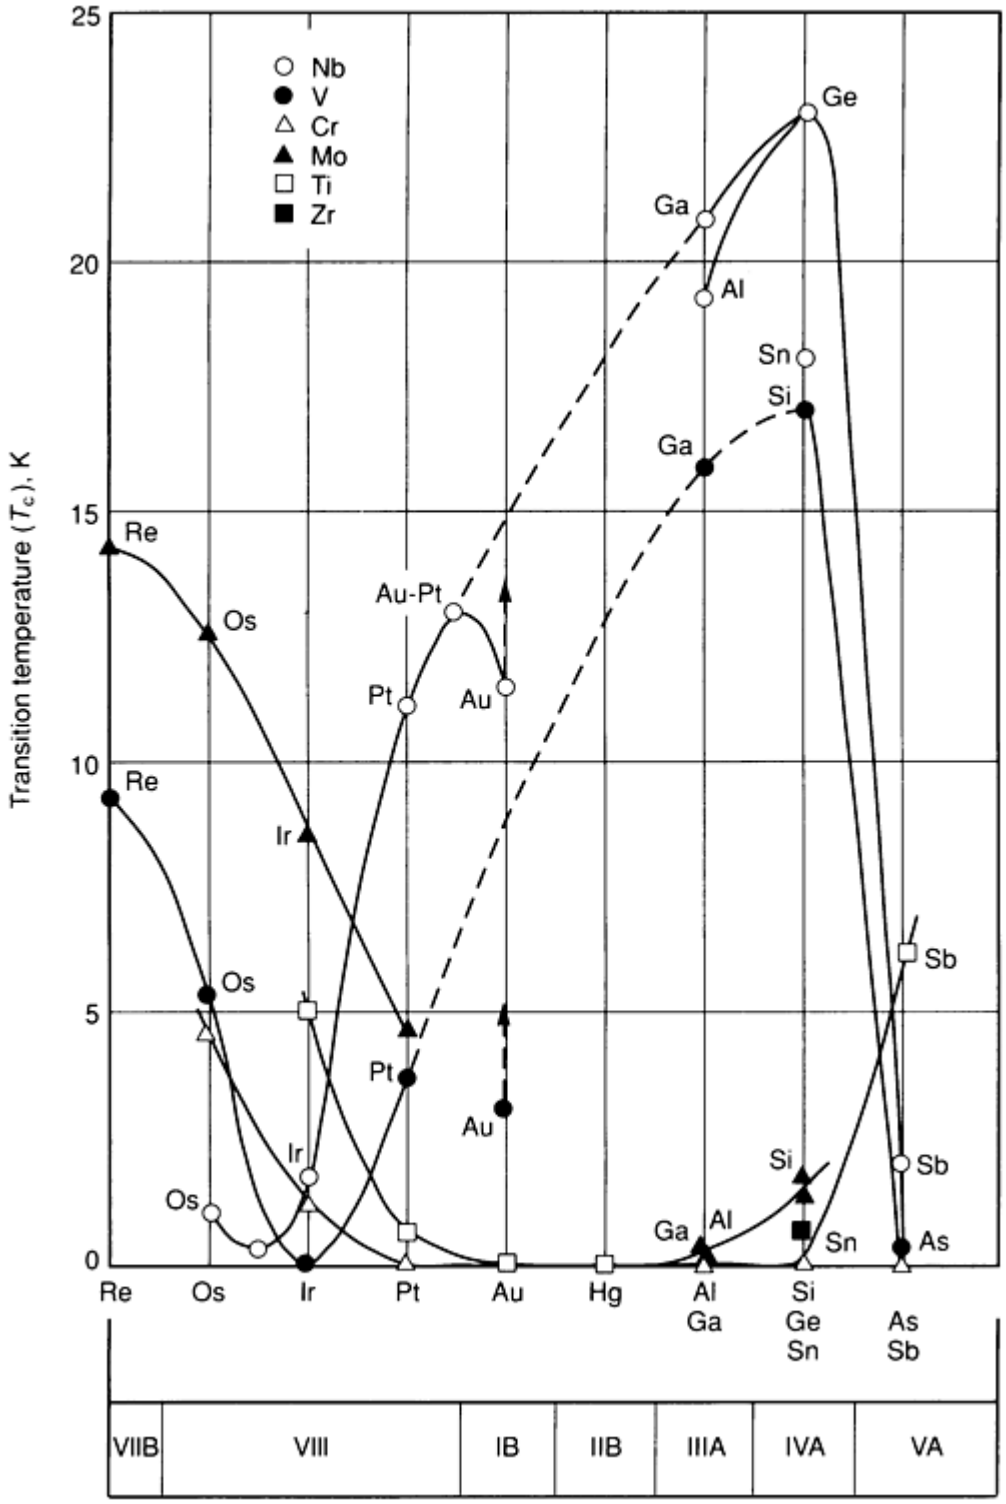

Fig. 3(a) Superconducting transition temperature, T_c, for different series of A15 compounds having the formula $A_{1-x}B_x$ as a function of the atomic number of the B atom. The expected T_c values for Nb~3Au and V~3Au would be higher if stoichoimetry could be reached. Source: Ref 2

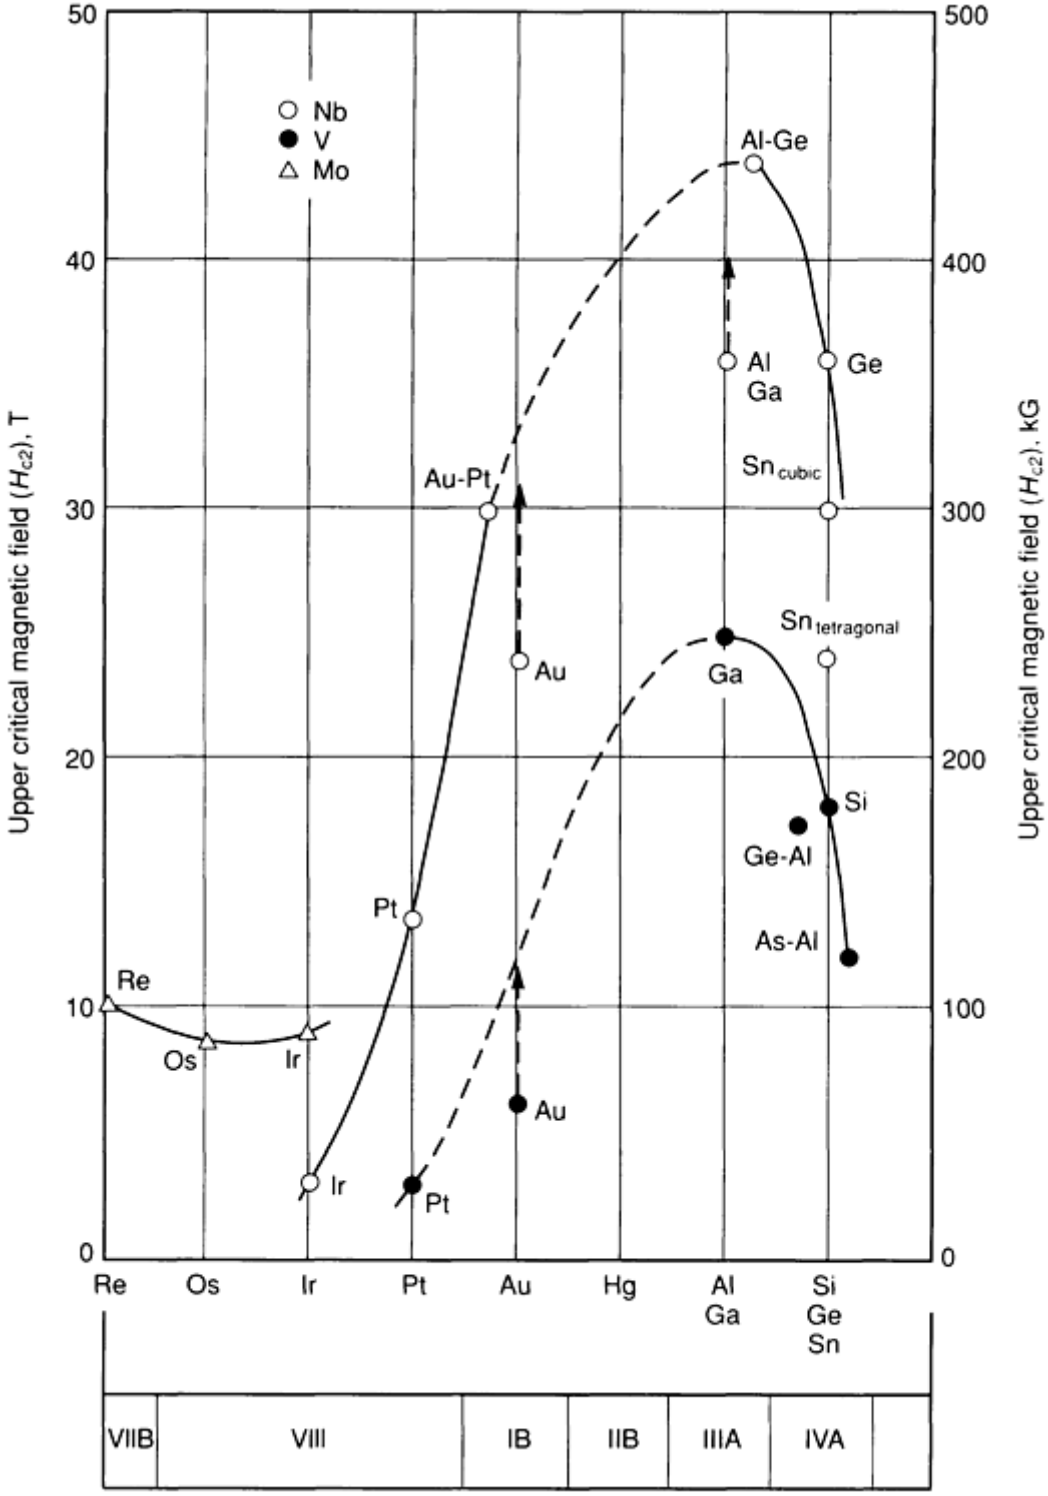

Fig. 3(b) Upper critical field, $H_{c2}(0)$, for different series of A15-type compounds having the formula A_3B as a function of the atomic number of the B atom. The $H_{c2}(0)$ values for stoichiometric V_3Au, Nb_3Au, and Nb_3Al are expected to be higher. Note the difference in $H_{c2}(0)$ between cubic and tetragonal Nb_3Sn. Source: Ref 2

The importance of the chain structure is also evidenced by the strong dependence on order in the compound. There can be compositional disorder or antisite disorder created by neutron irradiation or by the addition of third elements (Fig. 4). Beasley has pointed out that T_c in Nb_3Sn is dependent on disorder regardless of its origin (Ref 6). In general, A15 compounds exhibit a high degree of ordering (Ref 2).

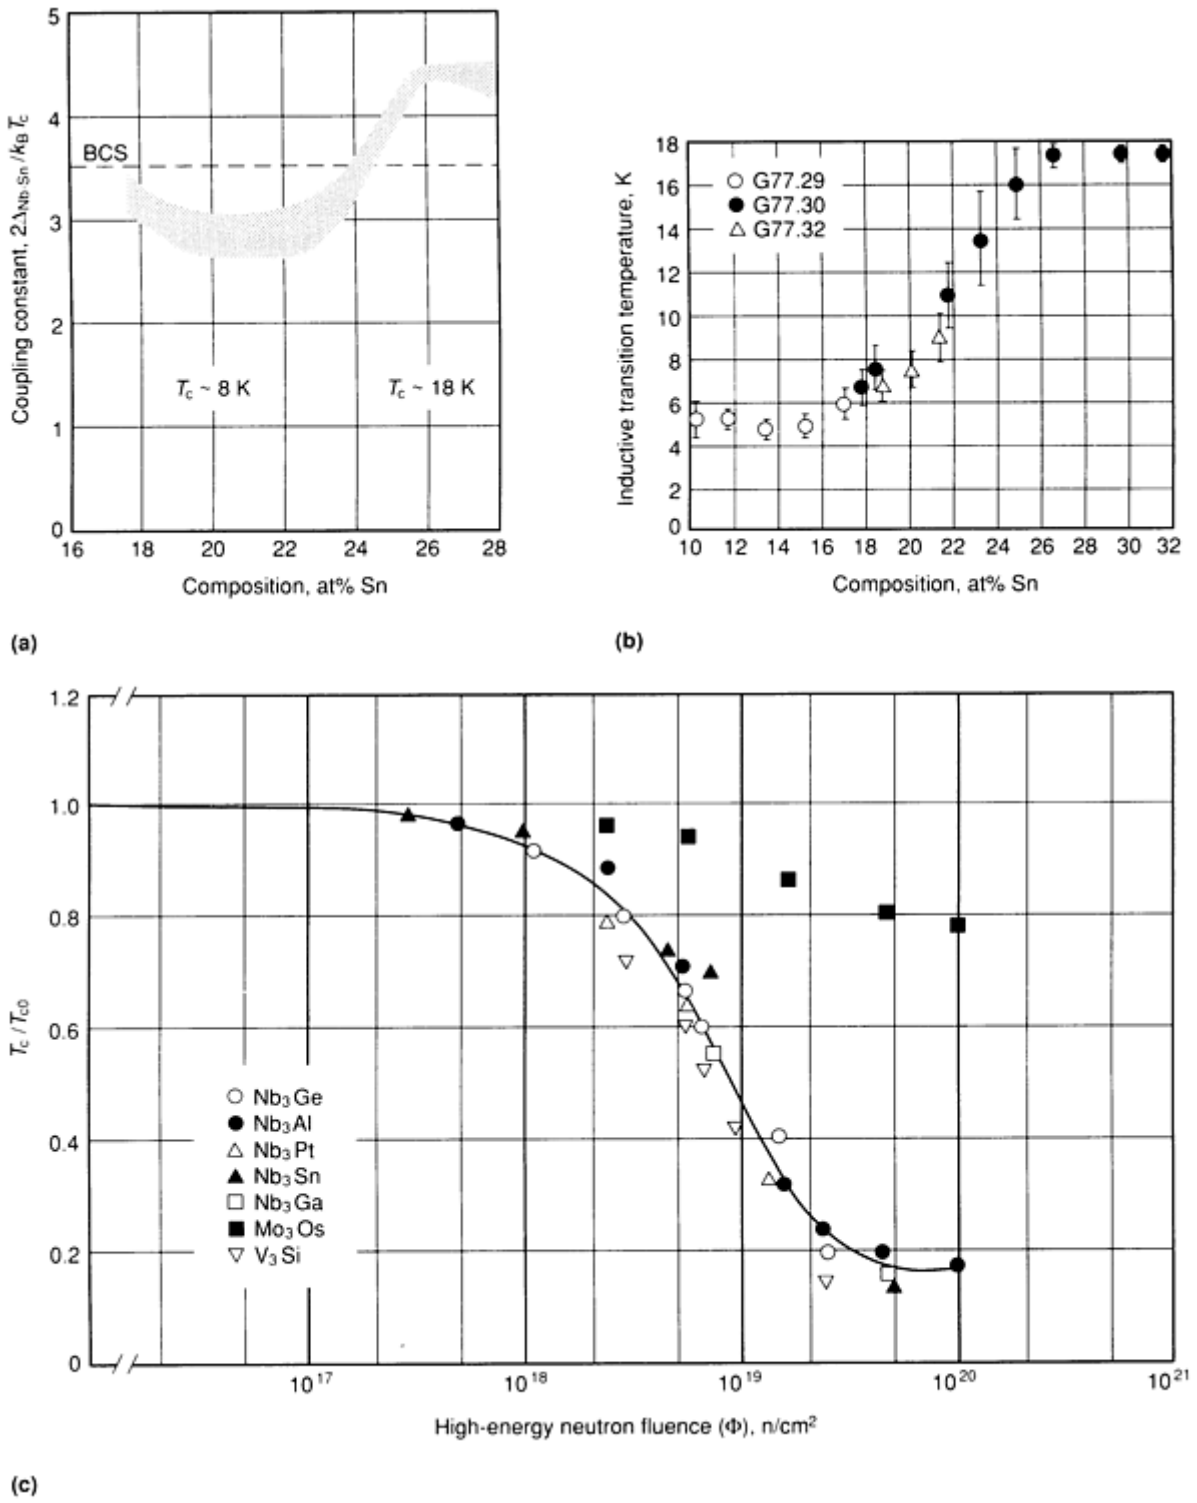

Fig. 4 Variation of superconducting properties with compositional or antisite disorder. (a) Variation of the coupling constant, $2\Delta/k_B T_c$ with composition of Nb_3Sn. The ratio is determined from tunneling data. Source: Ref 4. (b) Plot of superconducting transition temperature of optimum Nb-Sn films versus composition. The 5, 50, and 95% completion points are indicated on each transition. The films are 0.5 μm (20 μin.) thick and were deposited at ~1075 K at ~2.5 nm · s^{-1}. Source: Ref 4. (c) Reduced superconducting transition temperature normalized to the unirradiated value, T_{c0}, as a function of high-energy (E > 1 MeV) neutron fluence Φ for A15 compounds. Data are displayed on a semilogarithmic plot for easy comparison with other published data. Solid line is a visual aid. Source: Ref 5

Another intriguing feature of the A15 structure is its tendency to undergo a low-temperature martensitic transformation into a slightly tetragonal structure (the ratio of the lattice parameters, *c*/*a*, differs only by a few percent from unity). Why this transformation occurs only in V_3Si and Nb_3Sn is unknown (Ref 2). The cubic structure can be stabilized by the addition of small amounts of impurities.

The intermetallic compound is inherently brittle and presents unique handling problems when forming superconducting magnets. The compound fails brittlely at strains of about 0.5%.

The crystal structure is responsible for the high critical temperatures attained by the A15s but also leads to marked strain sensitivity of the superconducting properties T_c, B_{c2}, and I_c (Ref 7, 8, 9). Strain, ε, is the key parameter only because of the experimentaldifficulties of measuring uniaxial stress on a superconducting sample at 4.2 K in a magnetic field. A more recent problem, transverse stress, keys on stress for the same reasons, chief of which is the experimental difficulty of measuring strain under the conditions of the experiment (Ref 10).

All the A15 compounds studied show the strain sensitivity to varying degrees (Fig. 5 and Fig. 6). The magnitude of the variation has been correlated with the order parameter, S (Ref 9). The properties degrade in either tensile or compressive conditions. Residual strains can be retained on the A15 compound from the manufacturing process and must be considered in both conductor design and utilization. Handling limits can be improved by processes that put a compressive strain on the compound formed at the expense of critical current and temperature. Because the upper critical field is affected, the loss of critical current with strain is more severe at higher fields. Figure 7 shows the J_c-B-ε field for Nb_3Sn.

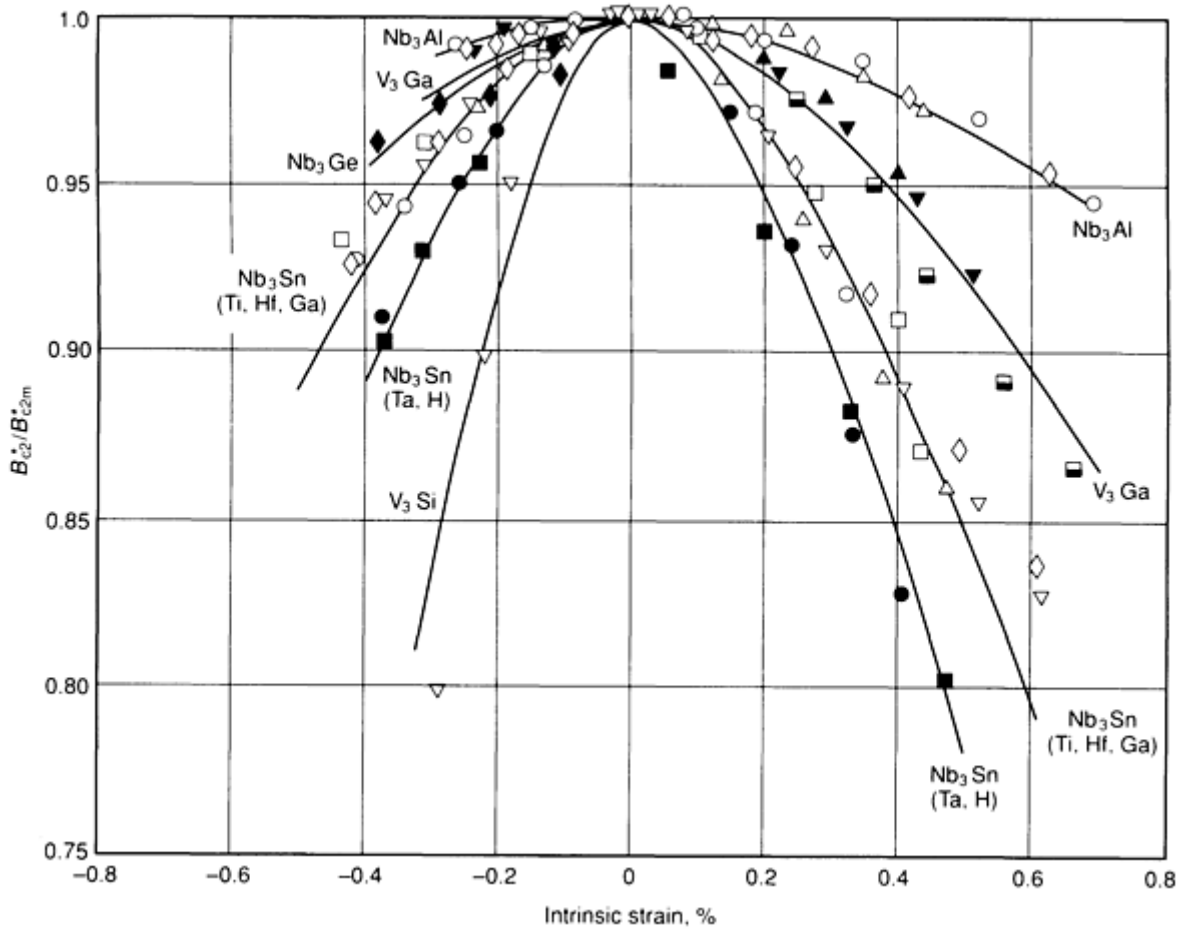

Fig. 5 Effect of uniaxial strain on the upper-critical field of practical A15 superconductors. B^*_{c2} has been normalized by its maximum (nearly strain-free) value B^*_{c2m}. Binary Nb_3Sn is represented by the same curve as for Nb_3Sn (Ti, Hf, Ga). Source: Ref 8)

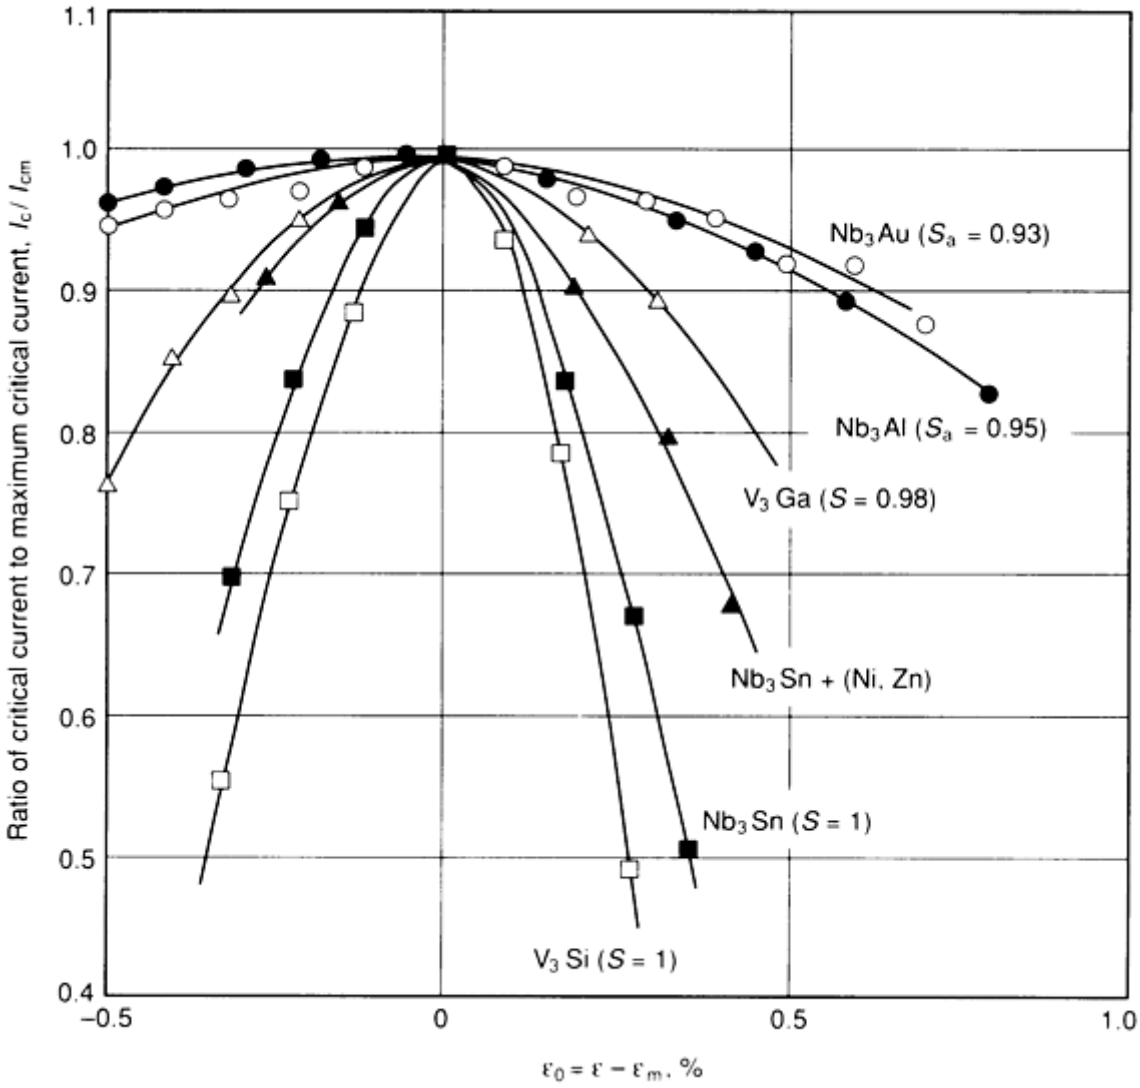

Fig. 6 I_c/I_{cm} versus ε for a series of mono- or multifilamentary wires based on A15-type compounds ($0.57 \leq h \leq 0.68$). S_a, order parameter for A-site atoms. Source: Ref 9

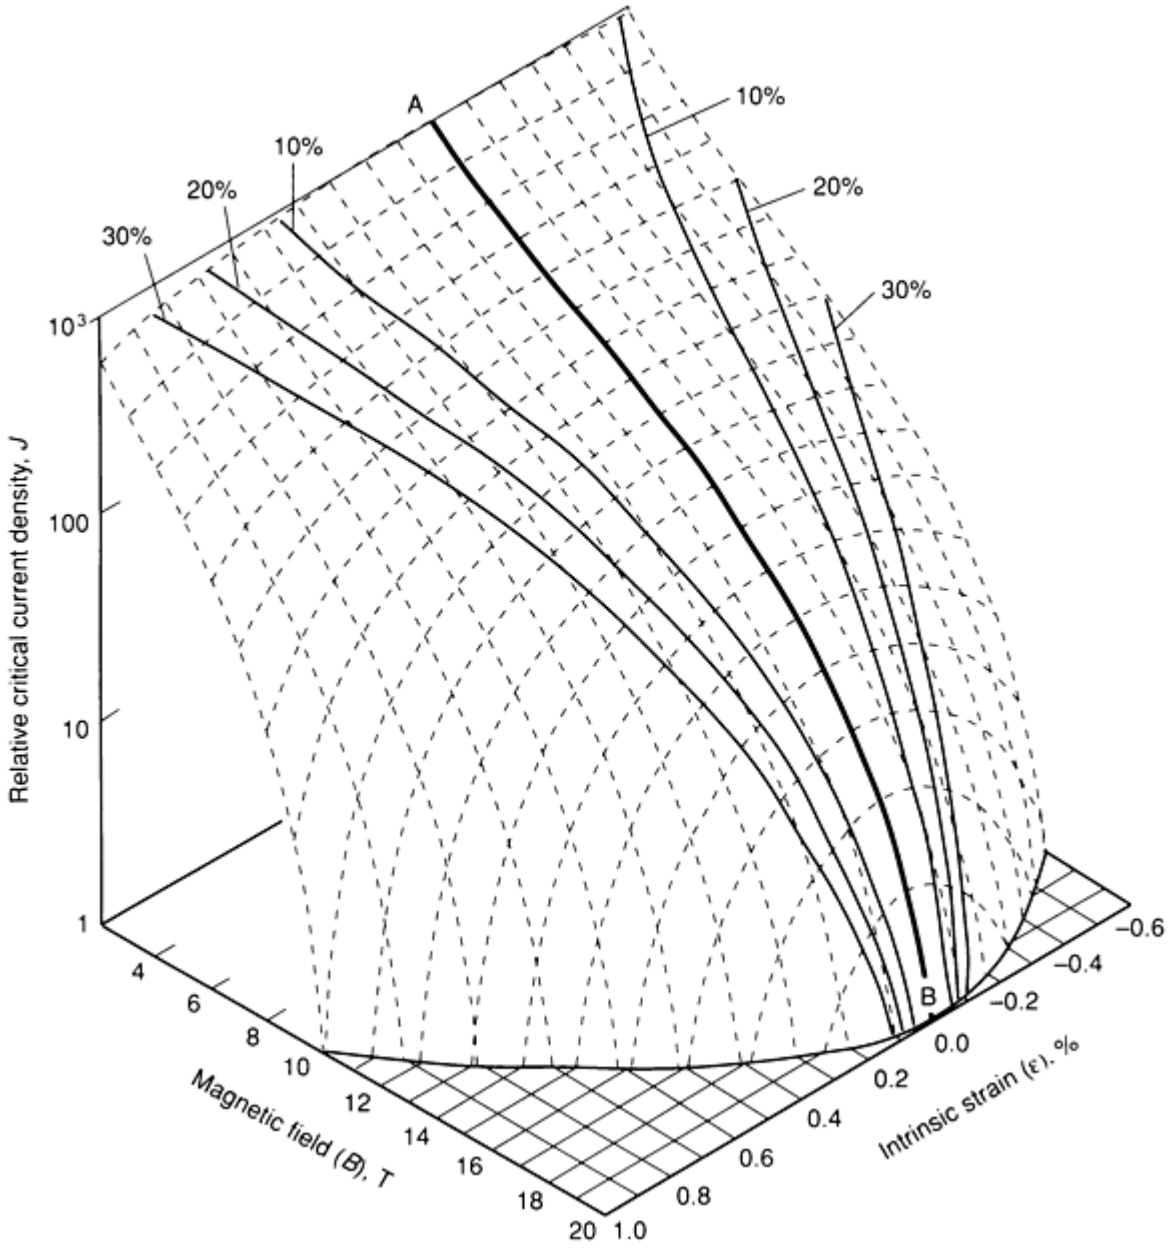

Fig. 7 *J-B-*ε critical surface for multifilamentary Nb_3Sn superconductors at T_c of 4.2 K. Line AB represents the maximum (nearly strain-free) value of the critical current as a function of magnetic field. Corresponding curves on each side of line AB represent the strain window for mechanical design that will result in a critical current within the indicated percentage of maximum. Source: Ref 8

Phase Diagrams

Flükiger has made an extensive review of the A15 phase diagrams (Ref 2). As there are wide variations in the metallurgy, only those for the high-T_c A15 compounds will be discussed here. These, as mentioned earlier, are compounds of vanadium and niobium. The A15 phase field in a binary phase diagram varies from metastability to a line compound to a broad compositional range. Some compounds include the stoichiometric 3:1 ratio as stable at low temperatures, others are stable only near the melting temperature, and some are not stable at all.

The range of phase diagrams for vanadium is shown in Fig. 8. The compounds of commercial interest are V_3Si and V_3Ga, both because of their high T_c values and the stability of the compounds. The stability is important for fabrication purposes. The V_3Ga diagram is unique in that there is considerable composition range on either side of stoichiometry. Only V_3Pt and Nb_3Pt have similar behavior (Ref 2).

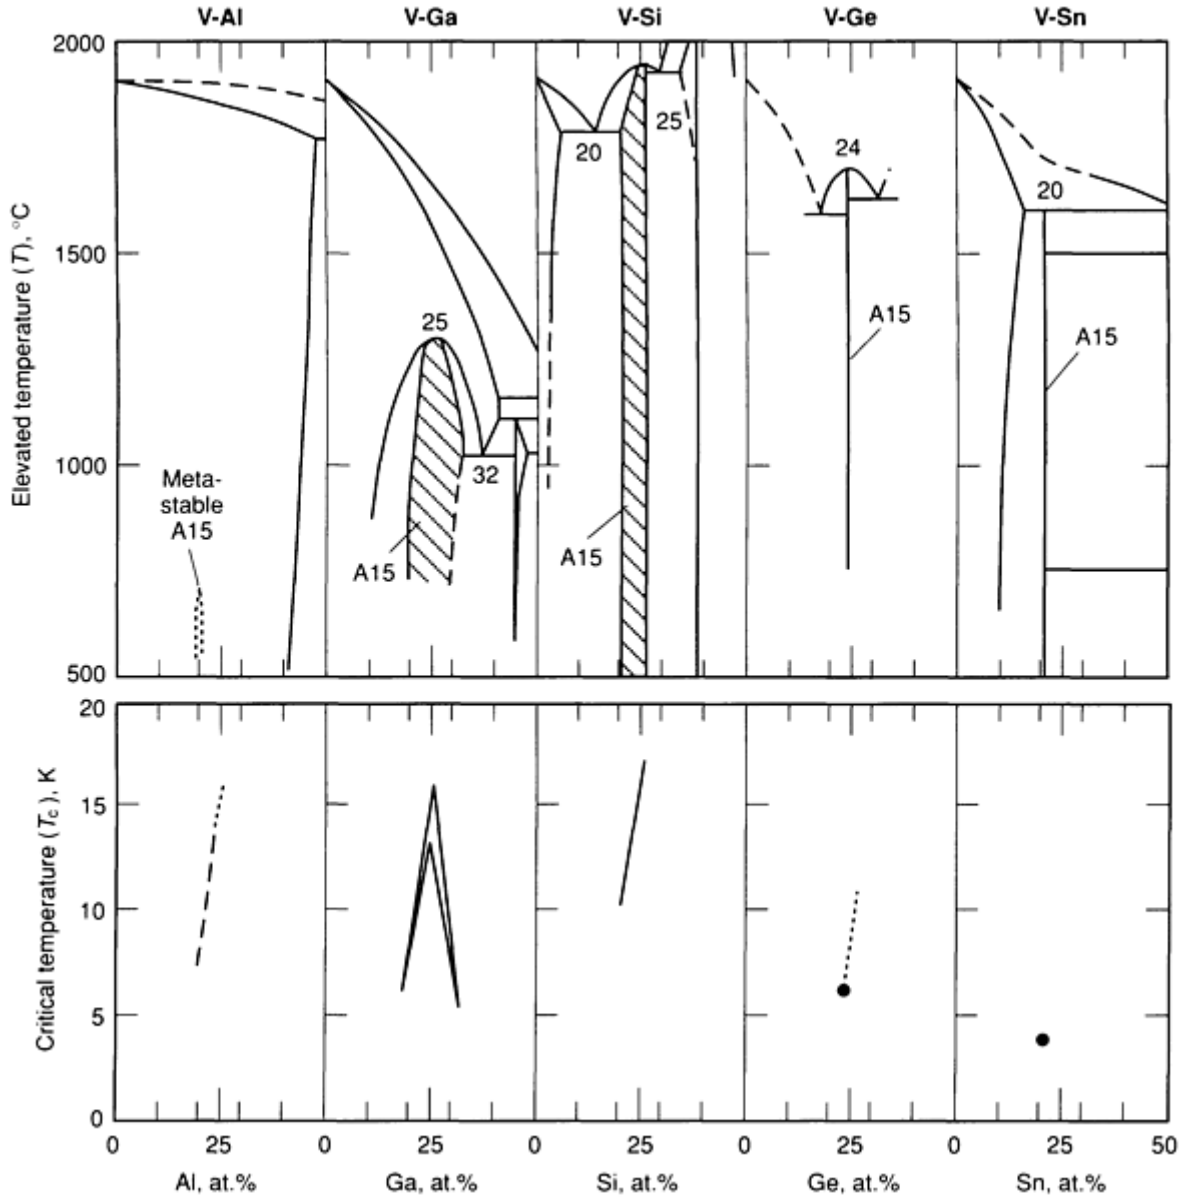

Fig. 8 A15 phase fields and superconductivity in V-Ga, V-Si, V-Ge, and V-Al. Source: Ref 2

Niobium compounds of interest fall into two general types of phase diagrams. Compounds with gallium, aluminum, and germanium form stoichiometrically only near the melting temperature (Fig. 9). Phase segregation can be controlled by the annealing temperature, and the behavior is reversible (Fig. 10). This condition has a drastic influence on the fabrication of bulk conductors of these compounds.

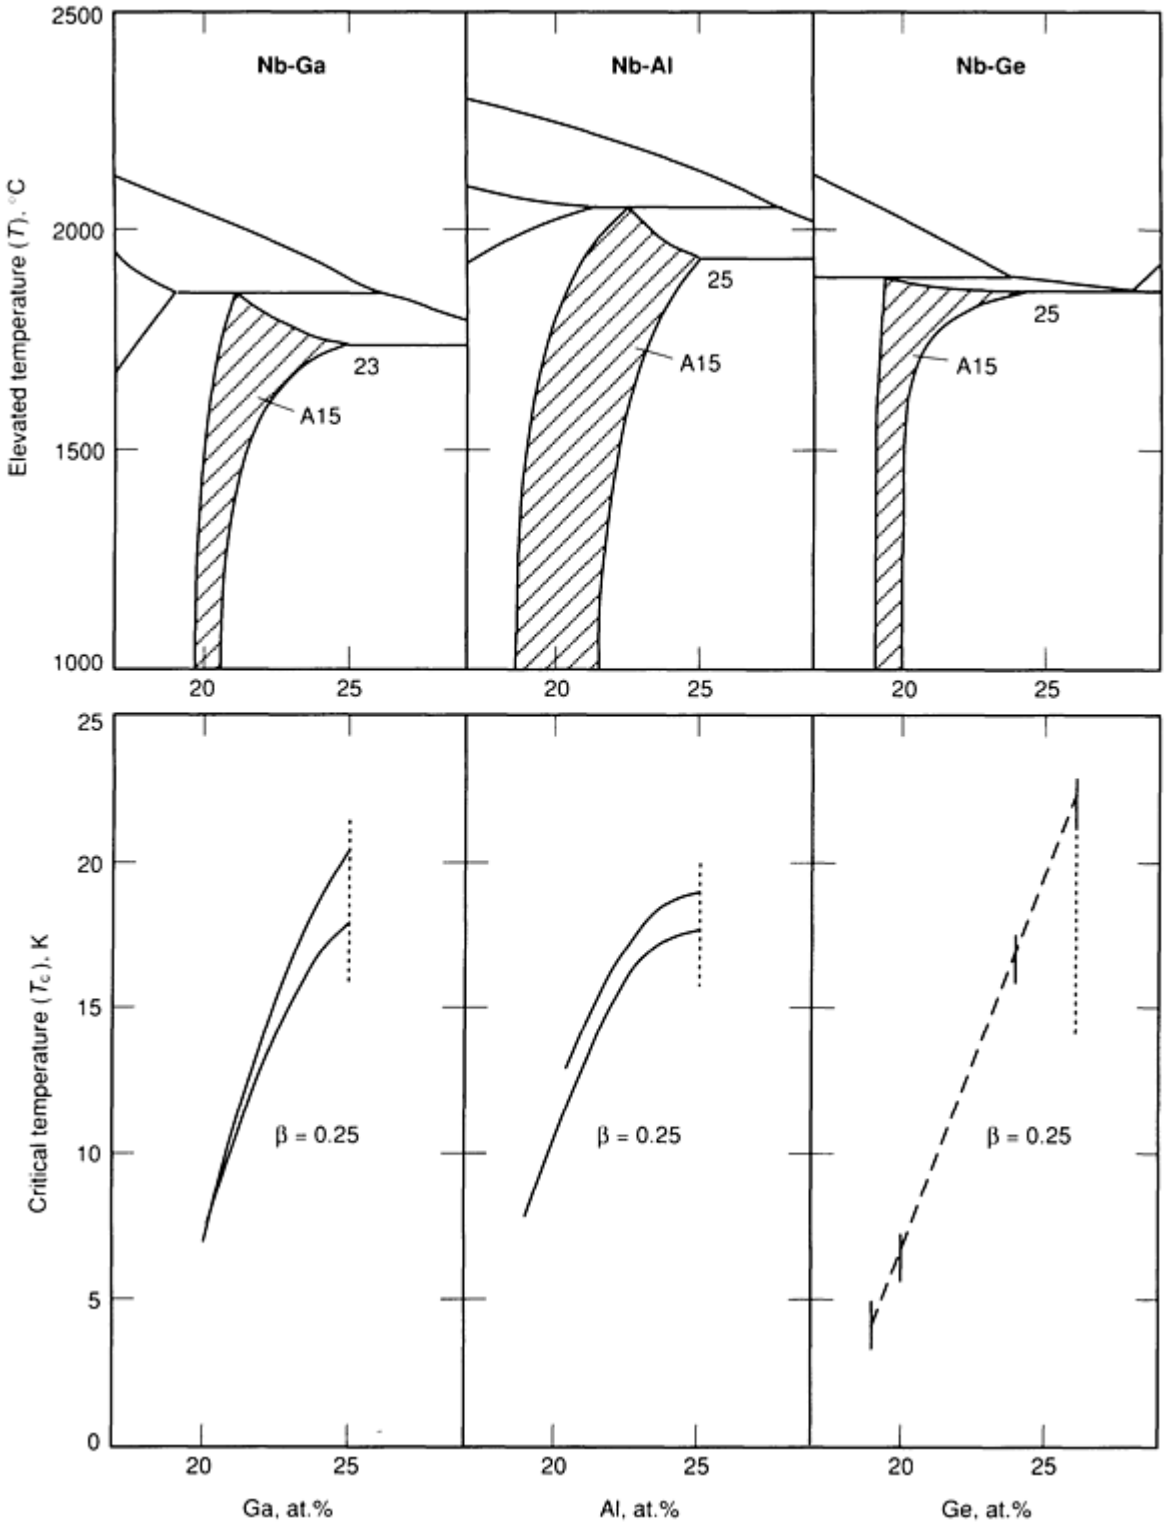

Fig. 9 A15 phase fields and superconductivity in Nb-Al, Nb-Ga and Nb-Ge. Note the saturation of T_c, very marked for Nb_3Al but less pronounced than in Nb_3Ga. Source: Ref 2

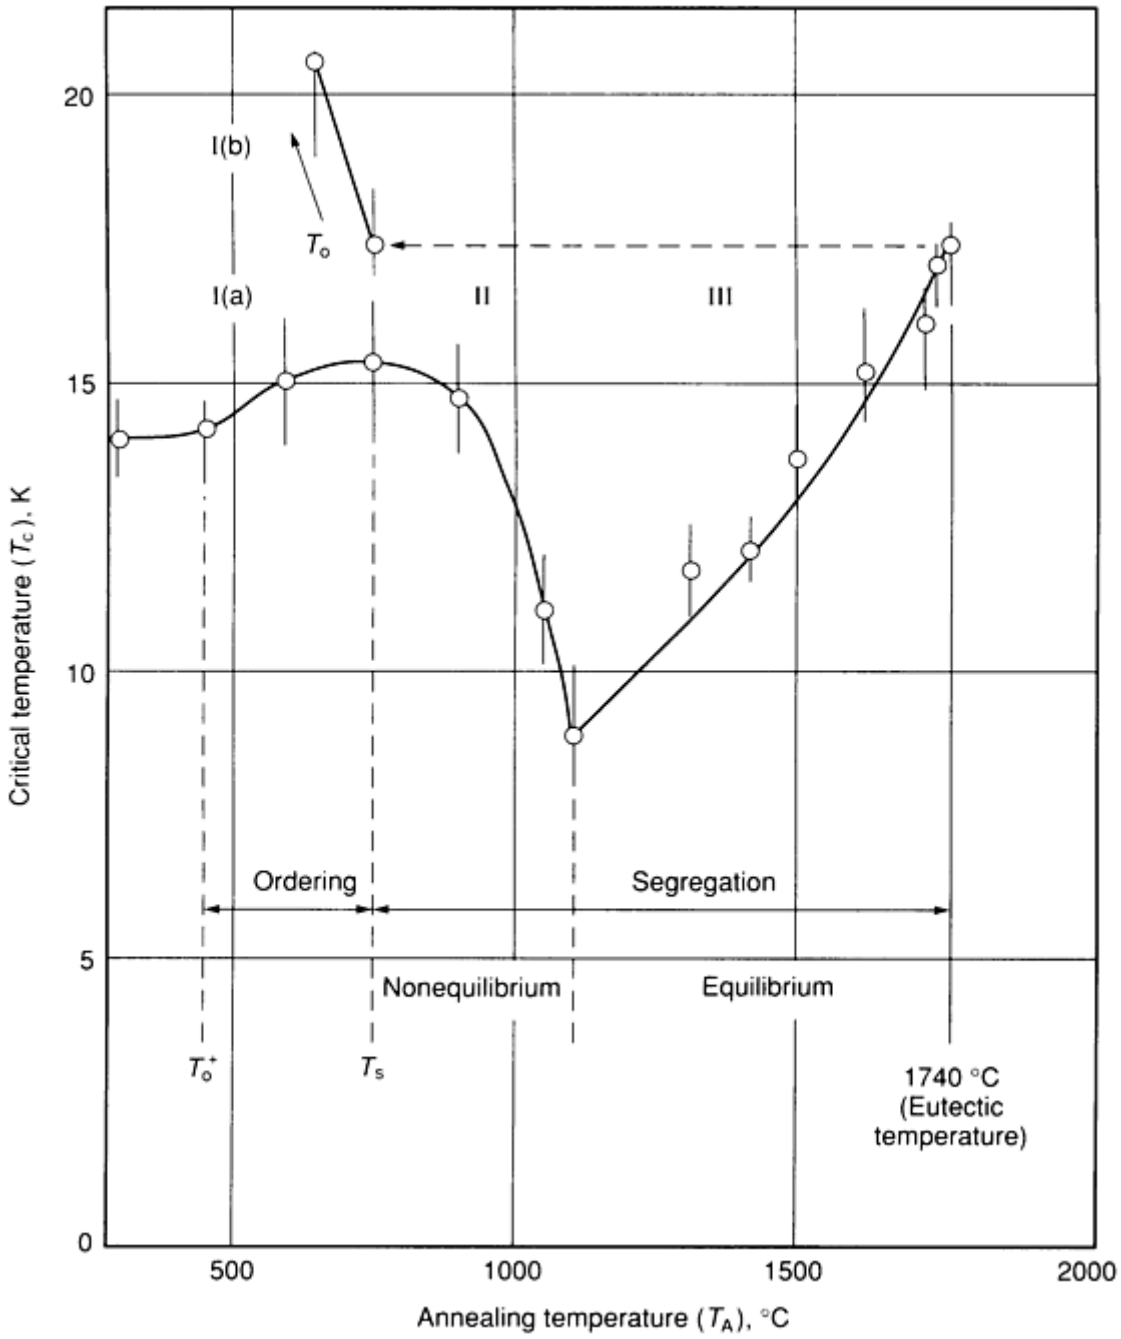

Fig. 10 Variation of T_c for an alloy of the total composition $Nb_{0.74}Ga_{0.26}$ as a function of the annealing temperature. Part I represents the region where only long-range order effects take place, whereas part II reflects the curved shape of the gallium-rich A15 phase boundary (see Fig. 9). T_O and T_S represent the minimum ordering and segregation temperature. Source: Ref 2

Niobium compounds of tin and antimony form stoichiometric compositions at lower temperatures and are stable at very low temperatures (Fig. 11). Only Nb_3Sn receives much attention because of its very good superconducting properties. The entire Nb-Sn binary diagram is shown in Fig. 12. There has been a lot of work on this system because of its commercial interest and considerable disagreement on the shape of the phase field at lower temperature. The work of Charlesworth *et al.* (Ref 11) and Flükiger (Ref 2) and definitive and establish stability to low temperatures.

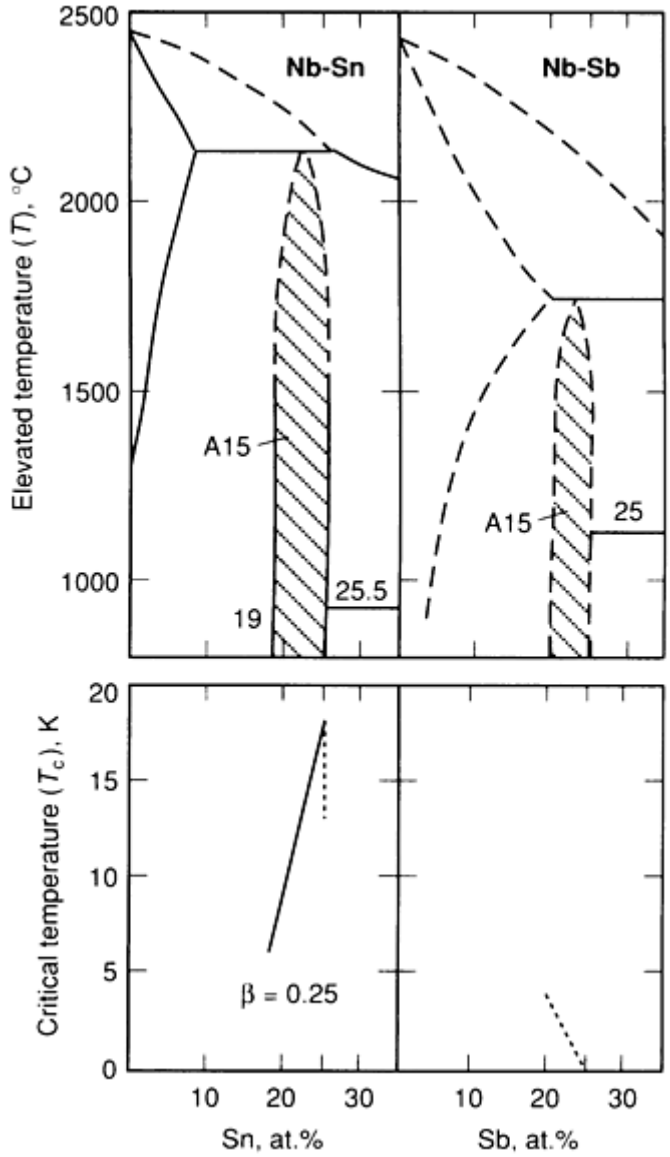

Fig. 11 A15 phase fields and superconductivity in the systems Nb-Sn and Nb-Sb. Source: Ref 2

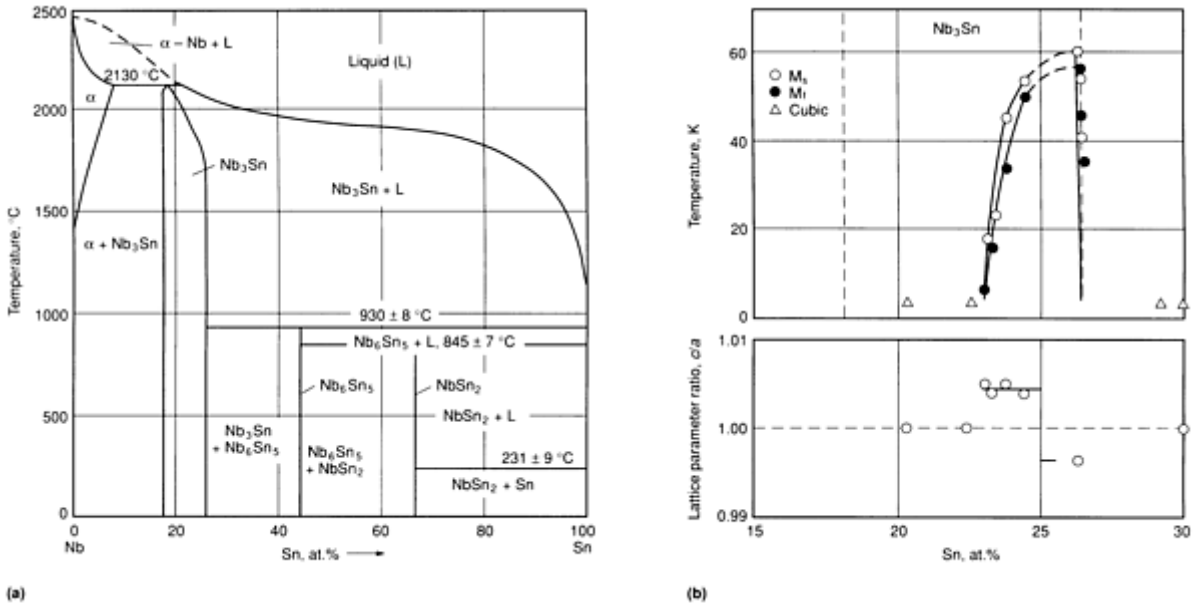

Fig. 12 Niobium-tin binary phase diagram. (a) Elevated temperatures. (b) Subzero temperatures. M_f, temperature at which martensite formation finishes during cooling; M_s, temperature at which martensite starts to form on cooling. Sources: Ref 11, 12

The stability of the stoichiometric compound at lower temperatures is important for forming this brittle structure into filamentary conductors. It is possible to form the compound by solid-state diffusion techniques at temperatures below 1000 °C (1830 °F) through direct couples between the A element and B element or a bronze containing copper and the B element. Copper appears to stabilize the A15 structure over other possible compounds, possibly by limiting the supply of B element (Ref 13). Though copper may be found in the A15 layers (Ref 14), it has been demonstrated to be in the grain boundaries and not in the bulk (Ref 15, 16).

Alloying With Third Element Additions

Historically, the route to improved superconductors is by elemental substitution designed to modify some desirable property. Third element additions to the A15s have been studied extensively with success. Nontransition metal additions generally substitute for the B element leaving the A chains unaffected. Such additions are often successful in raising the critical temperature, but only modestly (Table 2). Some additions serve to modify the growth kinetics without becoming incorporated into the A15 compound [magnesium (Ref 17, 18) and copper (Ref 15, 16)]. Transition metal additions prealloyed with the vanadium and niobium are thought to substitute on the A site, but this is still uncertain (Ref 13). The latter often increases the normal state resistivity faster than they cause a reduction in critical temperature. The result is an increased H_{c2} value for low alloy contents and a consequent increase in J_c at higher fields. These elements will affect grain morphology in compounds formed by solidstate diffusion. Elemental additions to Nb_3Sn that have been reported include hydrogen, beryllium, carbon, magnesium, aluminum, silicon, phosphorus, titanium, vanadium, manganese, iron,

nickel, copper, zinc, gallium, germanium, arsenic, zirconium, indium, antimony, hafnium, tantalum, thallium, lead, molybdenum, tungsten, bismuth, and ZrO_2. Not all alloy additions are beneficial, however.

Table 2 Summary of successful additions of third element to an A15 compound ($A_3B_{1-x}B'_x$) to raise T_c

Compound	Initial T_c, K	B' substitution	Amount (x)	New T_c, K
V_3Ga	14.5	Al	0.1	15.0
V_3As	[(a)]	Al	0.7	10
V_3Sb	0.8	Al	0.4	7
Nb_3Al	. . .	Si	0.13	19.2
Nb_3Al	. . .	As	0.4	19.2
Nb_3Al	. . .	Ga	0.2	19.4
Nb_3Al	18.0	Be	0.05	19.6
Nb_3Al	18.0	Cu	0.1	19.0
Nb_3Al	18.0	B	0.1	19.1
Nb_3Al	18.0	Ga	0.2	19.5
Nb_3Sn	. . .	Al	0.1	18.6

(a) Not superconducting.

In the case of Nb_3Ge, additives are necessary to stabilize the A15 phase at stoichiometry. Aluminum and oxygen serve this purpose. $Nb_3(Al_{0.75}Ge_{0.25})$ has the highest B_{c2} of all the A15 compounds at 43.5 T (435 kG).

Layer Growth

A15 compounds are brittle and lack ductility. In all practical cases, the A15 compound is a reacted layer formation whether deposited on a substrate or grown by solidstate diffusion. This will be addressed more in the section "Processing and Properties of Superconductors" in this article, but the layer growth concept is important in understanding the generation of the superconducting properties and the conductor processing.

The importance of grain size will become clear in the section "Matrix Materials" in this article. Deposited layers will generally have small columnar grains but will become more equiaxed as the layer thickens. Processing parameters are extremely important. Diffusion growth layers are more complex. It has been demonstrated that solidstate diffusion occurs through grain boundaries and that grain growth occurs simultaneously with layer growth (Ref 13). In addition, alloying can greatly influence both grain and layer growth (Ref 19). Thus, the reaction conditions are very important in determining conductor performance.

Critical Current Density

Though the mechanism of flux pinning in the A15 compounds is not well understood (Ref 20), it is clear that grain boundaries are the important pinning centers (Fig. 13) (Ref 14). The critical current density generally scales well and the flux-pinning force has the field dependence,

$$F_p = |\mathbf{J}_c \times \mathbf{H}| = [H_{c2}^{5/2}/A\kappa^2]h^{1/2}(1 - h)^2 \qquad \textbf{(Eq 1)}$$

where H^*_{c2} is determined by the extrapolation of $J_c^{1/2} H^{1/4}$ versus H, A is a constant, and κ is the Ginsberg-Landau parameter. While grain boundaries provide the pinning, there is no quantitative theory that connects the maximum pinning force with grain size. The $H_{c2}^{5/2}/\kappa^2$ has limited theoretical justification but is reasonably well established experimentally (Ref 20, 21).

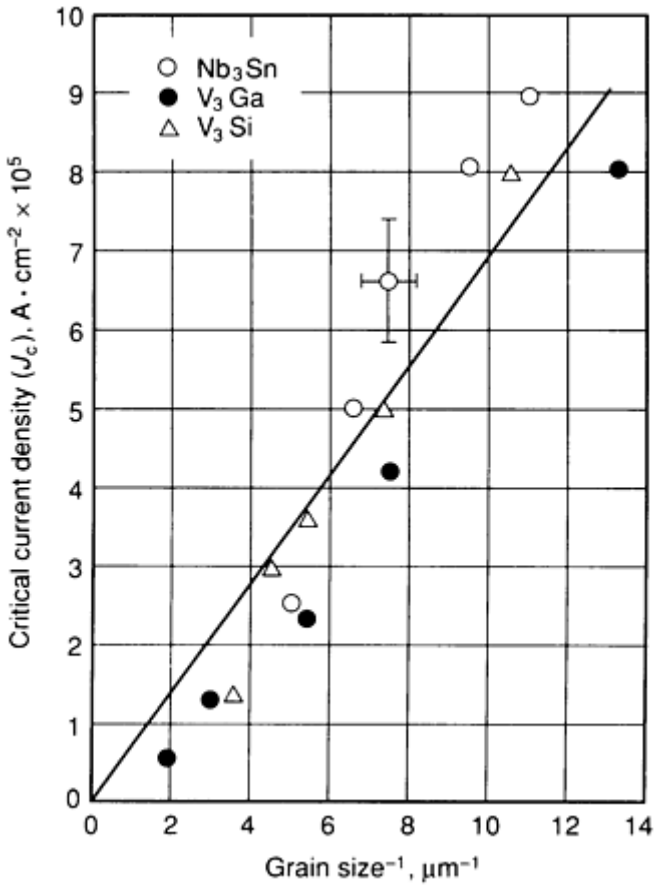

Fig. 13 Grain size dependence of critical current densities for bronze-processed Nb_3Ga, V_3Ga, and V_3Si at 4.2 K and H = 4 T (40 kG). Source: Ref 13

The field dependence of Equation 1 is always obeyed above h = 0.6 but may often deviate below h = 0 6. This deviation is correlated with grain morphology. The maximum pinning force that occurs at fields near h ~0.25 is diminished as the grains become less equiaxed (see Fig. 14). The general effect of alloy additions that increase H_{c2} is to reduce this F_{Pmax}. Thus, there is some crossover field where the critical current in alloyed material (relative to the binary compound) at high fields will be higher but lower at lower fields (15(a) and Fig. 15(b)).

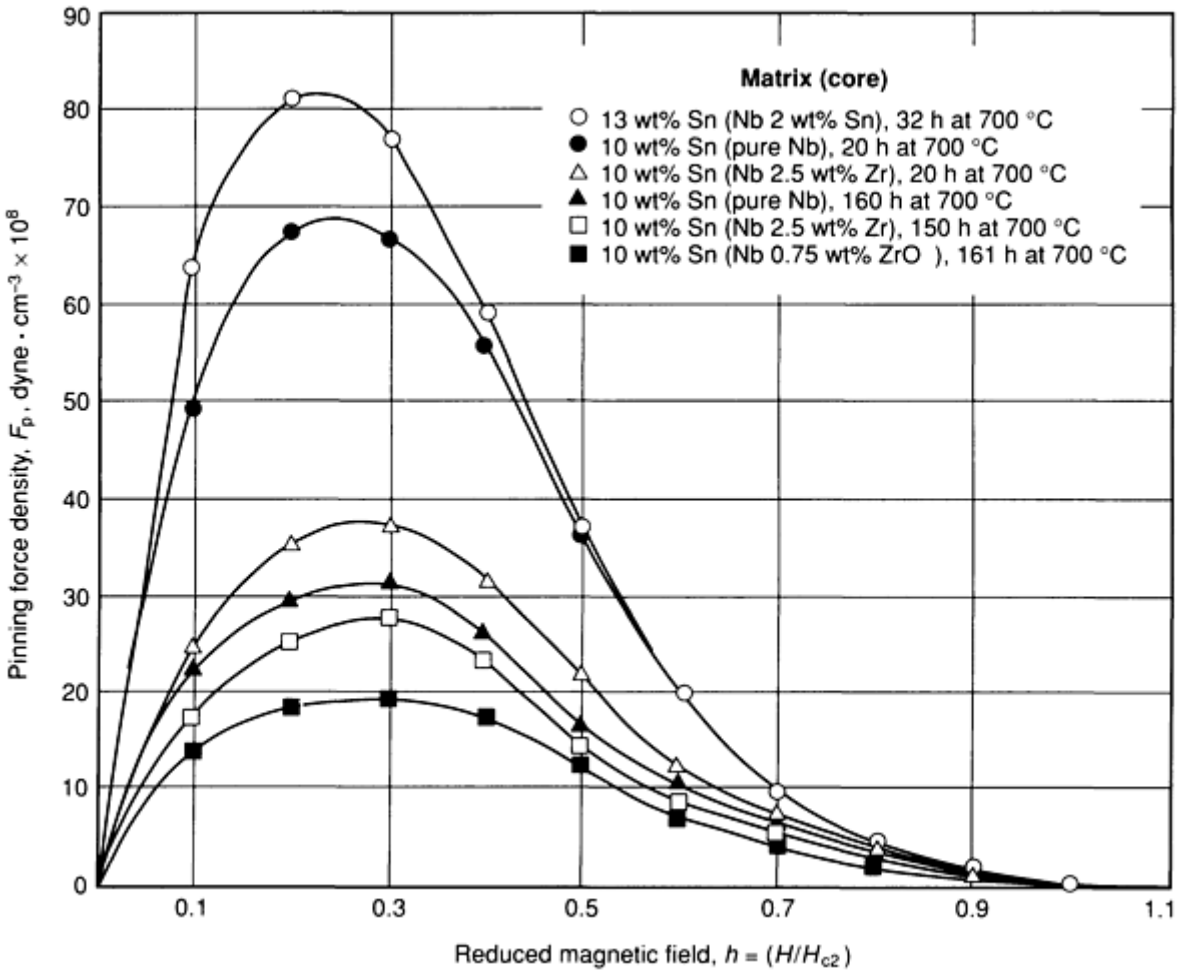

Fig. 14 Pinning force density as a function of reduced magnetic field for a series of bronze-processed Nb_3Sn wire conductors. Matrix (core). Source: Ref 22

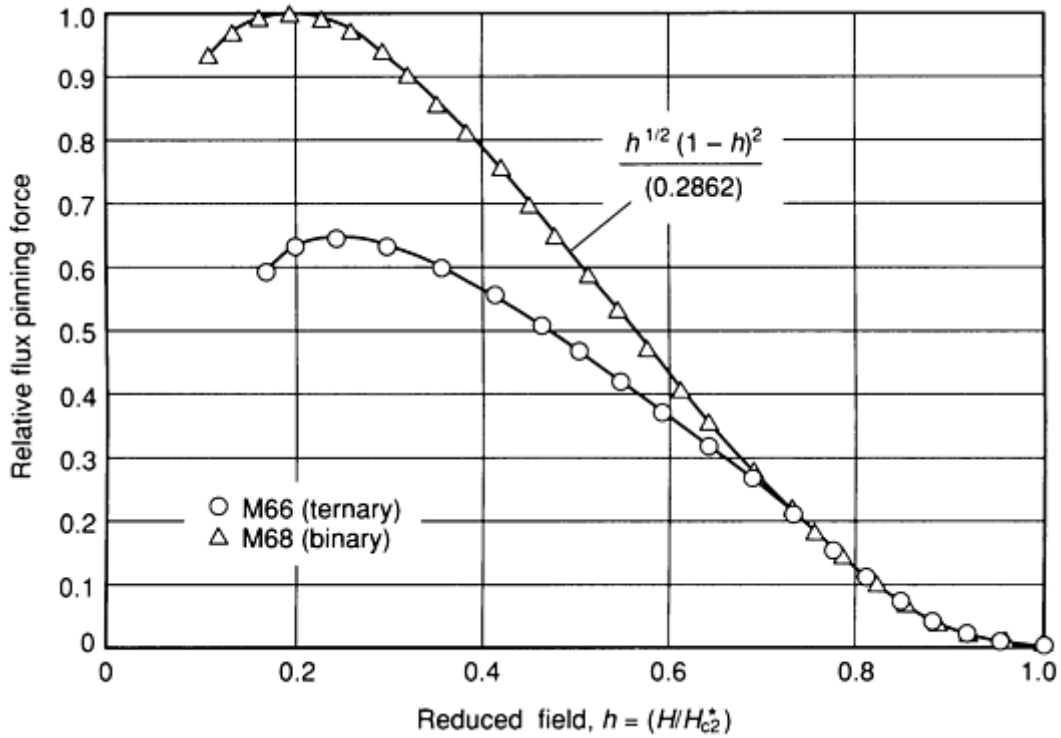

Fig. 15(a) Plot of the relative flux pinning force versus the reduced field. The relative flux pinning force is calculated from Equation 1 (see text). For binary Nb_3Sn, H^*_{c2} = 18.1 T and [$H_{c2}^{5/2}/A\kappa^2$] = 1.74 x 10^{10} dyne/cm^3. For ternary (Nb-1% Ti)$_3$Sn, H^*_{c2} = 21.4 T and [$H_{c2}^{5/2}/A\kappa^2$] = 1.54 x 10^{10} dyne/cm^3. Both conductors are bronze-processed modified jelly roll conductors.

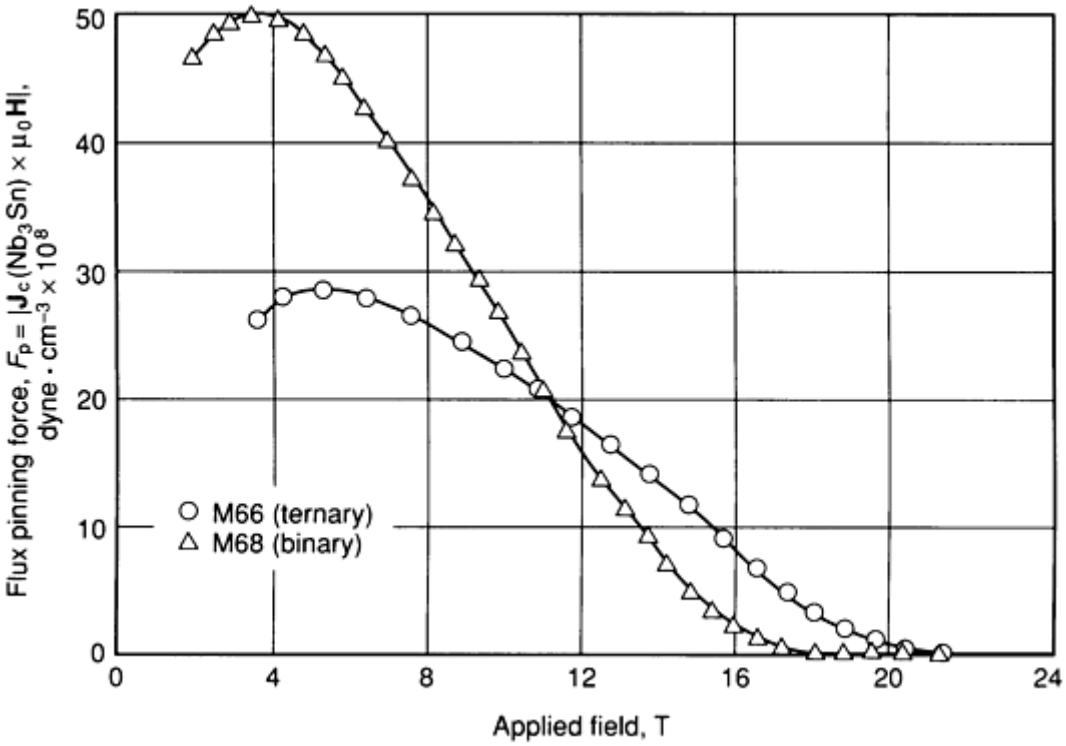

Fig. 15(b) Plot of actual flux pinning force versus applied field. Above 11 T, the ternary conductor will carry more supercurrent than the binary conductor. For scaling purposes, the relative flux pinning force is more instructive than plotting F_p/F_{pmax}. The term [$H_{c2}^{5/2}/A\kappa^2$] is

determined by fitting F_p versus h between $h = 0.6$ and 1.0. H^*_{c2} is determined by the extrapolation of $J_c^{1/2} \cdot H^{1/4}$ versus H to the abscissa.

There are two examples of precipitate pinning enhancements to the grain-boundary pinning. Nb-1%Zr can be internally oxidized to provide a fine ZrO_2 distribution that remains intact during the reaction heat treatment (Ref 22). Recent work in which niobium and tantalum are mechanically alloyed has been successful in increasing J_c by 30 to 50% at 10 T (100 kG) by reacting the wires such that the tantalum inclusions remain in the Nb_3Sn (Ref 23, 24).

The intended application greatly influences the choices of (H_{c2} and J_c) conductor design. Alloying generally improves high field properties. The brittleness and strain sensitivity must also be considered at every stage of the device design process.

Matrix Materials

Stabilizers. Like the NbTi conductors, it is desirable to have a parallel conducting path of a good normal material (low electrical resistivity) to shunt currents and aid in heat diffusion to the coolant. The choices for materials are the same as for NbTi, but reaction temperatures must be considered. Copper is most often used because the melting temperature (1080 °C, or 1975 °F) is higher than for most required heat treatments. Aluminum, melting at 660 °C (1220 °F), is not satisfactory.

Aluminum may be used as the stabilizer if it is added to the conductor following the reaction heat treatment. This may be accomplished by soldering or coextruding. Such processing of the brittle conductor requires careful control over strain to avoid filament breakage.

Deposited thick-film conductors may have aluminum or copper added by soldering or electrodeposition. Copper or aluminum may also be added in a cabling step.

Noncopper. As described in the introduction, practical conductors are typically composite materials containing a reacted A15 compound layer plus either a substrate or matrix that provides one or more reaction components as well as structural strength. In filamentary composites, a matrix of low-solute-content bronze remains around the filaments after reaction. In addition, a material is generally added that keeps the reactive material from contaminating the high-purity stabilizer material. This material is called the diffusion barrier and is chosen from a group of refractory metals (niobium, tantalum, or vanadium) that react minimally or produce nonsuper-conducting compounds at the barrier interface. These components must be present for reaction but serve little value after reaction. The matrix, contaminated with residual reactive B element, and the diffusion barrier are not useful stabilizing materials due to their high resistivities. This sum of the superconductor and reaction byproducts is generally called the noncopper. For conductors that have no stabilizer, the whole wire cross-section area is used as the overall area (Fig. 16).

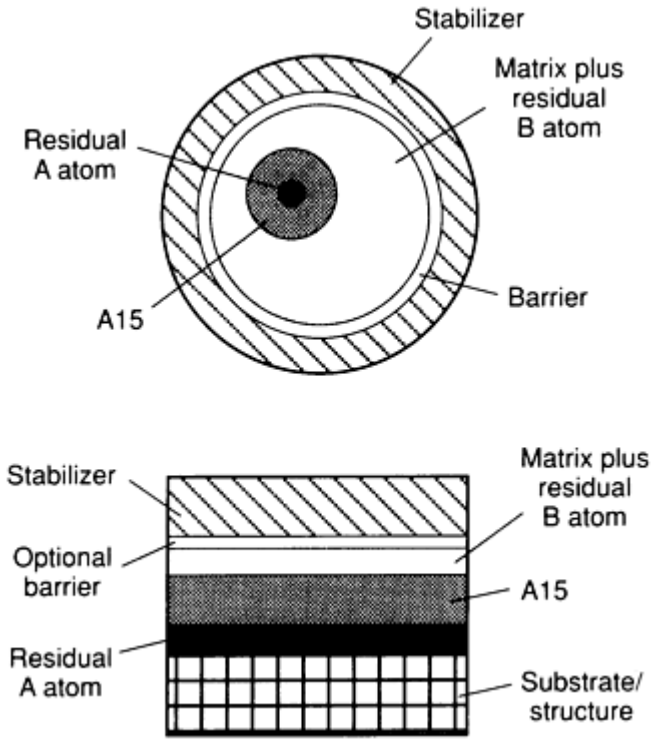

Fig. 16 Material components in a composite A15 conductor. Note all parts except stabilizer are included in calculation of noncopper current densities.

In NbTi conductors, the specified critical current density is referred to the area of NbTi only. For A15 conductors, the specified critical current density is referred to the noncopper or nonstabilizer (conductors stabilized with other than copper) area for engineering reasons. In general, the A15 current density is diluted 2 to 5 times by the nonsuperconducting components of the nonstabilizer. It should become clear that the A15s have extraordinary high J_c values, though these cannot be fully utilized for engineering conductors.

Reactive Component. Diffusional reactions require the reactive B element be either carried in a matrix or present in its pure form in close proximity to the A element core. This is most often accomplished using a bronze. The conductor geometry can be multifilamentary, and the residual bronze serves to keep the filaments separated. The bronze can initially be pure copper and alloyed tin as separate elements in the cross section. Elemental additions such as titanium, magnesium, indium, antimony, gallium, and silicon may be added through the bronze or tin. In some cases the B element is carried next to the A element, but this is impractical for small filament conductors and does not then constitute a matrix material.

Processing and Properties of Superconductors

For the purposes of this chapter, the goal of the conductor design is presumed to be a stabilized magnet conductor or high-current conductor. For electromagnet applications a multifilament geometry with filaments 70 μm (0.0028 in.) or smaller is desired. For diffusion times that are reasonable, filaments less than 10 μm (400 μin.) are desired. With the exception of tape geometries, the fabrication processes for A15 conductors are very similar to those described earlier for NbTi. In all cases we are describing a thick-film approach, though geometries vary considerably.

Assembly Techniques for Tape Conductors

Superconductor windings can be produced from tape conductors. Niobium-tin and other more exotic A15 conductors are often produced in the form of thin tapes because this enables techniques such as chemical vapor deposition (CVD), surface diffusion, or vacuum sputtering to be used. Such tapes are always thin enough to satisfy the adiabatic flux-jumping criterion when the field is parallel to the broad face but not when the field is perpendicular to it.

Chloride Deposition. The first 10 T (100 kG) superconducting magnet was wound using a 7 μm (280 μin.) layer of Nb_3Sn deposited on a stainless steel substrate with a 7 μm (280 μin.) layer of copper to act as the stabilizer (Ref 25). The large aspect ratio (300:1) leads to magnetic instability at low fields. The chloride process is based on a hydrogen reduction of the gaseous chlorides of niobium and tin above 900 °C (1650 °F) (Ref 26), according to the reaction:

$$3NbCl_4 + SnCl_2 + 7H_2 \Leftrightarrow Nb_3Sn + 14HCl \qquad \textbf{(Eq 2)}$$

This process is still exploited to make magnets aimed at 15 T (150 kG) and above.

Surface Diffusion. A thin niobium or niobium alloy strip (~0.025 mm, or 0.001 in.) may be coated with pure tin and reacted to form Nb_3Sn (Ref 27). The thin layer and ribbon allow the reacted tape to be bent without damaging the Nb_3Sn layer. The reaction occurs above 930 °C (1705 °F) to avoid the formation of Nb_6Sn_5 and $NbSn_2$ and occurs rapidly (recall the phase diagram in Fig. 12). If Nb-1%Zr foil is used, it may be anodized prior to tin coating. The zirconium will internally oxidize, and the fine ZrO_2 precipitates enhance the critical current density.

Bronze Tape. A bronze-niobium-bronze sandwich may be made either by corolling (Ref 28) or electron beam (EB) evaporation of bronze onto a niobium sheet (Ref 29). The Nb_3Sn is formed during a solid-state reaction and produces a material with low surface ac losses. The lower reaction temperature allows inclusion of a stabilizer prior to reaction.

Liquid Quenching. Liquid quenching on a hot substrate provides sufficient wetting, and thus, good cooling rates. Niobium-aluminum-germanium alloys have been prepared as supersaturated bcc-Nb_3(AlGe) and subsequently transformed into fine-grained A15 phase with high J_c. Proper choices of nozzle material, orifice diameter, and degree of superheating above the liquidus temperature are important because of the very high melting temperature (see Fig. 9). The alloy is quenched directly onto a moving copper tape. The tape then acts as the stabilizer material (Ref 30).

Assembly Techniques for Multifilamentary Wires

Superconductor multifilamentary wires can be produced by a variety of processes:

- Rod process
- Modified jelly roll process
- Nb tube process
- *In-situ* process
- Powder metallurgy process
- Jelly roll method

Rod Process. The various rod processes for A15 conductors resemble very strongly those described for NbTi conductors (see the article "Niobium-Titanium Superconductors" in this Volume). The bronze process consists of stacking vanadium or niobium alloy rods in bronze tubes or drilled bronze billets (Fig. 17), processing these rods to some intermediate-size wire, and restacking the wires. An excellent review is given by Hillman (Ref 31). The double extrusion route is required to reduce the filaments to micron dimensions. Cu-13%Sn or Cu-18%Ga both require frequent annealing during the drawing process to remain ductile. The unfortunate consequence of this is premature formation of the A15 phase at the interface, which can lead to severe filament distortion (Ref 32). This can be alleviated somewhat by including a copper layer between the bronze and the filament.

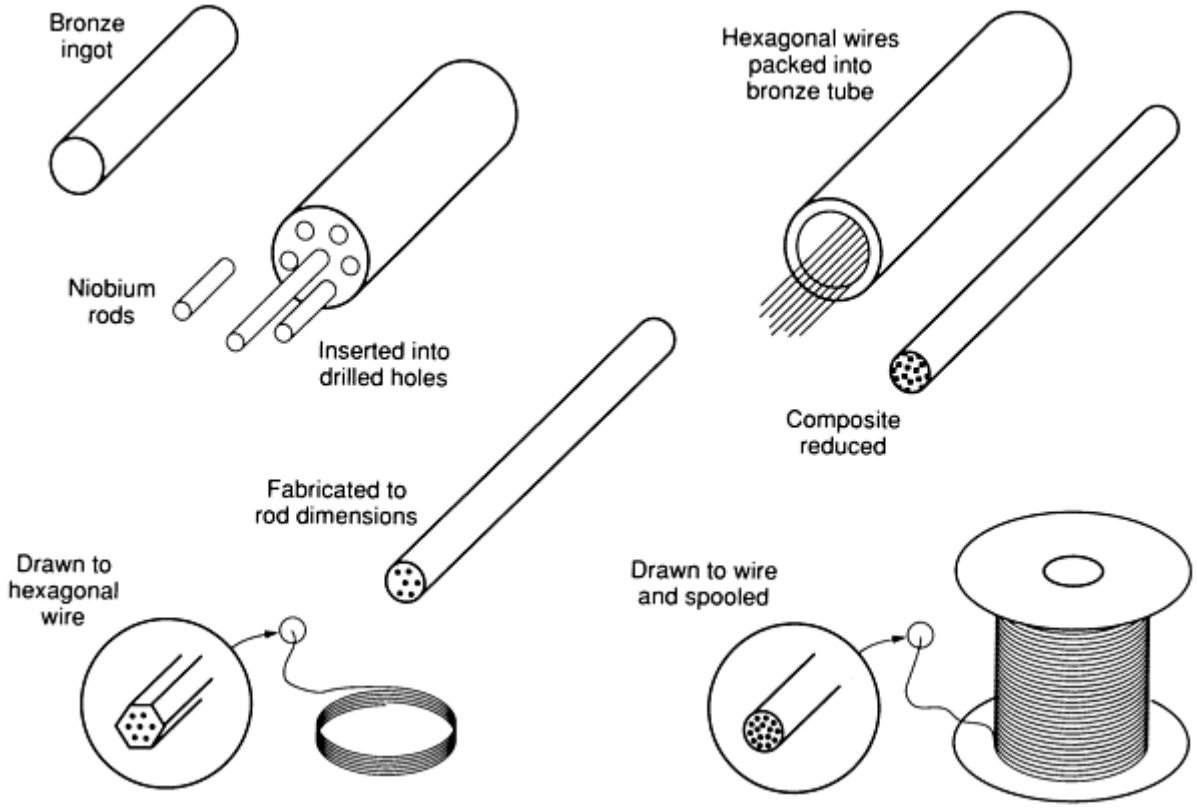

Fig. 17 Schematic illustration of the bronze-process multifilament conductor production routing. Source: Ref 22

To keep the bronze ductile it must remain single phase, thus limiting the available tin content. One makes a trade-off in A15 current density versus overall current density by providing excess or insufficient tin or gallium supply. Commercial bronze supply is a problem since phosphorus is very detrimental to Nb_3Sn formation (Ref 33).

These shortcomings are eliminated in the internal tin process. The bronze consists of a copper matrix around the filaments surrounding a tin core (Fig. 18). Though a double stacking process is still required, there is no filament distortion because of in-process annealing. In fact, the processing can proceed with no anneals. The limitation of tin (or gallium) in copper is no longer a factor, and excess tin can be provided with minimal cost in overall J_c. The low melting temperature of gallium precludes an internal gallium process.

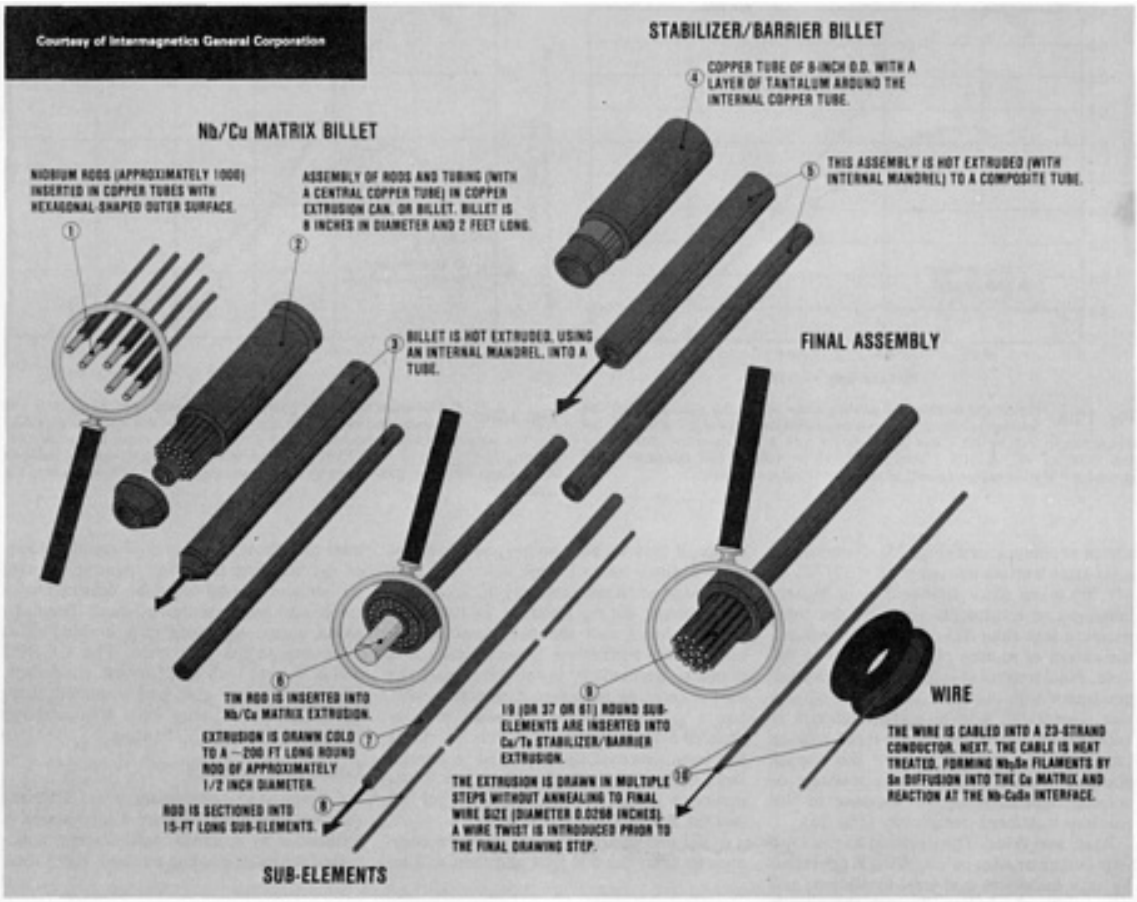

Fig. 18 Sequence of manufacturing operations involved in the formation of Nb_3Sn multifilamentary wire using the internal tin process.

In the external diffusion process vanadium or niobium alloy filaments are drawn in a copper matrix, and gallium or tin is diffused in from the outside. For tin the wire dimensions must be less than 0.25 mm (0.010 in.) to avoid balling during the reaction process (Ref 34).

Modified Jelly Roll Process. The modified jelly roll (MJR) process is a unique method of producing micron-size filaments in a single extrusion, which limits the amount of in-process annealing required (Ref 35, 36). A bronze sheet (matrix) is cowrapped with niobium (Ref 37) or vanadium (Ref 38) expanded metal onto a bronze or copper (Ref 39) core rod (Fig. 19). Rolled sheet is expanded by conventional means. The strands of the expanded metal are crossdrawn in the composite to micron-size filaments. A 13 mm ($\frac{1}{2}$ in.) length of expanded metal is drawn out to roughly 800 m (0.5 mi), depending on composite design. As many as 4 or 5 different materials with as many as 3 separate crystal structures are being codrawn uniformly to wire. Bronze MJR wires have shown very good performance in short sample (Ref 39) and magnet tests (Ref 40).

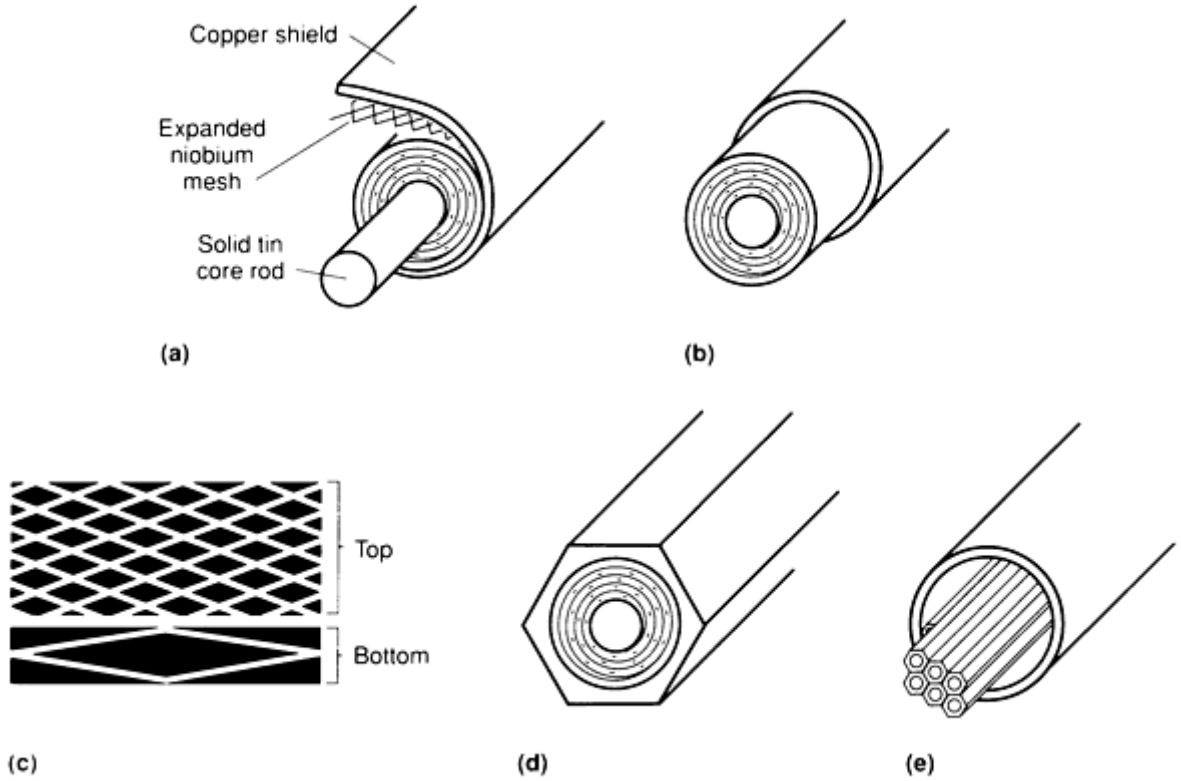

Fig. 19 Schematic of the modified jelly roll process. Because niobium-tin wire is fragile and brittle, multifilament superconducting wire cannot be made from these materials after the intermetallic niobium-tin compound has been formed. The two constituents, niobium and tin, as well as the copper for the matrix, are ductile materials. The multifilament wire, therefore, is made with the three metals in separate form. In this process, niobium, which has been formed into an expanded metal sheet, is interleaved with a sheet of copper and wound around a central mandrel made of tin. This initial preform is then drawn in successive stages to form the multifilament wire. The niobium-tin filaments are then formed in the wire by diffusing the tin into the niobium. This is accomplished by heating it to hundreds of degrees Celcius for $\geq$ 200 h. Because the resulting filaments are brittle, this is sometimes done after the wire is wound into its final coil form. The process yields superconducting wire in spools having 50,000 to 100,000 ft lengths. In (b), the jelly roll formed is inserted in outer copper tube. Billet is formed ready for drawing. In (c), the original niobium expanded mesh (top) becomes extremely long filaments (bottom) in the finished wire. A single diamond-shape segment will be reduced from $\frac{1}{4}$ in. to $\frac{1}{3000}$ in. in cross section and elongated from 1 in. to 1 mile. In (d), billet has been drawn down to $< \frac{1}{2}$ in. in diameter. In (e), rods $\sim \frac{1}{2}$ in. in diameter are cut to shorter lengths and rebundled in another copper tube. Up to 50 additional drawing steps reduce material to wire $\frac{1}{25}$ in. to $\frac{1}{100}$ in. in diameter.

The MJR method has also been successfully implemented in an internal diffusion version called the tin core MJR (Ref 41, 42). As noted earlier, this process is limited to Nb_3Sn. Versions of the tin-core MJR product are being used in the United States-demonstration poloidal coil (US-DPC) (Ref 43) and the Sultan III (Ref 44) project. There is also reasonable commercial interest for building compact high-field magnets. Figure 20 shows a cross section of multifilament wire manufactured by the tin-core MJR method.

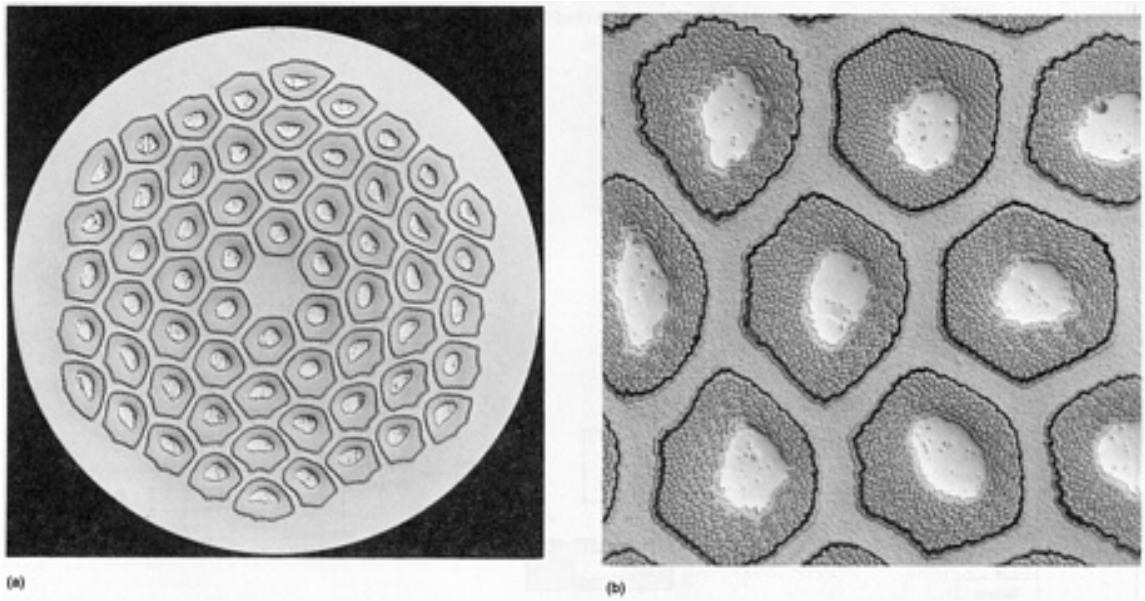

Fig. 20 Unreacted NbSn high-current density composite superconductor wire produced for high-field magnet application using tin-core MJR process. (a) 100× bright field illumination (B.F.). (b) 1000× differential interference contrast (D.I.C.). The 60 subelements in the 0.6 mm (0.024 in.) diam wire each have individual bimetal diffusion barriers composed of concentric rings of niobium around vanadium. The vanadium (inside layer) protects the niobium barrier (outside layer) from reacting with the tin while the niobium protects the copper from the vanadium at reaction temperatures above 700 °C (1290 °F). Courtesy of Paul E. Danielson, Teledyne Wah Chang Albany

There is a higher magnetization and ac loss with the internal diffusion conductors associated with filament bridging (Ref 45). The problem increases as the niobium filament content increases, and critical current density increases in a nonlinear fashion (Fig. 21) (Ref 46, 47).

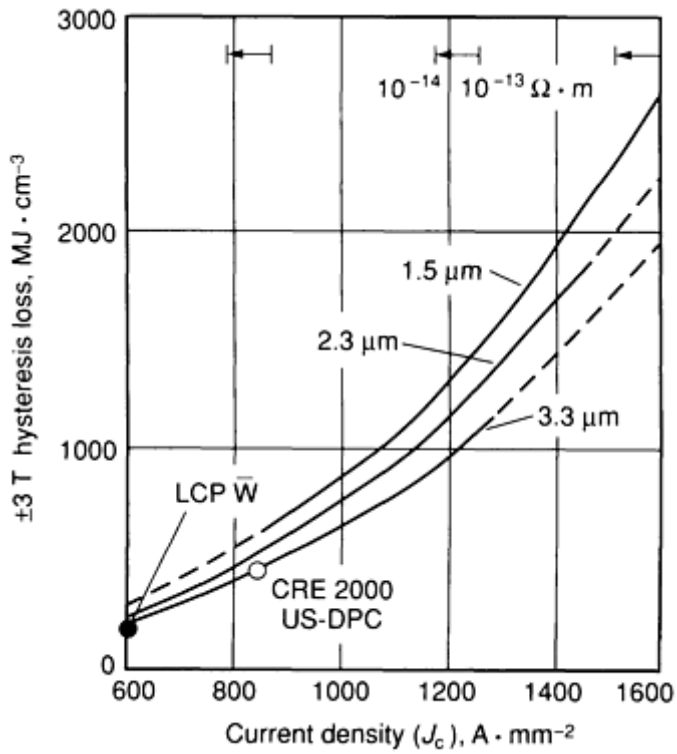

Fig. 21 Plot of noncopper hysteresis loss versus noncopper current density of the full range of current and filament size for tin-core $(Nb\text{-}1\%Ti)_3Sn$ superconductor. Modified jelly roll method was used. T_c was 4.2 K, $\mu_o H_{c2}$ of 10 T, and resistivity, ρ, of 10^{-13} Ω· m. US-DPC,

United States-demonstration poloidal coil; LCP $\bar{W}$, large coil project-Westinghouse

The choices for filament alloy are less restricted in the internal tin MJR. Conductors with C103 (Nb-10Hf-1Ti-0.2W). Nb-1%Zr, and Nb-(1 to 3%)Ti filaments in a copper matrix have been successfully processed (Ref 41). The elimination of in-process annealing is greatly beneficial in this respect.

Nb Tube Process. The desirability of including a diffusion barrier has generated several variations in which a thick-wall niobium tube is partially consumed in the reaction to Nb_3Sn, and enough remains to serve as a barrier. The disadvantage is that the effective filament size will be limited by the niobium tube dimensions in the wire (Ref 48). Variations on the tube lining include bronze (Ref 48), copper around tin (Ref 49), and $NbSn_2$ powder (Ref 50). The latter process produces very fine-grain Nb_3Sn after reaction. Reduction of the effective filament size, however, requires reducing the niobium tube dimensions. The number of tubes in a wire cross section must be increased to accomplish this with very high area reductions. The quality of both the tubes and the internal material must be very good.

***In-Situ* Process.** The *in-situ* process makes use of the immiscibility of the niobium-copper and vanadium-copper systems. Alloys cast from the melt may segregate completely. The dendrites formed in the matrix draw out into highly aspected filaments. Tin or gallium may be added by internal or external methods, much as in other multifilament routes. The impurities present in the melt greatly affect the morphology of the precipitation, and thus, the filamentary nature of the product. Originally investigated by Tsuei, the technique has been refined and improved (Ref 34). A minimum of 15% Nb is necessary for the filaments to be interconnected. The composite is drawn to produce filaments of a few tenths of a micron thick. *In-situ* composites generally show excellent irreversible strain limits and high compressive strains because of fine filament reinforcement (Fig. 22) (Ref 34). The high intrinsic strain reduces the H_{c2} of the wire, and therefore, reduces the critical currents at all fields.

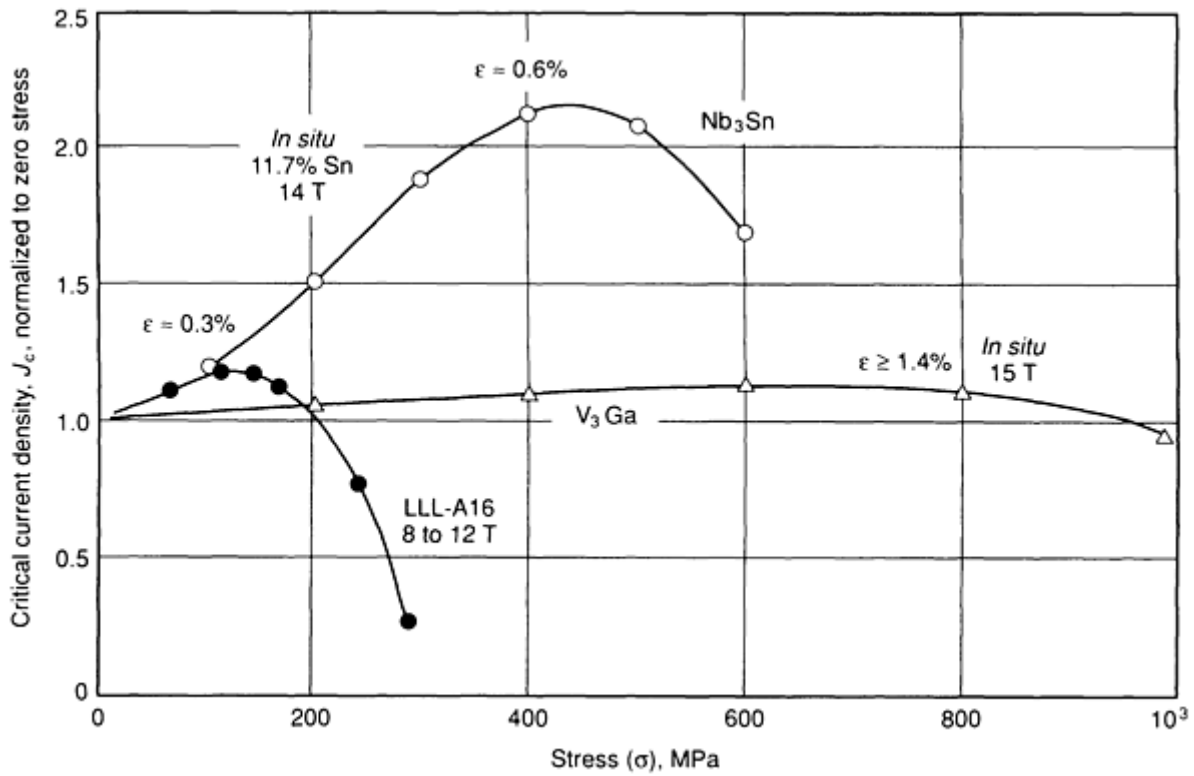

Fig. 22 J_c normalized to zero applied stress as a function of stress, σ, at indicated fields for Cu-Nb-Sn, Cu-V-Ga *in situ* composites, and a conventional commercial V_3Ga composite. Source: Ref 34

Powder Metallurgy. Powder metallurgy processes include the infiltrated tin and the mixed powder methods.

Infiltrated Tin. Niobium powder is sintered into a porous structure and then infiltrated with liquid tin (or aluminum) (Fig. 23). The result can be drawn to wire (or rolled to tape) and provide a very high critical current density (Ref 52).

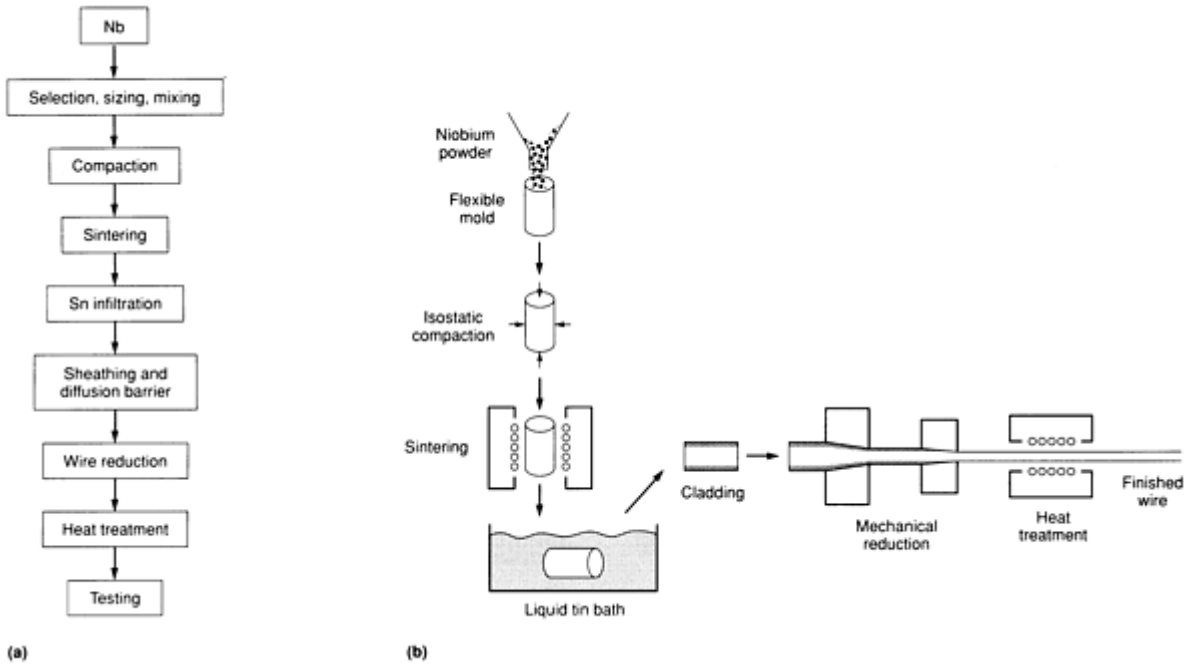

Fig. 23 Infiltrated tin P/M process for producing multifilamentary superconducting wire. (a) Flow diagram. (b) Schematic. Source: Ref 51

Mixed Powders. Cold or hot powder processes (Fig. 24) can be used to produce structures very similar to the *in-situ* process. There is more flexibility in the elemental combinations since the natural immiscibility of two molten metals is not a requirement. The oxygen content of the powders can result in limited deformation, however (Ref 34, 51). This method has been pursued commercially for Nb_3Sn (Ref 53).

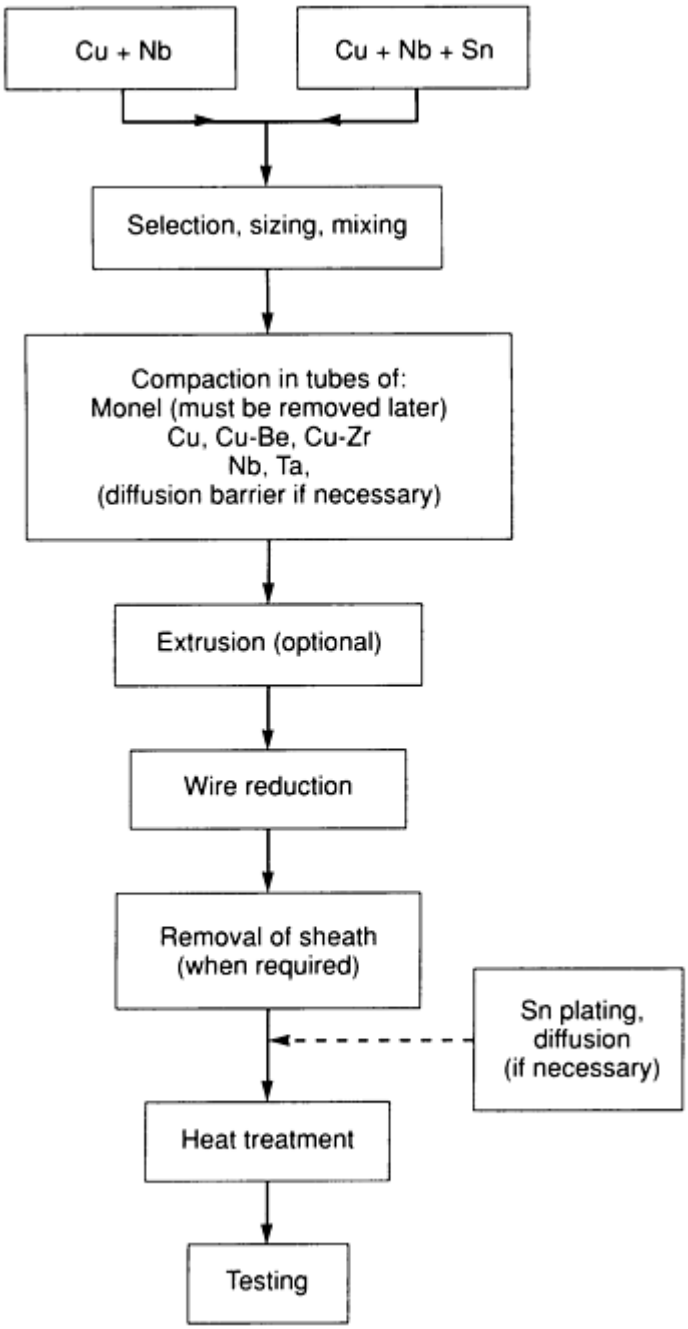

Fig. 24 Flow diagram for cold powder processes

The mixed powder method has been a successful technique for Nb_3Al manufacture (Ref 51). To form metastable Nb_3Al at low temperatures (600 to 800 °C, or 1110 to 1470 °F), the niobium and aluminum elements must be extremely finely interdispersed with aluminum thicknesses much less than 1 μm (40 μin.). Critical current densities increase as the aluminum thickness becomes a few hundred angstroms. This requires very high area reductions or very fine starting elements. The oxygen content of the niobium powder is critical in processing. T_c values of about 16 K are achieved. Nb_3Al holds promise for higher field applications and a reduced strain sensitivity compared to Nb_3Sn (Fig. 5 and Fig. 6).

Jelly Roll Method. An alternative method for finely dividing niobium and aluminum has been pursued by Ceresara (Ref 54). Thin sheets of niobium and aluminum are cowrapped onto a core in a swiss roll style. The composite is then drawn to wire. Again, the oxygen content of the thin foils is critical. The optimum separation of the niobium and aluminum is the same in the jelly roll process as it is in the powder process.

Deformation

The processing of multifilamentary A15 wire geometries is very much the same as for NbTi. Bronze processed wires require frequent softening anneals in the 400 to 500 °C (750 to 930 °F) range. Internal or external tin processed wires do not require these anneals. Bronze and external tin billets may be hot extruded, whereas internal tin billets may not, though cold hydrostatic extrusion is an option. Note that the A15 phase is not intentionally formed during deformation processes.

Reaction Heat Treatments

The reaction heat treatment is required at the end of wire processing to convert the ductile components to the desired, but brittle, superconductor. Subtle aspects of composite design are aimed at improving the critical current or strain tolerance as a result of this heat treatment. Bronze route conductors generally require a single-stage treatment, though two-stage treatments have often been recommended. The time and temperature employed must balance layer growth rate with A15 grain growth. The addition of third elements may increase both these rates, and lower reaction temperatures are then advised.

Internal and external tin composites require multiple-stage heat treatments. There must be several low-temperature steps (200 to 500 °C, or 390 to 930 °F) to alloy the copper and the tin before proceeding with Nb_3Sn formation. The copper-tin phase diagram is complicated (Fig. 25). Generally a solid-state wetting treatment (T < 227 °C, or 441 °F) takes place followed by a higher-temperature treatment. Keeping the temperature less than 415 °C (780 °F) reduces the extent of molten phases present in the wire. Final treatment is identical to a bronze conductor with the same filament alloy and size. Generally, a three-stage treatment is encouraged. These conductor types require long furnace times because of the copper alloying steps. The elimination of wire processing anneals is at the expense of the reaction treatment complexity (Fig. 26).

React and Wind. The decision to react the wire before or after coil winding is governed by such factors as coil size, insulation, and complexity of winding. Though the wire is brittle, it may be bent so long as the maximum bending strain is kept below the irreversible strain limit, generally 0.7% or higher. Damage during handling is the most serious threat, but the heat treatment is more easily performed. Wire sticking is a concern, particularly if the wire has been cabled prior to reaction. A sintered cable has a greatly reduced flexibility and increased risk of wire damage. This technique has been successfully employed in several large coil constructions such as the Westinghouse Large Coil Project coil (Ref 56) and the Sultan facility (Ref 57).

Wind and React. It is by far more common to wind the coil first and then to heat treat the whole. This method greatly reduces the handling risks but requires the coil former and insulation to be dimensionally stable and temperature resistant. The insulation commonly used is a braided glass fiber around the bare wire. The US-DPC coil is wound with a 225-strand conductor, heat treated as a coil, and insulated afterward (Ref 58). Large coils required large furnaces with uniform heating.

Cable and Winding

Cabling A15 conductors is no different than for any other material. Cable design is influenced by reaction requirements, anticipated stresses, cooling method, ramp rate, and required current. As in NbTi cables, there is often some degradation caused by the cabling process.

Winding can be an anxious time if using prereacted cable (Ref 56). In the case of the US-DPC coil, however, a work-hardened superalloy jacket complicated the winding because of its high springback. During the reaction heat treatment, the superalloy precipitation hardened and retained the wound shape (Ref 58). To prevent strand sintering, the US-DPC conductor wire was chromeplated prior to cabling (Fig. 27) (Ref 43, 46).

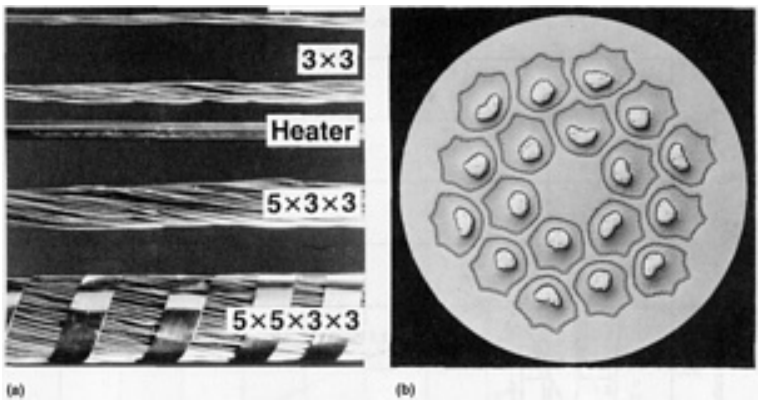

Fig. 27 Cabling elements for the 225-strand US-DPC conductor. The 3 mm (0.125 in.) heater shown in (a) was placed in the center of the cable in the final cabling operation. A15 Superconductor Applications

Commercial Magnets. It is efficient to wind solenoid magnets in concentric coils that make the most of the superconducting properties. To achieve fields above 9 T (90 KG) at 4.2 K, a high field material such as Nb_3Sn or V_3Ga is required, though a background field up to 9 T (90 kG) may be provided by NbTi. This is generally the case. Figure 28 shows the load lines for a hybrid 14.2 T (142 kG) coil system at the National Research Institute for Metals in Japan (N.R.I.M.) (Ref 59). V_3Ga inserts were used to boost the central field to over 18 T (180 kG) in an all-superconducting system (Ref 59).

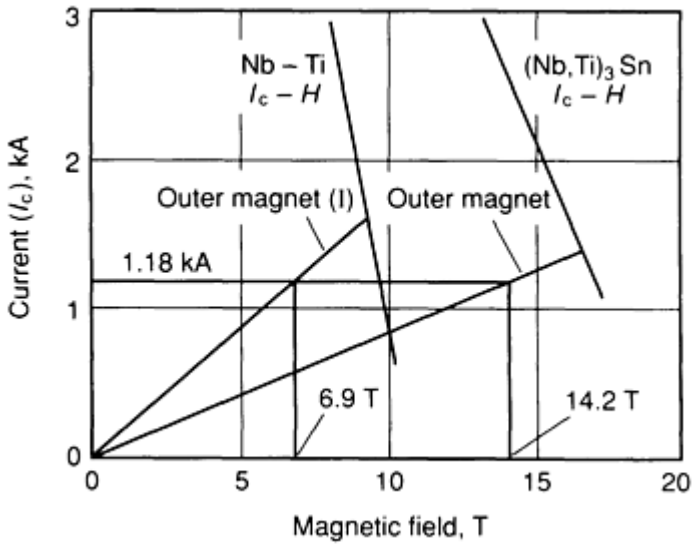

Fig. 28 Plot of current versus magnetic field at 4.2 K for the Nb-Ti and the $(Nb, Ti)_3Sn$ conductors in a hybrid coil system. Also shown are excitation load lines for the outer magnet (I) and the complete outer magnet. Source: Ref 59

Presently, 16 T (160 kG) hybrid (NbTi + Nb_3Sn) coils are commercially available with clear bores of greater than 50 mm (2 in.) and outer diameters less than 200 mm (8 in.) (Ref 60); 18 T (180 kG) magnets are advertised for sale as well (Ref 61). NMR systems with frequencies up to 600 MHz (14.1 T, or 141 kG) are available that utilize Nb_3Sn and NbTi in the persistent mode. The high field record for an all-superconducting system to date is 19.3 T (193 kG) using NbTi and alloyed Nb_3Sn (Ref 62).

Commercial solenoids are used for studying the magnetic behavior of materials and their chemistry by NMR techniques. A common application of superconducting solenoids is the study of superconducting materials. Magnetic refrigeration may use Nb_3Sn because of the desire to operate in the 10 to 15 K range.

Power Generation. Nb_3Sn has been pursued for ac motors and generators largely because of its 18 K critical temperature. The use of superconductors allows the current density of the armature to be raised because no iron is required and higher fields may be generated. The main advantages are the reduction in weight and volume with an increase in efficiency as well. Early prototypes were made using NbTi, but Nb_3Sn is preferred because of the higher temperature margin (Ref 63).

Power Transmission. Currently, overhead high-voltage lines remain the least expensive method for power transmission. However, concerns over electromagnetic fields (EMF) near these lines and public complaints may increase their cost of operation. There are also circumstances where underground transmission is desirable. Various high-power transmission cables have been researched, including versions employing Nb_3Sn. Nb_3Sn tapes, with smooth surfaces, have lower surface ac losses than NbTi or pure Nb. Brookhaven National Laboratory constructed and successfully operated a 100 m (330 ft) test facility using a Nb_3Sn-based cable (Fig. 29 and Fig. 30) (Ref 64).

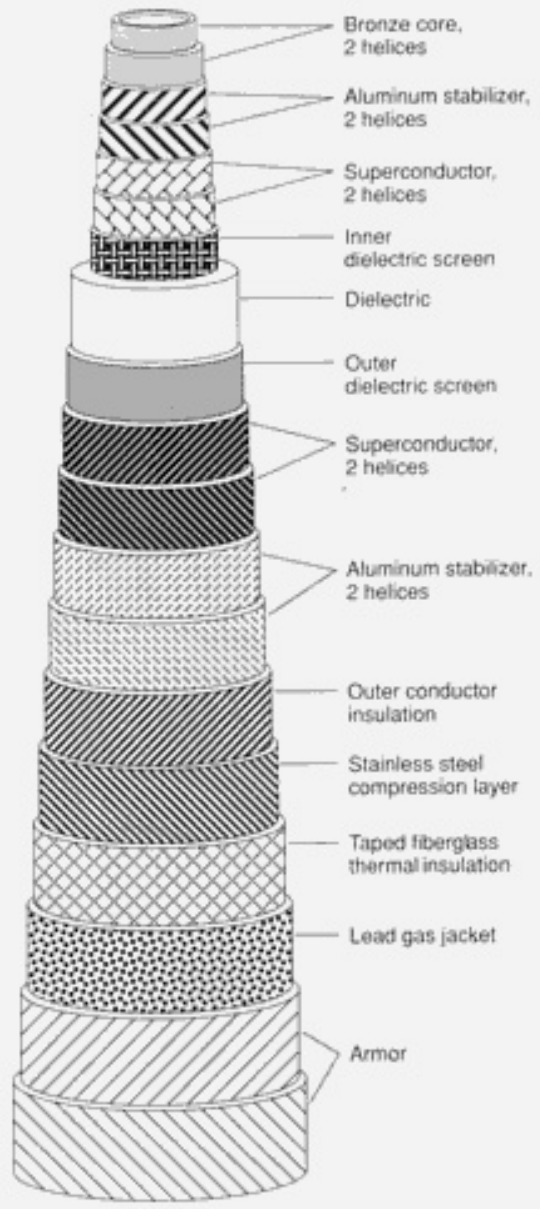

Fig. 29 Flexible Nb_3Sn ac coaxial power transmission cable being developed at Brookhaven National laboratory. Source: Ref 63

Fig. 30 The 100 m (330 ft) experimental test station at Brookhaven National Laboratory for power transmission

High-Energy Physics. The desire to build particle accelerators with ever higher energies has spurred interest in using A15 conductors in dipole magnets. A twin aperture, 10 T (100 kG) dipole was successfully constructed and tested demonstrating the technical feasibility (Ref 65). Scale up from 1 to 17 m (0.3 to 55 ft) (superconducting supercollider size) has not yet been achieved. Other applications include high-gradient quadrupoles and focusing magnets near the interaction region where the temperature is likely to rise above 4.2 K.

Fusion. The high fields required for magnetic confinement of plasma energy and the significant heat loads attained provide an exciting opportunity for the A15 materials, and fusion technology is the area most cited for their application. The US-DPC coil is a prototype cable for the central solenoid of a full-scale tokomak design (Ref 43, 46). The toroidal field coils (D shaped) have also been considered as Nb_3Sn coils. The next European torus (NET) design calls for Nb_3Sn in the poloidal field (PF) and toroidal field (TF) coils (Fig. 31). The Russians have built a tokomak, T15, using all Nb_3Sn coils and expect to test the system in 1990 (Ref 67). In competition with NET is the international thermonuclear experimental reactor (ITER), which is a joint European, American, Japanese, and Russian project in the design phase. This machine would also be a Nb_3Sn system (Ref 68).

The LCT project was an international demonstration project consisting of six D-shaped coils, one of which used Nb_3Sn conductors. The Westinghouse coil used forced flow technology with an internally cooled cable in conduit (ICCS) approach. This coil was a react and wind coil (Fig. 32) (Ref 56).

Danielson, Teledyne Wah Change Albany

Additional Applications. Nb_3Sn, V_3Ga, $Nb_3(AlGe)$, and Nb_3Al conductors are useful whenever fields greater than 10 T (100 kG) or operating temperatures up to 15 K are required. The easiest to fabricate of this group is Nb_3Sn, and this fact alone accounts for the variety of fabrication routes and its preference for these applications. The lower strain sensitivity of V_3Ga and Nb_3Al is much more attractive, as is the higher critical temperature of Nb_3Ge and $Nb_3(AlGe)$. As fabrication routes become more economical, these materials will also see increasing use.

Ternary Molybdenum Chalcogenides (Chevrel Phases)

Luc Le Lay, Applied Superconductivity Center, University of Wisconsin--Madison

Introduction

THE TERNARY MOLYBDENUM CHALCOGENIDES have generated many fundamental as well as applied research efforts since their discovery nearly two decades ago (Ref 1). This is essentially due to the originality of the materials and to the possible applications of some of them as high field superconductors (that is, >20 T, or 200 kG). For almost ten years, several research teams have been trying to fabricate high critical current density (J_c) superconducting filaments, solving first the wiring problem, then partially that of the transport of the current. Some research is still going on, due to the difficulties encountered for achieving good transport currents in the high-temperature oxides. Although the requirements for the construction of a coil are still not met, significant progress has been achieved year after year. After a very general presentation of the materials, an overview of the present status of the superconducting applications of the monofilaments at the dawn of this new decade will be discussed.

Ternary Molybdenum Chalcogenides

This name stands for a vast class of materials, whose general formula is $M_xMo_6X_8$, where M is a cation and X a chalcogen (sulfur, selenium, or tellurium). There are also some compounds in which Mo is partially substituted by Re, Ru, or Rh (Ref 2, 3). Figure 1(a) shows the fundamental structure unit: a Mo octahedron surrounded by an X cube; these cubes, set in a tridimensional network, are tilted, so as to create intercube Mo-X bonds (see Fig. lb), that give the solid its cohesion (Ref 4). The M atoms are located in the channels generated by this network (Fig. 1c), and, mostly depending on their size, their location in the network, and their stoichiometry can vary (Ref 5, 6). It is even possible to insert them reversibly (Ref 7, 8, 9).

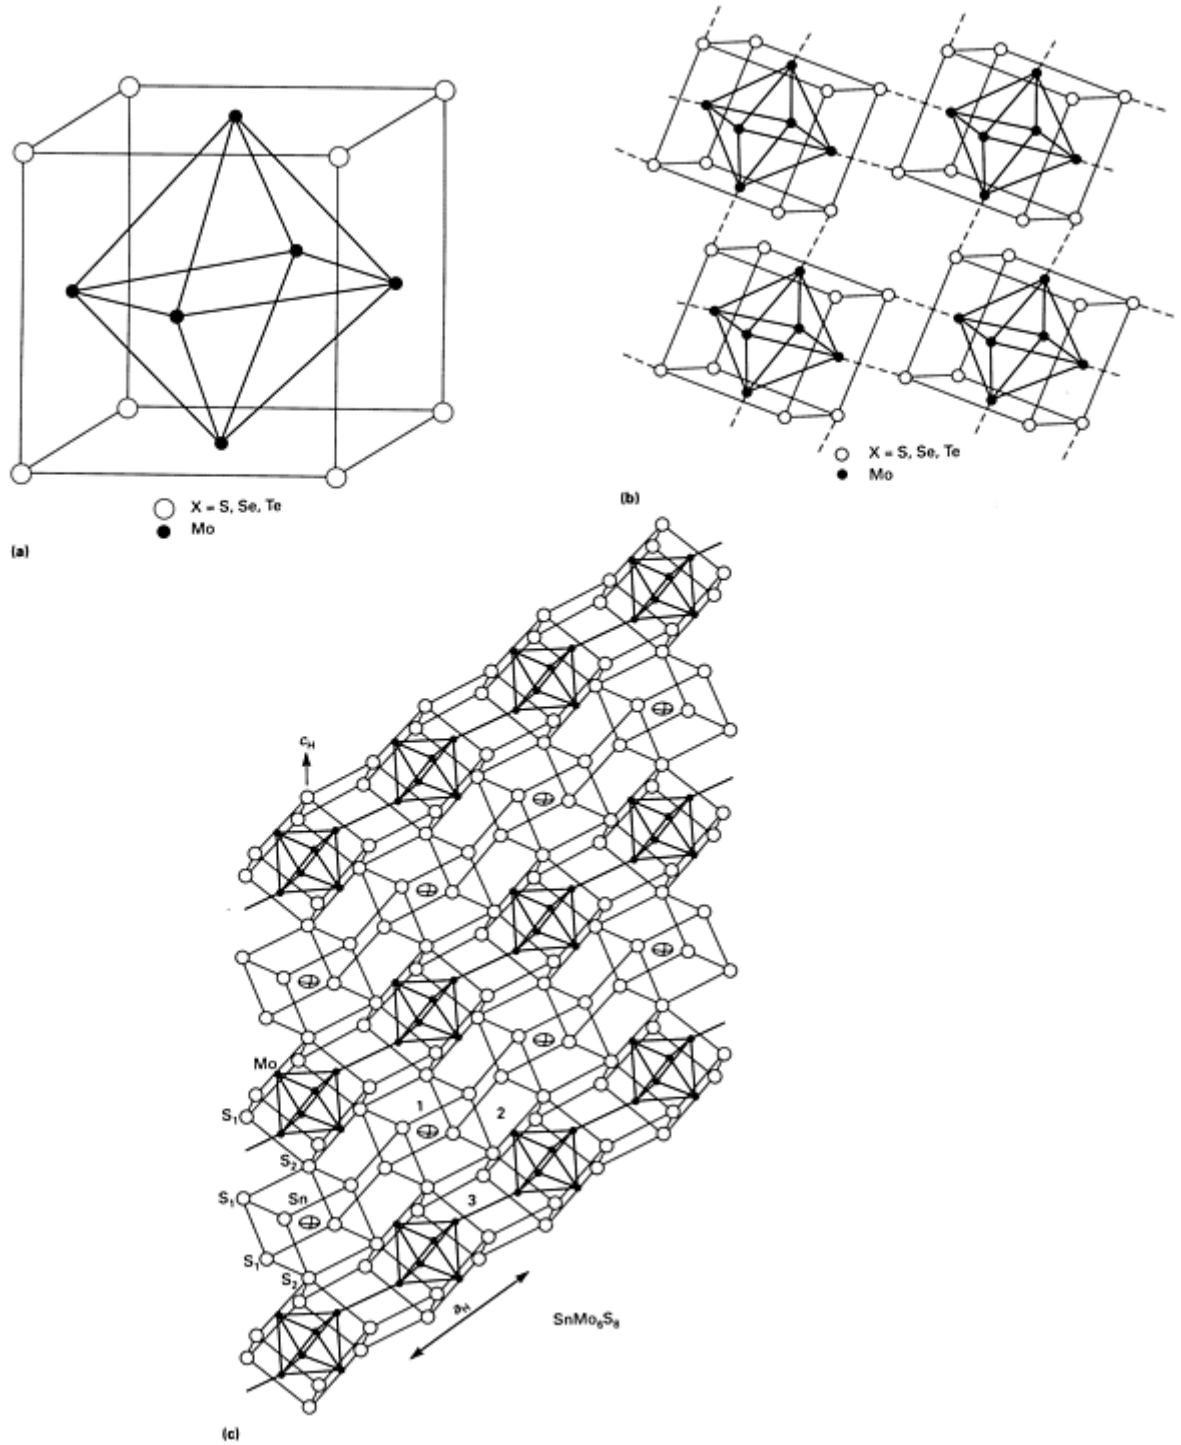

Fig. 1 Structure and bonding in ternary molybdenum chalcogenides. (a) Mo_6S_8 unit of the Chevrel phases. (b) Tilting of the fundamental structural units to form Mo-X bonds. (c) Generation of channel in $SnMo_6S_8$

The great flexibility of this structure (where both M and X can vary) originated the diversity of both the chemical and physical properties observed: superconductivity (Ref 10), catalysis (Ref 11), ion conduction (Ref 7, 8, 9), and so on. In superconductivity alone, several compounds exhibit exciting characteristics such as reentrant superconductivity (Ref 12), interplay with magnetic order (Ref 13, 14), double domain superconductivity (Ref 15), Jaccarino-Peter effect (Ref 16), and high critical fields (Ref 17). The main applications of the ternary molybdenum chalcogenides appear to use the latter property. It is found mainly in $PbMo_6S_8$ (designated PMS), $SnMo_6S_8$ (designated SMS), and $LaMo_6Se_8$ whose respective upper critical fields at 0 K are 60, 34, and 45 T (600, 340, and 450 kG) (see Fig. 2). Because the latter is not considered as a possible application for practical reasons, the research has been focused on the wiring of PMS and SMS chalcogenides.

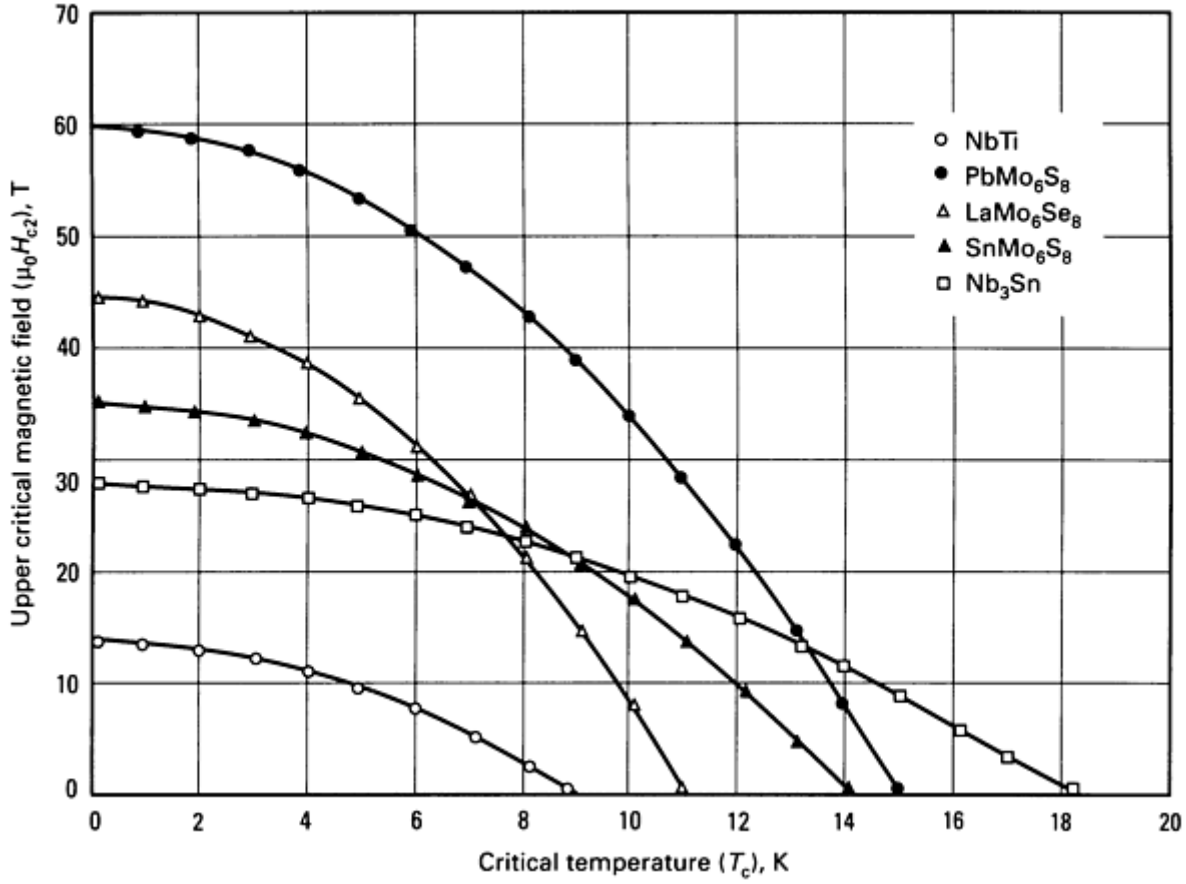

Fig. 2 Comparison of the critical fields of three ternary molybdenum chalcogenides ($PbMo_6S_8$, $LaMo_6Se_8$, $SnMo_6S_8$) and two commercially available superconductors (NbTi, Nb_3Sn)

Fabrication Technology

The following describes only the PMS technology, but it is understood that the same technology applies to SMS. Two features determine the kind of wiring technology used:

- PMS is easily synthesized as a powder
- Its fusion (it is indeed a noncongruent fusion) occurs at high temperatures [>1500 °C, or 2730 °F (Ref 18)]

Therefore, the available processing technique is the powder metallurgy one. Its principle is to fit the powder into a drawable casing and then to draw the whole set. Whatever the drawing conditions, a final heat treatment is always necessary in order to generate or restore the superconducting properties of the wire.

The handling and the choice of the initial powder appear to be crucial for the superconducting properties expected. The first emphasis is that, as sulfides, PMS and its precursors (for example, MoS_2, PbS, Mo_2S_3, and so on) are particularly sensitive to moisture and oxygen (Ref 19, 20). Hence, their handling has to be carried out in a controlled atmosphere (either vacuum or inert gas). The powder that is effectively drawn can be either PMS or a mixture of its precursors, given that a final heat treatment of the wire is necessary anyway (otherwise, it would have been logical to deal with PMS alone). In both cases, a compaction step is used before insertion in the sheath. This is either a hot or a cold process. The first yields a 100% packing density (Ref 21), the second an 85% packing density (Ref 22). Both processes allow a good mechanical behavior during the wiring operation, Figure 3 shows a typical PMS monofilament.

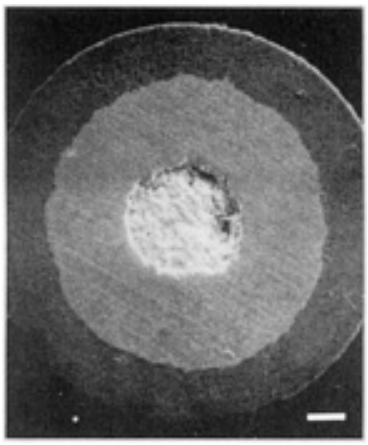

Fig. 3 Typical PMS monofilament with a niobium barrier (light gray) and a copper outer jacket (dark gray). The white line at the bottom is 100 μm (0.004 in.). Courtesy of P. Rabiller and M. Hirrien

In the past, gold and silver have been tried as matrices (Ref 23), but both yielded disappointing results. Today, molybdenum (Ref 24) or copper (Ref 25, 26, 27, 28) is mostly used, with stainless steel sometimes (Ref 24, 25, 29) as an external prestress layer. In the case of copper, an antidiffusion barrier is compulsory, otherwise the powder eventually reacts with the copper in the final heat treatment, yielding $Cu_xMo_6S_8$, whose superconducting properties are not desired here. This compulsory antidiffusion barrier is either niobium or tantalum. These options categorize two types of PMS wire fabrication: hot processing and cold processing.

Hot processing is the fabrication method used with the molybdenum sheath. The powder is first hot or cold compacted in a controlled atmosphere (either vacuum or inert gas), then fitted into a molybdenum billet (typical size is 6 mm, or $\frac{1}{4}$ in., ID, by 12 mm, or $\frac{15}{32}$ in., OD, by 100 mm, or 4 in., length). Stainless steel surrounds it. This' composite is then extruded

(~1000 °C, or 1830 °F), hot swaged, and finally drawn down to the desired diameter (the final drawing temperature is around 600 °C, or 1110 °F). The wire lengths produced usually are on the order of 1 km (0.6 mile) (Ref 24). Despite an extensive technology and the limited powder choice (if it were used, any mixture of precursors would indeed be reacted during the drawing operation, making this kind of choice equivalent to the prereacted powder method), this kind of casing possesses a fair advantage over niobium or tantalum. It is chemically nonreactive toward PMS, or one should rather say that molybdenum is in equilibrium with PMS (Ref 30). The usual temperature of the final heat treatment of the wire is on the order of 700 to 900 °C (1290 to 1650 °F) for 24 to 125 h (Ref 24, 29).

Cold processing refers to the fabrication method utilizing niobium and tantalum sheath technology. It is indeed similar to the hot processing fabrication method. The compacted powder is inserted in the antidiffusion barrier (typical dimensions, 6 mm, or $\frac{1}{4}$ in., ID by 10 mm, or $\frac{3}{8}$ in., OD by 250 mm, or 10 in., length) (Ref 25, 28), which is itself embedded in a copper matrix (10 mm, or $\frac{3}{8}$ in., ID by to 14 min, or $\frac{15}{32}$ to $\frac{9}{16}$ in., OD); the whole set is then drawn at room temperature down to a diameter on the order of several tenths of a millimeter. Stainless steel is sometimes added during the process, when the wire diameter is close to 2 mm (0.08 in.) (Ref 25). The temperature of the final heat treatment is slightly higher (900 to 1000 °C, or 1650 to 1830 °F), and the time is much shorter (10 min to 2 h). This allows the formation of an intermediate phase at the sheath-powder interface (Ref 22, 31), resulting from several diffusion processes. Although we have little knowledge of this reaction, the primary effect is certainly to change the stoichiometry of the central powder and hence its properties. Nevertheless, no one has given up on this process, for this drawback is counterbalanced by both the ease of the cold drawing technique and the critical current densities obtained (see the section "Superconducting Properties of Wire Filaments"). The choice of the starting powder is also wider because either PMS or precursors may be used.

Superconducting Properties of Wire Filaments

Mechanical Behavior. It has been shown that the expansion coefficient of PMS is greater than that of molybdenum, niobium, or tantalum (Ref 32, 33). This leads to a tensile stress of PMS inside the wire when it is cooled down at helium temperature. In order to avoid this, an external stainless steel layer whose thickness is chosen so that it precompresses the wire can be used in order to make the thermal expansions of the whole casing and the PMS match. This results in improved critical current densities (Ref 21, 34). In general, the mechanical behavior of PMS is comparable to Nb_3Sn in

the 10 to 15 T (100 to 150 kG) range (Ref 35), but because its upper critical field is about twice that of Nb_3Sn, PMS retains its mechanical characteristics (that is, the J_c dependence on the strain) in the 20 to 25 T (200 to 250 kG) range (Ref 25), where Nb_3Sn degrades dramatically.

Critical Current Densities. It has been ten years since PMS wires were first produced and their performance has steadily been improved. Several factors have contributed to that improvement:

- Advances in the handling and synthesis of the powders
- Use of an external stainless steel sheath
- Doping of PMS with Sn
- Better heat treatment conditions for the wires

Figure 4 summarizes the data of several researchers seeking to optimize chalcogenide properties. The transport J_c values of the best wires are slightly above 10^8 A · m^{-2} at 20 T (200 kG), which is calculated from the superconducting section only (as opposed to the usual literature that quotes the overall J_c values). It is important to point out that these data actually are for relatively short wires, wound in a coil shape (1 m, or 3.3 ft, long) or straight wires (several centimeters in length). It must be noted here that some empiricism prevails in obtaining optimum J_c values. It is still difficult to really pinpoint the factors that produce a given wire with better properties than another wire. One interesting hypothesis has recently been put forth (Ref 36) that relying on a phase transition of PMS would leave most of it nonsuperconducting at low temperatures. This would occur to a much lesser extent in SMS, thus explaining why the doping by tin improves the properties of SMS. Further investigation is required to confirm this hypothesis, which will be difficult because little is actually known about the microstructure of PMS and its influence on the superconducting properties of the wires. The objective is actually to raise the J_c values by a factor of 10 to 20 T (200 kG). While a tenfold increase in the present J_c values may be an overly ambitious goal, recent advances in SMS and PMS technology make it feasible.

Potential Applications

PMS wire applications include devices and processes that require high magnetic fields, such as high-energy physics, thermonuclear fusion, and nuclear magnetic resonance (NMR). However, research has not advanced to the stage where such devices and processes can utilize PMS technology efficiently. Current efforts are directed to improving the performance of the wires (which we know is possible because none of the published results showed that the wires have reached the expected upper critical field of about 50 T, or 500 kG, at 4.2 K) and eventually to construct small test coils. As of today, nobody has actually studied a coil longer than 2 m (6.7 ft) in length (Ref 37) and this will certainly be the focus of future SMS research and development, as well as seeking a better understanding of the factors that control the mechanism of the transport of the current.

Thin-Film Materials

Kenneth E. Kihlstrom, Department of Physics, Westmont College

Introduction

THE DISCOVERY of 30 K superconductivity in the La-Ba-Cu-O system by Bednorz and Muller (Ref 1) and the subsequent dramatic increase in critical temperature (T_c) to 93 K in the Y-Ba-Cu-O (YBCO) system by Wu *et al.* (Ref 2) has led to an intense research effort to understand and expand on these results. High-quality thin films have been made by electron beam (EB) codeposition, sputtering, laser ablation, and most recently, chemical vapor deposition (CVD). Subsequently, high-temperature superconductivity was found in the Bi-Sr-Ca-Cu-O (BSCCO) system by Maeda *et al.* (Ref 3) with T_c values up to 110 K and in the Tl-Ba-Ca-Cu-O (TBCCO) system by Sheng and Hermann (Ref 4) with T_c values up to 125 K. Despite these advances in high-T_c compounds, low-T_c materials such as NbN and Nb continue to be important for many applications. This article will initially focus on the different thin-film deposition techniques used to make superconducting films and then will briefly discuss advantages of high-T_c versus low-T_c materials in a number of applications.

Superconducting Materials

The high-T_c systems have much in common. They each exhibit planes of Cu-O in the *a-b* plane, which seems critical to the superconductivity of the materials. As a result, they are all highly anisotropic with a substantial drop in superconducting properties (for example, critical current density, J_c), when the *c*-axis is parallel rather than perpendicular to the substrate. Thus, it is critical to be able to orient film growth. Films that are polycrystalline suffer further degradation of superconducting properties as it appears that the grains are weakly Josephson coupled. Correct oxygen stoichiometry is also important in all three systems. All three systems show high critical current densities (J_c values range from 10^6 to 10^7 A/cm^2) and enormous upper critical field, H_{c2} values (dH_{c2}/dT > 4.5 T/K at T_c), but adequate pinning seems difficult to obtain. Therefore, in both J_c and H_{c2} results there is not a clean break to true zero resistance.

The low-T_c materials are certainly much easier to work with. For both Nb (T_c = 9 K) and NbN (T_c = 18 K) there is no anisotropy, and thin films are obtainable by the different deposition techniques with little difficulty (that is, with low substrate temperature and no need for a post anneal). A15 materials such as Nb_3Sn (T_c = 18 K), V_3Si (T_c = 17 K), and Nb_3Ge (T_c = 23 K) can also be deposited in thin-film form but in general need elevated substrate temperatures that limit their appeal for layered structures. Critical current densities near 10^7 A/cm^2 can be obtained here as well, but at much lower temperatures (for Nb_3Ge, $J_c = 9 \times 10^6$ A/cm^2 at 14 K (Ref 5).

Substrates and Buffer Layers

Early attempts at film growth used the traditional substrates such as sapphire (single crystal Al_2O_3), but it was quickly determined (Ref 6) that at the annealing temperatures necessary to form the superconducting phase substantial diffusion occurred from the substrate into the material, with a substantial degradation of superconducting properties. This, combined with the desire for oriented growth (hopefully single crystal), led to other substrates such as $SrTiO_3$ (Ref 7, 8). But $SrTiO_3$ is an expensive substrate with a large dielectric constant and loss tangent, putting it at a disadvantage for high-frequency use. $LaAlO_3$ (Ref 9) and $LaGaO_3$ (Ref 10) both have significantly lower values for the dielectric constant and loss tangent. Both have produced films with sharp T_c values. A number of buffer layers (to prevent interdiffusion with the substrate) have been used to provide reasonably good films (Ref 11, 12, 13). Still, growing *in situ* films (without need of post anneal) is often preferable.

For the low-T_c materials, there is little problem with interdiffusion with the substrate, so convenient materials such as sapphire can be used. For the A15 materials where elevated temperatures are necessary, it can be important to clamp the sample to the backing plate securely to ensure a constant temperature during deposition (Ref 5).

Thin-Film Deposition Techniques

The main deposition techniques currently used are:

- Electron-beam coevaporation
- Sputtering from either a composite target or multiple sources
- Laser ablation (also called pulsed laser deposition)

Chemical vapor deposition has been the slowest of the methods to come on line, but recent results (Ref 14) suggest that in time it may become competitive.

Electron-Beam Coevaporation. The earliest successful high-T_c thin-film results came with EB-deposited material (Ref 6, 15). This procedure typically requires separate sources for each component of the superconductor. This multisource evaporation creates problems with accurate rate control of each of the sources (especially if a large oxygen pressure is present) as well as geometrically induced composition variation on the substrates (remember, because these are line compounds, stoichiometry is very important). Oxidation of the sources (affecting evaporation rates) is less of a problem here than in sputtering. This allows greater possibilities of *in situ* film growth. For single-layer superconductors (allowing for a post anneal) the use of BaF_2 (Ref 16) (which is much more stable than barium metal) allows patterning of deposited films by photolithography after which an anneal (with O_2 and H_2O) produces the superconducting properties. Even apart from patterning considerations, use of BaF_2 improves film quality but is not useful when making *in situ* films because of the necessity of removing the fluorine.

Sputtering. Film deposition by sputtering can be done with either a single composite target or with multiple sources.

Composite target sputtering avoids geometric compositional variation (inherent in a multiple-source configuration) as well as the need for good rate control. The main drawback involves the difficulty in obtaining the desired composition in the film (which does not necessarily match the target composition). This can be addressed either by adjusting target composition (Ref 17, 18) or by varying sputtering conditions such as location of the substrates (Ref 19). The latter results because of bombardment of the film surface by negative oxygen ions. By moving the substrates to the side, stoichiometric films were obtained. Recent results from the Karlsruhe (Ref 20) have superconducting films as thin as 3.6 nm (36 Å).

Multiple target sputtering (Ref 21, 22, 23) has greater flexibility to vary composition but has drawbacks due to oxidation of the barium target and rate control. In the end, composite sputtering seems to have the advantage.

Laser ablation (or pulsed laser deposition) uses a composite target of the desired composition that is exposed to a focused laser beam from a pulsed excimer laser (typically). The area vaporizes and is projected in a narrow forward plume to the substrate. Initial results (Ref 24) with laser ablation required a post anneal, but high-quality *in situ* films are now available from laser ablation (Ref 13, 25, 26) with $J_c = 4 \times 10^6$ to 5×10^6 A/cm^2. Substrate temperatures as low as 400 °C (750 °F) without post annealing resulted (Ref 27) in the $R = 0$ point, where R is the bulk resistance, at 85 K with $J_c = 10^5$ A/cm^2. The drawback of small sample size (due to the superconductor or plume being very directional) can be overcome by rastering the substrate.

In Situ Film Growth

As mentioned earlier, films requiring a post anneal suffer substrate/film interdiffusion, causing degradation at high temperatures, limiting the choice of substrates. In addition, post-annealed samples tend to have very poor surfaces, limiting hope of layered devices (such as tunnel junctions) where a clean, abrupt interface is necessary. A number of *in situ* techniques have been used successfully. High-pressure (> 1 mtorr, or 0.13 mPa) methods (Ref 28, 29, 30) cause problems with rate control, oxidation of sources, and shortened lifetimes of system components but have produced films with T_c > 90 K and J_c of 4×10^6 A/cm^2. To succeed with low pressures requires activating the oxygen in some way. Techniques include producing atomic oxygen by radio frequency (rf) excitation (Ref 31) or microwave discharge (Ref 32), or the use of ozone (Ref 33). Each of these techniques has produced excellent films.

Superconducting Materials Properties

$YBa_2Cu_3O_7$ (YBCO) Properties. Despite the discovery of yet higher-T_c compounds, YBCO continues to be the most studied material for several reasons. Because it came first, most groups have a working knowledge of it including both the pitfalls and established protocols for deposition conditions, oxidation, and annealing. Switching to the other materials may mean largely starting over and losing the progress already made. High-quality YBCO films have been made by several techniques. The $R = 0$ point is typically about 95 K. Critical current densities (J_c) for YBCO films at 77 K are typically in the mid 10^6 A/cm^2 range both for *in situ* [Venkatesan *et al.* (Ref 25) $J_c = 4 \times 10^6$ to 5×10^6 A/cm^2] and for post-annealed [Itozaki *et al.* (Ref 27) $J_c = 3.5 \times 10^6$ A/cm^2] films. There is a report out of Japan (Ref 34) that the Sumitomo group has obtained a J_c of 1.5×10^7 A/cm^2. It should be noted as well that in large fields (15 T, or 150 kG) the critical current is 10^5 A/cm^2 at 50 K (Ref 35). The upper critical field slope (dH_{c2}/dT at T_c) for parallel field was found by Chaudhari *et al.* (Ref 36) to be 4.5 T/K. Finally, much progress has been made on *in situ* growth of YBCO films (as already discussed).

There are some drawbacks of YBCO however:

- YBCO is a single line compound on the equilibrium phase diagram, which makes correct stoichiometry essential. Any deviation from stoichiometry results in a nonconducting second phase inclusion that can lead to losses. This is in contrast to the bismuth and thallium compounds that have a number of superconducting competing phases
- YBCO is especially sensitive to oxygen content. Homogeneous samples are thus difficult to obtain

- Barium is very reactive with water vapor and has a tendency to migrate to the surface, giving rise to a nonsuperconducting surface while leaving the bulk stoichiometry off the mark

Bi-Sr-Ca-Cu-O (BSCCO Properties). This system has not been as intensively studied as YBCO, in part because of the discovery of higher transition temperatures in the thallium compounds. There has been a strong effort in Japan where the system was first studied, and a number of interesting properties have been discovered. First, there are at least two superconducting phases (Ref 37): the $Bi_2Sr_2CaCu_2O_x$ (2212) phase with T_c = 85 K and the $Bi_2Sr_2Ca_2Cu_3O_x$ (2223) phase with T_c = 110 K. The lower-T_c phase material seems less sensitive to having exact stoichiometry, which is an advantage. The higher-T_c phase has been more difficult to synthesize in pure form, although the partial substitution of lead for bismuth is very helpful (Ref 38, 39). The absence of barium makes the BSCCO films less sensitive to atmospheric degradation than YBCO. The upper critical field slope (dH_{c2}/dT at T_c) for parallel field was found by Palstra *et al.* (Ref 40) to be 45 T/K. J_c at 77 K was found to be 1.9×10^6 A/cm^2 and at 40 K, $J_c = 2.1 \times 10^7$ A/cm^2 by the Sumitomo group (Ref 41).

Tl-Ba-Ca-Cu-O (TBCCO) Properties. The highest confirmed T_c values to date come in the thallium system (Ref 42) where T_c = 125 K including films with R = 0 at 120 K (Ref 43). Here, as with the bismuth superconductors, there are multiple superconducting phases, the highest of which (T_c = 125 K) is the $Tl_2Ba_2Ca_2Cu_3O_x$ (2223) phase. It is a distinct advantage that if a second phase is present it is also superconducting even if at a lower T_c. This is especially true for polycrystalline films. There are, however, disadvantages with the thallium compounds. As with BSCCO systems, there is an extra component versus YBCO systems, often requiring a four-source deposition system. The presence of several phases makes purifying a single phase difficult. Also, at the necessary annealing temperatures, thallium is very volatile, making it difficult to get the correct stoichiometry (although there are tricks such as annealing the film in a sealed quartz tube with bulk TBCCO material to set up an equilibrium vapor pressure). Of course the toxicity of thallium is also a major concern, and care must be taken. The thallium results certainly are not optimized, but some respectable values for J_c have been reported, Hong *et al.* (Ref 44) found $J_c = 10^4$ A/cm^2 at 110 K and $J_c = 10^5$ A/cm^2 at 100 K, suggesting a slope that would make the thallium compounds comparable to YBCO systems. The upper critical field slope (dH_{c2}/dT at T_c) for parallel field was found by Kang *et al.* (Ref 21) to be 70 T/K (for the 2212 phase).

Table 1 summarizes the results of high-T_c thin films.

Table 1 Properties of high-T_c thin-film systems

System	Critical temperature (T_c), K	Critical current density (J_c), A/cm^2	Upper critical magnetic field slope $\left(\frac{dH_{c2}}{dT}\Big\|_{T_c}\right)$, T/K
YBCO	95	1.5×10^7(a)	4.5
		10^5(b)	4.5
BSCCO	110	2×10^6(a)	45
TBCCO	125	10^5(c)	70

(a) Measurement temperature, 77 K. (b) Measurement temperature, 50 K; applied field (H_a), 15 T (150 kG). (c) Measurement temperature, 100 K. Source: Ref 35

Low-T_c Materials. Despite the advances in high-T_c materials, there is still a great deal of interest in the low-T_c superconductors such as Nb (T_c = 9 K) and NbN (T_c = 18 K). The A15 superconductors also offer possibilities, but the higher T_c (up to 23 K for Nb_3Ge) may not offset the difficulties in fabrication. For Nb and NbN, it is relatively easy to make high-quality thin films with low deposition temperatures (which allows much greater latitude in processing the films). In addition, there is no anisotropy to worry about and the surfaces tend to be of good quality. Critical current densities for the low-T_c materials can be substantial but only at liquid-helium temperatures (T = 4.2 K). For NbN, J_c values up to 1.5×10^6 A/cm^2 have been reported (Ref 45) when some tantalum was cosputtered with the NbN. The upper critical field (H_{c2}) for the same material at T = 4.2 K is as high as 24 T (240 kG). The obvious drawback for these materials is the need for liquid-helium cooling. Yet for some applications, especially detectors, the low temperature is necessary to reduce thermal noise. In this case a high T_c is not a major advantage.

Applications of Thin-Film Superconductors

The promise of superconductive electronics is due to the inherent speed, low, loss, low noise, and low power dissipation as compared with semiconductor technology. The advantages are already present in the low-T_c materials such as Nb (T_c = 9 K) and NbN (T_c = 18 K), which will continue to be important. There exists a well-established superconductive integrated circuit technology based on niobium with work being done on NbN. The Fujitsu group (Ref 46) in Japan has produced a four-bit chip that ran at 1.1 GHz dissipating only 6.1 mW of power, which surpasses gallium arsenide semiconductor circuits by factors of 15 and 150, respectively.

Introducing high-T_c materials to applications brings both advantages and disadvantages. The increased operating temperature also means increased thermal noise. The greater superconducting energy allows an increase in the potential frequency (and higher speed) but requires greater operating voltages (and greater power dissipation). Fabrication and reliability of the high-T_c superconductors is a major problem, but the option of liquid-nitrogen temperature operation would allow superconductor-semiconductor hybrid circuitry (where liquid-helium operation would freeze out semiconductor technology).

Thus both high-low and low-T_c superconductors should have major roles in a number of areas. The high-speed, low-power dissipation has been discussed in digital electronics. Signal processing and analog electronic applications such as analog-to-digital (A/D) converters offer ultralinear high speed (Ref 47), high resolution (Ref 48) with low power dissipation. Josephson parametric amplifiers (Ref 49) and superconductor/insulating/superconductor (SIS) tunnel junction mixers (Ref 50) operate with very low noise levels. It is possible that even low-T_c superconductors could have high-frequency operation near 1 THz. The high-T_c superconductors hold the potential of 10 THz operation. Sensor applications such as infrared detectors and video detectors for millimeter radiometry also benefit from high-frequency broadband capabilities. Superconducting quantum interference device (SQUID) magnetometers represent another important application of superconductivity. These are the most sensitive detectors of small magnetic fields. High-T_c materials using liquid nitrogen rather than liquid rather than liquid helium could allow greater field use. Transmission lines operating at microwave frequencies make use of the other orders of magnitude that lower-loss superconductors have versus gold or copper. Very high quality factor (Q) circuits and nearly ideal filters are possible.

Future Outlook

In the end, laser ablation and composite target sputtering seem to be the most promising deposition methods with EB codeposition also being competitive, especially for *in situ* films (a necessary process when multilayer structures are contemplated). In choosing the superconducting material, YBCO probably has the edge because of the greater wealth of knowledge available especially for *in situ* deposition. It should be noted, however, that the low-T_c materials such as Nb and NbN continue to be important for applications. Also, what is learned in developing Nb and NbN technology will carry over to the high-T_c compounds when the material's problems are fully mastered. Superconductivity does not promise inexpensive operation but does not hold the potential of unrivaled performance.

High-Temperature Superconductors for Wires and Tapes*

R.D. Blaugher, Intermagnetics General Corporation

Introduction

THE INTEREST in applying superconductivity to power devices, transportation, electronics, and so on is directly related to predicted performance advantages and improved operating efficiency over conventional room-temperature (RT) approaches. The incorporation of superconducting wire or tape into large magnets and power generators, for example, provides the ability to transport large dc currents with no measurable resistive losses. High magnetic fields can thus be produced at a significantly reduced cost for the energy required for operation. Similar examples can be given for electronic applications with superconductivity offering lower losses, higher speed, and reduced signal dispersion at very high frequency (Ref 1, 2).

To demonstrate these predicted benefits, superconductivity, in fact, has been applied to many power-related and electronics applications with great success. Superconducting prototypes have been constructed, for power generators and motors, ac and dc transmission, energy storage, high-speed signal processing and computing, and high-sensitivity magnetic detectors, to name but a few (Ref 1, 2). It is also possible to operate power devices in an ac mode with acceptable losses, providing the superconductor is properly designed with respect to filament size, twist, and stabilizer. These past demonstrations, almost without exception, were tested and operated in liquid helium at 4.2 K. This requirement for liquid-helium cooling has, without a doubt, limited serious consideration for insertion of superconducting devices into existing power-generation equipment and electronic systems up to the present.

The discovery of the high-critical-temperature (high-T_c) oxide superconductors (Ref 3) in 1986 has accelerated the interest for superconducting applications because it offers the prospect for higher-temperature operation at liquid nitrogen (77 K) or above and thus reduces the refrigeration and/or liquid helium requirement.

The primary technical challenge that must be satisfied to permit usage of the high-T_c oxides in magnets or power applications is the successful demonstration of a high-current-carrying wire or tape with acceptable mechanical capability. The current-carrying performance of the oxide-base wire or tape must be functionally equivalent to the present liquid-helium-cooled conventional superconductors such as Nb-Ti or Nb_3Sn, which typically show a current density at 4.2 K of approximately 10^5 A/cm^2 at 5 T (50 kG). In addition, the high-T_c oxide conductor must have the mechanical ability to withstand the stresses produced during fabrication and winding, thermal contraction during low-temperature operation, and the Lorentz forces (F_L) due to the high magnetic fields (Ref 4).

Over the past three years, a large research effort has been directed at the understanding and processing of high-T_c oxide conductor materials. Much progress has been made, but to date there has been no actual demonstration of a technologically useful high-T_c wire or tape. The processing approaches have pursued many directions, but for the most part, follow either a powder precursor approach or a vapor deposition method. The powder techniques are mainly based on the production of an oxide powder precursor, which is then subjected to various processing and heat treatment schedules.

Processing of Primary Oxide Compounds

Y-Ba-Cu-O (YBCO) Systems. The worldwide efforts on producing wire and tape have concentrated for the most part on the $YBa_2Cu_3O_7$(123) or YBCO orthorhombic compounds or variants with other rare earths (REs) substituted for the yttrium. The 123 compound presents major processing difficulties:

- High reactivity with most metallic and ceramic interfaces
- Sensitivity to cation and anion stoichiometry, which degrades the superconducting properties
- Sensitivity to copper substitution, which degrades the superconducting properties

Once formed, the compound is highly brittle with strong crystalline anisotropy, which shows marked thermal expansion coefficient differences for its major axes with a resultant high tendency for microcracking. These processing problems, however, are balanced to some degree by the ability to produce a high percentage of single-phase material if the processing is properly followed. A fairly high 92 K superconducting transition and production of satisfactory critical current density in idealized thin-film samples also add to the interest for using this compound. Furthermore, an enormous amount of research has been conducted on the 123 compound, which provides a wealth of information with an almost unparalleled reference base for the materials scientist.

Bi-Sr-Ca-Cu-O (BSCCO) Systems. The $Bi_2Sr_2Ca_{n-1}Cu_nO_x$ system provides the other major oxide compounds under investigation for wire and tape development. The bismuth compound shows similar processing problems as the Y-123, but in contrast to Y-123, is more difficult to synthesize as a single phase. A high-T_c (110 K) phase is found at the composition 2223 with a lower-transition 85 K phase forming at 2212. Partial substitution of lead for the bismuth appears to promote the development of the 2223, 110 K phase. The bismuth compound's major advantage over the Y-123 is its relative insensitivity to oxygen loss during processing, and it does not require special low-temperature oxygenation to achieve optimum superconducting properties.

Ti-Ba-Ca-Cu-O (TBCCO) Systems. The thallium-base 125 K oxide superconductor with barium, calcium, and copper provides the third major compound of interest for high-T_c wire and tape development. Processing for the thallium system has not been as active, primarily due to the high volatility of the thallium oxides and their high toxicity. Processing for the thallium-base superconductors must be conducted in a confined facility and much care followed to prevent toxic exposure.

Powder Precursor Preparation

Shake-and-Bake Method. The simplest method employed for producing oxide powder precursors is to use the so-called shake-and-bake method. The constituent powders, usually the metallic oxides (BaO, Y_2O_3, and CuO for example), are physically mixed and ground followed by calcining at 800 to 950 °C (1470 to 1740 °F) in air or flowing oxygen. This process is repeated a number of times with a final oxygenation (for the RE-Ba-Cu-O compounds) performed at 400 to 500

°C (750 to 930 °F) in flowing oxygen. The resulting powder obtained by this method is fairly close to stoichiometry for both the anion and cation composition and meets most processing requirements.

Additional Methods. More exotic techniques (sol-gel, coprecipitation, aerosol, and so on) have been developed that provide more precise control on phase purity and stoichiometry, minimize preparative contamination, and offer some control on the shape and size of the powder particulates.

Aerosol Pyrolysis Technique. One method that has achieved a high degree of success for the Y-Ba-Cu-O system is the aerosol pyrolysis technique. An aqueous metal nitrate solution is prepared from the respective oxides, which is then dispersed into a carrier flow stream (typically air or oxygen) to form an aerosol. The aerosol is passed through a high-temperature furnace that flash evaporates the solvent followed by nitrate decomposition and formation of the metal oxide. The oxide powder is either filtered or gravity collected and subsequently heat treated to complete the process. The superconducting properties of the powders produced by this method have been quite good, showing a very low percentage of impurity phases and fairly sharp superconducting transitions (Ref 5, 6). More importantly the powders are submicron in size, which is attractive for producing wire using the powder-in-tube method.

Powder-in-Tube Processing

The powder-in-tube approach is the most common method used to date for producing an oxide-base wire or tape. The oxide precursor powder is packed into a hollow metallic tube. Usually silver or gold are preferred due to their relative inertness to the oxide and ability to permit oxygen diffusion. The composite tube is then swaged or drawn into a wire, and if desired, rolled into a tape.

The most common heat treatment schedule for the powder-in-tube wire or tape provides a high-temperature reaction heat treatment near the melting point, which either sinters or partially melts the superconductors followed by a slow cool down, which may include a final low-temperature anneal required to completely oxygenate and equilibrate the RE-$Ba_2Cu_3O_7$ superconductor. The heating and cooling schedules must be carefully configured to minimize separation of the superconductor core due to the thermal expansion mismatch (Ref 7). It is possible with a silver sheath to diffuse sufficient oxygen to restore stoichiometry that may be lost during the high-temperature reaction. The best critical current densities (J_c) observed to date (at 77 K) for the various powder-in-tube processing approaches are shown in Fig. 1. The best critical current density data for an oxide wire or tape is $J_c = 1.7 \times 10^4$ A/cm^2 at 77 K, with the applied field (H_a) of $H_a = 0$ obtained by Sumitomo on silver-sheathed Bi-Pb-Sr-Ca-Cu-O material, which was drawn into wire and then cold rolled to a tape configuration (Ref 8). The current density for this tape, however, rapidly degraded in a magnetic field showing only 1.7×10^3 A/cm^2 at an applied field of 0.1 T (1.0 kG). The highest current density for a Y-Ba-Cu-O compound similarly processed in a silver sheath is 4×10^3 A/cm^2 at 77 K, for zero field, which was also reported by Sumitomo (Ref 9). Examples of $YBa_2Cu_3O_7$ rolled tape and multifilament wire are shown in Fig. 2.

The powder-in-tube current density and behavior in an applied magnetic field is significantly degraded compared to the conventional superconductors Nb-Ti and Nb_3Sn shown in Fig. 1 at 4.2 K. The critical current density requirements for two of the most prominent large-scale applications are also noted: magnetic resonance imaging (MRI) magnets and the

superconducting supercollider (SSC). Both of these devices require current density performance near 10^5 A/cm^2 at a 5 T (50 kG) magnetic field.

It is significant to note two recent achievements for powder-in-tube superconducting oxide wire and tape measured at 4.2 K that indicate promise for oxide conductors at high magnetic fields. A silver sheathed Y-Ba-Cu-O wire showed 10^3 A/cm^2 at 4.2 K in a 10 T (100 kG) field (Ref 10). An even higher critical current density of 10^4 A/cm^2 was observed for Bi-Sr-Ca-Cu-O wire measured at 4.2 K in magnetic fields up to 26 T (260 kG) (Ref 11). This latter result (see Fig. 3) shows higher critical current density at 4.2 K and 26 T (260 kG) than conventional Nb_3Sn wire or tape. This result thus presents a new opportunity for the oxide superconductors in providing a conductor for use in constructing very high field magnets, that is, H > 25 T (250 kG) operating at a 4.2 K temperature. Consideration of a superconducting design for a high field magnet is currently limited to 20 to 22 T (200 to 220 kG) using conventional, that is, nonoxide, superconductors.

Vapor Deposition Processing

The vapor deposition methods for producing a tape or wire have generally employed conventional physical deposition approaches such as radio frequency (rf) magnetron sputtering, laser ablation, and evaporation and chemical techniques such as metallo-organic chemical vapor deposition (MOCVD).

The vapor deposition approach offers some advantages in that the deposition can be performed at temperatures well below the oxide superconductor decomposition temperature. This minimizes substrate contamination, reduces postreaction heat treatment and oxygen equilibration, and minimizes the thermal expansion problem that occurs on heating. Thin films of approximately 0.5 μm (20 μin.) to a few μm are typical for the vapor deposition methods.

The critical current densities observed for thin films of the oxide superconductor have shown the highest values reported to date for high-T_c materials. These thin films, however, are highly idealized in that the film is of epitaxial grade grown on a specially prepared highly expensive substrate such as $SrTiO_3$. The critical current densities for these epitaxial films are shown in Fig. 1. Values in excess of 10^6 A/cm^2 have been observed at 77 K for RE-Ba-Cu-O oxide compounds with outstanding magnetic field properties comparable to the conventional superconductors (Ref 8). The thin-film results thus present some optimism that technologically useful current densities may be eventually produced in bulk wires and tapes. The mechanism leading to the high critical current densities in thin films is not presently understood but is related to the ability of the thin films to achieve higher pinning and reduced flux flow compared to bulk materials.

The critical current density for vapor deposited (VD) tapes or wires on a metallic substrate is considerably degraded compared to the epitaxial films. Prototype VD tapes produced to date typically show 10^3 to 10^4 A/cm^2 at 77 K and zero field, which is a direct result of their polycrystalline nature (Ref 12). The metallic substrate does not provide growth conditions comparable to the micro-electronics grade substrates, which results in polycrystalline development and lower critical current density. Promising results for the VD approach have been obtained for MOCVD films on MgO (Ref 13) and for laser-ablated films also on MgO (Ref 14) with critical current densities near 10^5 A/cm^2 observed at 77 K. The microstructural development for these latter examples is apparently improved over the polycrystalline condition with a higher degree of texturing.

Microstructural, Anisotropy, and Weak Link Influences

The critical current density for the best wire and tape shows over two orders of magnitude lower critical current and severe magnetic field degradation in contrast to the critical current density observed for high-quality thin films. The inability to realize bulk critical current densities comparable to thin films is presently attributed to microstructural and mechanical causes. The brittle nature of the ceramic material presents great difficulty in preserving the physical continuity necessary for optimum current transport. Physical separation or microcracking can easily occur, which severely degrades the critical current density. Even with perfect material, that is, with no microcracks evident, microstructural weak link problems are evident, which severely limits critical current density.

It is fairly well accepted that this degradation is mainly attributed to weak link Josephson-type coupling between grains. The oxides, which are either orthorhombic or tetragonal, exhibit crystalline anisotropy that results in strong anisotropy in the current density. Current flow in the *a-b* planes is orders of magnitude higher than current flow in the *c*-axis direction.

The poor coupling between grains or the weak link mechanism is dominated by this current density anisotropy and grain-boundary-related problems such as precipitate or impurities along the grain boundaries, compositional inhomogeneities, microcracking, and misalignment of the *a-b* planes across the grain boundary.

A superconducting weak link is normally associated with a weakly connected microscopic bridge or narrow constriction between two bulk superconductors. Weak link superconducting behavior was first predicted by Josephson and forms the basis for the Josephson junction. A weak link behaves much like an ordinary bulk superconductor with respect to a critical current and sensitivity to magnetic field, but because of its size it can only support a fraction of the current that can be carried by a bulk superconductor (Ref 15.)

Recent work has shown that, even with essentially clean grain boundaries with no evidence of impurities or second phase, current flow across the boundary is still compromised. It is suspected that dislocation networks adjacent to the boundary create strain fields, which in turn limits the ability to transport current (Ref 16).

The presence of high-angle boundaries in the oxide superconductor even under the best conditions thus appears to limit the critical current density. It is important to note that the epitaxial films that exhibit high critical current density have very few high-angle boundaries. The processing followed for bulk materials must have an inherent capability for limiting high-angle development and achieving a high degree of crystalline development in the high-current *a-b* planes.

Melt Processing

In an attempt to reduce the problem of weak links, melt processing of bulk materials has been pursued at numerous laboratories. Jin *et al.* (Ref 17) and Salama *et al.* (Ref 18) have demonstrated elongated, oriented grain development in bulk 123 materials by processing (see Fig. 4) above the peritectic at 1000 to 1250 °C (1830 to 2280 °F) in the (211 + L) region. High-J_c properties have been reported using melt processing that may have been optimized by careful sample selection and their methods used for critical current measurements.

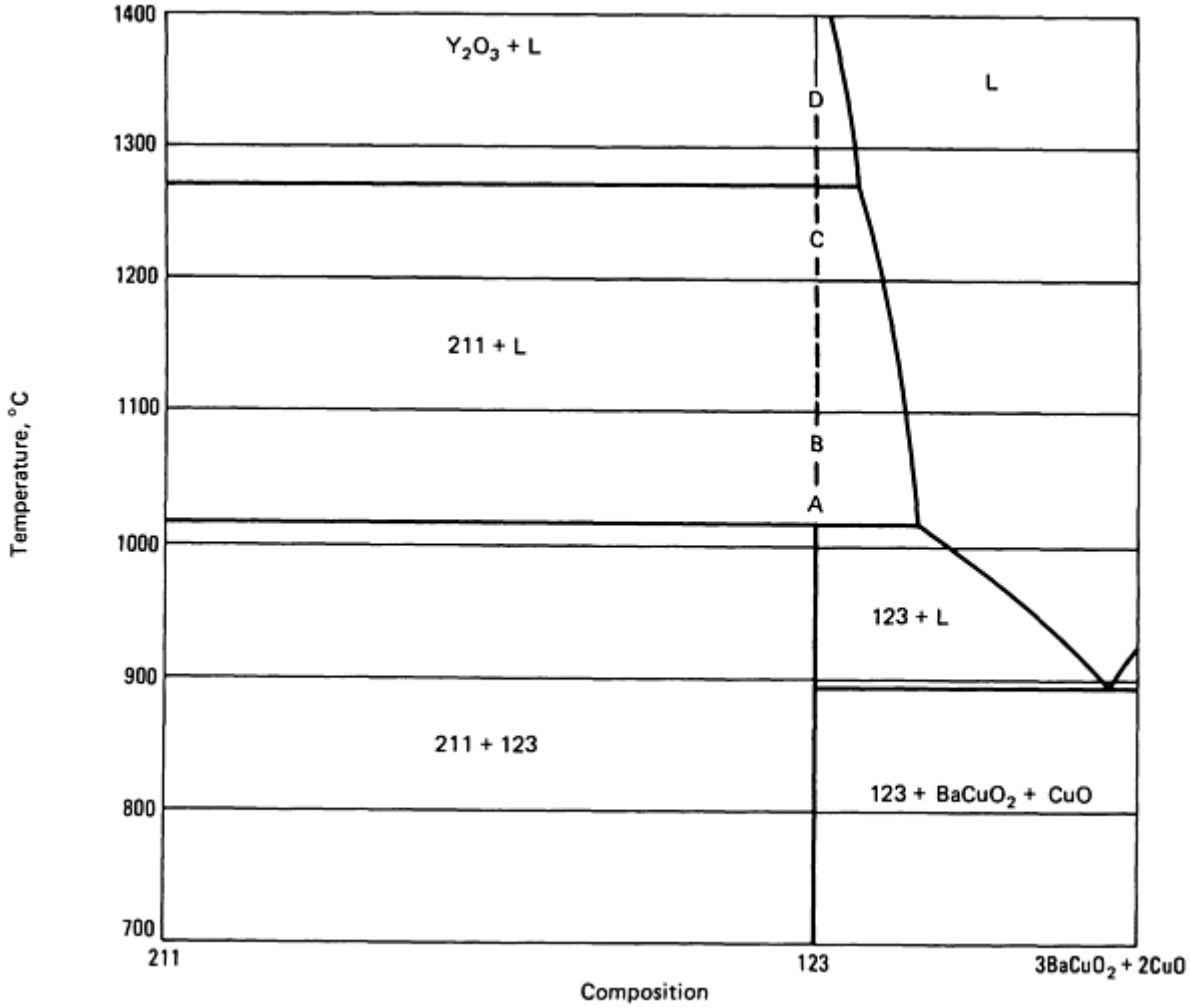

Fig. 4 Pseudobinary Y-Ba-Cu-O phase diagram along the tie line 211-123-(035)

Murakami *et al.* (Ref 19) has recently expanded on the original melt processing approach used by Jin with the melt-quench growth (MQG) technique. A high degree of bulk-oriented 123 material consisting of 123 with a dispersion of 211 is obtained by the MQG method. This was done by an initial melting into the (Y_2O_3 + L) region above 1270 °C, or 2320 °F (point D in Fig. 4) and fast quenching to form a fine dispersion of Y_2O_3. Reheating into the (211 + L) regime (point B in Fig. 4) and slow cooling through the peritectic maximizes the formation of 123 from the reaction of the finely dispersed Y_2O_3 with the liquid to nucleate 211, which then reacts with the remaining liquid to form 123. As can be seen in Fig. 1, the resultant J_c values are much improved over the sintered powder values and earlier melt processing and show a much improved J_c versus magnetic field behavior. Blaugher *et al.* (Ref 20) have taken this one step further by successfully performing the MQG process on a metallic substrate representative of a prototype tape with steady-state magnetization J_c approaching 10 kA/cm^2 at 50 K in fields up to 4 T (40 kG). Large polycrystalline melt-processed samples (25 × 10 × 2 mm, or 1.0 × 0.4 × 0.08 in.) have recently been measured by four-probe steady-state dc current transport and indicate critical current density >1 kA/cm^2 at 77 K in a 2 T (20 kG) magnetic field (Ref 21). In addition, Okada *et al.* (Ref 22) of Hitachi have recently reported the fabrication of gold- (palladium-) sheathed melt-processed 123 tape with promising J_c characteristics (see Fig. 5).

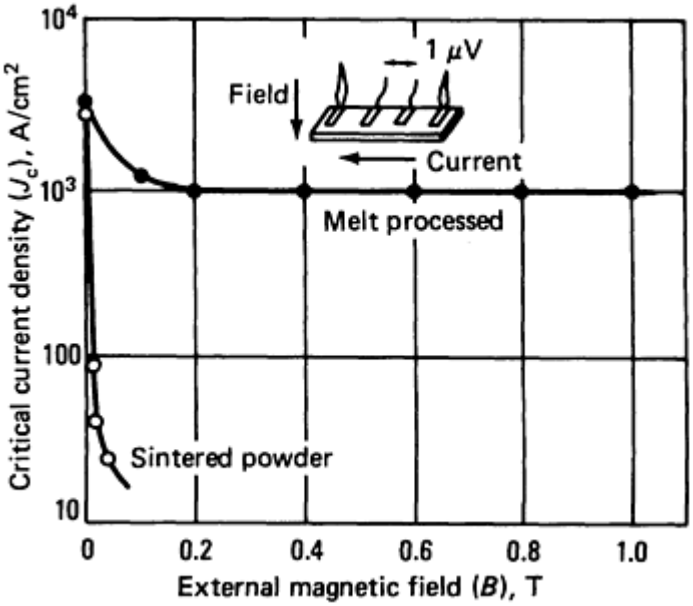

Fig. 5 Plot of critical current density versus external magnetic field at measurement temperature of 77 K to compare sintered powder YBCO tape-shaped wire with melt-processed YBCO tape-shaped wire. Source: Ref 21

These recent melt-processing results present highly encouraging data, indicating that large transport currents can in fact be realized for oxide-base conductors. Despite experiments related to flux flow and predicted poor pinning at 77 K, the melt-processing approach produces elongated grains with minimum high-angle boundaries that provide the ability to support high critical current density at significant magnetic field level (Ref 23). Further work on the melt-processing approach is being pursued at various institutions with the prospect of producing long lengths of oxide super-conductor suitable for numerous applications.

Preparation and Characterization of Pure Metals

G.T. Murray, Materials Engineering Department, California Polytechnic State University; T.A. Lograsso, Ames Laboratory, Iowa State University

Introduction

AS A RESULT of the constant quest for the true values of physical and chemical properties of metals, there has been continual improvement in the purity levels attainable and in the accuracy and capability of techniques for measuring these levels. Therefore, the property values reported for pure metals in this section of the Handbook, which were determined at different times and in different laboratories, vary considerably in meaningfulness from one metal to another and from one property measurement to another.

The rapidly growing electronic microcircuit industry also has placed severe demands on metal suppliers to provide metals of the highest reproducible purity attainable. Trace impurity elements in concentrations below 1 ppm can prevent proper functioning of certain electronic devices.

The need for ultrapure metals for both the measurement of physical and chemical properties and the electronic microcircuit industry poses two important problems: how to obtain such purity and how best to measure levels of trace impurity elements

Preparation Methods

Metal of the type commonly referred to as commercial-purity is normally used as the starting material in ultrapurification operations. Depending on the metal in question, commercial purity usually means a purity between 99.0 and 99.95%. Commercial-purity metal can be prepared by a variety of processes, of which such electrolytic processes as electrowinning and electrorefining are among the most common. In both of these processes, metal is deposited by electroplating from a bath. In electrowinning, the starting material usually is in the form of a concentrated ore or compound; in electrorefining, it is in metallic form. Many different types of baths are employed. For titanium and vanadium, fused salt baths are used, whereas chromium sometimes is produced by electrolysis of an aqueous solution of chromium-alum or chromic acid. For applications such as semiconductors, material produced by electrolytic processes is of insufficient purity and must be subsequently ultrapurified by one of the methods described below.

Fractional crystallization is a liquid-phase method that relies on differences in solubility in a liquid solvent among the various solid phases present in the impure metal. In this process, the metal to be purified is dissolved in a hot, often organic, solvent. The solvent selected is such that the metal is much more soluble at higher temperatures but that impurities are fairly soluble even at lower temperatures. On subsequent cooling of the solution, then, the pure metal precipitates out of solution, whereas most of the impurities remain. This process can be repeated many times, using fresh solvent each time. Gallium has been purified to the 99.9999% level using this method. This purity is required for the manufacture of semiconducting gallium arsenide, which is used in light-emitting diodes and as substrates for high-speed digital and monolithic microwave integrated circuits. Additional information is available in the article "Gallium and Gallium Compounds" in this Volume.

Fractional crystallization can also be used to produce ultrapure silver, gold, palladium, and platinum. In some instances, the metal being refined is precipitated and impurities are left in the solvent (as described above); in others, the impurities are precipitated (as compounds). Maximum purity in these metals, however, is obtained by zone refining following fractional crystallization.

Zone refining, also a liquid-phase technique, is probably the most widely used of all preparation methods. The classic zone refining experiments by Pfann (Ref 1) led to the production of germanium sufficiently pure to be used in the development of the first transistor.

In zone refining, a molten zone is made to move slowly from one end of a bar of impure metal to the other. During this zone pass, impurities are redistributed because of differences between the solubility limits of impurity elements (limiting impurity concentrations) in the liquid phase of the metal and the corresponding limits in the solid phase. Under equilibrium conditions, the resulting distribution is measured by the coefficient K_0, which is defined as follows:

$$K_o = \frac{C_s}{C_1} \qquad \textbf{(Eq 1)}$$

where C_s is the impurity concentration in the just-freezing solid phase and C_1 is the impurity concentration in the liquid phase. In practically all instances of freezing, equilibrium is not attained. Therefore, it is more appropriate to use an effective distribution coefficient, K_e, which is a function of freezing velocity, impurity diffusion, and thickness of the diffusion layer, as well as the ratio C_s/C_1. When, as in most instances, K_e is less than 1, and when there is slow movement

of the zone (for example, 10 mm/h or 0.39 in./h), the impurity concentration in the solid phase, C_s, at distance x from the starting end after a single pass of a liquid zone of length l, is as follows:

$$\frac{C_s}{C_0} = 1 - (1 - K_c)\exp\left[-\frac{K_e x}{l}\right] \qquad \textbf{(Eq 2)}$$

where C_0 is the initial concentration in the liquid phase. Additional passes of the zone in the same direction cause further concentration of impurities at one end of the bar. After many zone passes, this end is removed and discarded.

Metals and semiconductors were first zone refined by placing a bar of the material in a long boat-type crucible. Later to be introduced was the floating-zone technique (Ref 2), in which the metal is suspended in a vertical position and the molten zone is held in place by its own surface tension. Heat sources commonly used for this technique include an electron beam and an induction coil. Although the diameter of the bar is limited to approximately 15 mm (0.59 in.) in the floating zone technique, this method has a distinct advantage in that the material being refined is not contacted by a crucible and thus not contaminated by a crucible reaction. This is particularly advantageous for high-melting-temperature reactive metals such as titanium, zirconium, niobium, tantalum, vanadium, tungsten, and molybdenum. By contrast, metals such as gold, silver, copper, aluminum, zinc, lead, tin, and bismuth, which melt below about 1200 °C (2190 °F) and are less reactive, are usually zone refined in a boat. However, silicon crystals as large as 150 mm (6 in.) in diameter have been made by the floating zone method (Ref 3).

Vacuum Melting. Zone refining of materials often is conducted in a dynamic vacuum in order to enhance the degree of purification. However, many metals--particularly those with high melting points--can be purified to a significant degree by the vacuum melting process alone. Although vacuum melting may not produce the degree of purity attainable with zone refining, it is less expensive and yields material of sufficient purity for a wide variety of applications.

In vacuum melting, purification occurs by degassing--that is, removal of oxygen, nitrogen, and hydrogen, as well as CO or CO_2 formed by side reactions of oxygen with carbon--and by vacuum distillation of high-vapor-pressure impurity elements. Degassing takes place because the solubility of gaseous elements in the liquid decreases when the partial pressure of the same elements in the surrounding gaseous medium is decreased. This was experimentally verified for partial pressures of about 10 to 100 kPa (75 to 750 mm Hg) in the early experiments of Sieverts, which led to the well-known relationship:

$$S a \sqrt{P} \qquad \textbf{(Eq 3)}$$

where S is the solubility of a gas in the liquid phase and P is the partial pressure of the same gas in the surrounding medium.

This purification process is dependent on:

- Ability of the vacuum system to maintain a sufficiently low gas partial pressure near the molten surface
- Diffusion of gas atoms through the liquid to the surface
- Presence or absence of any stirring action that might enhance transport of gas atoms in the liquid phase
- Composition of the starting material

Vacuum melting can result in a purification process based on preferential evaporation of solute. The degree of purification is dependent on the ratio of the vapor pressure of the solute to that of the solvent. For a high degree of purification, the solute vapor pressure must be high relative to solute partial pressure in the gaseous medium in the immediate vicinity of the molten surface. As the solute concentration at the liquid/vapor interface diminishes, a concentration gradient is set up within the liquid. At this time, which may be very early in the melting operation, material transport in the liquid phase becomes the rate-controlling process. Thus, provided that vapor pressures are favorable and the pumping speed of the vacuum system is sufficient to maintain a low partial pressure of the solute element, purification should proceed at a rate that depends on the diffusivity of the solute in the liquid.

Distillation. Like vacuum-melting distillation, straight distillation (in which heated material changes from solid to liquid to vapor) is an important vapor-phase purification process. If the distillation is conducted under conditions of near-equilibrium between the liquid and vapor phases, impurity elements will concentrate in either the liquid phase or the vapor phase. The vapor or the liquid will then be a material of higher purity than that of the starting material. The most common distillation method is fractional distillation, in which the metal is repeatedly vaporized and condensed to liquid on a series of plates placed in a vertical column. A high reflux ratio (the ratio of the amount of liquid returning to the column from the condenser to the amount of vapor removed to the condenser) is desirable in this method. Some metals, however, can be purified in a single stage by simply condensing all the vapor produced by the still; this process has been used for alkali metals such as barium, calcium, lithium, and sodium (Ref 4). Distilled magnesium is further purified by zone refinement.

A variation of straight distillation is sublimation, in which the metal passes directly from the solid phase to the vapor phase. Only metals that have high vapor pressure when in the solid state are suited to this process. Such a metal usually has a higher vapor pressure than most impurity metals, so that impurities are left to concentrate in the remaining solid while the vapor is condensed to form a higher-purity metal.

Chemical Vapor Deposition. In purification by chemical vapor deposition (CVD), the starting material is reacted to form a gaseous compound, and that compound is subsequently decomposed in the vapor state. The metal vapor then is condensed to form a solid higher in purity than the starting material.

One of the more popular of the chemical vapor deposition processes is the iodide process, which has been used extensively to purify titanium, zirconium, and chromium (Ref 5). For each of these metals, the starting charge of metal is reacted to form a volatile metal-iodide compound, which in turn is thermally decomposed to liberate iodine vapor. The pure metal is allowed to condense onto a suitably heated substrate (glass tubes and wires of the base metal have been used), while the iodine returns to the metal charge to form more iodide compound. Hence, the iodine acts as a carrier of the metal, from the charge to the substrate.

In this process, some impurities are almost always carried over to the vapor phase along with the metal being purified. However, if a proper temperature is maintained, oxygen, nitrogen, hydrogen, and carbon, as well as many metallic impurities, will not be carried over. Typical purities obtained are about 99.96% for titanium, 99.98% for zirconium (plus hafnium, which is present at about the 200-ppm level), and 99.995% for chromium. In all cases, the starting metal has a purity of about 99.9%. Chromium has been purified to its highest state to date by this method. Only iron is carried over with these metals to a significant extent. Thus, if a low-iron starting metal is used, the condensed vapor will approach a purity level of 99.999%.

Other metals that have been purified by chemical vapor deposition include hafnium, thorium, vanadium, niobium, tantalum, molybdenum, and many less commercially important metals (Ref 5).

Solid State Refining Techniques. Solid state refining techniques have been used to prepare some of the purest metals in the world (Ref 6) for applications that require extreme purity. These methods rely on diffusion of impurities in the solid state, require long times at high temperatures, and are usually limited to small quantities of material (<100 g, or 0.20 lb). Furthermore, purification is restricted to those impurities that have high mobilities in the host metal, most notably carbon, nitrogen, oxygen, and hydrogen. Purification therefore requires starting materials that are relatively pure in nondiffusing elements. The most widely used techniques are external gettering, solid-state vacuum degassing, and electrotransport purification.

External gettering is the removal of impurities by reaction with chemically active elements through surface contact. The decarburizing of steel is a common example in which carbon can be removed by a hydrogen atmosphere to levels as low as 0.02 ppm. Hydrogen, oxygen, and nitrogen levels can be reduced to the parts-per-million range through heat treatment with materials that have greater affinity for the impurities than does the base metal. These materials include titanium, zirconium, yttrium, and liquid calcium.

Solid-State Vacuum Degassing. Reduction of interstitial levels can also be accomplished through vacuum degassing, which is a process similar to vacuum melting. This process can result in lower interstitial content because of the lower solubility of impurities in the solid than in the liquid state in equilibrium with the surrounding environment.

Electrotransport purification uses electricity to move impurities out of the metal. A direct current of 10 to 20 MA/m^2 (6.5 to 13 $kA/in.^2$) is applied to the metal (heating it to 80% of its melting point) and, depending on the interaction with the direct

current, an impurity will migrate toward one end or the other. The process was first used to purity zirconium metal and metals in the rare earth and actinide series.

Characterization of Purity

The traditional system of describing metal purity is based on measuring the total impurity-element content and subtracting this number from 100%. The result is reported in terms of number of nines--for example, five nines indicate a purity of 99.999% or total impurity content of 10 ppm. In order to characterize the purity to five nines, all impurity elements must be measurable to at least 100 to 200 ppb. Qualification of higher metal purity levels requires even greater measurement sensitivity. In many analyses, certain elements are not measured, and often the method employed is not sensitive enough to detect impurity levels near the low end of the parts-per-million range, let alone parts-per-billion. For many applications, this system is adequate. However, unless the method of measurement and its sensitivity are reported, the system is meaningless and unacceptable for some technical fields.

Trace Element Analysis. A number of analytical techniques are available for trace element detection. These techniques, which are described in detail in *Materials Characterization,* Volume 10 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,* generally employ one of the following methods for elemental identification.

- *Emission spectroscopy,* for simultaneous determination of metallic elements in the parts-per-million range and greater
- *Mass spectroscopy,* for determination of metallic elements in the parts-per-billion range. The analytical results are as accurate as the reference standard used
- *Neutron activation,* for determination of metallic elements, and particularly oxygen, in the parts-per-million range
- *Atomic absorption,* for sequential determination of metallic elements in the parts-per-billion range
- *Vacuum or inert gas fusion,* for determination of oxygen, hydrogen, and nitrogen in the parts-per-million range
- *Combustion technique for carbon,* sensitive in the parts-per-million range
- *Inductively coupled plasma* (ICP), for multielement qualitative and quantitative analysis of over 70 elements in the parts-per-billion to parts-per-million range

Emission spectroscopy is the most common analytical method and normally is used for detecting trace elements in concentrations of 10 to 1000 ppm. It is relatively inexpensive and yields results for most metallic elements in one analysis.

Mass spectroscopy is more sensitive (and more expensive) than emission spectroscopy and can easily detect impurity levels as low as 0.01 ppm. However, accuracy depends on the standards used, and the technique is not accurate above the 50- to 100- ppm level for some elements. Generally, emission spectroscopy is the best method for verifying purity at the five nines level and for obtaining information on all residual elements in the sample.

Neutron activation analysis can be more sensitive than mass spectroscopy but cannot detect many elements because of their inherent radioactive characteristics. It is an expensive method, but for some elements that are difficult to quantify, it can be extremely sensitive and accurate.

Atomic absorption analysis is excellent for concentrations of 0.1 to 10 ppm, when only a few elements are present. However, the specific elements being sought must be known, which generally requires emission spectroscopic analysis as a first step.

The combustion technique is commonly used for determining the carbon and sulfide content of metals. The sample is combusted with oxygen, and the resulting CO_2 or SO_2 are measured by infrared radiation (IR) absorption. The absorption of the IR signal is proportional to the CO_2 concentration.

In vacuum fusion, the sample is dissolved in a liquid platinum bath contained in a graphite crucible. Dissolved hydrogen and nitrogen are liberated as gases and the dissolved oxygen is reacted with carbon from the crucible to form CO gas. The partial pressure of each gas and the total pressure is measured and the level of each impurity in the original sample is determined.

In the ICP methods a metal sample is dissolved, for example, in an acid solution, and then injected into an argon plasma (at about 8000 K). Free atoms and ions are electronically excited to a higher energy state. When they return to a more stable state (within nanoseconds), the ultraviolet radiation emitted is measured in terms of both wavelength and intensity by a suitable spectrometer. An alternate method is to use the ionized sample as a source for a traditional quadrupole mass spectrometer.

All factors considered, mass spectroscopy is the preferred method for measuring trace elements in ultrahigh-purity metals. Several new mass spectroscopy techniques have recently been developed and represent the state of the art in analytical measurement techniques: glow discharge mass spectroscopy (GDMS), inductively coupled plasma mass spectroscopy (ICPMS), and laser ionization mass spectroscopy (LIMS). The GDMS and ICPMS techniques are bulk sample analyses and have detection limits in the range of 1 to 10 ppb, while LIMS provides surface analysis of sizes from 0.5 to 5 μm (20 to 200 μin.) with detection limits of 0.1 to 1 ppm. The main advantage of LIMS is that it places relatively few limitations on the material to be analyzed or sample shape. GDMS requires an electrically conductive or semiconducting material, and ICPMS samples must be dissolved. These techniques are capable of providing a quantitative survey of all elements, although, for the gaseous elements and carbon, residual gases and/or surface contamination may yield erroneous analyses.

In summary, the only way of describing purity that is both accurate and meaningful is to state the entire list of possible impurities, the amounts detected, and the limits of detection applicable to the specific analytical procedure used.

Resistance-Ratio Test. The resistance to passage of electrons through a sample of high-purity metal, particularly at low temperatures, is extremely sensitive to the amount of trace elements present in the sample. This fact gives rise to the resistance-ratio test, which is a very sensitive qualitative method of measuring purities of 99.999% and higher. This test is valuable not only because of its sensitivity but also because the measurement of electrical resistance is relatively simple.

Making a resistivity measurement at a single low temperature would require very accurate dimensional measurements. To avoid this requirement, resistance measurements are made both at the low temperature and at room temperature, and the ratio of the room-temperature value to the low-temperature value is reported. Unless otherwise stated, it can be assumed that the low-temperature measurement was made at liquid helium temperature (4.2 K).

The electrical resistivity of a metal can be conveniently divided into three parts:

$$\rho_T = \rho_{th} + \rho_d + \rho_i \qquad \textbf{(Eq 4)}$$

where ρ_T is total resistivity, ρ_{th} is resistivity due to thermal vibrations of the lattice, ρ_d is resistivity due to lattice imperfections (consisting primarily of vacancies, dislocations, and grain boundaries) and ρ_i is resistivity due to impurity atoms. Variation of ρ_T with temperature in terms of the components ρ_{th} and $\rho_d + \rho_i$ is depicted in Fig. 1. The sum $\rho_d + \rho_i$ is essentially temperature independent, whereas ρ_{th} is strongly temperature dependent ($\rho_{th} \alpha T^5$), approaching zero at absolute zero temperature. Thus, resistivity near absolute zero affords a measure of $\rho_d + \rho_i$.

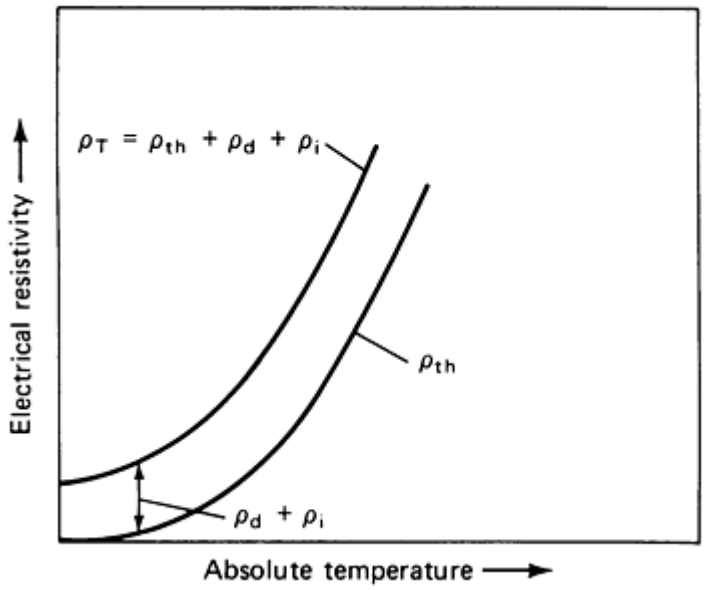

Fig. 1 Idealized graph of the components of total electrical resistivity of a metal as the temperature approaches absolute zero

Point defects (vacancies) contribute to resistivity to about the same extent as impurity atoms. However, well-annealed metals contain far fewer point defects than do impurity atoms. Dislocations of a typical density of 10^{11} per m^2 contribute an insignificant amount to the resistance ratio. In the highest-purity metals obtained to date (impurity concentrations of 10^{-5} to 10^{-6} at.%), the contribution of ρ_d is still small compared with that of ρ_i. Total resistivity near 0 K, therefore, is a good measure of the impurity contribution.

For several reasons, caution should be exercised in using the resistance ratio as a characterization of purity. Most important is the fact that in resistance-ratio testing the impurity element in question is not determined (different impurity elements have vastly different effects on ρ_i). In addition, because only impurity atoms in solid solution are effective electron-scattering centers, nothing is learned about the impurity content in precipitate (compound) form. Finally, even for impurity atoms in solid solution, the resistance ratio is a sensitive measure of purity only when the impurity level is about 100 ppm or less. This is illustrated in Fig. 2, which is an estimate of variation in resistance ratio with concentration of interstitial atoms (O_2, N_2, and C) in refractory metals. This graph shows that the impurity level can be reduced from 500 to 250 ppm without appreciably affecting the ratio, whereas a reduction of 5 to 2.5 ppm has a marked effect.

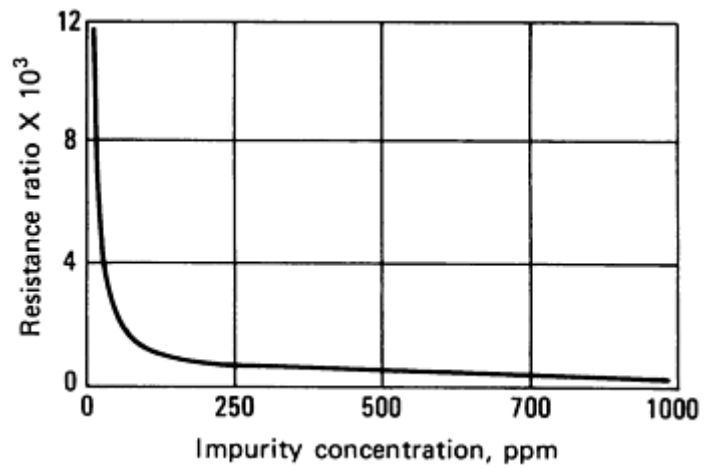

Fig. 2 Effect of interstitial impurity-atom concentration on resistance ratio of refractory metals

Resistance ratios of zone-refined metals are listed in Table 1. Their corresponding chemical compositions, as measured by mass spectroscopy for metallic elements and Leco combustion method for carbon, oxygen, nitrogen, and hydrogen are listed in Table 2. Ratios higher than those shown in Table 1, and ratios for other metals, have been reported (Ref 7); however, they were not accompanied by chemical analyses. In fact, some of the ratios were so large that the impurity concentrations they indicated were too low to be detected by methods currently available.

See the section "Properties of the Transplutonium Actinide Metals (Am-Fm)" in this article.

Antimony (Sb)

Compiled by S.C. Carapella, Jr., ASARCO Inc.; Reviewed for this Volume by Douglas Hayduk, ASARCO Inc.

Antimony is used as an alloying element in lead alloys (for battery grids, printers' type, solder, bearings, cable sheathing, and ammunition) and in tin alloys (such as pewter and costume jewelry alloys). Trace quantities are added to copper-base alloys, to prevent dezincification; to ductile iron (in the amount of 50 ppm, preferably with some cerium added), to assist in forming nodular graphite; and to gray iron (in the amount of 0.05%), the antimony acts as a powerful pearlite former. In the form of Sb_2O_3, antimony is used in enamels, glass, pigments, catalysts, and flame retardants. Antimony is used as a component of III-V semiconductors such as InSb, AlSb, and GaSb, and as an alloying ingredient in thermoelectric alloys.

Chemical Composition

Composition limits. See Table 3.

Table 3 Nominal compositions and uses of antimony alloys

Uses	Composition, %			
	Sb	Sn	Pb	Other
Type metal	4-23	17-3	bal	0-2 Cu
Battery grids	2.5-5	0.25-0.50	bal	0.25-0.5 Sn
Bearing metal	4-15	89-0.9	bal	1-3 As, 0.5-8 Cu
Cable covering	1-6	. . .	bal	. . .
Sheet and pipe	2-6	. . .	bal	. . .

Bullets, shrapnel	0.5-12	0.25-1.0	bal	

Structure

Crystal structure. Hexagonal (rhombohedral equivalent); a = 0.4307 nm, c = 1.1273 nm

Mass Characteristics

Atomic weight. 121.75

Density. 6.697 g/cm^3 at 26 °C

Thermal Properties

Melting point. 630.7 °C

Boiling point. 1587 °C

Coefficient of linear thermal expansion. 8 to 11 μm/m · K at 20 °C

Specific heat. 0.207 kJ/kg · K at 25 °C

Latent heat of fusion. 163.17 kJ/kg

Latent heat of vaporization. 1602 kJ/kg

Thermal conductivity. 25.9 W/m · K

Electrical Properties

Electrical resistivity. 370 nΩ · m at 0 °C

Magnetic Properties

Magnetic susceptibility. Volume: -10.2 × 10^{-6} mks

Optical Properties

Spectral reflectance. 70% for λ= 58.9 μm

Chemical Properties

Resistance to specific corroding agents:

Corroding agent	**Resistance**
Air	Moderate general attack when air is moist and light is present
Alkalis and alkali salts	General attack
Ammonia	Resistant
Aqua regia	Severe general attack
Carbon dioxide	Resistant

Chlorine	Severe general attack
Hydrochloric acid	Moderate attack in presence of air
Hydrofluoric acid	Resistant
Nitric acid	Severe general attack
Sulfuric acid	Severe general attack by warm concentrated acid; resistant to cold or dilute acid

Mechanical Properties

Tensile strength. 11.40 MPa

Hardness. 30 to 58 HB

Elastic modulus. Tension, 77.759 GPa; shear, 19 GPa

Arsenic (As)

Compiled by S.C. Carapella, Jr., ASARCO Inc.; Reviewed for this Volume by Douglas Hayduk, ASARCO Inc.

In quantities of 0.5 to 2%, arsenic improves the sphericity of lead shot. Small percentages are added to lead alloys for battery grids and cable sheathing to improve their hardness. In amounts up to 3%, arsenic improves the properties of lead-base bearing alloys. Minor additions improve the corrosion resistance and increase the recrystallization temperature of copper and stabilize pearlite in ductile and gray cast irons.

Phosphorized deoxidized arsenical copper (alloy 142) is used for locomotive fireboxes, staybolts, straps, and plates, and for heat exchangers and condenser tubes. Copper-arsenical leaded Muntz metal (alloy 366), Admiralty brass (alloy 443), naval brass (alloy 465), and aluminum brass (alloy 687) all find use in condensers, evaporators, ferrules, and heat exchanger and distillation tubes. The compositions of these alloys are listed in Table 4. Arsenic is a component of III-V semiconductors such as GaAs, GaAsP, and InAs.

Table 4 Nominal composition of selected arsenical copper alloys

Alloy number	Composition, %						
	Cu	As	Pb	Fe	Sn	Zn	Other
142	99.4	0.015-0.50	. . .	. . .	. . .	. . .	0.015-0.040 P
366	58-61	0.02-0.10	0.40-0.9	0.15	0.25	bal	. . .
443	70-73	0.02-0.10	0.07	0.06	0.9-1.2	bal	. . .
465	59-62	0.02-0.10	0.20	0.10	0.5-1.0	bal	. . .

687	76-79	0.02-0.10	0.07	0.06	. . .	bal	1.8-2.5 Al

Arsenic is normally available in the α-metallic and β-amorphous form. Other allotropes of arsenic have been reported, but supportive evidence is meager.

The toxicity of arsenic is related to its chemical state and can be extremely high. The degree of toxicity of arsenic in the elemental state is relatively low. Metallic arsenic on exposure to the atmosphere will develop an oxide coating, and, for this reason, care must be taken not to ingest or handle it. Inhalation of dust and fumes is to be avoided. Controlled exhaust ventilation of work areas is required to comply with the OSHA standard of 10 μg of arsenic per cubic meter of air.

Structure

Berkelium (Bk)

See the section "Properties of the Transplutonium Actinide Metals (Am-Fm)" in this article.

Beryllium (Be)

Revised by J.M. Marder and A.J. Stonehouse, Brush Wellman Inc.

Unalloyed beryllium is used in weapons, spacecraft, nuclear reactor reflector segments, neutron sources, windows for x-ray tubes and radiation detection devices, rocket nozzles, aircraft brake discs, precision instruments, and mirrors.

Beryllium is used as an alloying addition to copper and nickel to produce an age-hardening alloy used for springs, electrical contacts, spot welding electrodes, and non-sparking tools. Beryllium is also added to aluminum and magnesium to achieve grain refinement and oxidation resistance.

Inhalation of respirable beryllium and its compounds should be avoided. Users should comply with the occupational safety and health standards applicable to beryllium in Title 29, Part 1910 of the Code of Federal Regulations.

Structure

Crystal structure. α phase, close-packed hexagonal; a = 0.22858 nm, c = 0.35842 nm at room temperature. βphase, body-centered cubic; a = 0.255 nm at 1270 °C

Slip planes. Primary: (0002), $(10\bar{1}0)$. Secondary: $(10\bar{1}1)$

Nuclear Properties

Thermal neutron cross section. 0.01 b

Chemical Properties

General corrosion behavior. Beryllium, a highly reactive metal, forms stable compounds with most other elements. It has excellent corrosion resistance at room temperature (except to certain acids and alkalies) because of a thin protective oxide coating.

Resistance to specific corroding agents. Beryllium reacts appreciably with oxygen and nitrogen above 760 °C. Impure beryllium containing carbide or chloride reacts with moist air at room temperature. Beryllium does not react with hydrogen at any temperature; it reacts with fluorine at room temperature and with Cl, B, I, HCl, HF, and CO_2 at elevated temperatures. Beryllium has excellent resistance to pure water at temperatures up to 300 °C if carbide and chloride are absent and if grain size is fine. Beryllium is attacked by dilute HF, HCl, H_2SO_4, and HNO_3 at room temperature.

Fabrication Characteristics

Machinability. Powder metallurgy material is readily machined to close tolerances. In machining operations, carbide tools are used. Chip formation is similar to that of cast iron. All machining, especially careless grinding, produces a damaged surface layer that must be removed by etching a minimum of 0.05 mm per surface for critical highly stressed applications.

Recrystallization temperature. 725 to 900 °C, depending on amount of cold work and annealing time

Hot-working temperature. 800 to 1100 °C

Mechanical Properties

Tensile properties. Tensile properties, especially elongation, depend strongly on preferred orientation and grain size. Beryllium mill products are produced chiefly by powder metallurgy using different consolidation procedures. Wrought products are produced from powder metallurgy input materials. Extreme anisotropy in elongation occurs in wrought material; therefore, uniaxial tensile results are valueless as indications of behavior under conditions of complex stress. Tensile properties of different wrought forms can vary extremely, with the greatest uniformity occurring for vacuum hot-pressed and hot isostatically pressed powder. See Table 5 for some representative values.

Table 5 Tensile properties of beryllium

Temperature, °C	Tensile strength, MPa	Yield strength at 0.2% offset, MPa	Elongation, %
Vacuum hot-pressed block, grade S-200 F			
Room temperature	380-413[(a)]	262-269	2-5

Bismuth (Bi)

Compiled by S.C. Carapella, Jr., ASARCO Inc.; Reviewed for this Volume by Douglas Hayduk, ASARCO Inc.

Bismuth is used extensively in the production of fusible alloys (low-melting-point alloys) as a carbide stabilizer in the manufacture of malleable iron, and as an additive to low-carbon steel and aluminum to improve machinability. Compounds of bismuth are used for catalysts, in pharmaceutical and for semiconductor applications. Bismuth has shown potential to be an effective ingredient in the 123 copper oxide superconductive materials. However, it is not yet commercially available in this form.

Boron (B)

Compiled by James C. Schaefer, JCS Consulting

Elemental boron can be prepared by several methods. The purest forms are black and are prepared by the reduction of boron halides on a hot tungsten wire. Electrolytic boron, prepared by molten salt electrolysis, is a black powder of 40 to 325 mesh. Electrolytic boron has a purity of 99% and above. Magnesium-reduced boron, which is prepared by the reduction of boric oxide (B_2O_3) with magnesium, is a light brown powder in the purity range of 95 to 97%.

Boron formed on hot tungsten wire is used for weight reduction and reinforcement of metals and plastics. Electrolytic boron powder is used for the preparation of borides for the deoxidation of alloys.

Boron compounds are used for medicinal and cleaning purposes. Traces of boron are beneficial to plant growth, but large concentrations are toxic. Boron compounds are added to aluminum alloys to improve electrical and thermal conductivity and for microstructure grain refining. Boron compounds have been used in rocket fuels and as diamond substitutes. Isotropic B-10 and its compounds are used for neutron absorption.

Elemental boron is nontoxic. Boron in the form of fine dust will slowly oxidize and should be kept under an inert gas. The dust is abrasive, and personnel should be protected from the dust. Normal air filtration and facial mask procedures should be followed. Metallic borides require no handling or storage precautions. Special precautions must be taken with the boron halides. Boron halides are very sensitive to shock and can detonate easily. The halides are toxic and corrosive.

Structure

Crystal structure. Material prepared at about 800 °C and below: amorphous. Prepared between about 800 and 1100 °C: α phase, rhombohedral, $R\bar{3}m$; a = 0.506 nm, α= 58°4'; unit cell contains a single B_{12} icosahedron. Prepared between about 1100 and 1300 °C γ phase, tetragonal, $P4_2/nnm$; a = 0.875 nm, c = 0.506 nm; the 50 atoms per unit cell are distributed among four equivalent B_{12} icosahedrons of required symmetry 2/m and two tetrahedral positions 42m. Prepared above about 1300 °C: βphase, rhombohedral, $R\bar{3}m$; a = 1.012 nm, α= 65°28'; unit cell contains approximately 108 atoms. Values differ slightly according to investigator.

Dielectric constant. Approximately 12

Optical Properties

Color. Crystalline is black; amorphous is brown

Refractive index. 2.5 using mercury line (579 nm)

Nuclear Properties

Stable isotopes. B-10, atomic weight 10.01294, 19.9% abundant; B-11, atomic weight 11.00931, 80.1% abundant

Neutron absorption. B-10, 3850 b; B-11, 0.05 b; natural boron, 755 b

Unstable isotopes:

Isotope	Atomic weight	Half life, s	Particles emitted
^{8}B	. . .	0.78	β^+
^{9}B	9.01333	3×10^{-19}	P, (2α)
^{12}B	. . .	0.019	β^-
^{13}B	. . .	0.035	β^-

Chemical Properties

Effects of specific corroding agents. Reactivities and conditions for reaction of boron with several materials are:

- Fluorine, instantaneous at room temperature
- Chlorine, above 500 °C
- Bromine, above 600 °C
- Iodine, about 900 °C
- Hydrochloric acid, none
- Hydrofluoric acid, none
- Nitric acid (hot, concentrated), slow
- Oxygen, slight at room temperature, rapid above 1000 °C
- Hydrogen iodide, explosive
- Hydrogen, above 840 °C
- Nitrogen, bright red heat
- Sodium hydroxide, no reaction at room temperature, slow at 500 °C
- Boron nitride, none

- Metals, *Caution: above 900 °C, many metals react rapidly with boron, and the reactions are exothermic*

Mechanical Properties

Tensile properties. Tensile strength: 98.8% pure, amorphous, 1.6 to 2.4 MPa; fibers, 2.6 to 3.1 MPa

Compressive properties. Compressive strength: with B_2O_3 present, up to 0.5 MPa

Hardness. 99.9% crystalline: 3300 HK (with 100 g load), 9.3 moh

Elastic modulus. Tension: amorphous, 440 MPa

Cadmium (Cd)

Compiled by Hugh Morrow, Cadmium Council, Inc.

Cadmium is a relatively rare metal that is present in the crust of the earth at an average level of only 0.00005%, or 0.5 ppm. It is a soft and malleable silvery-white metal, and it is most often found in nature as the sulfide associated with zinc sulfide ores. Cadmium is, in fact, produced as a by-product of zinc-refining operations.

Metallic cadmium is used for corrosion-resistant coatings, mainly on iron and steel, but also on aluminum and magnesium. It is a minor but important alloying element in certain brazing and soldering alloys and in some copper-base alloys. Cadmium compounds (mainly cadmium oxide) are used in the manufacture of nickel-cadmium batteries; cadmium sulfides and organic cadmium salts are used as pigments or stabilizer additives to certain types of engineering plastics. At present, cadmium consumption in the western world can be roughly divided into these areas of application:

Use	**%**
Batteries	45
Coatings	16
Pigments	20
Stabilizers	14
Alloys and other	5

The appropriate ASTM specifications for cadmium products and processing are:

ASTM standard	Description
B 440	Standard specification for cadmium
B 201	Testing chromate coatings on zinc and cadmium surfaces
B 766	Electrodeposited coatings of cadmium
B 696	Coatings of cadmium mechanically deposited
B 635	Coatings of cadmium-tin mechanically deposited
B 699	Coatings of cadmium vacuum-deposited on iron and steel products

Cadmium fumes and dust can be toxic if inhaled in sufficient quantity. In September 1989, the Occupational Safety and Health Administration (OSHA) issued an interim standard, designated PUB 8-1.4A, that recommends a cadmium exposure level of no more than 50 μg/m^3, measured as an 8-h time-weighted average. Therefore, any occupational situation that generates cadmium fumes and/or dust should be well ventilated to remove these products. Cadmium compounds such as cadmium sulfide are equally regulated, but the solubility of these compounds is much less than that of other compounds such as cadmium chloride; therefore, they should pose much less of a health risk.

Structure

Crystal structure. Close-packed hexagonal, D^4_{6h} ($P6_3/mmc$); a = 0.29793 nm and c = 0.56181 nm at 26 °C

Chemical Properties

General corrosion behavior. The chemical properties of cadmium resemble those of zinc, especially under reducing conditions and in covalent compounds. In oxides, fluorides, and carbonates and under oxidizing conditions, cadmium may behave similarly to calcium. It also forms a relatively large number of complex ions with other ions such as ammonia, cyanide, and chloride. Cadmium is a fairly reactive metal. It dissolves slowly in dilute hydrochloric or sulfuric acids, but dissolves rapidly in hot dilute nitric acid. Other elements that react readily with cadmium metal when heated include the halogens, phosphorus, sulfur, selenium, and tellurium.

Unlike zinc, cadmium is not markedly amphoteric, and cadmium hydroxide is virtually insoluble in alkaline media. Like zinc, however, cadmium forms a protective oxide that reduces its corrosion rate in atmospheric service. Both metals exhibit low corrosion rates over the range from approximately pH 5 to 10. In more acid or more alkaline environments, their corrosion rates increase dramatically. Cadmium is preferred for marine or alkaline service, whereas zinc is often as good or better in heavy industrial exposures.

As a protective coating on steel and cast iron parts, cadmium offers corrosion protection in marine atmospheres, under alkaline conditions, and in damp indoor applications. Cadmium-plated steel fasteners resist galvanic attack when used with aluminum parts.

Mechanical Properties

Calcium (Ca)

Compiled by J.F. Smith, Ames Laboratory, U.S. Department of Energy, Iowa State University

Metallic calcium is used as a reducing agent in the preparation of thorium, zirconium, uranium, chromium, vanadium, and the rare earths. It is also used as a deoxider, decarburizer, or desulfurizer for various ferrous and nonferrous alloys. Calcium is used as an alloying or modifying agent for aluminum, beryllium, copper, lead, tin, and magnesium alloys. Other uses for calcium include getters for residual gases in high vacuums and vacuum tube applications, and reagents for

purification and scavenging of inert gases. Calcium reacts readily with atmospheric components, particularly water vapor, and is not inert to nitrogen. To avoid contamination, it must be handled in a dry inert-gas atmosphere or in a vacuum.

Structure

Crystal structure. α-phase, face-centered cubic, *cF*4 (*Fm*3*m*); a = 0.5588 nm at 26.6 °C. β-phase, body-centered cubic, *cI*2 (*Im*3*m*); a = 0.4480 nm at 467 °C. Minor amounts of hydrogen stabilize a hexagonal form, and a low-symmetry form of undetermined structure results from contamination by nitrogen and/or carbon.

Minimum interatomic distance. 0.3952 nm at 25 °C

Mass Characteristics

Atomic weight. 40.08

Density. Solid, 1.55 g/cm^3 at 25 °C; liquid, 1.37 g/cm^3 at 842 °C

Density versus temperature. Solid, $\Delta d/d_0 \cdot K = -66.9 \times 10^{-6}$ at 0 to 400 °C; liquid, $\Delta d/d_0 \cdot K = -221 \times 10^{-6}$ at 842 to 1382 °C

Volume change on freezing. 4.7% contraction

Volume change on phase transformation. β to α-phase, 0.04% contraction

Thermal Properties

Melting point. 842 °C at 1 atm; $\Delta T_m/\Delta P$ = 170 μK/Pa

Boiling point. 1495 °C

Phase transformation temperature. 443 °C; $\Delta T_{trans}/\Delta P$ = 33 μK/Pa

Coefficient of linear thermal expansion. α-phase; up to -267 °C, $\Delta l/l_0 \cdot K = 5 \times 10^{-11}\ T + 81 \times 10^{-12}\ T^3$, where T is in K; 1 μm/m · K at -253 °C; 3.3 μm/m · K at -243 °C; 14.16 μm/m · K at -198 °C; 22.15 μm/m · K at 10 °C; 22.3 μm/m · K (average) for 0 to 400 °C. βphase: 33.6 μm/m · K for 467 to 603 °C. Hall coefficient. -0.228 nV · m/A · T (independent of temperature from -193 to 27 °C)

Work function. Thermionic, 0.359 aJ; photoelectric, 0.46 aJ

Magnetic Properties

Magnetic susceptibility. Volume: 2.71×10^{-5} mks

Magnetic permeability. 1.0000271

Optical Properties

Color. A fresh clean surface is a lustrous silvery white but darkens upon exposure to the atmosphere.

Dielectric constant. Ellipsometry has been used to determine the real (ε_1) and imaginary (ε_2) parts of the complex dielectric constant as a function of vacuum wavelength (λ):

Wavelength (λ), nm	$-\varepsilon_1$	ε_2
1771.2	65.2	. . .
1549.8	51.8	11.7
1377.6	41.8	8.58
1239.8	34.2	7.08
1033.2	24.2	4.71
885.6	17.5	3.40
774.9	12.8	2.48
688.8	9.6	1.95
619.9	7.5	1.62
563.6	5.8	1.39
516.6	4.5	1.22
476.9	3.6	1.09
442.8	2.8	1.01
413.3	2.2	1.01
364.7	1.4	1.02
326.3	. . .	0.95

Reflectivity. At normal incidence (r), the refractive index (n) and adsorptive index (A) may be generated from these quantities through the following relations: $\varepsilon_2 = 2nK$; $\varepsilon_1 = n^2 + K^2$; $A = 4\pi K/\lambda$; $r = [(n - 1)^2 + K^2]/[(n + 1)^2 + K^2]$

Nuclear Properties

Stable isotopes:

Mass number	Abundance, %
40	96.97
42	0.64
43	0.145
44	2.06
46	0.0033
48	0.185

Unstable isotopes. Isotopes with mass numbers 37, 38, 39, 41, 45, 47, 49, and 50 have been produced. Number 45 has the longest half-life (180 days); it is used in tracer experiments.

Chemical Properties

General corrosion behavior. Extremely poor corrosion resistance

Fabrication Characteristics

Recrystallization temperature. Below 300 °C; even at room temperature, x-ray diffraction patterns show no broadening or distortion after extensive deformation.

Mechanical Properties

Tensile properties. Annealed: tensile strength, 48.0 MPa; yield strength, 13.7 MPa; elongation, 51 to 53%; reduction in area, 58 to 62%. As rolled: tensile strength, 115 MPa; yield strength, 84.8 MPa; elongation, 7%; reduction in area, 35%

Hardness. Annealed: 16 to 18 HB

Poisson's ratio. 0.31

Elastic modulus. Tension, 19.6 GPa; shear, 7.38 GPa; bulk, 15.2 GPa

Compressibility. For 0 to 3900 MPa, $\Delta V/V_0$ Pa = $-6.578 \times 10^{-5} + 7.732 \times 10^{-11} P - 4.9 \times 10^{-13} P^2$, where P is in MPa

Liquid surface tension. For 839 to 1000 °C, $\gamma = 0.472 - 10^{-4} T$, where T is in K and γ is in N/m

Cesium (Cs)

Compiled by John H. Madaus, Callery Chemical Company; Revised by Michael Stevens, Los Alamos National Laboratory

Cesium ignites immediately on contact with air if poured or sprayed, and it reacts explosively with water. Cesium may form peroxide compounds if allowed to oxidize in the absence of water normally present in atmosphere. The resulting peroxides may be shock sensitive with easily reduced compounds in the same manner that potassium superoxide is shock sensitive with mineral oil. Cesium metal must be contained under vacuum, inert gas, or anhydrous liquid hydrocarbons and protected from oxygen or air exposure. Safety and handling information is available from suppliers.

Because it produces electromagnetic energy that is accurate and stable in frequency, cesium is used in electronic devices and atomic clocks, providing accuracy of 5 s in 10 generations.

Structure

Crystal structure. Body-centered cubic; *Im*3*m*, *cI*2; a = 0.613 nm at -10 °C

Mass Characteristics

Atomic weight. 132.9054

Density. 1.903 g/cm^3 at 0 °C, 1.892 g/cm^3 at 18 °C (Ref 17), 1.827 g/cm^3 at 40 °C (liquid) (Ref 18)

Chromium (Cr)

Compiled by H.C. Aufderhaar, Union Carbide Corporation; Revised by F.H. Perfect, Reading Alloys, Inc.

Elemental chromium (also known as chrome metal or electrolytic chromium) is finding use in commercial quantities as an alloying element in titanium alloys. Earlier chromium alloys contained aluminum and were produced directly from chromium-bearing master alloys (Ref 28, 29, 30). Nitrogen is believed to be the element most detrimental to ductility in chromium metal (Ref 30, 31, 32, 33, 34).

About 98% of the total U.S. consumption of chromium is used in the form of ferrochromium for the production of stainless steels and heat-resistant alloys. Total chromium consumption in the first five months of 1989 was 96,281 Mg (metric tons). This total was consumed in the following forms (Ref 35):

Raw material	Consumption, %
High-carbon ferrochrome	88
Low-carbon ferrochrome	7
Ferrochrome-silicon	3
Chromium metal	2

The 2% (1849 Mg) consumed in the form of chromium metal was used for the following products:

Product	Consumption, %
Superalloys	55
Welding rods	22
Aluminum alloys	19
Miscellaneous	4

Chromium controls the microstructure in aluminum and copper. Chromizing is an application that takes advantage of the excellent corrosion resistance of chromium; chrome plating is the most widely known chromizing application. Table 7 lists typical compositions obtained by two processes used to produce commercially pure chromium metal.

Table 7 Nominal compositions of commercially pure chromium metal produced by two processes

Process	Composition, %								
	Al	C	Cr	Fe	N	O	P	Si	S
Electrolytic	0.015	0.05	99.50	0.35	0.02	0.05	0.01	0.04	0.01

Structure

Crystal structure. Body-centered cubic, *cI*2 (*Im*3*m*); a = 0.28844 to 0.28848 nm at 20 °C (Ref 36, 37, 38). Above 1840 °C: face-centered cubic; a = 0.38 nm (Ref 36)

Mass Characteristics

Atomic weight. 51.996

Density. 7.19 g/cm^3 at 20 °C (Ref 37, 39)

Thermal Properties

Melting point. 1875 °C (Ref 37, 38, 39)

Boiling point. 2680 °C (Ref 37)

Phase transformation temperature. 1840 °C (Ref 36)

Coefficient of linear thermal expansion. 6.2 μm/m · K (Ref 37)

Specific heat. 0.4598 kJ/kg · K at 20 °C (Ref 37, 38)

Latent heat of vaporization. 6168 kJ/kg (Ref 37, 38)

Thermal conductivity. 67 W/m · K at 20 °C, 76 W/m · K at 426 °C, 67 W/m · K at 760 °C (Ref 36)

Vapor pressure. From Ref 36:

°C	Pa
965	3.2×10^{-4}
1093	2.8×10^{-3}
1197	2.7×10^{-2}

1288	2.4×10^{-1}
1875	9.9×10^{2}

Electrical Properties

Electrical conductivity. 13% IACS at 20 °C (Ref 37, 38, 39)

Electrical resistivity. From Ref 36:

°C	nΩ · m
-260	5
20	130
152	180
200	200
407	310
600	400
652	470
1000	660

Temperature coefficient of electrical resistivity. At 0 °C, 0.03 nΩ · m per K (Ref 36)

Electrochemical equivalent. Valence 3, 0.17965 mg/C; valence 6, 0.08983 mg/C (Ref 38)

Electrolytic solution potential. For valence 3, 0.5 V versus hydrogen electrode (Ref 40)

Hydrogen overvoltage. 0.38 V (Ref 40)

Temperature of superconductivity. 0.08 K (Ref 38)

Work function. 0.7337 aJ (Ref 36)

Magnetic Properties

Magnetic susceptibility. Volume: 4.5×10^{-5} mks (Ref 37)

Optical Properties

Color. Steel gray

Reflectance. 67% at λ= 300 nm; 63% at λ= 1000 nm; 70% at λ= 500 nm; 88% at λ= 4000 nm (Ref 37)

Refractive index. 1.64 to 3.28 for λ from 257 to 608 nm (Ref 37)

Absorptive index. 3.69 to 4.30 for λfrom 257 to 608 nm (Ref 41)

Nuclear Properties

Stable isotopes. ^{50}Cr, 4.31% abundant; ^{52}Cr, 83.76% abundant; ^{53}Cr, 9.55% abundant; ^{54}Cr, 2.38% abundant (Ref 36)

Unstable isotopes. From Ref 36:

Isotope number	Half-life
48	23-24 h
49	41.7-41.9 min
51	27.5-27.9 days
55	3.52-3.6 min
56	5.9 min

Chemical Properties

Resistance to specific corroding agents. (A 10% solution at 12 °C was used unless otherwise noted.) Chromium is resistant to the following acids: acetic, aqua regia, benzoic (saturated), butyric, carbonic, citric, fatty, formic, hydrobromic, hydroiodic, lactic, nitric, oleic, oxalic, palmitic, phosphoric, picric, salicylic, stearic, and tartaric. Chromium is not resistant to hydrochloric acid or other halogen acids.

Chromium is resistant to the following agents: acetone, air, ethyl and methyl alcohol, higher alcohols, aluminum chloride, aluminum sulfate, ammonia, ammonium chloride, barium chloride, beer, benzyl chloride (saturated and 100%), calcium chloride, carbon dioxide, carbon disulfide, carbon tetrachloride (saturated and 100%), dry chlorine, chlorobenzene (saturated and 100%), chloroform, copper sulfate, ferric chloride, ferrous chloride, foodstuffs, formaldehyde, fruit products, glue, hydrogen sulfide (100%), magnesium chloride, milk, mineral oils, motor fuels, crude petroleum products, phenols, photographic solutions, printing ink, sodium carbonate, sodium chloride, sodium hydroxide, sodium sulfate, sugar, sulfur (100%), sulfur dioxide (100%), chlorinated water, distilled water, rainwater, zinc chloride, and zinc sulfate (Ref 36, 38, 42, 43)

Mechanical Properties

Tensile properties. Iodide chromium at room temperature, as-swaged: tensile strength, 413 MPa; 0.2% yield strength, 362 MPa; elongation, 44%; reduction in area, 78% (Ref 37, 44). Iodide chromium at room temperature, swaged and

recrystallized: tensile strength, 282 MPa; elongation, 0%; reduction in area, 0% (Ref 37, 44). Electrolytic chromium, see Table 8.

Table 8 Tensile properties of recrystallized, swaged, arc cast electrolytic chromium

Recrystallized at 1200 °C in hydrogen. Strain rate of testing, 0.017 m/m per min

Temperature, °C	Tensile strength, MPa	Proportional limit, MPa	Elongation in 25 mm, %	Reduction in area, %	Modulus of elasticity, GPa
20	83	. . .	0	0	248

Cobalt (Co)

Compiled by D.J. Maykuth, Metals, and Ceramics Information Center, Battelle Memorial Institute; Revised by M.J.H. Ruscoe, Sherritt Gordon Ltd.

Cobalt is used as an alloying element in:

- Permanent and soft magnetic materials
- High-temperature creep-resistant super-alloys
- Hardfacing and wear-resistant alloys
- High-speed steels, tool steels, and other steels
- Cobalt-base tool materials
- Electrical-resistant alloys
- High-temperature spring and bearing alloys
- Magnetostrictive alloys
- Special expansion and constant-modulus alloys

Structure

Crystal structure. α-phase, close-packed hexagonal, *hP*2 (*P*6$_3$/*mmc*); *a* = 0.25071 nm, *c* = 0.40686 nm. βphase, face-centered cubic, *cF*4 (*Fm3m*); *a* = 0.35441 nm

Minimum interatomic distance. βphase, 0.25061 nm

Mass Characteristics

Atomic weight. 58.9332

Density. At 20 °C: 8.832 g/cm^3 for α-phase; 8.80 g/m^3 for β-phase

Volume change on phase transformation. β-1 to α-phase (cooling), -0.3% (approximate)

Thermal Properties

Melting point. 1495 °C

Boiling point. 2900 °C (approximate)

Phase transformation temperature. β to α-phase (cooling), 417 °C; a transformation near 1120 °C has not been confirmed.

Coefficient of linear thermal expansion. 13.8 μm/m · K near room temperature; 14.2 μm/m · K at 200 °C; see also Fig. 5.

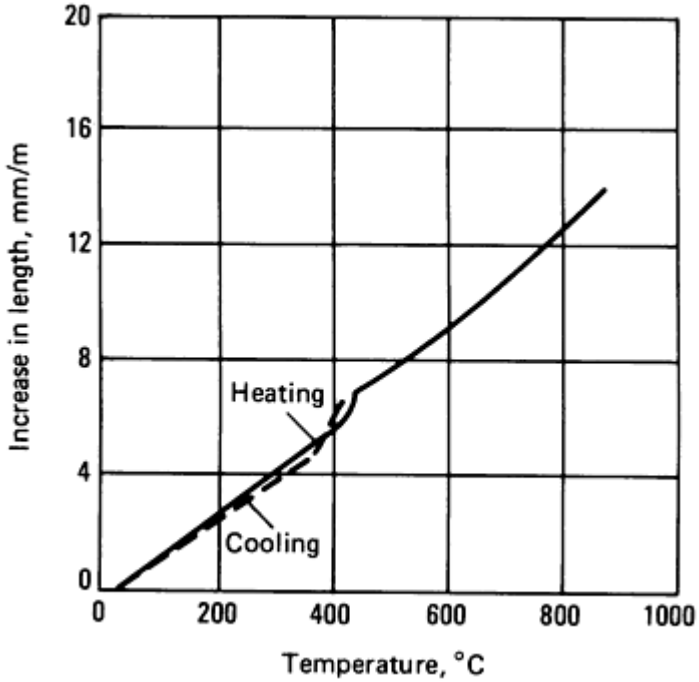

Fig. 5 Linear thermal expansion of cobalt (relative to 30 °C)

500	3.210
600	3.695
800	4.750
1000	5.959

Thermoelectric potential versus platinum. From Ref 46, 47:

°C	**mV**
-200	-0.19
-100	0.37
0	0
100	0.76
200	1.83
300	3.15

400	4.68
500	6.41
600	8.34
700	10.47
800	12.81
900	15.37
1000	18.16

Electrochemical equivalent. 0.3294 mg/C for Cu^{2+}; 0.6588 mg/C for Cu^{+}

Electrolytic solution potential. All versus standard hydrogen electrode (Ref 46): $Cu^{2+} + e^{-}$ € Cu^{+}, 0.158 V; $Cu^{2+} + 2e^{-}$ € Cu, 0.3402 V; $Cu^{+} + e^{-}$ € Cu^{+}, 0.522 V

Ionization potential. Cu(I), 7.724 eV; Cu(II), 20.29 eV; Cu(III), 36.83 eV (Ref 46)

Hydrogen overvoltage. In 1 *N* H_2SO_4. $\eta = a + b (\log i)$, where η is overvoltage in V, *i* is current density in A/cm^2, constant *a* is 0.80 V, and constant *b* is 0.115 V (Ref 51)

Hall effect. Hall voltage, -5.24×10^{-4} V at 0.30 to 0.8116 T; Hall coefficient, -5.5 mV · m/A · T (Ref 47)

Electron emission. Secondary electron emission: 1.3 max secondary electron yield; 600 eV primary electron energy for max yield; 200 eV for *E*(I) crossover; 1500 eV for *E*(II) crossover

Work function:

Work function, eV	**Conditions**	**Method of determination**
4.5	1160-1200 K	Thermionic
4.6	1350 K	Thermionic
4.4	1100-1300 K	Thermionic
4.76	<111>	Photoelectric

4.86	<111>	Photoelectric
5.61	<110>	Photoelectric
4.60	. . .	Contact potential
4.51	. . .	Contact potential

Source: Ref 47

Magnetic Properties

Magnetic susceptibility. Determined largely by the quantity of iron present as an impurity. If the copper is free from oxygen, the iron is present in solid solution and has a small effect. The presence of oxygen results in the precipitation of Fe_3O_4; in this form, iron has a greater effect on magnetic properties. The measurements below were probably made on oxygen-bearing coppers:

Temperature, °C	Volumetric, mks
18	-1.08×10^{-6}
1080	-0.97×10^{-6}
1090	-0.68×10^{-6}
-259 to -253	-1.22×10^{-6}

Optical Properties

Color. Reddish metallic (Ref 46)

Spectral reflection coefficient. For incandescent light, 0.63 (Ref 46)

Reflectance. Mirror coatings, see Table 15; calculated, see Table 16. Polished or electroplated surfaces (data are for polished surfaces at close-to-normal incidence) (Ref 47):

Wavelength, µm	Reflectance, %
0.25	25.9

0.30	25.3
0.35	27.5

		β^+, EC	1.677
^{66}Cu	5.10 ± 0.02 min	β^-	2.633
^{67}Cu	61.88 ± 0.11 h	β^-	0.576
^{68}Cu	30 s	β^-	4.6

(a) EC, electron capture

Chemical Properties

General corrosion behavior. Insoluble in hot and cold water (Ref 46)

Resistance to specific corroding agents. Soluble in HNO_3 and in hot H_2SO_4. Slightly soluble in HCl and NH_4OH (Ref 46)

Mechanical Properties

Tensile properties. Tensile strength: annealed, 209 MPa; cold drawn, 344 MPa (Ref 47); See also Fig. 11 and 13. Yield strength at 0.5% extension, under load; annealed, 33.3 MPa; cold drawn, 333.4 MPa (Ref 47). Elongation: annealed, 60%; cold drawn, 14% (Ref 47); see also Fig. 11. Reduction in area: annealed, 92%; cold drawn, 88% (Ref 47)

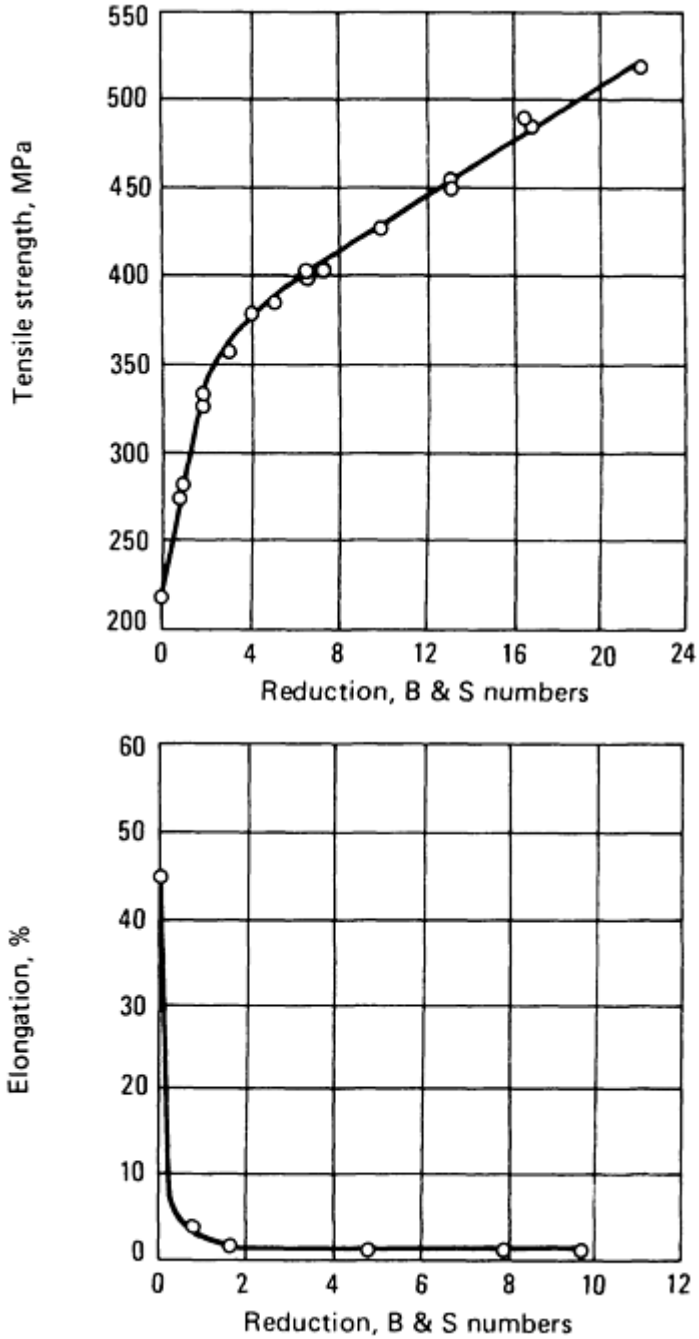

Fig. 13 Variation of tensile properties with amount of cold reduction for pure copper wire

Hardness. Cold drawn, 37 HRB

Poisson's ratio. 0.308 calculated from the elastic modulus; annealed, 0.343 (Ref 50); cold drawn, 0.364 (Ref 47)

Strain-hardening exponent. Annealed, 0.54 (Ref 48)

Elastic modulus:

Tension, GPa	Ref
128	47
112 (cold drawn)	47
125 (annealed)	48
129.8	50

Shear, GPa	Ref
46.8	47
46.4 (annealed)	48
48.3	50

Bulk, GPa	Ref
140	47
137.8	50

Elastic modulus along crystal axes. Tension: <100>, 68 GPa; <111>, 21 GPa. Shear: <100>, 77 GPa (Ref 48)

Specific damping capacity. Log decrement: 3.2×10^{-3} (Ref 47)

Dynamic liquid viscosity. From Ref 46:

°C	mPa · s
1085	3.36
1100	3.33

1200	3.12

Liquid surface tension. 99.99999% purity, in vacuum: 1.300 N/m at the melting point. 99.999% purity, in N_2: 1.341 N/m at 1100 °C; 1.338 N/m at 1150 °C; 1.335 N/m at 1200 °C. 99.997% purity, at the melting point: 1.355 N/m in He or H_2; 1.358 N/m in Ar; 1.352 N/m in vacuum

Coefficient of friction. Static. Cu on Cu: 4.0 in H_2 or N_2; 1.6 in air or O_2; 1.4 (clean); 0.8 in paraffin oil (Ref 46); 0.7 in paraffin oil plus 1% lauric acid (Ref 47)

Velocity of sound. 4759 m/s for longitudinal bulk waves; 3813 m/s for irrotational rod waves; 2325 m/s for shear waves; 2171 ms for Rayleigh waves

Gallium (Ga)

Compiled by H. Clinton Snyder, Aluminum Company of America, and R. Frankena, Ingal International, Gallium, GmbH; Revised by M.W. Chase, National Institute of Standards and Technology

Gallium is used predominantly in the electronics industry, where it is combined with elements of group III, IV, or V of the periodic table to form semiconducting materials; most often, it is combined with arsenic and/or phosphorus for uses in lightemitting diodes, laser diodes, solar cells, transistors, and so on. In the oxide form, it is combined with other oxides in garnets for magnetic bubble domain devices; in metallic form, it is used for heat transfer media, eutectic alloys, liquid seals, and high-temperature lubricants; it is used in superconducting compounds such as GaV_3 and in compounds in organic reactions.

Commercially available gallium metal ranges in purity from 99.5% to 99.9999+%. The most common impurities are mercury, lead, tin, zinc, and copper. If certain impurity limits of high-purity gallium are exceeded, the optoelectric properties of electronic materials are degraded or destroyed. Gallium is tested for purity using emission spectrography and mass spectrography, and by residual resistivity measurement.

Gallium ordinarily is not considered to be hazardous, but it can be toxic in compounds or alloys, depending upon the nature of the other components or ions. Gallium in aluminum causes severe intergranular corrosion of the aluminum.

Structure

Crystal structure. Orthorhombic, *Cmca*: a = 0.45258 nm; b = 0.45186 nm; c = 0.76570 nm at 24 °C. Metastable high-pressure phases also exist.

Minimum interatomic distance. 0.2437 nm

Mass Characteristics

Atomic weight. 69.723 ± 0.001

Density:

°C	Phase	g/cm^3
20	Solid	5.907
29.65	Solid	5.9037
29.8	Liquid	6.0947
32.4	Liquid	6.093
200	Liquid	5.972
500	Liquid	5.779
600	Liquid	5.720
1010	Liquid	5.492
1100	Liquid	5.445

Volume change on freezing. 3.2% expansion

Thermal Properties

Melting point. 29.78 °C

Triple point. 302.9169 ± 0.0005 K (29.7669 °C)

Boiling point. 2477 K (per International Practical Temperature Scale 48), or 2204 °C; some sources list 2237 °C as the boiling point, but this is reported to be an error caused by gallium suboxide pressure.

Coefficient of thermal expansion. Linear, along crystal axes, from 0 to 20 °C: 11.5 μm/m · K along *a* axis, 31.5 μm/m · K along *b* axis, 16.5 μm/m · K along *c* axis (Ref 56). Volumetric: solid from 0 to 29.7 °C, 58,000 mm^3/m^3 · K; liquid at 100 °C, 120,000 mm^3/m^3 · K; liquid at 900 °C, 97,000 mm^3/m^3 · K;

Specific heat.

K	°C	Phase	kJ/kg · k
4.3	-268.9	Solid	1.22×10^{-4}
16.1	-257.1	Solid	0.01925
60.1	-213.1	Solid	0.1757

200	-73.2	Solid	0.3416
273-297	0-24	Solid	0.3723
298.15	25	Solid	0.3738
500	227	Liquid	0.3847
1000	727	Liquid	0.3811

Latent heat of fusion. 80.16 kJ/kg

Enthalpy of fusion. 79.82 kJ/kg at the temperature of fusion

Enthalpy of sublimation. 3887 kJ/kg at 298.15K

Enthalpy of combustion. To form Ga_2O_3: -15,648 kJ/kg

Thermal conductivity. Polycrystalline, at 29.8 °C: 33.49 W/m · K. Along crystal axes at 20 °C: 40.82 W/m · K along *a* axis; 88.47 W/m · K along *b* axis; 15.99 W/m · K along *c* axis. Liquid at 77 °C: 28.68 W/m · K along *a* axis; 34.04 W/m · K along *b* axis; 38.31 W/m · K along *c* axis

Vapor pressure:

K	Pa
1000	6.281×10^{-4}
1200	1.279×10^{-1}
1400	5.636
1600	9.527×10^{1}
1800	8.590×10^{2}
2000	4.932×10^{3}
2200	2.05×10^{4}
2477	1.0×10^{5}

Electrical Properties

Electrical resistivity. Polycrystalline, at 20 °C: 150.5 nΩ · m. Along crystal axes at 20 °C: 174 nΩ · m along *a* axis, 81 nΩ · m along *b* axis, 543 nΩ · m along *c* axis (Ref 57). Supercooled liquid: at 0 °C, 252 nΩ · m; at 20 °C, 256.1 nΩ · m. Liquid: at 40 °C, 260 nΩ · m; at 600 °C, 378 nΩ · m

Electrochemical equivalent. Valence +3: 0.241 mg/C

Electrolytic solution potential. Versus H_2: -0.56 V at 25 °C

Hydrogen overvoltage. Near melting point: solid, -0.31 V; liquid, -0.44 V

Temperature of superconductivity. 1.078 K

Magnetic Properties

Magnetic susceptibility. Volume (mks units): solid at 80 K (-193 °C), 3.07×10^{-4}; solid at 17 °C, 2.71×10^{-4}; liquid at 40 °C, 0.31×10^{-4}

Optical Properties

Color. Liquid metal is silvery white; solid metal is silvery with a bluish cast

Reflectance. Solid: 75.6% for λ= 436 nm; 71.3% for λ= 589 nm. Liquid: 88.8% for λ= 435 nm; 88.4% for λ= 546 nm; 88.6% for λ= 691 nm

Nuclear Properties

Stable isotopes. ^{69}Ga, isotope mass 68.9255809, 60.1% abundant; ^{71}Ga, isotope mass 70.9247006, 39.9% abundant

Chemical Properties

General corrosion behavior. Liquid gallium oxidizes rapidly to form a protective layer of oxide. The reaction of gallium with mineral acids depends on concentration and temperature. Gallium reacts with caustic -- especially in the presence of iron metal. The rate of gallium corrosion is inversely related to the purity as is the tendency to super cool. At elevated temperatures, gallium is a corroding agent for many metals (Ref 58). At room temperature, diffusion of gallium into many metals takes place, and this results in the formation of an often low-melting compound in grain boundaries and grains of the corroded metal.

Mechanical Properties

Hardness. 1.5 to 2.5, Mohs scale

Elastic modulus. Compressibility, at 20 °C: 0.021 $nm^3/m^3 \cdot Pa$ between 15 and 50 MPa

Fracture behavior. Polycrystalline masses shatter easily.

Kinematic liquid viscosity. 287 m^2/s at 30 °C; 183 m^2/s at 500 °C

Liquid surface tension. In vacuum: 0.709 N/m at 30 °C; 0.712 N/m at 100 °C; 0.718 N/m at 200 °C; 0.743 N/m at 500 °C

Indium (In)

Compiled by C.E.T. White and L.G. Stevens, The Indium Corporation of America

The major uses of indium include solders and fusible alloys (low-melting-point alloys), production of compound semiconductors, nuclear reactor control rods, and bearings. Indium compounds, in particular the oxides and tin-doped oxides, find major applications in transparent electrodes for flat panel displays, conductive coatings for demisting windshields, and fluorescent panels. Minor applications include low-resistance contacts to aluminum wire, gaskets, and battery additives.

Iridium (Ir)

Compiled by Leonard Bozza, Engelhard Corporation; Reviewed for this Volume by Louis Toth, Engelhard Corporation

Small crucibles made of iridium have been used for studying high-temperature reactions. A major use for iridium is crucibles for producing large, pure, defect-free man-made crystals for electronic and industrial applications. Single crystals so formed are used as substrates in magnetic bubble memory devices, solid-state lasers, insulating substrates for semiconductors, monoclinic filters, and substitutes for natural gemstones in jewelry. Iridium also is used as an alloying element to harden platinum; as electrodes in spark plugs for severe operating conditions, such as those experienced by jet engine igniters; as thermocouple elements; and as radioactive isotopes for industrial applications and cancer therapy.

Magnetic susceptibility. Mass: 0.19×10^{-8} mks at 18 °C (Ref 72)

Optical Properties

Reflectivity. 64% at λ= 0.45 μm; 70% at λ= 0.55 μm; 78% at λ= 0.75 μm (Ref 73)

Emissivity. 0.30 at 0.65 μm for solid unoxidized metal (Ref 70, 74)

Chemical Properties

General corrosion behavior. Iridium is the most corrosion-resistant element. It is not affected by common acids, including hot sulfuric acid. It is slightly attacked by sodium hypochlorite solutions but not by aqua regia at ordinary temperatures. However, at elevated temperatures and pressures, aqua regia does attack iridium, and it may be used under these conditions for dissolving iridium and its refractory alloys for analysis. Iridium is virtually insoluble in lead even at high temperatures, and use is often made of this fact in preliminary steps in chemical analysis.

Fabrication Characteristics

Working data. Iridium can be arc melted (inert-gas cover), electron beam melted, or consolidated by powder metallurgy techniques. It is hot worked using procedures similar to those used for tungsten. Final working is done at warm temperatures, which produce a fibrous structure. Iridium has limited malleability at room temperature.

Mechanical Properties

Tensile properties. Properties of 0.5 mm wire. Tensile strength: annealed at 1000 °C, 1100 to 1240 MPa; hot drawn, 2070 to 2480 MPa. Elongation: annealed, 20 to 22%; hot drawn, 13 to 18% (Ref 75). See also Table 17.

Table 17 Tensile properties of iridium annealed at 1500 °C

Temperature, °C	Tensile strength, MPa	0.2 % yield strength, MPa	Reduction in area, %
24	623	234	6.8
500	530	234	12.7
750	450	142	51.0
1000	331	43.4	80.6

Hardness. Annealed at 1000 °C, 200 to 240 HV; as-cast, 210 to 240 HV; hot drawn, 600 to 700 HV (Ref 75)

Modulus of elasticity. Tension: static, 517 GPa; dynamic, 527 GPa. Compression: 210 GPa (Ref 76)

Poisson's ratio. 0.26

Iron (Fe)

Compiled by L.R. Smith, Ford Motor Company (formerly with University of Michigan), and W.C. Leslie (retired), University of Michigan

Iron of sufficient purity so that its properties are essentially those of the element is commonly called high-purity iron. Such iron is not an article of commerce; instead, it is employed almost exclusively in research. Iron of very high purity can be prepared by a variety of methods, but the last stage of the process is purification by floating-zone refining, often combined with treatment in oxidizing and reducing atmospheres. In order to maintain this purity, it is essential to avoid contamination of the iron, which can occur by reactions with the atmosphere or with containers.

Structure

Crystal structure. The various phases of iron are shown as a function of temperature and pressure in Fig. 18. The crystal symmetry and the space group for each phase are:

- αiron and δiron: bcc, *Im*3*m*
- γiron: fcc, *Fm*3*m*
- ε iron: hcp, $P6_3/mmc$

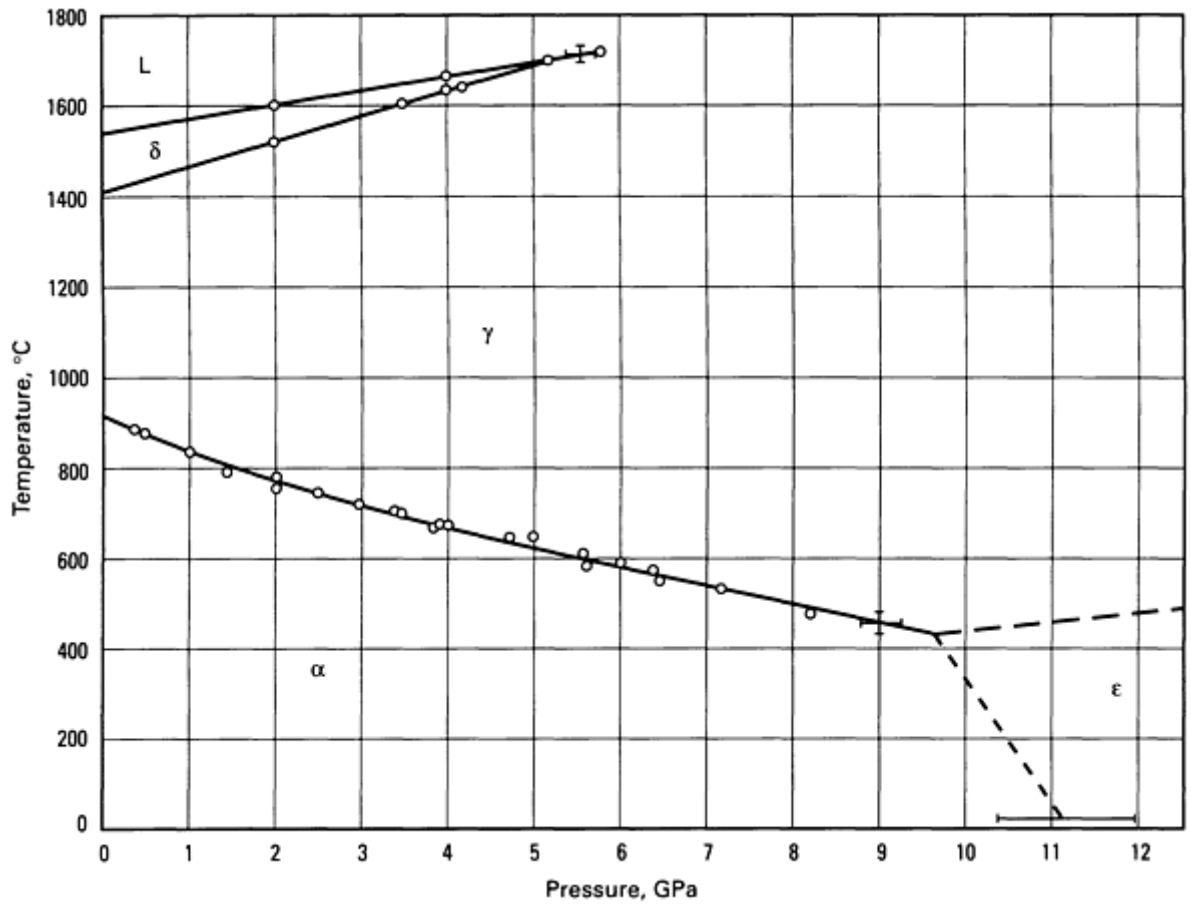

Fig. 18 Phase diagram for iron. Source: Ref 77

Lattice parameter. As a function of temperature, see Table 18. The pressure dependence of the lattice parameters of the bcc and hcp phases of iron at 23 ± 3 °C are $a(\text{bcc}) = 0.2866\ (1 + P/27.5)^{-0.056}$ and $a(\text{hcp}) = 0.2523\ (1 + P/32.5)^{-0.033}$, where

c/a(hcp) = 1.603 ± 0.001 and is independent of pressure; P is the pressure in GPa; and a(bcc), a(hcp), and c are lattice parameters in nanometers (Ref 79).

Source: Ref 78

Slip plane and direction.

Phase	**Slip direction**	**Slip plane**
α-iron	<111>	{110}, {112}, {123}[(a)]
γiron	<101>	{111}
E iron	$<11\bar{2}0>$	$\{10\bar{1}0\}$

(a) It is generally considered that slip in body-centered cubic (bcc) iron at room temperature and above can occur on any plane containing <111>.

Twinning plane. {112}, direction <111>

Cleavage plane. {100}

Minimum interatomic distances: α-iron: 20 °C, 0.24825 nm; 907 °C, 0.25119 nm. γ iron: 950 °C, 0.25815 nm; 1361 °C, 0.26029 nm. δ-iron: 1390 °C, 0.25388 nm; 1508 °C, 0.25458 nm

Microstructure. Zone-refined iron shows an essentially featureless equiaxed grain structure.

Fracture behavior. Zone-refined iron can exhibit considerable ductility at -296 °C (4.2 K) (reduction in area of almost 100%), whereas less-pure irons become brittle at temperatures below -153 °C (120 K) (Ref 80, 81). Impure irons show either cube-face cleavage or conchoidal grain-boundary fracture, depending on grain size and impurities present (Ref 82).

Mass Characteristics

Atomic weight. 55.847 (based on $^{12}C = 12$, International Union of Pure and Applied Chemistry, 1961)

Density. α-Fe at 20 °C, ρ= 7.870 g/cm^3; γ-Fe at 912 °C, 7.694 g/cm^3; δ-Fe at 1394 °C, 7.406 g/cm^3 (Ref 83). Liquid Fe at melting point (1538 °C), ρ= 7.035 g/cm^3; at 1550 °C, 7.01 ± 0.03 g/cm^3; at 1564 °C, 7.00 g/cm^3 (Ref 83)

Density versus temperature. α-Fe (to 912 °C), $10^5 \cdot \Delta\rho/\rho_0 \cdot K = 4.3$; γ-Fe (912 to 1394 °C), 6.7; δ-Fe (1394 to 1539 °C), 4.8 (Ref 84)

Density versus deformation. The density of high-purity α¨-iron will decrease very slightly with increasing cold work. The decrease in density can be estimated from the Stehle-Seeger relation (Ref 85): $N = (\Delta\rho/\rho_0)/2\mathbf{b}^2$, where N is the dislocation density and **b** is the Burgers vector. The appropriate value of N at a strain of 0.20, taken from Ref 86, yields an estimate of $\Delta\rho/\rho_0 = 2.5 \times 10^{-5}$.

Volume change on freezing. Liquid to δ, -3.4%

Volume change on phase transformation. δto γ(1394 °C), -0.52%; γ to α(912 °C), + 1.0% (computed from changes in lattice parameter)

Thermal Properties

Melting point. 1538 °C (Ref 87)

Boiling point. 2870 °C (Ref 87)

Phase transformation temperatures. α to γ, 912 °C;γ toδ, 1394 °C

Coefficient of linear thermal expansion. Values recommended in Ref 88 are shown in Fig. 19 and Table 19. These values are considered accurate to within ±3% at temperatures below 627 °C, ±5% below 912 °C, and ±20% above 912 °C. The volume per atom as function of temperature is shown in Fig. 20.

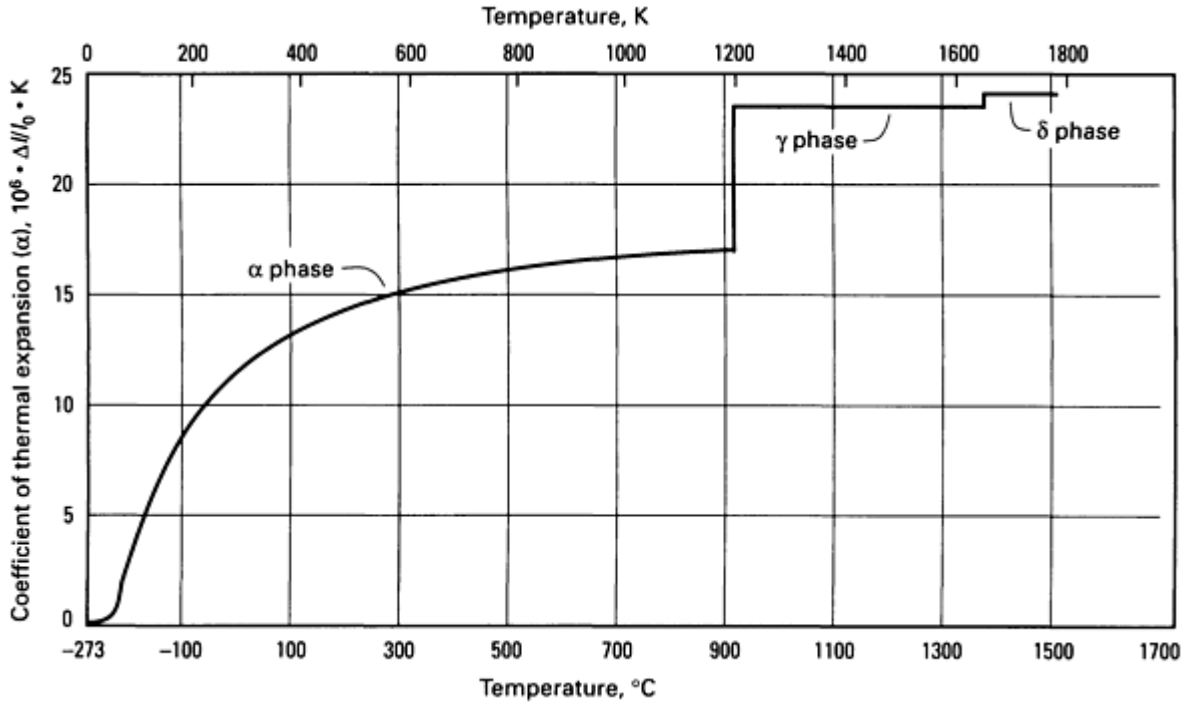

Fig. 19 Coefficient of linear thermal expansion for iron. Source: Ref 88

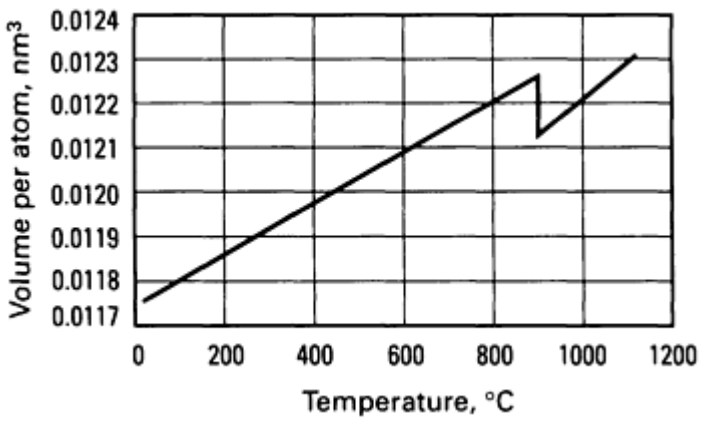

Fig. 20 Volume per atom for iron. Source: Ref 89

Coefficient of volumetric thermal expansion (liquid). $10^6 \cdot \Delta v/v_0 \cdot K = 140$ (somewhat greater than three times the linear coefficient in the δ range) (Ref 90)

Specific heat. The specific heats at constant pressure of α, γ, δ, and liquid iron, as a function of temperature, are shown in Fig. 21 and Table 20. Data for temperatures below 27 °C are primarily taken from the compilation reported in Ref 82. Data for temperatures above 27 °C are taken from Ref 91.

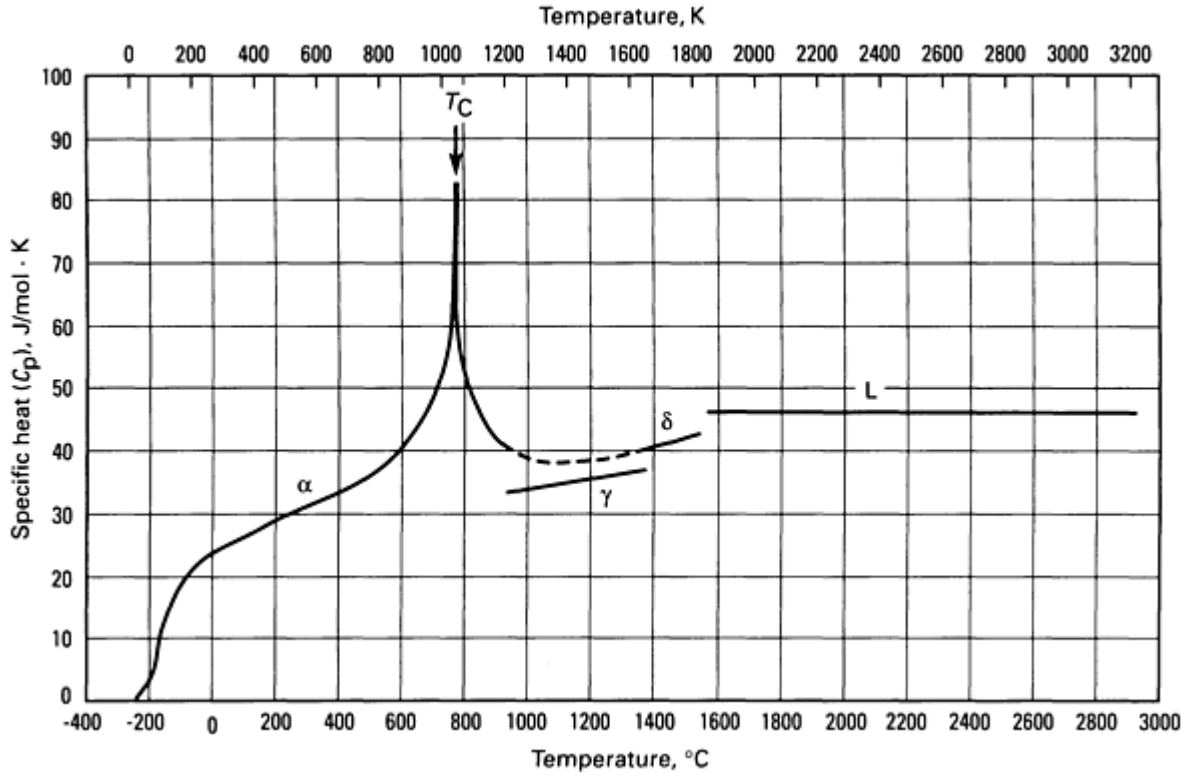

Fig. 21 Specific heat of iron from 0 to 3200 K. Sources: Ref 82, 91

Enthalpy, entropy, and free-energy function. See Table 20.

Latent heat of fusion. Adopted average value, 247 ± 7 kJ/kg for α-iron at the melting point (1538 °C) (Ref 91)

Latent heat of phase transformation. Selected experimental averages are:

Transformation	Temperature, K	Latent heat ($\Delta H°_t$), kJ/kg
α to γ	1185	16
γ to δ	1667	15

Source: Ref 91

Values at other temperatures can be derived from Table 20.

Latent heat of vaporization. 7018.3 kJ/kg at the boiling point of iron (2870 °C) (Ref 92)

Thermal conductivity. Figure 22 shows thermal conductivity as a function of temperature. The recommended values (Table 21) are for well-annealed high-purity iron, and those below -73 °C apply only to iron having a residual electrical resistivity of 0.143 nΩ · m. The values are accurate to within ±5% below -173 °C, ±3% from -173 °C to room temperature, ±2% from room temperature to +727 °C, and ±3 to 8% at higher temperatures.

(a) Extrapolated or estimated values.

(b) Values for liquid iron are provisional.

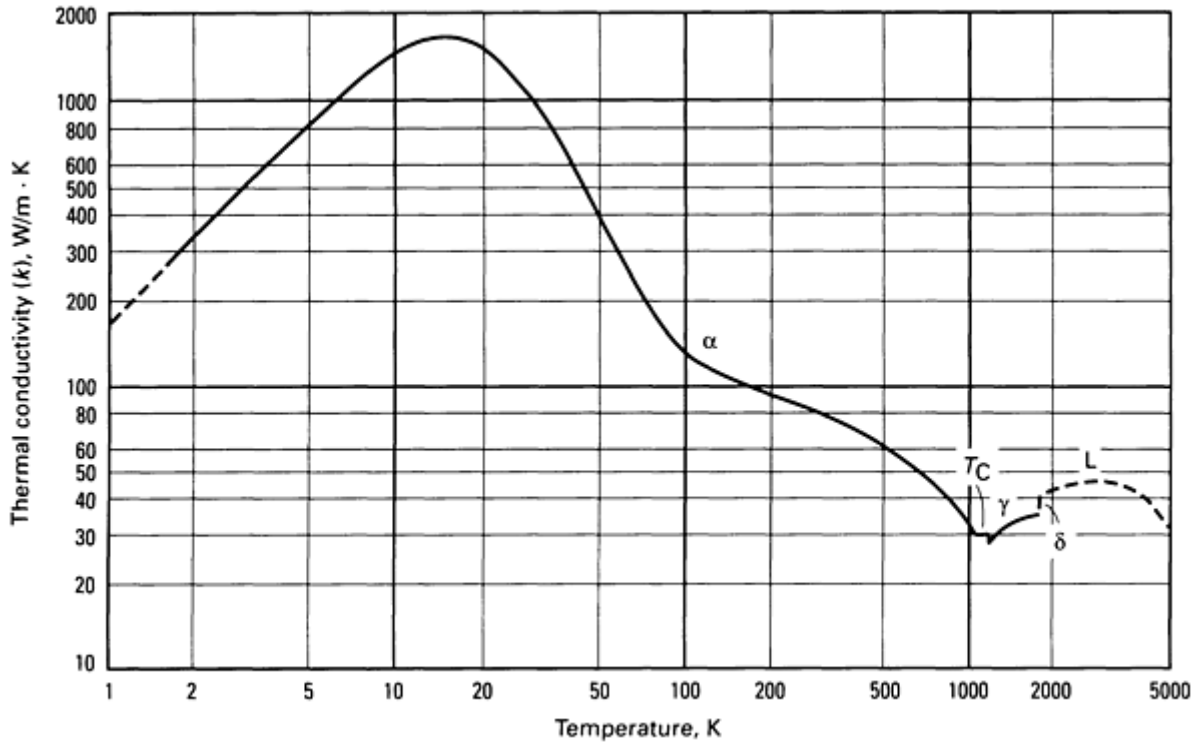

Fig. 22 Thermal conductivity of iron. Source: Ref 93

Heat of combustion and free energy of formation. The following values are for 25 °C:

Oxide	Molecular weight	$-\Delta H°_f$, kJ/kg Fe	$-\Delta F°_f$, kJ/kg Fe
$Fe_{0.947}O$	68.89	4,758±14	4,357±18
Fe_2O_3	159.70	14,700±75	13,245±113
Fe_3O_4	231.55	19,990±150	18,146±165

Source: Ref 94

Vapor pressure. See Fig. 23. For the temperature range 1178 to 1394 °C: log $p = m/T + b$, where m is -20,908 ± 109, b is 12.161 ± 0.070, T is in K, and p is in Pa (Ref 96)

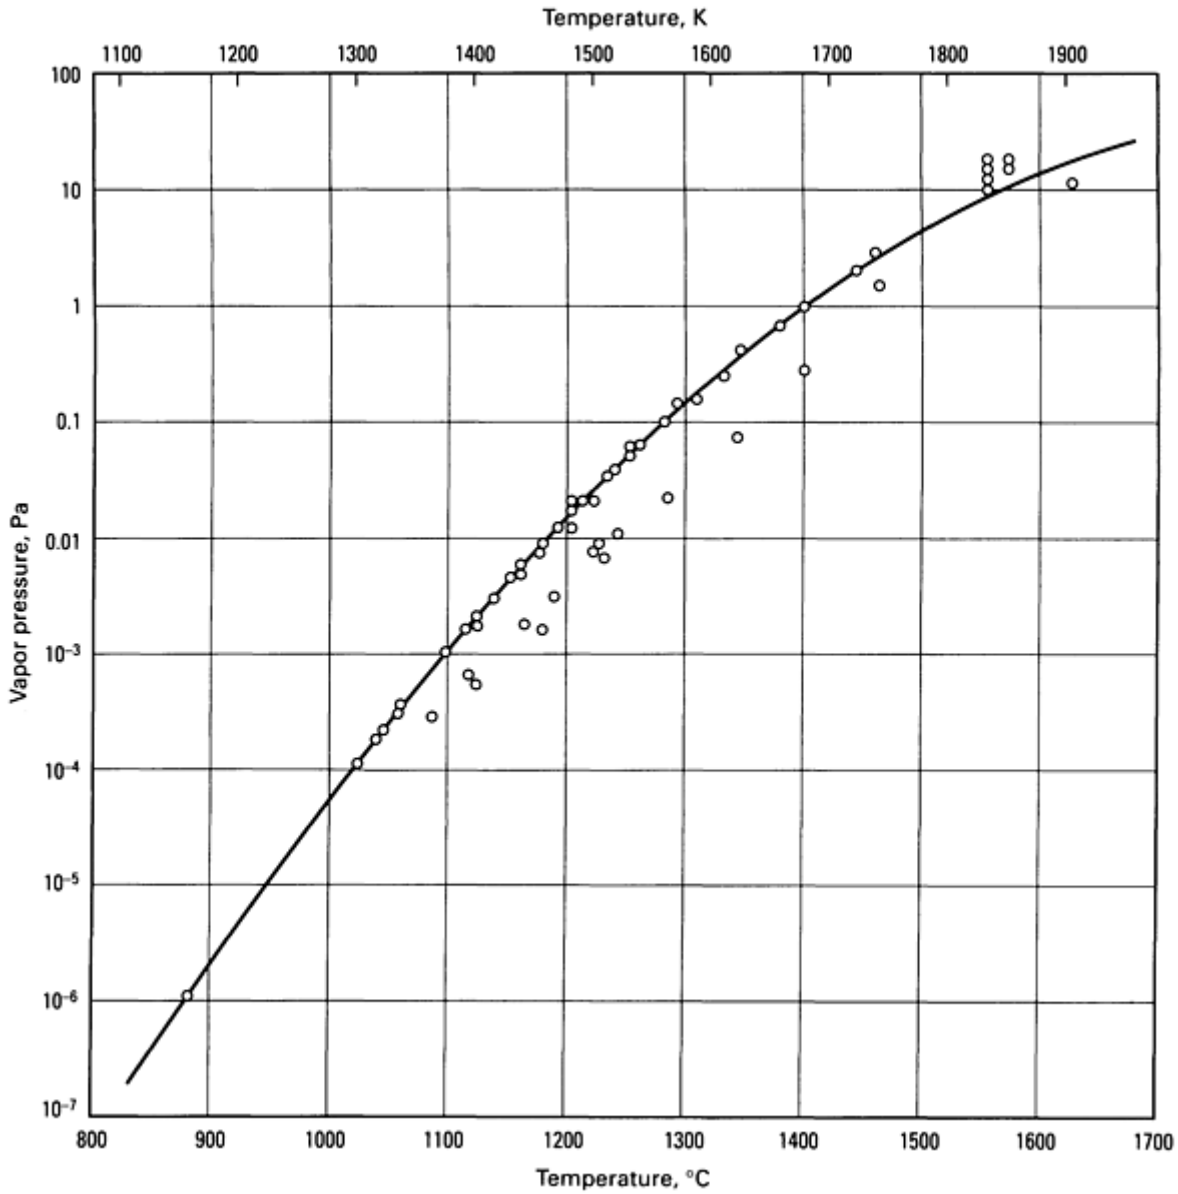

Fig. 23 Vapor pressure of iron. Source: Ref 95

Diffusion coefficient:

	Diffusion constant (D_0), mm^2/s	**Activation energy (Q), MJ/kg**
In γ-Fe	70	5.12
In paramagnetic α-Fe	16	4.30

In ferromagnetic α-Fe	50	4.30

Source: Ref 97

The diffusion constant (*D*) can be calculated using the Arrhenius equation:

$$\ln D = \ln D_o - \frac{Q}{RT}$$

In ferromagnetic iron, the Arrhenius plot of *D* cannot be approximated by a straight line; instead, it shows strong curvatures (see Fig. 24). For practical purposes, the diffusion coefficients for alloying elements differ from the self-diffusion of iron by factors that are independent of temperature. These factors (Fig. 25) can be used to determine the diffusion constant for other elements in γ iron or α iron. Grain-boundary diffusion, in γ iron and α iron, of iron and some alloying elements can be described by:

$$D_o = \frac{0.054 mm^3/s}{d}$$

where δ represents the thickness of the grain boundary in μm. For grain-boundary diffusion in both α iron and γ iron, *Q* is 2.78 MJ/kg.

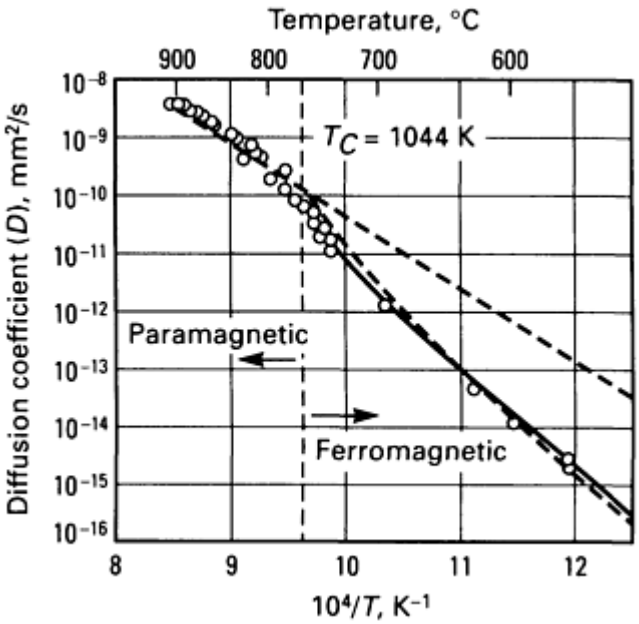

Fig. 24 Arrhenius plot of self-diffusion in para- and ferromagnetic α-iron. Source: Ref 98

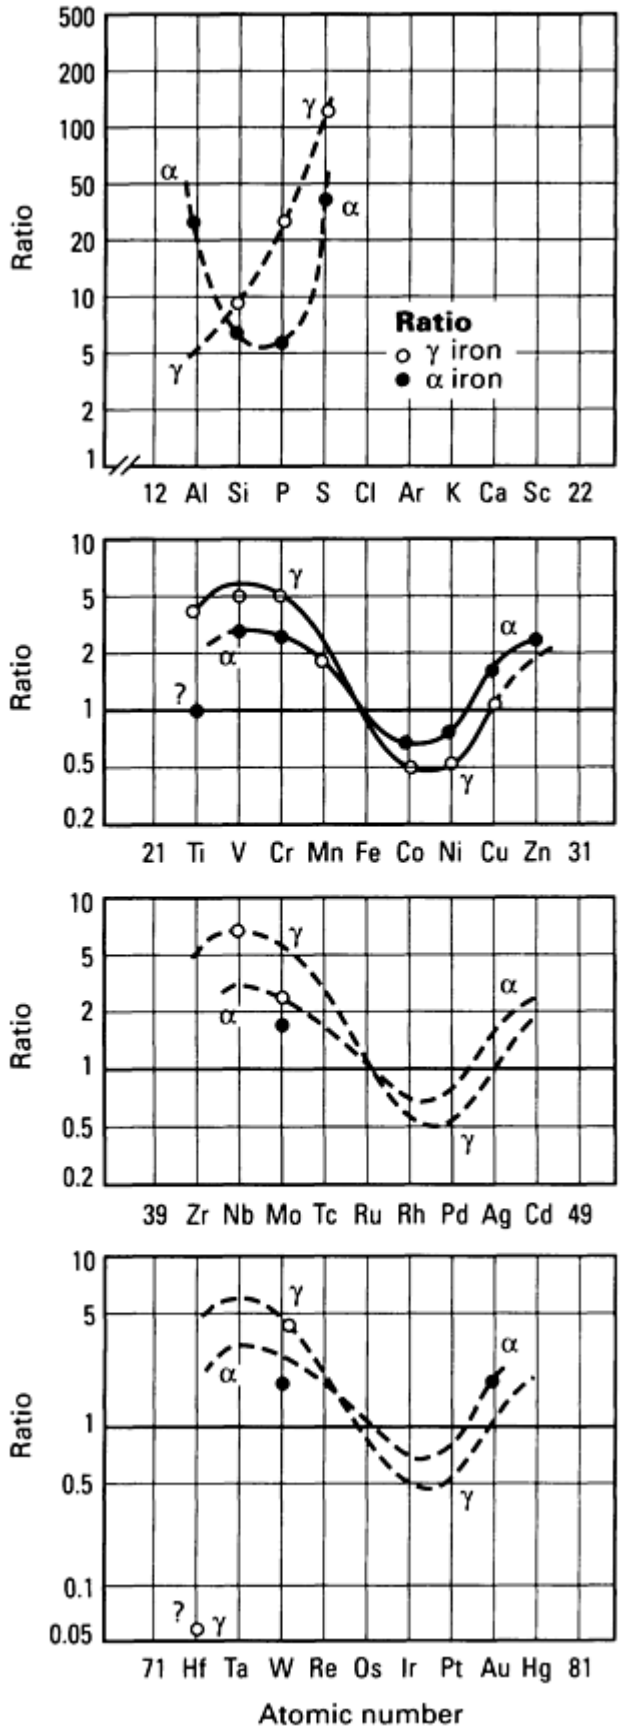

Fig. 25 Ratio between diffusion coefficients of alloy elements and self-diffusion of iron. Source: Ref 97

Vacancy formation and migration. Reference 99 gives the following enthalpies for formation and migration of monovacancies in iron:

	Enthalpy (*H*), aJ	
	Formation	**Migration[(a)]**
In γ-Fe	0.245±0.024	0.147
In paramagnetic α-Fe	0.257±0.024	0.202
In ferromagnetic α-Fe	0.256±0.024	0.202±0.040

(a) The significance of these values is that monovacancy migration occurs only at temperatures well above ambient (>450 K, or >180 °C).

Electrical Properties

Volumetric electrical conductivity. 17.59% IACS at 25 °C

Electrical resistivity. The variation with temperature for solid iron is shown in Fig. 26(a) and 26(b). For liquid iron at the melting point (1536 °C), 1.39 μΩ· m (Ref 82)

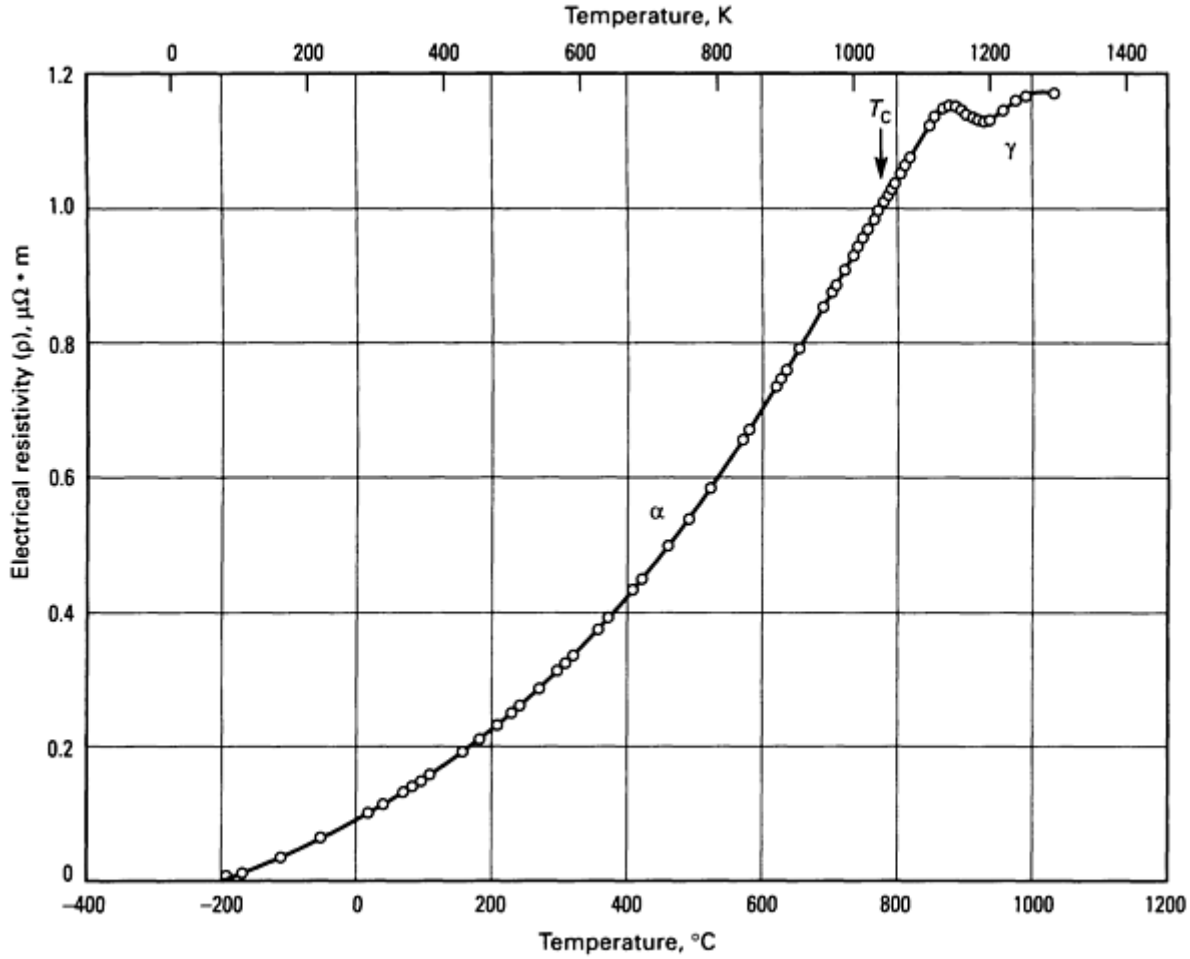

Fig. 26(a) Electrical resistivity of iron from -273 to 1027 °C. Source: Ref 100, 101

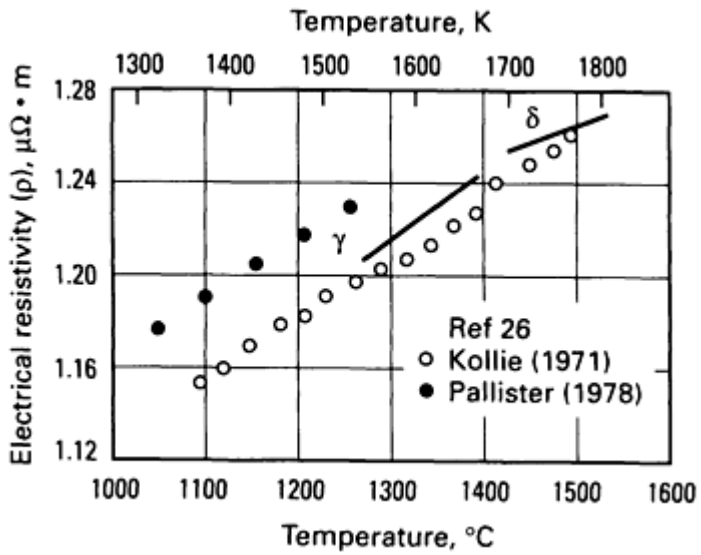

Fig. 26(b) Electrical resistivity of iron from 1027 to 1527 °C. Source: Ref 102

Temperature coefficient of electrical resistivity. The fundamental coefficient is $(\rho_{100\ ^\circ C} - \rho_{0\ ^\circ C})/\rho_{0\ ^\circ C} = 0.00616$, or 0.616% increase per K (Ref 103). The temperature coefficient in the neighborhood of the Curie temperature is shown in Fig. 27.

The resistivity ratio ($\rho_{300\ K}/\rho_{4\ K}$) of several high-purity irons is tabulated in Table 22. This ratio shows a fair correlation with purity, provided measurements are made in the proper longitudinal magnetic fields (Ref 105).

Table 22 Resistivity ratios of iron

Sample	Impurity, ppm	Ratio ($\rho_{300\ K}/\rho_{4\ K}$)
Arajs B (1965)	200-500	27
Rosenberg (1965)	~100	50, 83

Takaki and Kimura (1973)	. . .	>5000

Source: Ref 101, 104

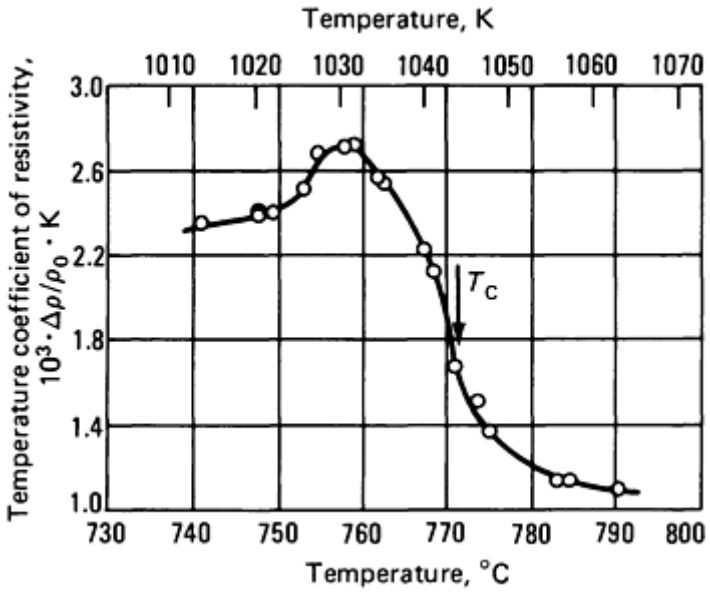

Fig. 27 Temperature coefficient of the electrical resistivity of iron in the neighborhood of the Curie temperature (T_C). Source: Ref 101

Pressure coefficient of electrical resistivity. The variation of resistivity with pressure at 25 °C is shown in Fig. 28. According to Fig. 28, the pressure coefficient is -0.18 per Pa. The resistance increases at the α to ε transition (at 13 GPa) by 366%.

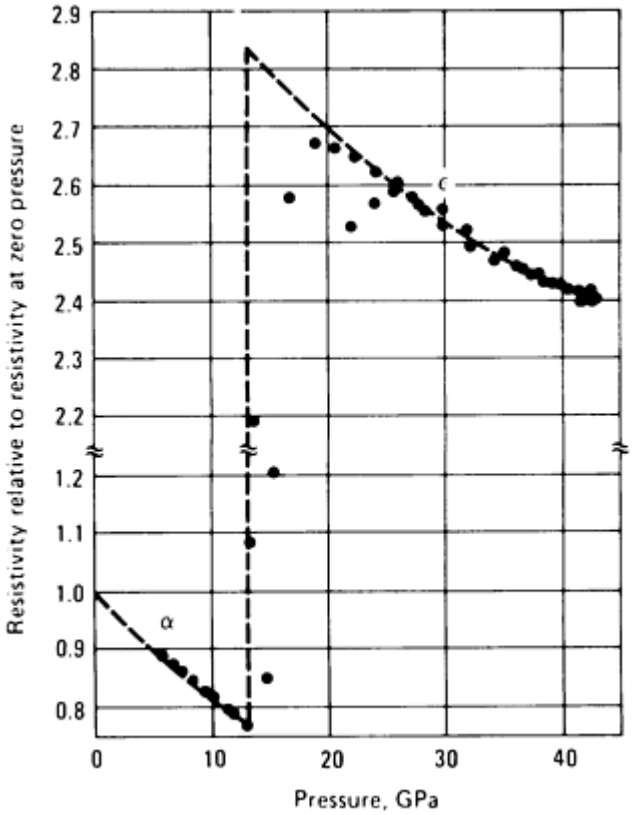

Fig. 28 Pressure dependence of the electrical resistivity of iron. Source: Ref 106

Electrical properties versus deformation. The change in resistivity with true strain for iron deformed at -196 °C ($\rho = 5.8\ n\Omega \cdot m$) is shown in Fig. 29. At 25 °C, the conductivity changed from 17.593% IACS (no reduction in area) to 17.577% IACS (9.5% reduction in area).

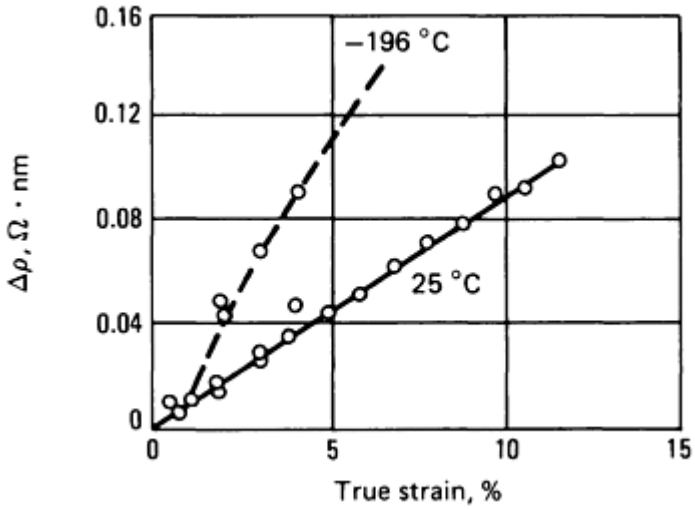

Fig. 29 Resistivity change (Δρ) of iron deformed in tension at -196 °C and at 25 °C. Source: Ref 107

Thermoelectric power. The variation with temperature is shown in Fig. 30.

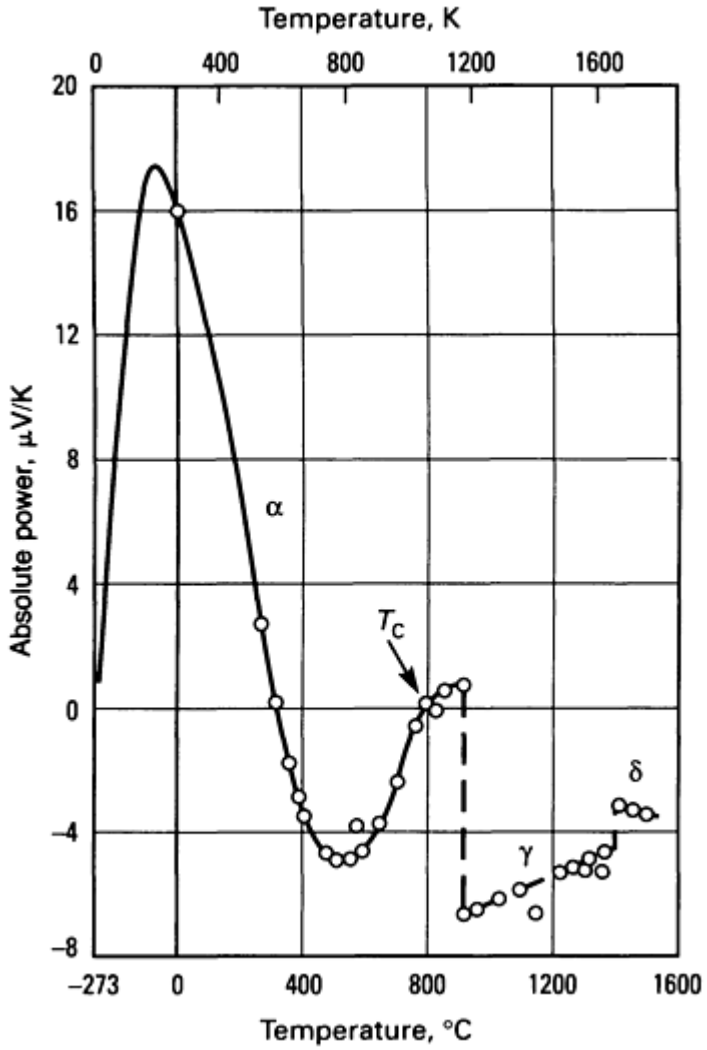

Fig. 30 Thermoelectric power of iron. Source: Ref 108

Electrochemical equivalent. Based on an atomic weight of 55.85 and a value of 96,495 coulombs (C) per gram equivalent weight for the Faraday, the electrochemical equivalents are 0.1929 and 0.2893 mg/C for Fe^{3+} and Fe^{2+}, respectively.

Standard electrode potential. -0.4402 V for the reaction $Fe = Fe^{2+} + 2e^-$ at 25 °C, where iron would be the negative terminal in a cell whose second electrode is a standard hydrogen electrode (SHE) and where the Fe^{2+} activity is unity (Ref 109)

Temperature coefficient of standard electrode potential. The thermal temperature coefficient, $(dV°/dT)_{th}$, at 25 °C is given in Ref 109 as +0.923 mV/K, and the isothermal temperature coefficient, $(dV°/dT)_{iso}$, at 25 °C is given as +0.052 mV/K. The thermal temperature coefficient is given a positive value because the hot electrode is the (+) terminal in a thermal cell. The isothermal temperature coefficient is given a positive value because the electromotive force of the isothermal cell, SHE/iron, increases with temperature.

First ionization potential. 7.87 eV (1.27 aJ) (Ref 110)

Hydrogen overvoltage. As given in Ref 111, the relationship between hydrogen overvoltage (activation) (η_a) and current density (i) is $\eta_a = -\beta \log (i/i_0)$, Where β (the slope of the Tafel region) and i_0 (the exchange current density) are constants that depend on the environment. The current density consists of contributions from the external applied current density and the local-action current density. When the external applied current is zero, the overvoltage equals the corrosion potential (E_{corr}) and the local-action current density equals the corrosion current (i_{corr}). The variation in hydrogen overvoltage of pure iron in 4% NaCl (2.0 pH) is shown in Fig. 31. In 4% NaCl, the overvoltage is essentially constant for pH 1 to 4. Hydrogen overvoltage of pure iron in 0.1 *M* citric acid and 0.1 *M* malic acid is shown in Fig. 32. Overvoltage

constants are given with the figures. Because there is a significant variation in overvoltage constants for different crystal orientations of pure iron, the data in the figures should be considered as average values for random orientation.

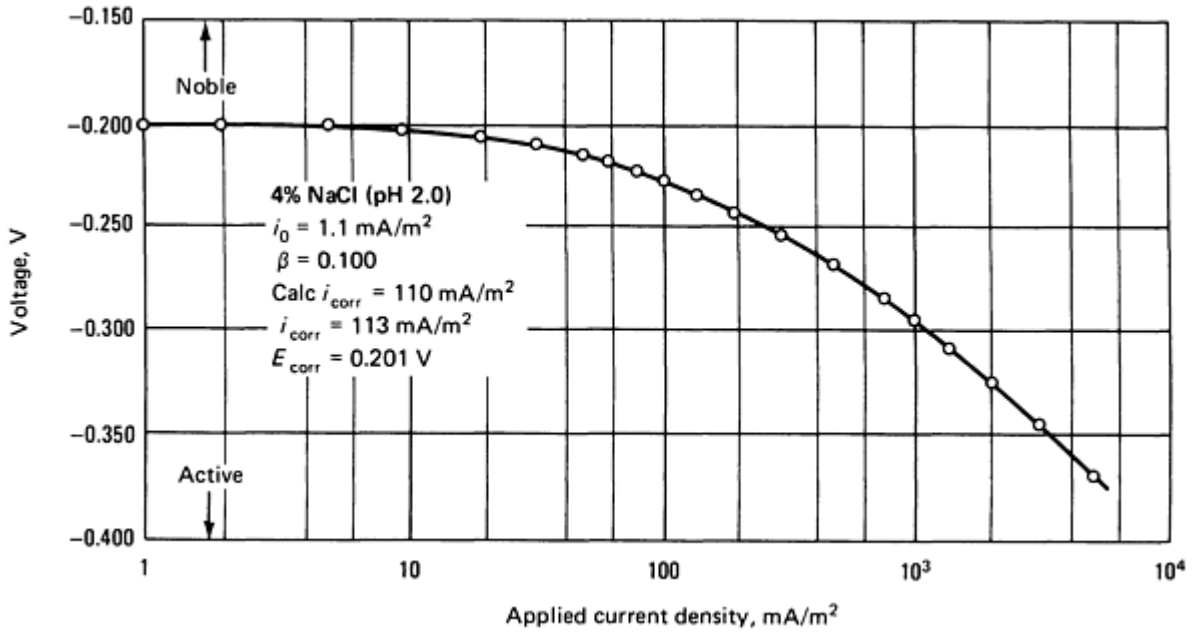

Fig. 31 Hydrogen overvoltage (activation) of iron in aqueous solution on NaCl. Source: Ref 111

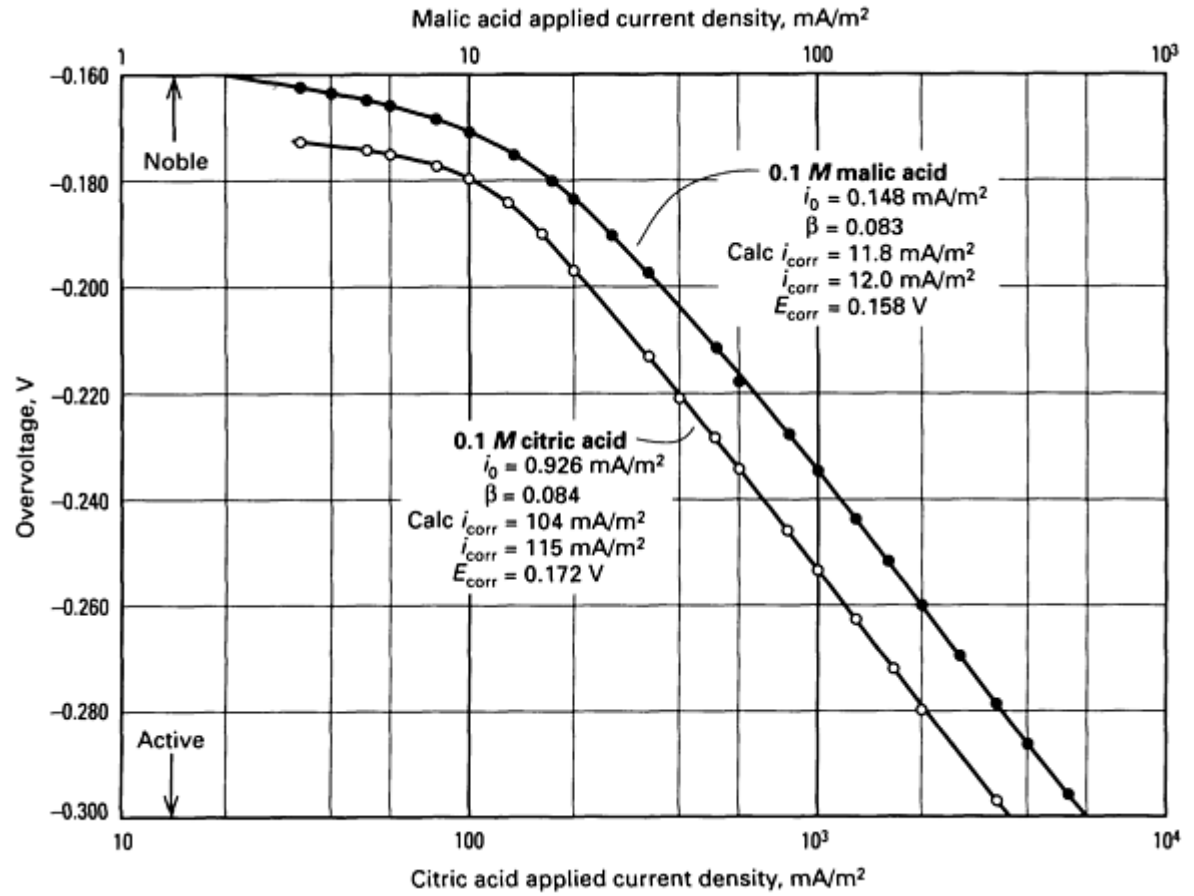

Fig. 32 Hydrogen overvoltage (activation) on iron in citric acid and malic acid. Source: Ref 111

Hall effect. The Hall resistivity of polycrystalline ferromagnetic metals can be empirically expressed $\rho_H = R_0H + R_1M$, where R_0 and R_1 are the respective coefficients of ordinary and extraordinary Hall effect, H is the applied magnetic field, and M is the magnetization. The temperature dependence of ρ_H is shown in Fig. 33. Figures 34 and 35 show the temperature dependence of ordinary and extraordinary Hall coefficients. For single crystals, the extraordinary Hall coefficient is dependent on the orientation of the crystal (Ref 114) (see Fig. 36). A detailed discussion of galvanomagnetic effects in iron whiskers (at -273 to 27 °C) is given in Ref 115 and 116.

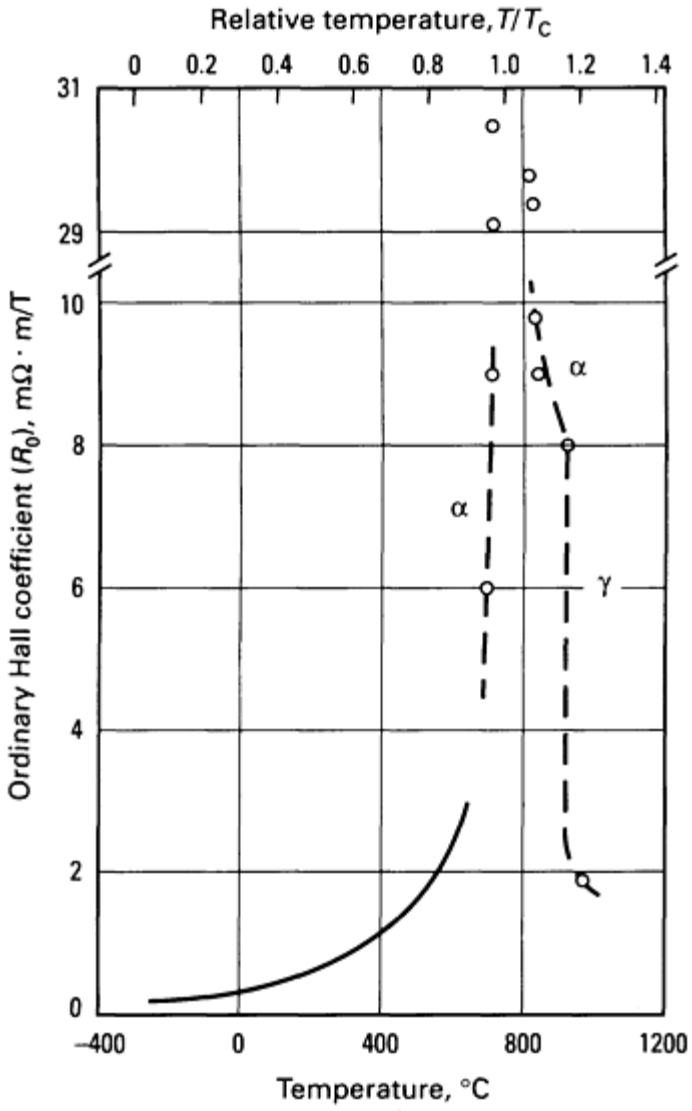

Fig. 34 Temperature dependence of the ordinary Hall coefficient of iron. Source: Ref 113

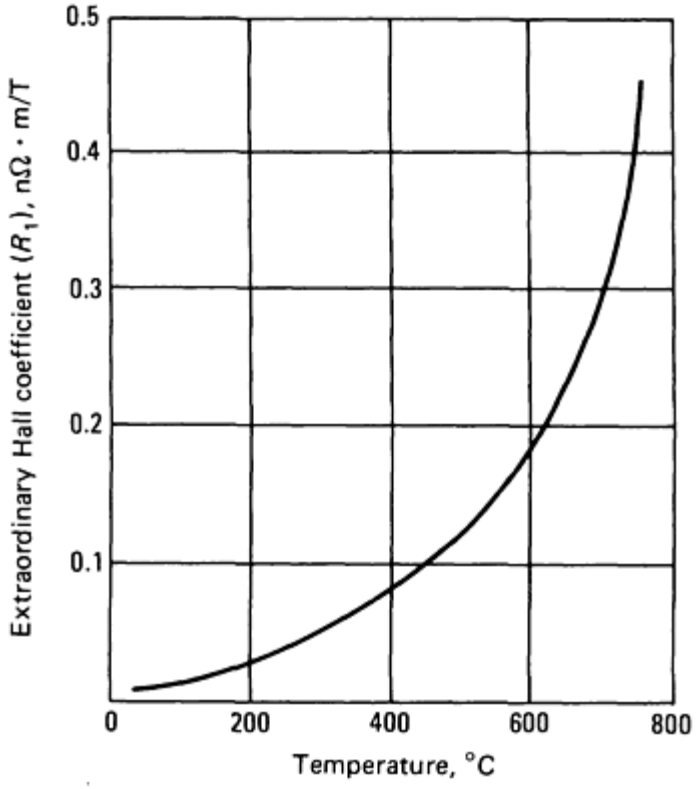

Fig. 35 Temperature dependence of the extraordinary Hall coefficient of iron. Source: Ref 112

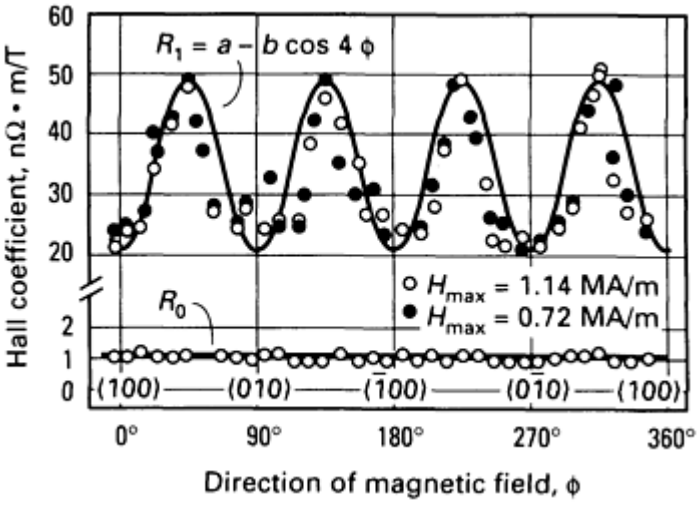

Fig. 36 Effect of magnetic field direction on Hall coefficients of iron at 27 °C. f is the angle between the magnetic field and the [100] axis when current is passed along the [001] axis. Source: Ref 114

Electrical resistivity versus alloying. The electrical resistivity of some binary iron alloys at -269 °C (4.2 K) versus solute concentration in atom percent is shown in Fig. 37. Results from the iron-nickel system overlap those of the iron-palladium system; the iron-tungsten system data are identical with the results for the iron-manganese system. For clarity, low-concentration points for some alloys have been omitted from the figure.

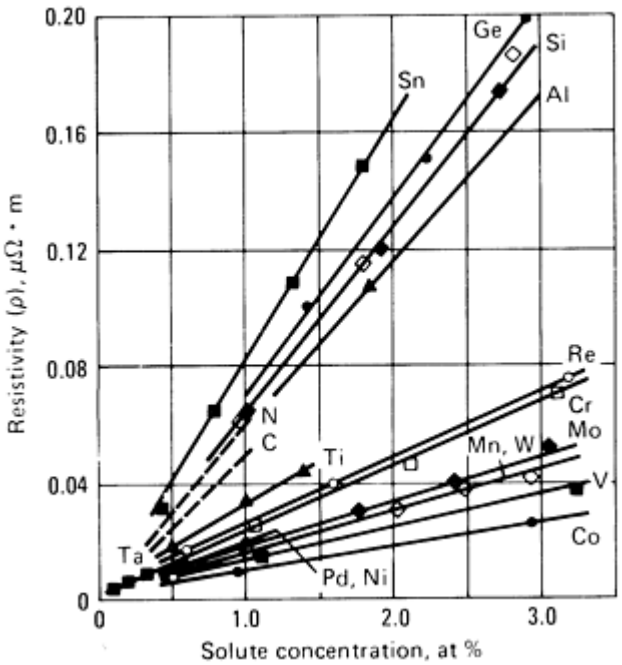

Fig. 37 Electrical resistivities of selected binary iron alloys at -269 °C (4.2 K). Source: Ref 117

Electron emission. 260 kA/m^2 · K^2 for α iron and 15 kA/m^2 · K^2 for γ iron (Ref 118)

Work function. In high-purity iron, the work function is sensitive to impurities and surface condition. Using iron that was electropolished and then cleaned through repeated cycles of ion bombardment (with argon) and annealing, the value of the work function for the (100) plane of α iron was found to be 4.67 ± 0.03 eV (0.748 ± 0.005 aJ) (Ref 119). Using positive-ion-emission and electron-emission data, the change in work function at the α to γ transformation ($f\ \gamma / f\ \alpha$) was found to be between +0.06 and +0.09 eV (+0.010 to +0.014 aJ) (Ref 120).

Magnetoresistance. The variation at -269 °C (4.2 K) of residual resistance in longitudinal and transverse magnetic fields is shown in Fig. 38. This effect can also be seen as a dependence of the residual electrical resistance upon measuring current density (see Fig. 39).

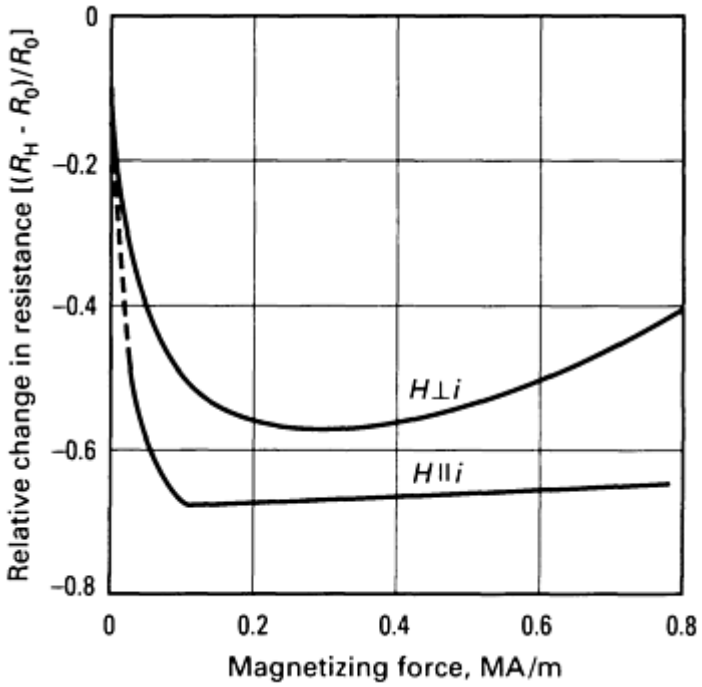

Fig. 38 Magnetoresistance of iron at -269 °C (4.2 K). Curves represent data for the application of the magnetic field strength (*H*) parallel and perpendicular to the electrical current (*i*). R_H resistance in field *H*; R_0, resistance in no field. R_0 at 293 K is 258 times greater than R_0 at 4.2 K. Source: Ref 121

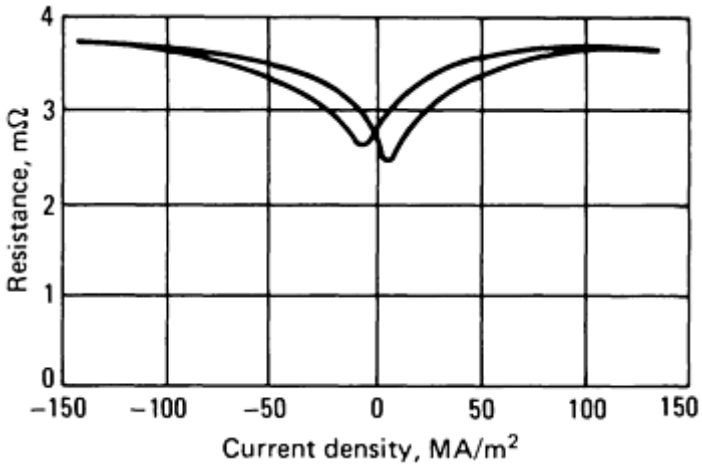

Fig. 39 Residual resistance of iron at -269 °C (4.2 K) as a function of measuring current density. Source: Ref 121

Magnetic Properties

Magnetic properties versus treatment and composition. Magnetic properties can vary over a wide range, depending on such factors as impurity content (particularly of carbon, sulfur, nitrogen, and oxygen), impurity distribution (high-temperature solution anneal or low-temperature precipitation or aging), grain size, grain orientation, and strain or cold work.

Magnetic susceptibility. Temperature variations of the reciprocal of the mass paramagnetic susceptibility of iron are shown in Fig. 40.

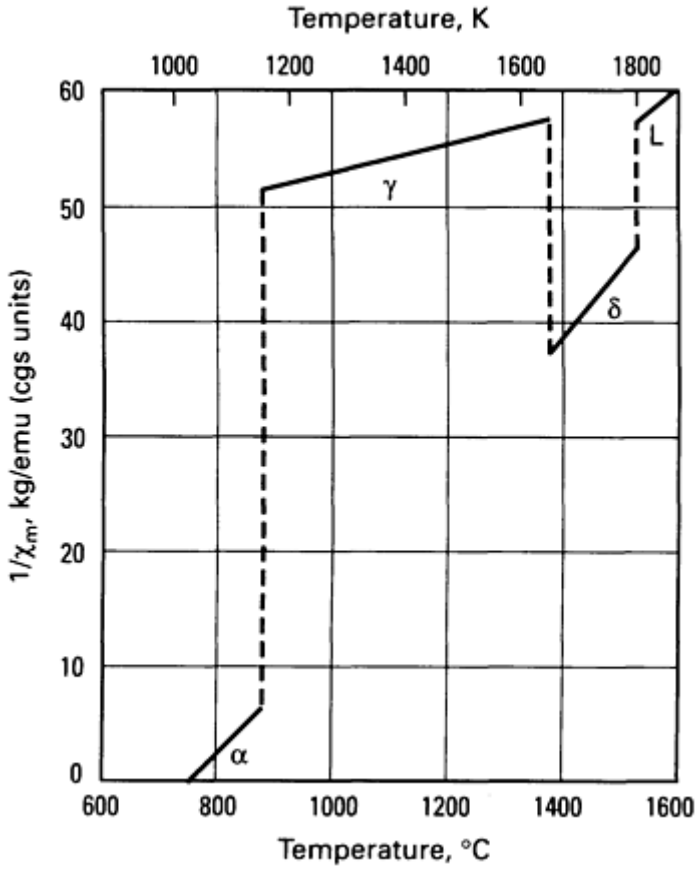

Fig. 40 Temperature dependence of the reciprocal of the mass paramagnetic susceptibility (c_m) of iron. To change susceptibility values from cgs units to mks units, multiply by 4π. Source: Ref 122

Magnetic permeability. For polycrystal H_2-treated iron, 0.0176 H/m for the initial permeability; 0.314 to 0.352 H/m for the maximum permeability at room temperature (Ref 82). For an iron single crystal: maximum permeability in the [100] direction, 1.80 to 1.82 H/m

Coercive force. For zone-refined iron, the coercive force (H_c) follows the relation $H_c = 1.83 + 4.14/Q^{1/2}$, where Q is the grain size in mm^2. After heat treatment for 10 h at 880 °C in H_2 with a furnace cool, the coercive force at room temperature was reported to be 10.74 A/m. A different treatment (60 h at 1300 °C in H_2, followed by 20 h at 870 °C in H_2, then furnace cooling) gave a coercive force of 1.35 A/m (Ref 123).

Saturation magnetization. 2.158 T at room temperature (Ref 124). Magnetization per atom at 0 K (M_0): 2.216 μ_B (Bohr magnetons), or 2.055×10^{-23} J/T (Ref 125)

Residual induction. 1.183 T (Ref 124)

Hysteresis loss. 15 to 19 J/m^3 per cycle (Ref 82)

Magnetostriction. Data for single-crystal and polycrystalline annealed electrolytic iron are shown in Fig. 41. If the directions of magnetization and strain measurement relative to the [100] direction for a cubic crystal are f and ψ, respectively, then the variation of the magnetostriction of a self-saturated domain (which depends on the angular position of the vector **M** at saturation) can be expressed by five constants, as shown in the formula:

$$\Delta l/l_0 = \{\tfrac{1}{8}\,(h_1 - h_2 - h_3) + \tfrac{5}{48}\,h_4\}\cos 2f$$

$$+ \{\frac{1}{64}\ (-6h_3 + h_4 - 2h_5\} \cos 4f$$
$$+ \{\frac{3}{8}\ h_1 + \frac{1}{8}h_2 + \frac{5}{16}h_4\} \cos 2f\ \cos 2\psi$$
$$+ \{\frac{1}{2}\ h_2 + \frac{1}{8}h_5\} \sin 2f\ \sin 2\psi$$
$$+ \{\frac{3}{64}\ h_4 + \frac{1}{32}h_5\} \cos 4f\ \cos 2\psi$$
$$+ \{-\frac{1}{16}\ h_5\} \sin 4f\ \sin 2\psi$$

where the room-temperature values for the constants are h_1 = 36.1 ± 2.1, h_2 = - 34.5 ± 1.4, h_3 = -1.2 ± 0.5, h_4 = 3.3 ± 0.7, and h_5 = 0.8 ± 0.3 (Ref 127). The variation of these constants with temperature is treated in Ref 128.

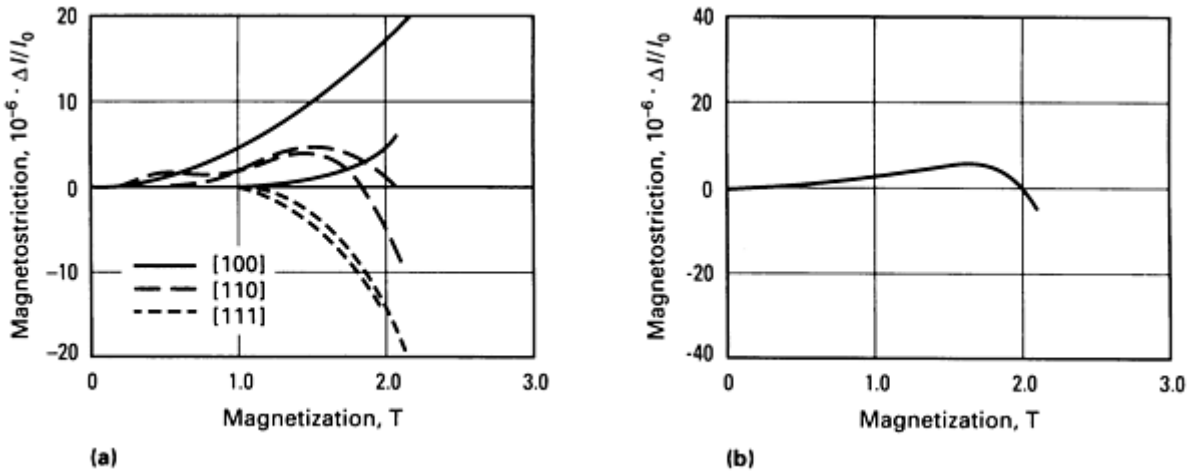

Fig. 41 Longitudinal magnetostriction in (a) single crystals of iron and (b) polycrystalline iron. Source: Ref 126

Magnetic transformation (Curie) temperature. 1044 ± 2 K (Ref 129).

Optical Properties

Color. Silvery white, resembling platinum more than ingot iron or steel.

Reflectance. The normal spectral reflectance of polished iron varies from 65% at a wavelength of 1.5 μm to 97% at 15 μm (Ref 95, 130).

Absorption. The normal spectral absorptance of polished iron varies from about 0.33 at a wavelength of 1.5 μm to 0.03 at 15 μm (Ref 130).

Emittance. Normal spectral emittance of polished iron at about 927 °C: 35% at a wavelength of 0.65 μm, 26% at 1.5 μm, 11% at 15 μm (Ref 130)

Nuclear Properties

Stable isotopes:

Isotope	Atomic weight[(a)]	Percent of total
^{54}Fe	53.9396	5.82
^{56}Fe	55.9349	91.66

(a) EC, electron capture.

Effects of neutron irradiation. Neutron irradiation affects the properties of materials principally through the production of lattice defects. These defects influence structural, mechanical, electronic (associated with trapping of charge), and diffusion-controlled properties (see Ref 132). The effect of irradiation on yield strength and reduction in area of vacuum-melted iron (0.003% C, 0.0055 O_2, 0.0005% N) is shown in Fig. 42. For a review of mechanical properties of irradiated iron and iron alloys, see Ref 134. Corrosion effects are discussed in Ref 135.

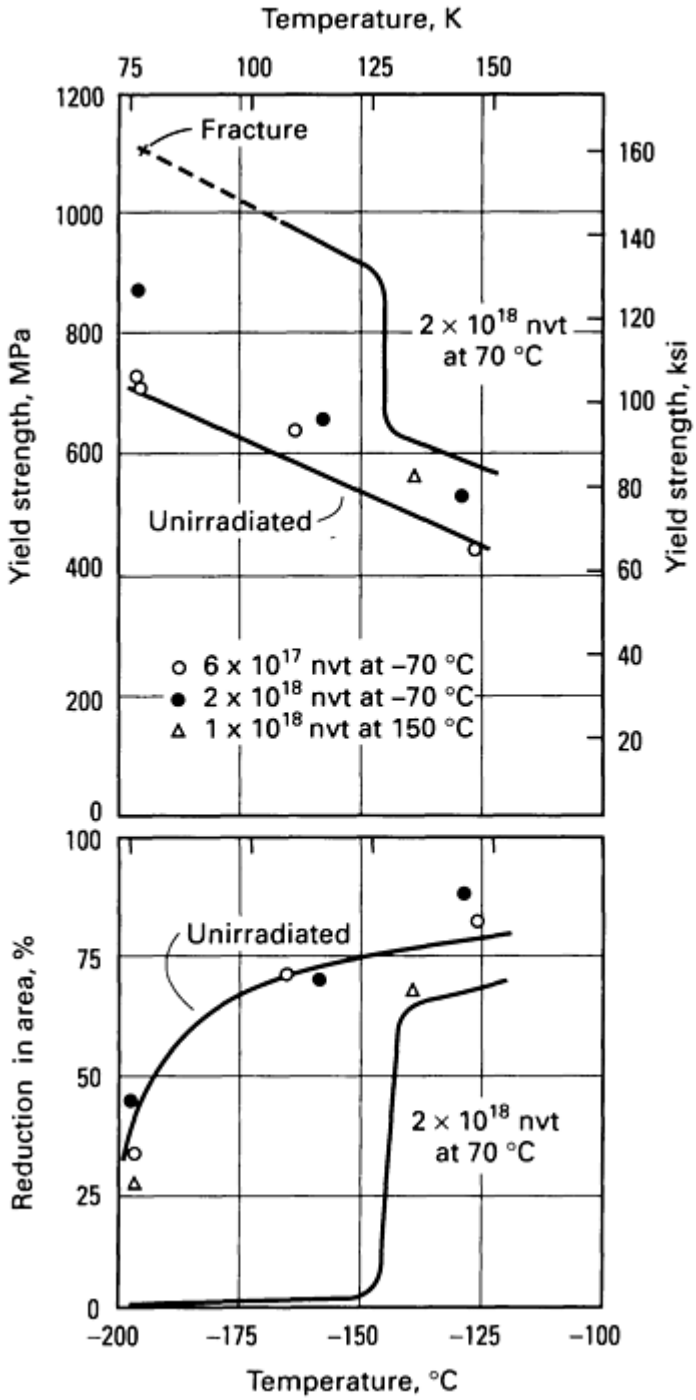

Fig. 42 Effect of temperature on yield strength and reduction in area of iron before and after irradiation. nvt, neutron dose (equivalent to the number of neutrons per square centimeter). Source: Ref 133

Chemical Properties

General corrosion behavior. The corrosion behavior of iron in aqueous solutions is shown schematically in Fig. 43. Irons of high purity show a remarkably high resistance to corrosion, sometimes remaining untarnished in laboratory atmospheres for months or years (Ref 82). Zone-refined iron corrodes at the same rate in hydrochloric acid wether cold worked or annealed and is not affected by any heat treatment schedule (Ref 137). Results reported in Ref 111 indicate an orientation effect; that is, certain crystals faces are attacked more than others.

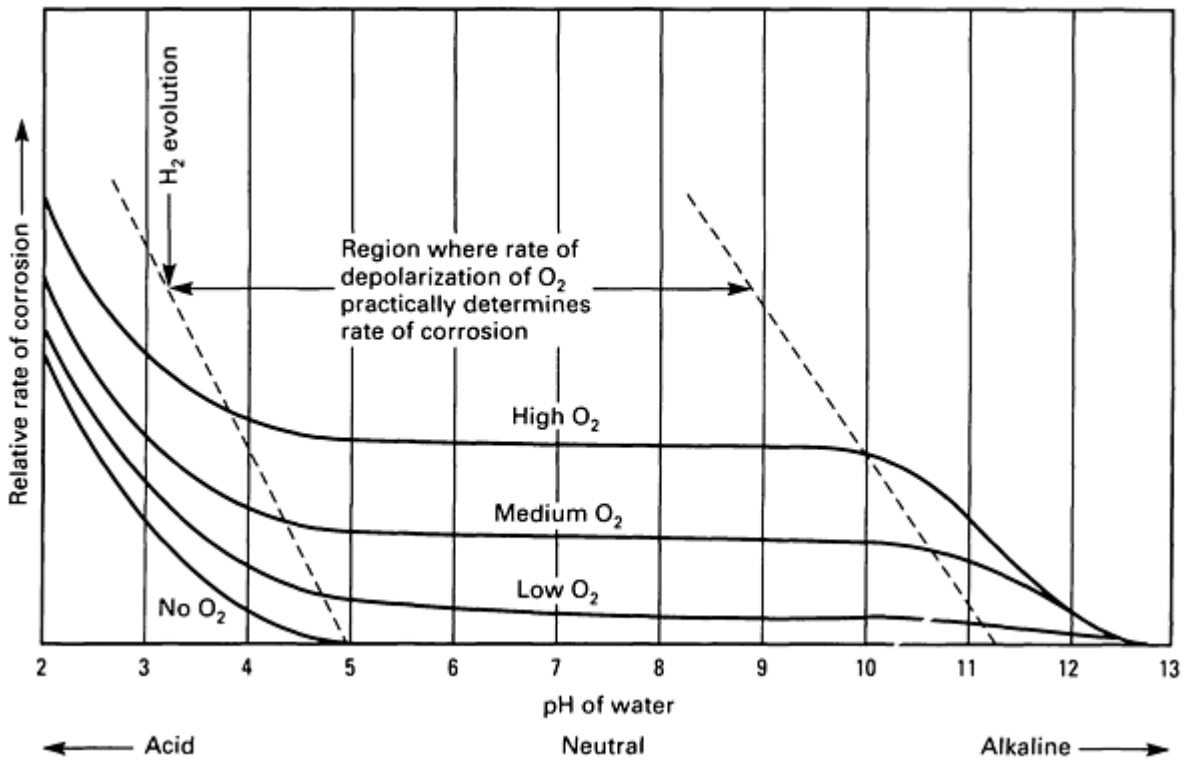

Fig. 43 Corrosion of iron by aqueous solutions. Source: Ref 136

Effects of specific corroding agents. Effects of acids on zone-refined iron at 25 °C:

Acid (oxygen-free)	pH	Corrosion rate, g/m^2/day
0.1 *M* citric	2.06	2.9
0.1 *M* malic	2.24	0.3
4% NaCl	1-4	3.0
0.12 *N* HCl	1.01	2.0

Sources: Ref 111, 137, 138

Stability (Pourbaix) diagrams. The regions of stability of various species of iron in water at 25 °C are shown as a function of potential (relative to a standard hydrogen electrode) and pH in Fig. 44.

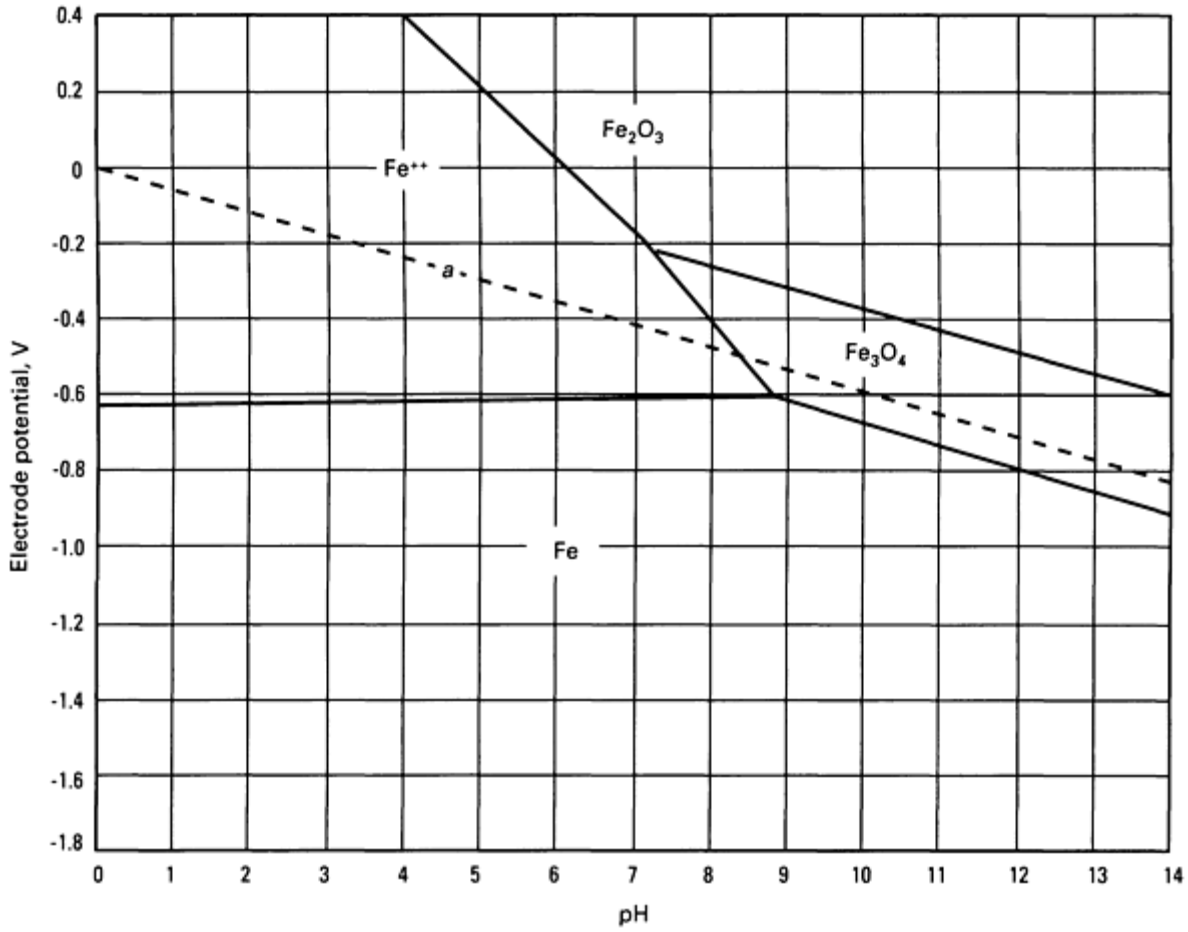

Fig. 44 Pourbaix diagram for the iron-water system at 25 °C. Fe, Fe_3O_4, and Fe_2O_3 are solid substances; water is stable above line *a*, H_2 gas is stable below line *a*. Source: Ref 139

Mechanical Properties

Tensile properties. The data for zone-refined iron have been summarized in Ref 81. Plots of the temperature dependence of yield stress are shown in Fig. 45. The very strong dependence shown is an inherent characteristic of α iron. The yield stress, however, is not a smooth function of temperature; instead, there is a concave-downward region in the plot, centered at about -30 °C (about 240 K), that has been observed by several researchers (see Ref 81, 140, 141). The scatter in these data for zone-refined iron is due principally to the single-crystals or bamboo-structure specimens that were employed. The dependence of the yield stress and flow stress of interstitial-free iron of grain size ASTM No. 5 to 6 on strain rate and temperature is shown in Fig. 46 and 47. The grain size dependence of the yield stress is discussed in Ref 144 and 145.

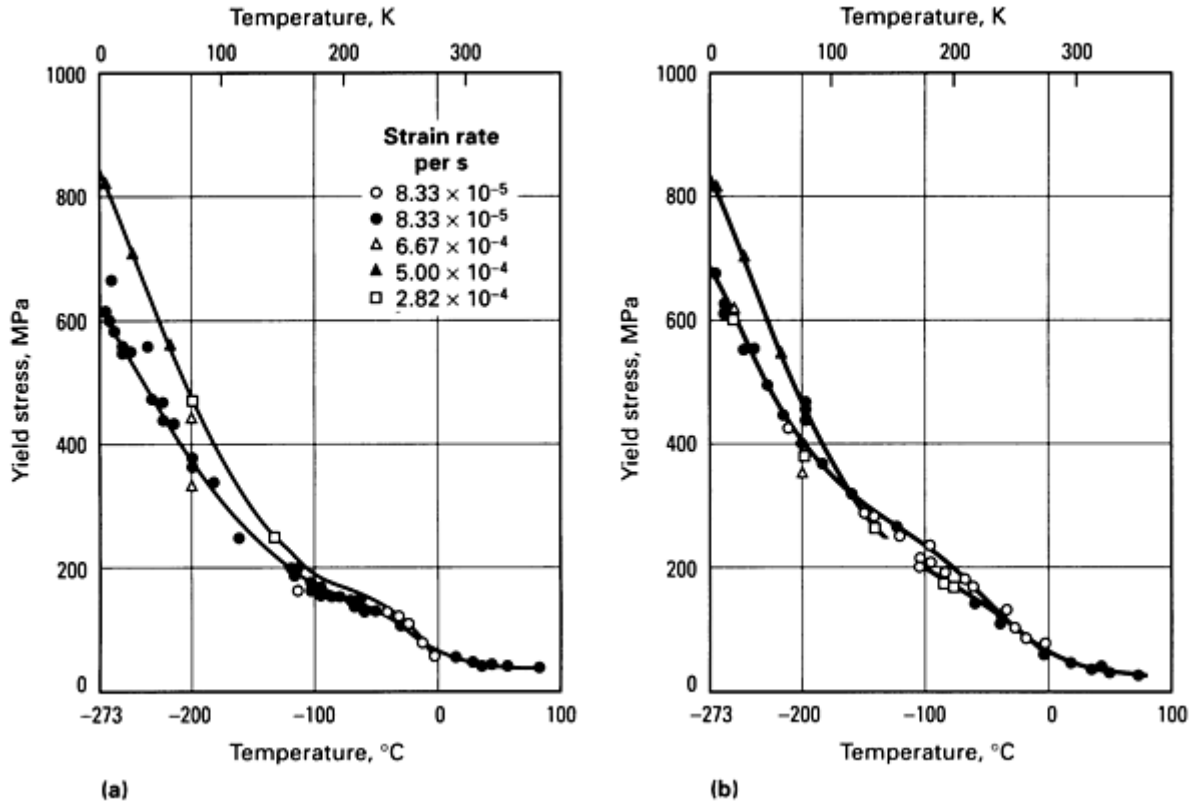

Fig. 45 Temperature dependence of the tensile yield stress of iron. (a) Stress at 0.1% strain. (b) Stress at 0.5% strain. The solid and open circles represent samples zone refined to residual resistivity ratio values of 3600 and >5000, respectively. Data from three other investigations are also shown. Source: Ref 81

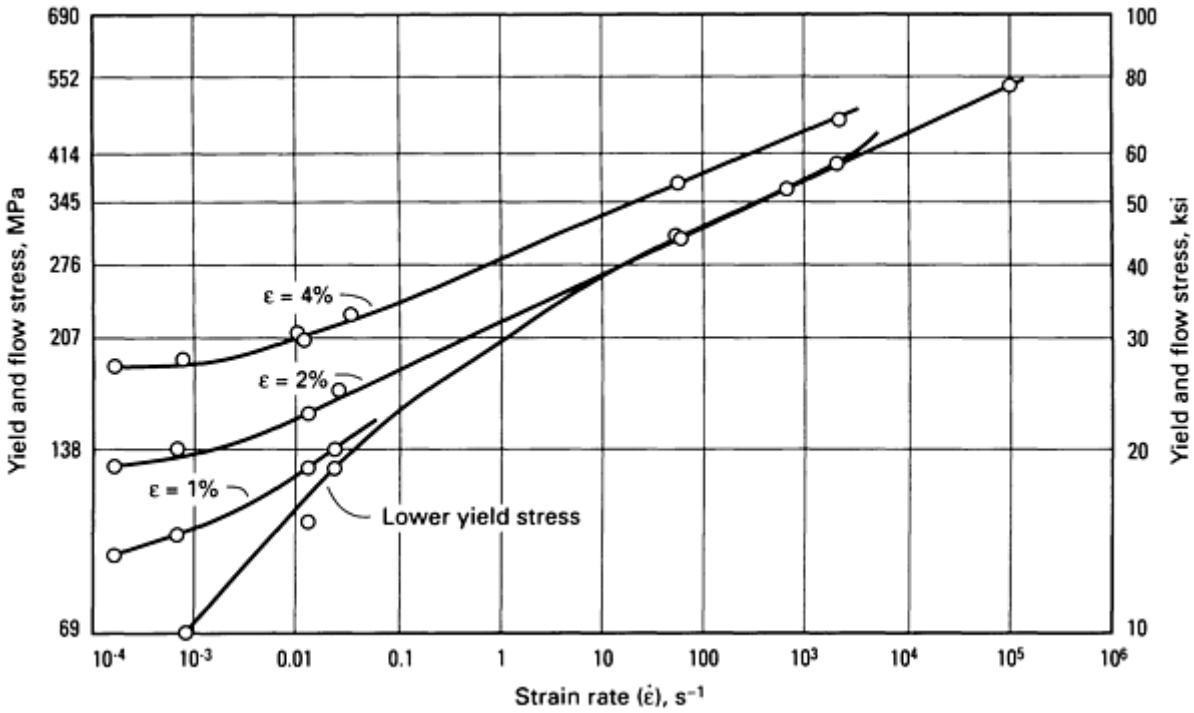

Fig. 46 The effect of strain rate ($\dot{\epsilon}$) on the strength of polycrystalline iron at room temperature. Source: Ref 142

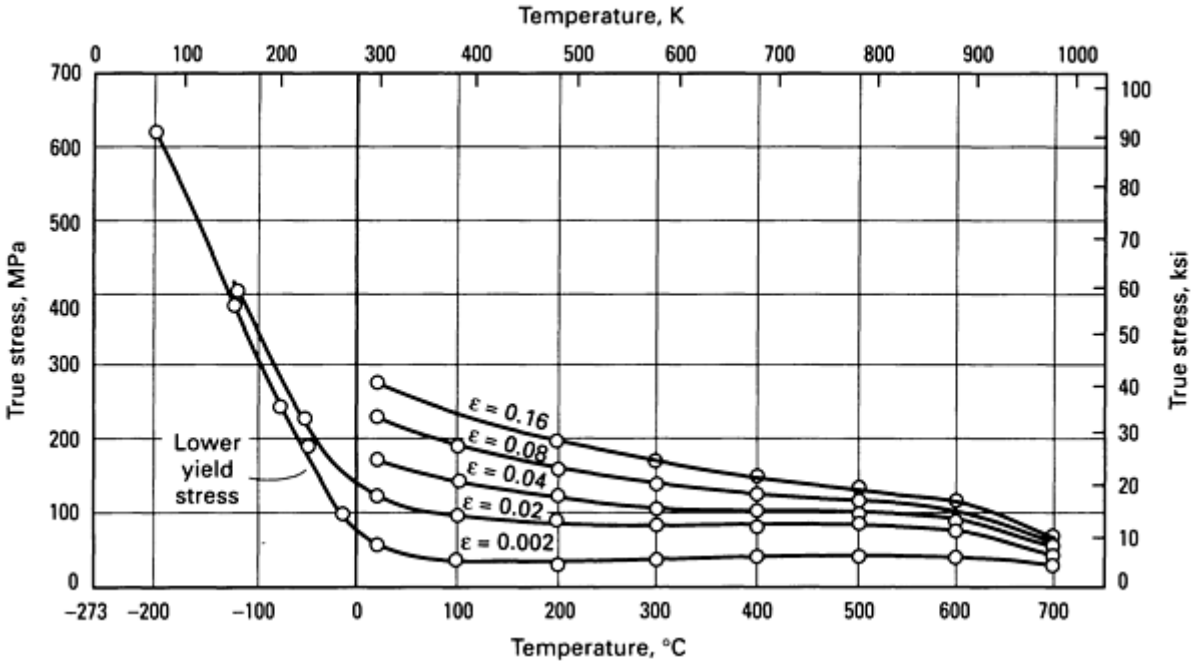

Fig. 47 Temperature dependence of yield and flow stresses in titanium-gettered iron. $\dot{\epsilon} \cong 2.5 \times 10^{-4}$ s^{-1}. Grain size, ASTM No. 5 to 6. Source: Ref 143

Compressive properties. The yield strength in compression is the same as in tension. For a further discussion, see Ref 146.

Hardness. Vickers hardness as a function of temperature for pure iron single crystals and crystals containing 300 ppm carbon is shown in Fig. 48(a). The anisotropy of the hardness of pure iron single crystals is shown in Fig. 48(b).

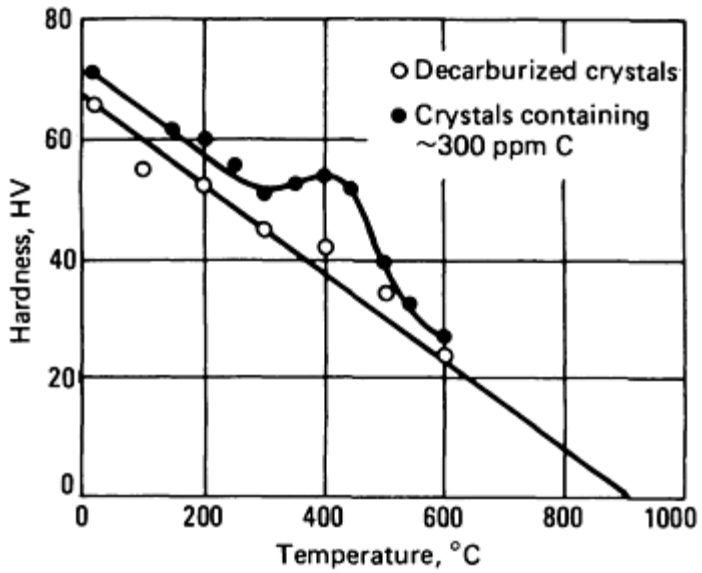

Fig. 48(a) Hardness of iron single crystals as a function of temperature. Source: Ref 147

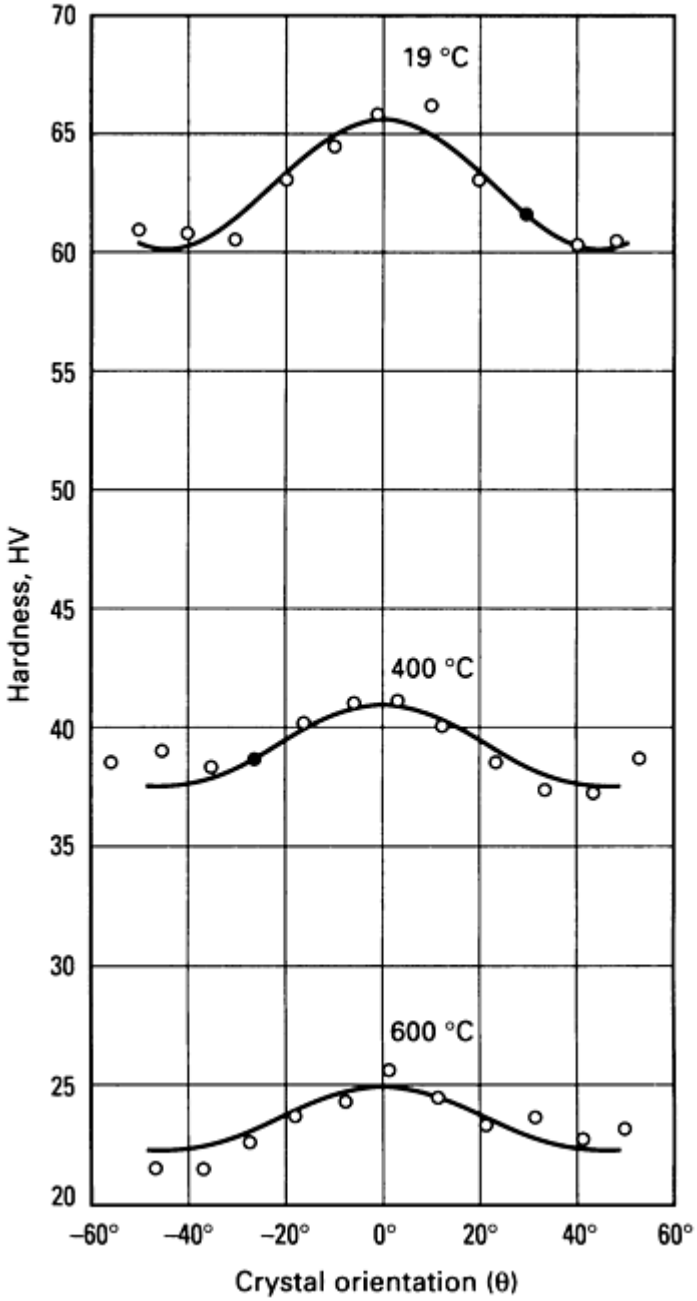

Fig. 48(b) Hardness of decarburized crystals of iron as a function of crystal orientation (θ). At θ= 0, the diagonal of the hardness impression is the projection of the <100> direction on the crystal surface. Source: Ref 147

Poisson's ratio. 0.291 at room temperature (Ref 145)

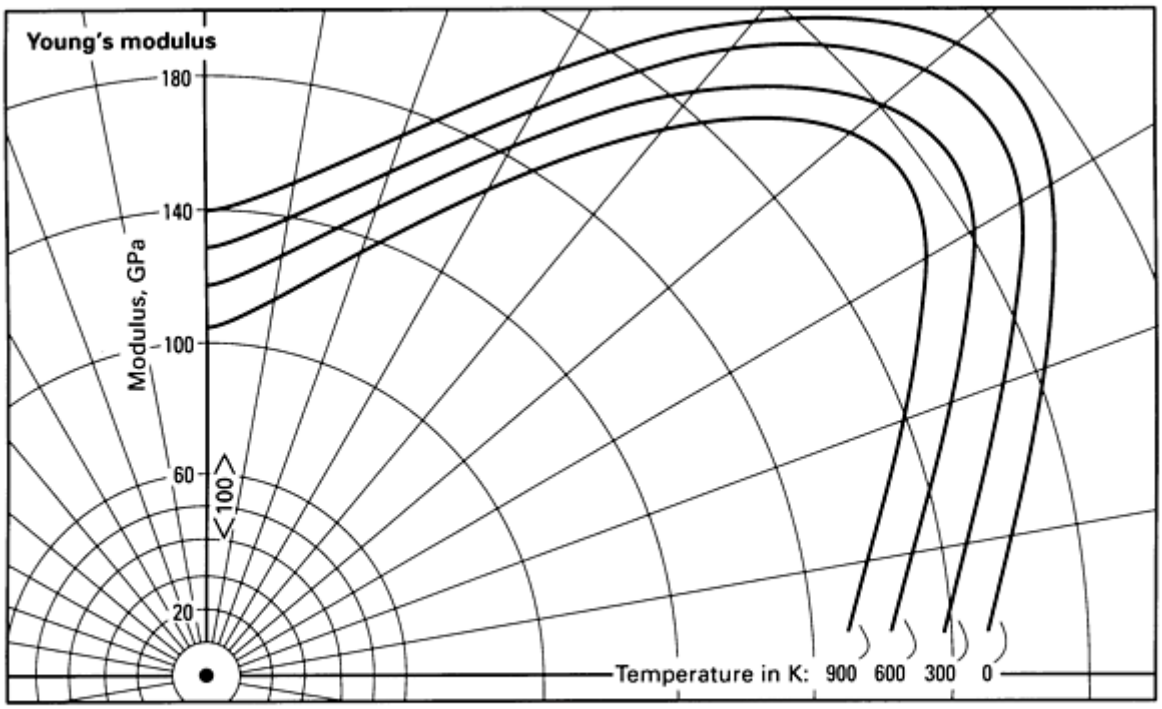
Strain-hardening exponent. About 0.3

Elastic moduli. At room temperature (Ref 148):

- Young's modulus: 208.2 GPa
- Bulk modulus: 166.0 GPa
- Shear modulus: 80.65 GPa
- Compressibility: 6.024 TPa^{-1}

First-, second-, and third-order elastic stiffness values are given in Ref 149.

Elastic moduli along crystal axes. The directional dependence of Young's modulus and shear modulus is shown in Fig. 49(a). The directional dependence of Poisson's ratio is shown in Fig. 49(b).



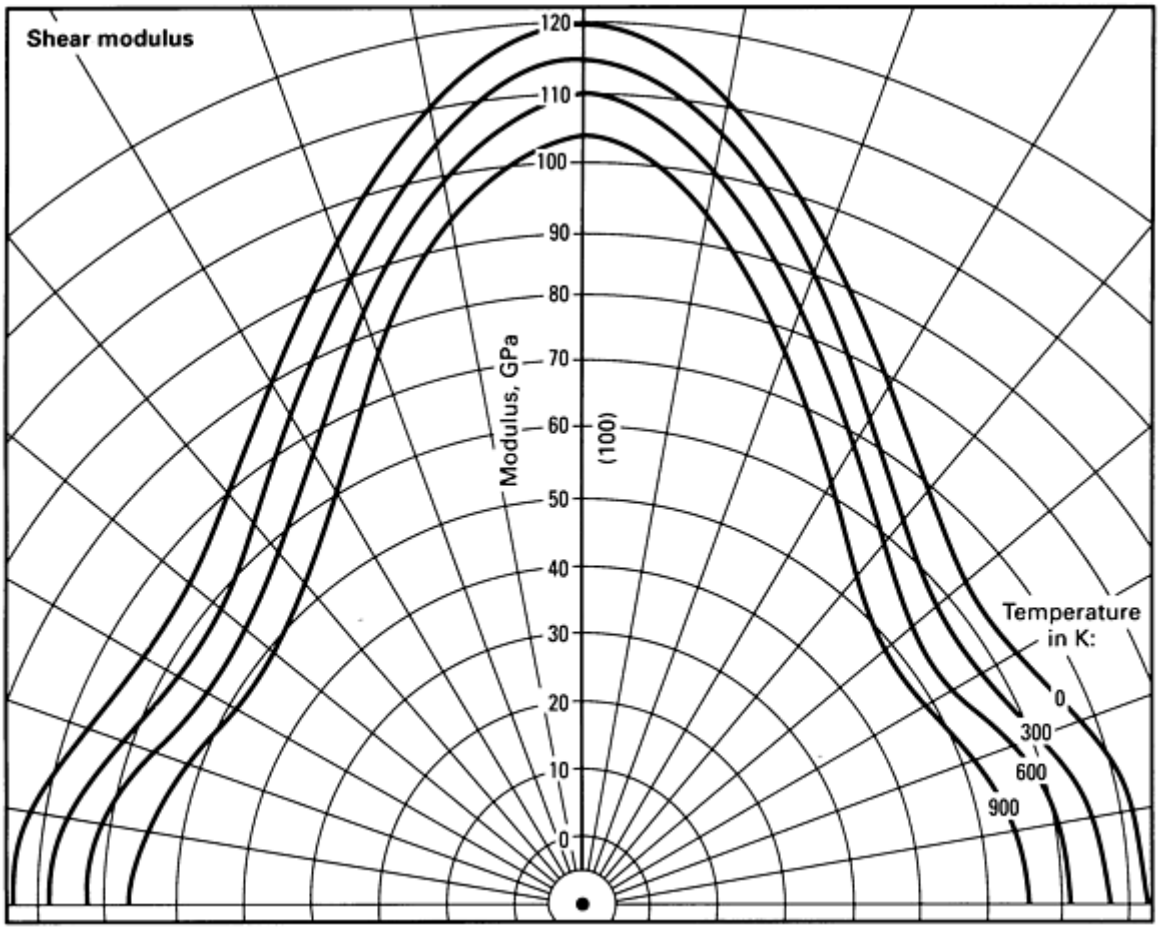


Fig. 49(a) Direction dependence of the Young's modulus and shear modulus values for iron in the (100) plane. Source: Ref 150

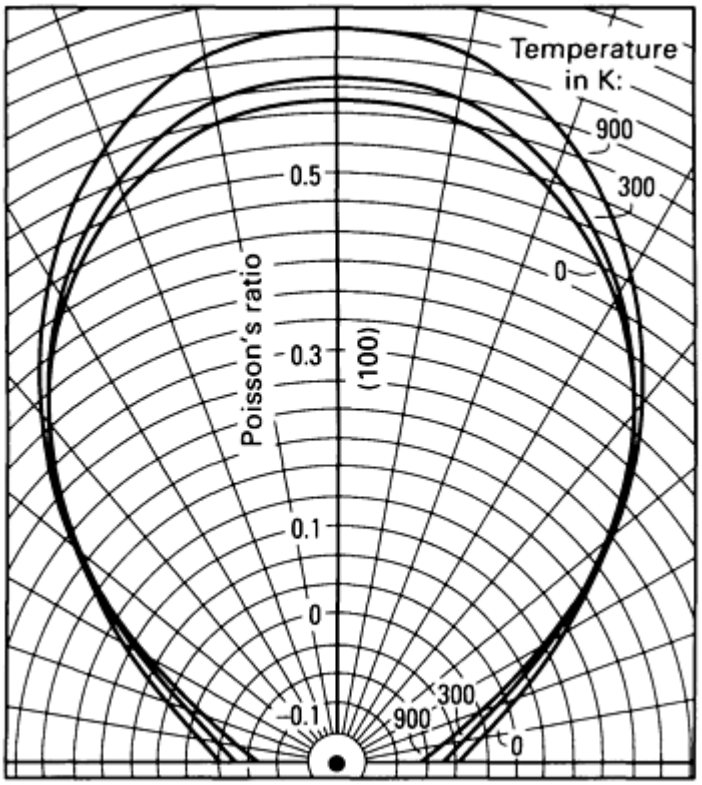

Fig. 49(b) Directional dependence of Poisson's ratio for iron in the (100) plane. Source: Ref 150

Properties of single crystals. Plastic-flow characteristics of single crystals are described in Ref 151. Three-stage hardening was observed at room temperature for all crystal orientations. At -130 and -196 °C (143 and 77 K), the critical resolved shear stress law was not obeyed. The critical resolved shear stress was greater in an antitwinning direction than in a twinning direction.

Ductile-to-brittle transition temperature (DBTT). For interstitial-free iron (Charpy V-notch, $\frac{1}{2}$ size): -34 °C for ASTM grain size No. 4 to 5; -29 °C for ASTM grin size No. 0 to 2 (Ref 143)

Viscosity of liquid. See Fig. 50.

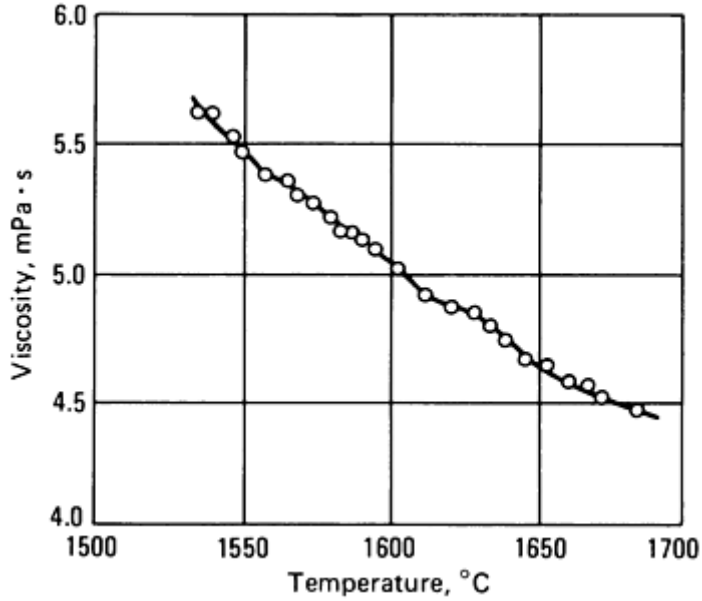

Fig. 50 Temperature dependency of viscosity for liquid iron. Source: Ref 152

Liquid surface tension. See Fig. 51.

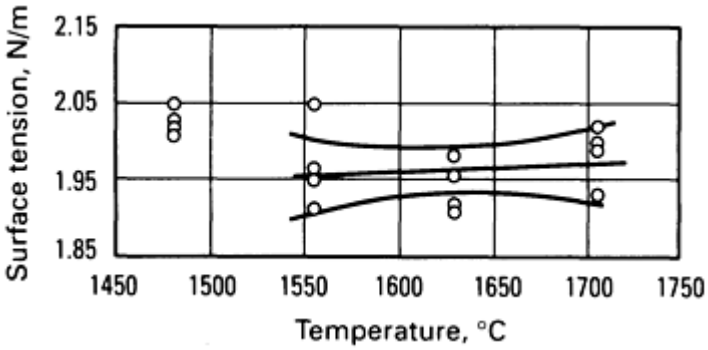

Fig. 51 Surface tension of pure iron. Source: Ref 153

Coefficient of friction. See Fig. 52.

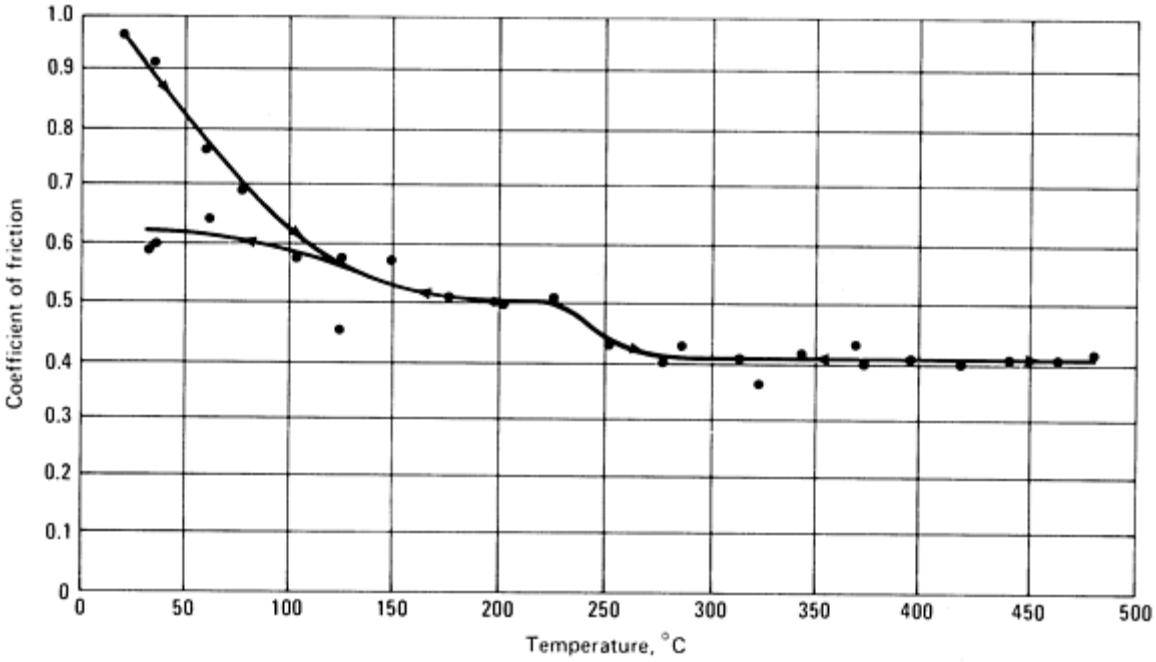

Fig. 52 Effect of temperature on the coefficient of friction for iron against iron during temperature cycling. Load, 1.88 kg; velocity, 7.6 mm/s. Source: Ref 154

Velocity of sound. At room temperature. Longitudinal, 5952 m/s; transverse, 3222 m/s (Ref 155)

Lead (Pb)

Compiled by J.F. Smith, Lead Industries Association, Inc. and A.T. Balcerzak, St. Joe Lead Company

Lead is used in lead acid storage batteries, ammunition, cable sheathing, pipe, sheet, counterweights, bearings, ballast, gaskets, type metal, low-melting alloys, steel coatings, and foil. Applications include sound and vibration control and x-ray shielding. Lead is used as an alloying ingredient in steel and copper alloys to improve machinability; it is also used in many chemicals.

Caution:

Lead presents a health hazard, and should not be used to conduct very soft water for drinking, nor should it come in contact with foods. Inhalation of lead dust and fumes should be avoided.

Structure

Crystal structure. Face-centered cubic, a = 0.49489 nm

Minimum interatomic distance. 0.3499 nm

Mass Characteristics

Atomic weight. 207.19

Density. See Fig. 53.

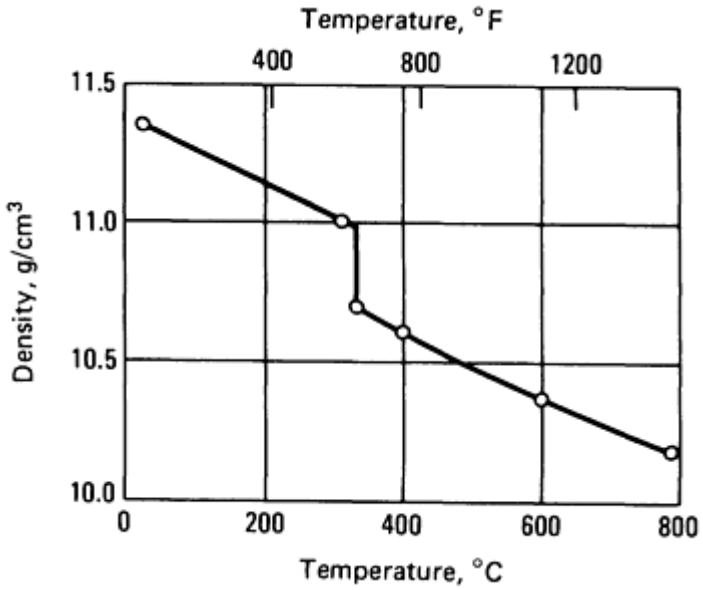

Fig. 53 Temperature dependence of the density of lead

X-ray absorption characteristics. See Fig. 1 in the article "Lead and Lead Alloys" in this Volume.

Thermal Properties

Melting point. 327.4 °C

Boiling point. 1750 °C

Coefficient of linear thermal expansion. 26.5 μm/m · K at -190 to 19 °C; 29.3 μm/m · K at 17 to 100 °C

Specific heat and enthalpy:

°C	Specific heat (C_p), kJ/kg · K	Enthalpy (ΔH), kJ/kg
25	0.1287	0
127	0.1320	13.24
227	0.1368	26.67
327.4 (solid)	0.1421	40.76
327.4 (liquid)	0.1479	63.94

427	0.1465	78.53
527	0.1449	93.16
627	0.1433	107.54
727	0.1404	121.81
827	0.1390	135.94

Latent heat of fusion. 22.98 to 23.38 kJ/kg

Latent heat of vaporization. 945.34 kJ/kg

Thermal conductivity. See Fig. 54.

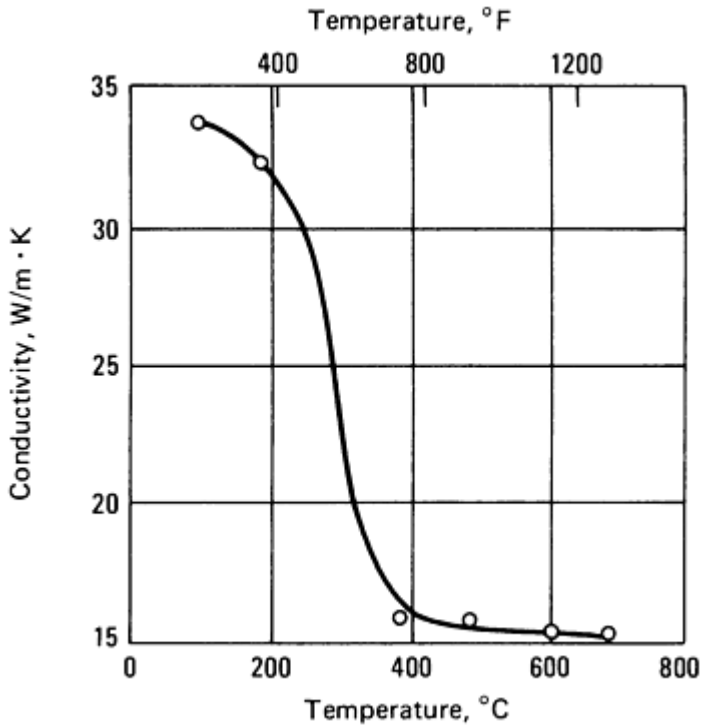

Fig. 54 Temperature dependence of the thermal conductivity of lead

Vapor pressure:

°C	**kPa**

957	0.1013
1140	1.013
1389	10.13
1750	101.3

Electrical Properties

Electrical resistivity:

°C	**nΩ · m**
20	206.43
100	270.21
200	363.78
300 (solid)	479.38
340 (liquid)	978.67
400	1014.18

Electrochemical equivalent. Valence +2, 1.0736 mg/C; valence +4, 0.5368 mg/C

Standard electrode potential. 0.122 V versus standard hydrogen electrode

Temperature of superconductivity. 4 K (-269 °C)

Magnetic Properties

Magnetic susceptibility. Volume: -1.5×10^{-6} mks

Optical Properties

Spectral reflectance. 62% at $\lambda = 589$ nm

Refractive index. Solid, 2.01 in yellow light; molten, 0.415 for $\lambda = 602$ nm

Absorptive index. Solid, 3.48 in yellow light

Chemical Properties

Resistance to specific corroding agents. See the article "Corrosion of Lead and Lead Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Mechanical Properties

Damping capacity. See Fig. 2 in the article "Lead and Lead Alloys" in this Volume.

Dynamic liquid viscosity. 1.67 mPa · s

Liquid surface tension. 438 kN/m at 400 °C

Velocity of sound. 1227 m/s at 18 °C

Lithium (Li)

Compiled by J.E. Selle, Oak Ridge National Laboratory; Revised by R.K. Williams, Oak Ridge National Laboratory

Lithium is used as a scavenging agent for inert gases; as an alloying element with aluminum, magnesium, zinc, and lead; in heat transfer applications; in tritium breeding; in the synthesis of organic compounds; and in battery anode material. Compounds containing lithium are used as refrigerant dryers and catalysts, high-temperature lubricants, and reagents in the ceramic and chemical industries.

Lithium is very reactive, and care must be taken to avoid reaction with air, water vapor, or other reactive gases. Airtight containers should be used for containment. Niobium, tantalum, and molybdenum containers are preferred for temperatures above 600 °C. Ferrous alloys are not recommended for long-term use above 550 °C but perform satisfactorily below this temperature.

Structure

Crystal structure. α phase, close-packed hexagonal: a = 0.3111 nm; c = 0.5093 nm. β phase, body-centered cubic: a = 0.35089 nm

Minimum interatomic distance. Distance of closest approach, β phase: 0.3039 nm. Goldschmidt atomic radii, 12-fold coordination: 0.157 nm

Mass Characteristics

Atomic weight. 6.939

Density. 0.5334 g/cm^3 at 20 °C

Density versus temperature. From 200 to 453.7 K:

$$\rho_S = 0.5633 - (8.898 \times 10^{-5})\, T - \frac{1.16}{T}$$

From 453.7 to 1700 K:

$$\rho_L = 0.5584 - (1.01 \times 10^{-4})T$$

where T is in K and ρis in g/cm^3

Expansion on melting. 1.5% of solid volume

Expansion on phase transformation. 0.12% (calculated)

Thermal Properties

Melting point. 180.7 °C

Boiling point. 1336 °C

Phase transformation temperature. α to βphase (cooling), -193 °C

Coefficient of linear thermal expansion. 56 μm/m · K at 20 °C

Specific heat. 3.3054 kJ/kg · K at 20 °C; 3.5146 kJ/kg · K from 0 to 100 °C; 4.2258 kJ/kg · K from 180 to 500 °C

Enthalpy. H_{st} - H_0 = 666.88 kJ/kg at 25 °C. Liquid: H_1 - H_{273} = $-7.517 \times 10^5 + 4.169 \times 10^3 T$ J/kg (T in K). Solid: H_s - H_{273} = $-1.030 \times 10^6 + 3.7799 \times 10^3 T$ J/kg (where T is in K)

Entropy. S_{st} = 4.219 kJ/kg · K

Latent heat of fusion. 433.9 kJ/kg

Latent heat of phase transformation. 6.452 kJ/kg

Latent heat of vaporization. 22.73 MJ/kg

Thermal conductivity. 44.0 W/m · K at 180.7 °C

Thermal conductivity versus temperature. From 200 to 453.7 K:

$$k_S = 44.00 + 0.02019\ T + \frac{8037}{T}$$

From 453.7 to 1700 K:

$$k_L = 21.42 + 0.05230T - (1.371 \times 10^{-5})T^2$$

where k is in W/m · K and T is in K

Vapor pressure. From 200 to 453.7 K:

$$\log_{10} P = \frac{-8310}{T} + 10.673$$

From 453.7 to 1700 K:

$$\log_{10} P = \frac{-7975.6}{T} + 9.9624$$

where P is in Pa and T is in K

Self-diffusion coefficient. For 195 to 450 °C:

$$D = 1.41\ (\pm 0.12) \times 10^{-7} \left(\exp \frac{2825 \pm 90}{RT} \right) \text{m}^2/\text{s}$$

Electrical Properties

Electrical resistivity. Solid: 93.5 nΩ · m at 20 °C. Liquid: 250 nΩ · m at 180.7 °C

Temperature dependence of electrical resistivity. From 200 to 453.7 K:

$$R_S = \frac{-2.508 \times 10^9}{T^4} + \frac{1.225 \times 10^5}{T^2} - 4.330 + 0.04271\ T$$

From 453.7 to 1700 K:

$$R_L = 5.819 + 0.05282\ T - (2.843 \times 10^{-5})T^2 + 9.474 \times 10^{-8}\ T^3$$

where R is in 10^{-8} Ω· m and T is in K

Thermoelectric potential. Versus platinum (reference junction, 0 °C):

Hot junction temperature, °C	Thermal emf, mV
-200	-1.12
-100	-1.00
100	1.82

Ionization potential. Li(I), 5.39 eV; Li(II), 75.619 eV; Li(III), 122.419 eV

Magnetic Properties

Magnetic susceptibility. Volume: 2.242×10^{-3} mks

Nuclear Properties

Stable isotopes. ^{6}Li, isotope mass 6.01512, 7.42% abundance; ^{7}Li, isotope mass 7.01600, 92.58% abundance

Unstable isotopes:

Isotope	Half-life, s	Decay	Energy, MeV
$^{5}L^{(a)}$	10^{-21}	p	. . .
^{8}L	0.85	β^-	13
^{9}L	0.17	β^-	13.5 (75%); 11 (25%)

(a) Isotope mass, 5.0125

Thermal neutron cross section. ^{6}Li, 45 ± 10 mb; ^{7}Li, 37 ± 4 mb

Chemical Properties

General corrosion behavior. Lithium tarnishes quickly in oxygen, nitrogen, and moist air. Solubilities of various metallic elements are very sensitive to the lithium purity.

Mechanical Properties

Hardness. 0.6 (Mohs scale)

Dynamic viscosity. μ= 0.645 MPa · s at 180.7 °C; 0.140 MPa · s at 1335 °C. From 453.7 to 1700 K: $\mu = 0.1157 - 1.418 \times 10^{-4} T + 4.229 \times 10^{-8}$, where $\mu$is in MPa · s and T is in K

Liquid surface tension. σ= 0.396 N/m at 180.7 °C; σ= 0.240 N/m at 1335 °C. From 453.7 to 1700 K: $\sigma = 0.4738 - (1.627 \times 10^{-4})T$, where σ is in N/m and T is in K

Velocity of sound. For 185 to 827 °C: $v = 4784.5 - 0.591\ T$, where v is in m/s and T is in K

Magnesium (Mg)

Compiled by S.C. Erickson, The Dow Chemical Company; Reviewed for this Volume by Carl Vass, Fansteel Wellman Dynamics

Primary magnesium has a minimum purity of 99.8% and must meet definite specifications limiting individual impurities. This purity is sufficient for most chemical and metallurgical uses. Most of the pure magnesium sold is produced electrolytic as primary magnesium. For application requiring a minimum of specific impurities, special grades of electrolytic magnesium are available. Silicothermic magnesium is produced by thermal reduction of magnesium oxide. High-purity sublimed magnesium is produced by sublimation of primary electrolytic magnesium under vacuum. Typical analyses are shown in Table 23. Unless otherwise indicated, the properties listed for pure magnesium were determined on metal of 99.98% + % purity.

Table 23 Typical chemical compositions of pure magnesium available commercially

Designations	Composition, %										
	Al	Ca	Cu	Fe	Mn	Ni	Pb	Si	Sn	Other metallics	Mg[(a)]

										Each	**Total**

Sources: Ref 156, 157, 158

(a) Magnesium by difference.

(b) 0.006 H_2, 0.0025 N_2, 0.0022 O_2; hydrogen, nitrogen, and oxygen not reported for other grades.

(c) Not available commercially.

Alloyed with small amounts of aluminum, manganese, rare earths, thorium, zinc, or zirconium, magnesium yields alloys with high ratios of strength to weight at both room and elevated temperatures. The alloys have unexcelled machinability, are workable by all common methods, are stable in many atmospheres, and have a high damping capacity.

Magnesium is an active chemical element and reacts with many common chemical oxidizing agents. A number of metals such as thorium, titanium, uranium, and zirconium are prepared by thermal reduction with magnesium. As a catalyst, magnesium is useful for promoting organic condensation, reduction, addition, and dehalogenation reactions. It is useful for the synthesis of complex and special organic compounds by the Grignard process. Its use in pyrotechnics is well established. Magnesium powder can be dispersed in hydrocarbons and mixed in solid propellants for high-energy fuels.

Magnesium alloyed with other metals, such as aluminum, copper, cast iron, lead, nickel, and zinc, improves their properties. It also deoxidizes copper and brass, desulfurizes iron and nickel, and debismuthizes lead.

As a galvanic anode, magnesium provides effective corrosion protection for water heaters, underground pipelines, ship hulls, ballast tanks, and other underground and underwater structures. Small lightweight high-current-output primary batteries use magnesium alloy as the anode. Magnesium has a low-capture cross section for thermal neutrons and a low-level retention on induced radioactivity; these properties make it suitable for varied uses in atomic energy applications.

Structure

Crystal structure. Close-packed hexagonal. At 25 °C: a = 0.32087 ± 0.00009 nm; c = 0.5209 ± 0.00015 nm; c/a = 1.6236 (Ref 159, 160)

Slip planes. Primary (0001), $<11\bar{2}0>$; secondary, $\{10\bar{1}0\}$, $<11\bar{2}0>$; $\{10\bar{1}1\}$, $<11\bar{2}0>$; at elevated temperatures (Ref 161, 162, 163, 164)

Twinning planes. Primary $\{10\bar{1}2\}$; secondary, $\{30\bar{3}4\}$; $\{10\bar{1}3\}$ at elevated temperatures (Ref 165, 166)

Cleavage plane. No definite cleavage plane (Ref 161, 167)

Minimum interatomic distance. 0.3196 nm

Fracture type. See Ref 161 and 167.

Mass Characteristics

Atomic weight. 24.312

Density. 1.738 g/cm^3 at 20 °C; solid, approximately 1.65 g/cm^3 at 650 °C; liquid, approximately 1.58 g/cm^3 (Ref 168, 169). See also Fig. 55.

Volume change on freezing. 4.2% shrinkage

Volume change during cooling. From 650 (solid) to 20 °C: 5% shrinkage

Thermal Properties

Melting point. 650 °C (Ref 171, 172)

Boiling point. 1107 ± 10 °C (Ref 158, 172, 173)

Thermal expansion. Polycrystalline at 20 °C: 25.2 μm/m · K (Ref 174, 175, 176, 177, 178). Values for all magnesium alloys are approximately the same: $L_t = L_0 [1 + (24.8t + 0.0096t^2) \times 10^{-6}]$, where t is in °C. Along crystal axes, from 15 to 35 °C: 27.1 μm/m · K along *a* axis; 24.3 μm/m · K along *c* axis (Ref 179)

Specific heat. 1.025 kJ/kg · K at 20 °C (Ref 180). See also Fig. 56.

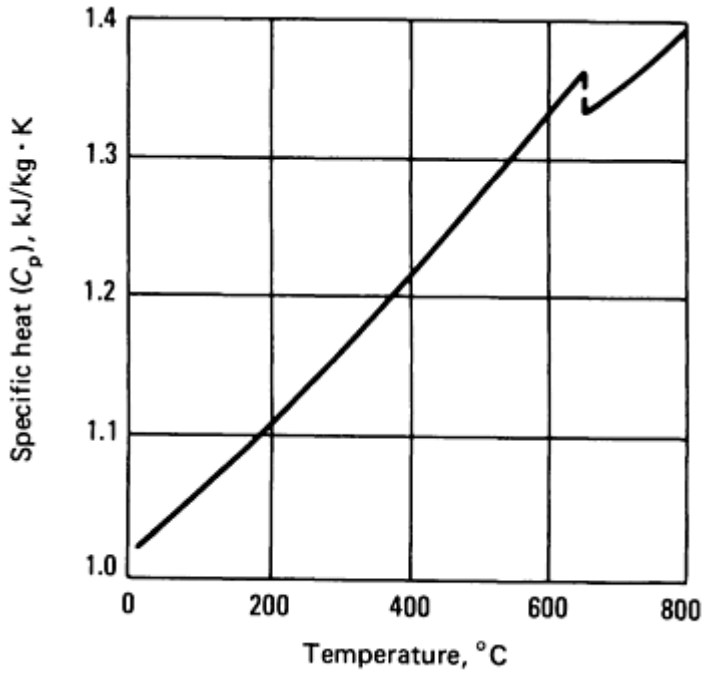

Fig. 56 Temperature dependence of the specific heat of magnesium. Source: Ref 180

Latent heat of fusion. 360 to 377 kJ/kg (Ref 180)

Latent heat of sublimation. 6113 to 6238 kJ/kg at 25 °C (Ref 172)

Latent heat of vaporization. 5150 to 5400 kJ/kg (Ref 172)

Thermal conductivity. 418 W/m · K at 20 °C (Ref 181)

Temperature dependence: $K/T = 0.017 + 2.26 \times 10^{-5}/\rho$, where ρ is in nΩ · m, T is in K, and K is in W/m · K (Ref 157)

Heat of combustion. 24,900 to 25,200 kJ/kg Mg

Electrical Properties

Electrical conductivity. 38.6% IACS

Electrical resistivity. Polycrystalline at 20 °C: 44.5 nΩ · m (Ref 175, 182). Liquid at 650 °C: 247 nΩ · m (Ref 183, 184, 185). Along crystal axes at 20 °C: 44.8 nΩ · m along *a* axis; 37.4 nΩ · m along *c* axis (Ref 186). Temperature coefficient: polycrystalline at 20 °C, 0.165 nΩ · m per K (Ref 182). Along crystal axes at 20 °C: 0.165 nΩ · m per K along *a* axis; 0.143 nΩ · m per K along *c*axis (Ref 186). Effect of temperature, see Fig. 57. Effect of alloying, see Fig. 58

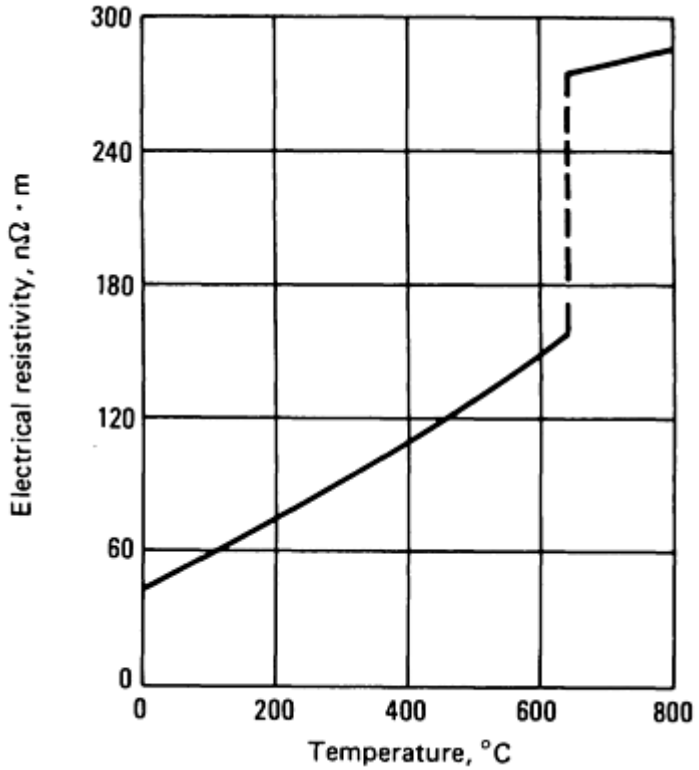

Fig. 57 Temperature dependence of the electrical resistivity of magnesium. Sources: Ref 183, 184, 185, 187, 188, and 189

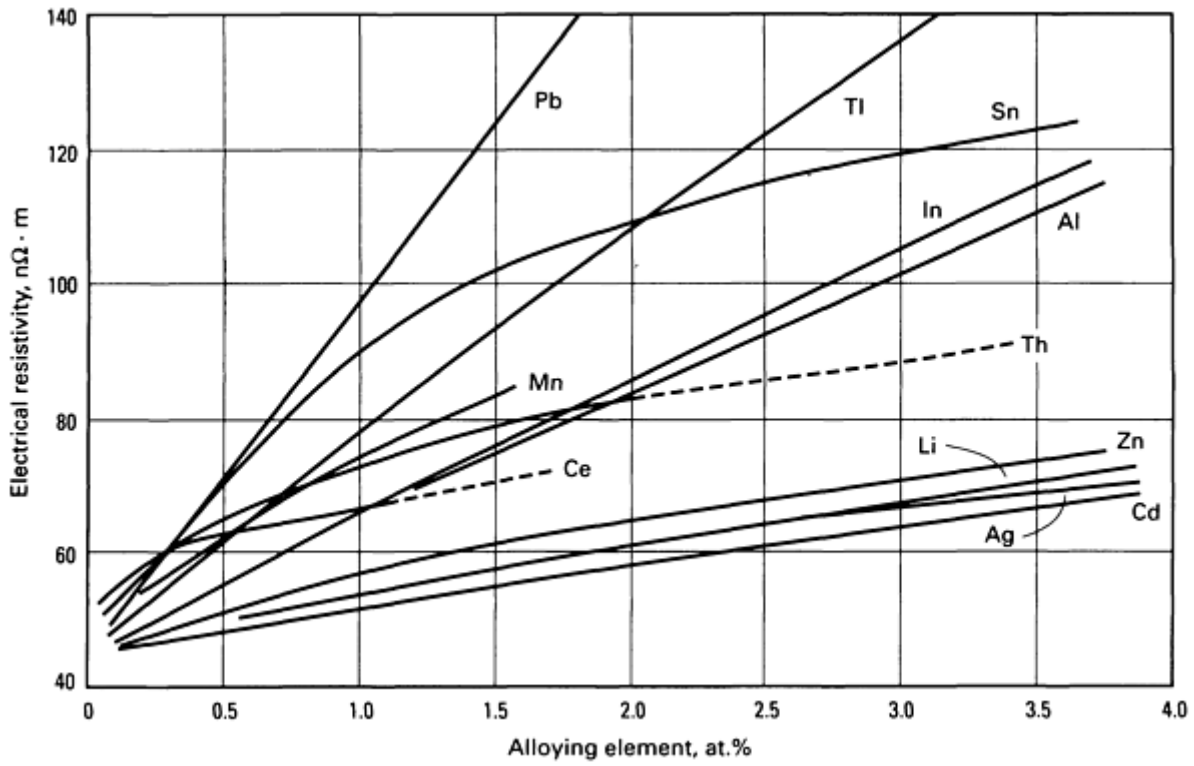

Fig. 58 Effect of alloying additions on the electrical resistivity of magnesium. Sources: Ref 169, 182

Contact potential. +0.44 mV versus platinum at 0 to 100 °C (Ref 190); -0.222 mV versus copper at 27 °C (Ref 182)

Electrochemical equivalent. 126 mg/C

Electrolytic solution and potential. 1.63 mV versus saturated calomel electrode at 25 °C in aerated 3% NaCl solution (Ref 191)

Magnetic Properties

Magnetic susceptibility. Mass: 0.00627 to 0.00632 mks (Ref 192)

Magnetic permeability. 1.000012

Optical Properties

Reflectivity. 72% at λ= 0.500 μm; 74% at λ= 1.00 μm; 80% at λ= 3.0 μm; 93% at λ= 9.0 μm (Ref 193)

Refractive index. 0.37 at λ= 0.589 μm (Ref 194)

Absorption constant. 4.42 at λ= 0.589 μm (Ref 194)

Color. Bright silvery white

Emissivity. 0.07 at 22 °C (Ref 195)

Nuclear Properties

Thermal neutron absorption cross section. 0.063 ± 0.004 b (Ref 196)

Chemical Properties

General resistance to corrosion. The corrosion resistance to magnetism is dependent on surface film formation; the rate of formation, solution, or chemical change of the film varies with the medium to which it is exposed and also with the alloying elements or impurities present in the metal. Magnesium has good resistance to both indoor and outdoor atmospheres and, in the absence of galvanic couples, even shows resistance to more aggressive environments such as seawater. Indoor tarnishing is controlled largely by the relative humidity. In mild marine and industrial inland atmospheres, the degree of corrosion resistance far exceeds that of mild steel. In stagnant distilled water at room temperature, magnesium forms a protective film that stops action (Ref 197).

Resistance to specific agents. The action of salt solutions on magnesium is dependent on both the anion and the cation of the dissolved salt. Neutral solutions of heavy metal salts will generally cause severe attack. Magnesium suffers little, if any, attack in alkalies, chromates, fluorides, nitrates, or phosphates; more vigorous corrosion occurs in solutions of chloride, bromides, iodides, and sulfates.

Mineral acids, except hydrofluoric and chromic acids, dissolve magnesium rapidly. Aqueous solutions of organic acids attack magnesium, whereas fatty acids (hot or cold, dry or containing water) do not.

Magnesium is not affected by aliphatic and aromatic hydrocarbons, ketones, ethers, glycols, and alcohols, with the exception of anhydrous methyl alcohol. The latter reaction is inhibited, but not completely suppressed, by the presence of water in the methyl alcohol.

Pure halogenated organic compounds do not attack magnesium at ordinary temperatures, but at elevated temperatures, or if water is present, corrosion can be severe. No marked reaction was found to occur between magnesium and methyl chloride, carbon tetrachloride, or chloroform, even after prolonged heating under increased pressures.

Lower alkyl halides, up to amyl derivatives, have been shown to react with magnesium only under pressure and at temperatures in excess of 270 °C, but higher alkyl halides are reported to react with magnesium at their boiling points. In general, the presence of water greatly stimulates the reaction between magnesium and halogenated compounds at elevated temperatures. Fluorinated hydrocarbons are generally without action on magnesium when dry (Ref 197). Additional

information is available in the articles "Selection and Application of Magnesium and Magnesium Alloys" in this Volume and "Corrosion of Magnesium and Magnesium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Fabrication Characteristics

Casting temperature. 705 to 760 °C

Type of flux. Open-pot melting, Dow No. 250; crucible melting, Dow No. 310

Precautions in melting. Molten metal must be protected from the atmosphere by the use of inert gas or protective fluxes. Molten magnesium does not react with carbon, silicon carbide, or combinations of these materials. There is little, if any, reaction with molybdenum, tungsten, or tantalum. Low-carbon (welded or cast) steel crucibles are used as containers for molten magnesium of commercial purity; nickel-bearing steels should not be used for this purpose. Use a protective agent (Dow No. 181) to prevent magnesium from burning when it is being poured in an open atmosphere. The usual safety precautions observed with any molten metal should be observed. Preheat all tools or metal introduced in molten magnesium. Keep pot settings free from iron scale.

Precautions in fabrication. A supply of an approved extinguishing agent should be readily accessible to any machining, grinding, or similar operations on magnesium (additional information is available in the article "Machining of Magnesium and Magnesium Alloys" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*). Good housekeeping and sharp machine tools are the best deterrents to magnesium fires. Heat treating furnaces should have a protective atmosphere, such as SO_2 or BF_3, when operating at high temperatures. Magnesium powder must be kept dry (Ref 198).

Machinability index. For pure magnesium and all magnesium alloys, 500 (free-cutting brass = 100) (Ref 199)

Hot-working temperature range. 93 to above 482 °C for 99.98% Mg; 177 to above 482 °C for 99.80% Mg

Annealing temperature. 150 to 200 °C. Maximum reduction between anneals, 50 to 60% under suitable conditions

Forming temperature. 150 to 200 °C for best results

Joining. Rivet composition, aluminum alloy 5056. Oxyacetylene weld with pure magnesium welding rod, magnesium welding flux, and neutral flame. Resistance welding is satisfactory. Helium arc or argon arc welding is preferred. Use pure magnesium welding rod and no flux.

Recrystallization temperature. 93 °C for 1 h anneal after 30% cold reduction (99.98% Mg); 177 °C for a 1 h anneal after 30% cold reduction; 93 °C for a 1 h anneal after 60% cold reduction (99.80% Mg) (Ref 174)

Mechanical Properties

Tensile properties. See Table 24; see also Ref 200.

Table 24 Typical mechanical properties of magnesium at 20 °C

Form and section	Tensile strength, MPa	0.2% tensile yield strength, MPa	0.2% compressive yield strength, MPa	Elongation in 50 mm (2 in.), %	Hardness	
					HRE	HB[(a)]
Sand cast, 13 mm ($\frac{1}{2}$ in.) diam	90	21	21	2-6	16	30

Extrusion, 13 mm ($\frac{1}{2}$ in.) diam	165-205	69-105	34-55	5-8	26	35
Hard rolled sheet	180-220	115-140	105-115	2-10	48-54	45-47
Annealed sheet	160-195	90-105	69-83	3-15	37-39	40-41

(a) 500 kg load; 10 mm diam ball

Compressive properties. See Table 24.

Hardness. See Table 24.

Elastic modulus. Tension at 20 °C. 99.98% Mg: dynamic, 44 GPa; static, 40 GPa. 99.80% Mg: dynamic, 45 GPa; static, 43 GPa. See also Fig. 59.

Manganese (Mn)

Compiled by Howard S. Avery, Consultant

Manganese is a silvery-gray or gray-white metal like iron, but with a faint pinkish tinge. It oxidizes in moist air and in powder form, and thus may appear black. The powder, especially if it contains impurities or iron, may be pyrophoric; therefore, manganese dust suspended in air may be an explosion hazard along with being toxic at levels above 5 mg/m^3. Manganese is attacked by weak acids.

Manganese is most widely used in alloys of iron; lesser amounts are used in other alloys, in batteries (where the oxide MnO_2, or pyrolusite, serves as a depolarizer), and in the chemical, glass, and ceramic industries. Most steels contain manganese at levels ranging from <1% up to several percent. Manganese serves as a scavenger in steel because of its affinity for sulfur; it also moderately enhances hardenability. At concentrations of 10 to 14% it is the basis of the very tough and highly work-hardenable austenitic manganese steel (Ref 210).

For ironmaking and steelmaking, manganese is usually added in the form of spiegeleisen or various grades of ferromanganese. However, some alloys require the high purity of electrolytic manganese because manganese ores and derived ferromanganese may contain phosphorus as a tramp element, and phosphorus degrades the weldability of steels and can cause hot cracking. Iron-chromium-manganese stainless steels and such specialty nonferrous alloys as copper-manganese, manganese-containing brasses and bronzes, some nickel silvers, and manganese-bearing aluminum alloys also use electrolytic manganese, which typically contains (Ref 211):

Impurity	**Wt%**
Fe	0.0015
Cu	0.001
As	0.0005
Co	0.0025
Ni	0.0025
Pb	0.0025
Mo	0.001
S^{2-}	0.01
S^{6+}	0.014
C	0.002
H_2	0.015

The gas content of electrolytic manganese has a significant effect on some properties. Some degassed highly purified grades of the metal can reach a purity of 99.999%.

Thin films of manganese have interesting properties for strain gages (Ref 212) and for developing spectrally selective surfaces (Ref 213). Thin-film strain gages require a large gage factor, a low-temperature coefficient of resistance, low thermoelectric powder, and excellent thermal and temporal stability. Manganese films exhibit very high resistivity (375 μ

Ω· cm), a very low temperature coefficient of resistance (5 × 10^{-6} per °C), extremely low thermoelectric powder, and excellent thermal and temporal stability.

Quality control is crucial for thin film applications. Optical property measurements must be done with care because film properties are greatly affected by preparation factors such as substrate temperature during deposition, environmental conditions, storage, heat treatment, aging, thickness, surface contamination, and original purity.

Structure

Crystal structure. α phase: *a* = 0.89139 nm at 20 °C. β phase: *a* = 0.63145 nm at 20 °C. γ phase: *a* = 0.38624 nm; *c* = 0.940 nm at 1095 °C. δ phase: *a* = 0.30806 nm at 1134 °C (Ref 214)

Mass Characteristics

Atomic weight. 54.938

Density. Solid at 20 °C and 1 atm: α phase, 7.43 g/cm^3; β phase, 7.29 g/cm^3; γ phase, 7.18 g/cm^3 (Ref 215). Solid at 1246 °C: δ phase, 6.11 g/cm^3. Liquid at 1246 °C: 6.01 g/cm^3

Volume change on freezing. 1.7% (Ref 215)

Thermal Properties

Melting point. 1246 °C

Boiling point. 2065 °C (Ref 216)

Phase transformation temperatures. α to β, 707 °C; β to γ, 1087 °C; γto δ, 1138 °C

Coefficient of linear thermal expansion:

Absorptive index. See Fig. 66(b).

Nuclear Properties

Stable isotopes. ^{55}Mn

Radioactive isotopes. ^{50m}Mn, ^{50}Mn, ^{51}Mn, ^{52m}Mn, ^{52}Mn, ^{53}Mn, ^{54}Mn, ^{56}Mn, ^{57}Mn, and ^{58}Mn, where superscript *m* indicates isomers of manganese (Ref 242)

Mechanical Properties

Tensile properties. α and β phases are quite brittle, but γ has useful mechanical properties (yield strength, 241 MPa; tensile strength, 496 MPa; 40% elongation) (Ref 215). The β phase can be preserved by quenching. Pure γ cannot be preserved at ambient temperature by quenching, but alloying with 2% Cu and 1% Ni (Ref 211) or 0.01 to 0.06% Cu (Ref 243), or electrolytic deposition can provide the γ toughness after quenching.

Hardness. γ phase, 35 HRC

Elastic modulus. Tension, 191 GPa (Ref 244); shear, 76.4 GPa (Ref 245); bulk, 92.6 GPa (Ref 244)

Viscosity:

Temperature		Viscosity, mPa · s[(a)]
K	°C	
1519	1246	5.28
1550	1277	5.02
1600	1327	4.65

Mercury (Hg)

Compiled by M. Nowak, Troy Chemical Corporation

Mercury is the only common metal that is liquid at room temperature. It is rarely found in the free and uncombined state in nature and most often occurs as the ore cinnabar (HgS). Mercury is widely used for thermometers, barometers, diffusion pumps, and other laboratory instruments. It is used commercially in mercury vapor lamps, in lamps and lamp tubes for advertising signs, in switches for instruments and control devices, in dental preparations, and in batteries. Mercury chemicals ar widely used for making pesticides, antifouling paints, high-grade paint pigments, explosives, and medicines. Mercury cells are used in the production of caustic chlorine.

Prime virgin mercury as commonly obtained by refining directly from mercury has a purity of at least 99.9%, and in many instances 99.99%. Metal of lesser purity is generally obtained by reclaiming discarded mercury.

Precautions in Use.

Mercury is toxic in both its organic and inorganic forms. Mercury vapor is readily absorbed through the respiratory tract, the gastrointestinal tract, or unbroken skin. Mercury acts as a heavy-metal poison, but its effect becomes known only after prolonged exposure. Acute poisoning from mercury vapor is extremely rare. Mercury absorbed from vapor is eliminated from the human body fairly quickly through the urinary and fecal tracts. Mercury levels resulting from exposure to mercury vapor or to inorganic mercury compounds (including aryl mercury compounds such as phenylmercuric acetate) are rapidly reduced and do not accumulate. On the other hand, mercury levels resulting from exposure to alkyl mercury compounds such as methyl mercury or ethyl mercury compounds cannot be eliminated quickly and tend to accumulate.

Mercury is a very volatile element, and dangerous levels of mercury vapor are readily attained at room temperature in enclosed spaces that are not adequately ventilated. The present toxicity limit for mercury vapor in air is 0.05 mg/m^3. At 20 °C, air saturated with mercury vapor contains a concentration more than 100 times this limit.

Because of the toxic nature of mercury and many mercury compounds, certain precautions are mandatory during handling and disposal. Containers should be securely covered. All operations involving mercury metal should be carried out in a well-ventilated are or in a closed system to prevent accumulation of mercury vapor in the workspace; this is of utmost importance if the operation involves heating mercury above room temperature. Work-spaces should be continually monitored with special electronic instruments to detect any rise in mercury vapor concentration above the established safe working limit. Workers should be provided with masks or special breathing devices, and the level of mercury in the body of every worker should be periodically monitored by specially trained medical personnel. Any spills of liquid or escape of vapor from a closed heated system must be countered by immediate decontamination of the affected workspace.

Disposal is ordinarily accomplished by sending impure mercury or concentrated mercury compounds to reclamation centers, where purified metal is produced from the discards. Mercury compounds such as methyl mercury are dangerous pollutants and are required to be removed from effluents before they are discharge into natural waters. Sludges and other solid wastes that are contaminated with small concentrations of mercury are sometimes buried at approved sites.

Structure

Crystal system. Rhombohedral below -39 °C. Structure symbol, *A*10; space group, *R*: $\bar{3}$ *m*; *hR*1

Mass Characteristics

Atomic weight. 200.59

Density. Solid: 14.193 g/cm^3 at -39 °C. Liquid: 14.43 g/cm^3 at melting point; 13.595 g/cm^3 at 0 °C; 13.546 g/cm^3 at 20 °C; 13.352 g/cm^3 at 100 °C; 13.115 g/cm^3 at 200 °C; 12.881 g/cm^3 at 300 °C

Compressibility. Volumetric, from 1 to 493 atm: 4×10^{-6} per atm at 20 °C

Thermal Properties

Boiling point. 356.58 °C at 1 atm

Freezing temperature. -38.87 °C

Vapor pressure:

Temperature, °C	Vapor pressure
-20	2.41 mPa
0	24.6 mPa
20	160.0 mPa
50	1.689 Pa
100	36.40 Pa
150	374.2 Pa
200	2.305 kPa
220	4.284 kPa

(a) Ideal

Entropy. See Table 31.

Latent heat of fusion. 11.8 kJ/kg

Heat of vaporization. 61.42 kJ/kg at 25 °C

Latent heat of vaporization. 272 kJ/kg

Thermal conductivity. 8.21 W/m · K at 0 °C; 9.67 W/m · K at 60 °C; 10.9 W/m · K at 120 °C; 11.7 W/m · K at 160 °C; 12.7 W/m · K at 220 °C

Electrical Properties

Electrical resistivity:

Temperature, °C	Resistivity, nΩ · m
20	958
50	984
100	1032
200	1142
300	1275
350	1355

Temperature coefficient, 0.9 nΩ · m/K at 20 °C

Thermoelectric potential. Mercury versus platinum: -0.60 mV for 100 °C hot junction and 0 °C cold junction

Standard electrode potential. Versus hydrogen electrode at 20 °C: 0.851 V for $Hg^{2+} + 2e^-$ € Hg; 0.7961 V for $2Hg^{2+} + 2e^-$ € $2Hg^+$; 0.905 V for $2Hg^{2+} + 2e^-$ € $(Hg_2)^{2+}$

Ionization potential. Hg(I), 10.43 eV; Hg(II), 18.75 eV; Hg(III), 34.30 eV; Hg(IV), 72 eV; Hg(V), 82 eV

Hydrogen overvoltage. 1.06 V

Contact potential. Mercury versus antimony, -0.26 V; mercury versus zinc, +0.17 V

Magnetic Properties

Magnetic susceptibility. Volume: -1.9×10^{-6} mks at 18 °C

Optical Properties

Color. Filtered mercury has a bright, clean, silvery appearance if the metal contains less than 1 ppm of impurities.

Spectral reflectance. 71.2% for λ= 550 μm

Refractive index.. 1.6 to 1.9 at 20 °C

Nuclear Properties

Thermal neutron cross section. Capture, 420 b; scattering 5 to 15 b

Mechanical Properties

Dynamic viscosity. 1.55 mPa · s at 20 °C

Surface tension. 0.465 N/m at 20 °C; 0.454 N/m at 112 °C; 0.436 N/m at 200 °C; 0.405 N/m at 300 °C; 0.394 N/m at 354 °C. Angle of contact on glass: 128° at 18 °C

Molybdenum (Mo)

Compiled by J.Z. Briggs; Reviewed for this Volume by Joseph Linteau, Climax Specialty Metals

---

Molybdenum is used as an alloying addition in steels, and molybdenum and its alloys are used for electrical and electronic parts, missile and aircraft parts, high-temperature furnace parts, die casting cores, hot-working tools, boring bars,thermocouples, nuclear energy applications, corrosion-resistant equipment, equipment for glass-melting furnaces, and metallizing. Molybdenum also finds use as a catalyst in chemical reactions. Molybdenum is not suitable for continued service at temperatures above 500 °C in an oxidizing atmosphere unless protected by an adequate coating.

Structure

Crystal structure. Body-centered cubic, a = 0.31468 nm at 25 °C

Slip planes. {112} at 20 °C; {110} at 1000 °C

Slip direction. [111]

Interatomic distance. 0.27252 nm min

Metallography. Electrolytic polishing is preferred. Etching: (1) 10 g NaOH + 30 g $K_3Fe(CN)_6$ + 100 liters water; (2) 1 g NaOH + 35 g $K_3Fe(CH)_6$ + 600 liters water; (3) Murakami's reagent

Mass Characteristics

Atomic weight. 95.94

Density. At 20 °C: 10.22 g/cm^3; see also Fig. 67.

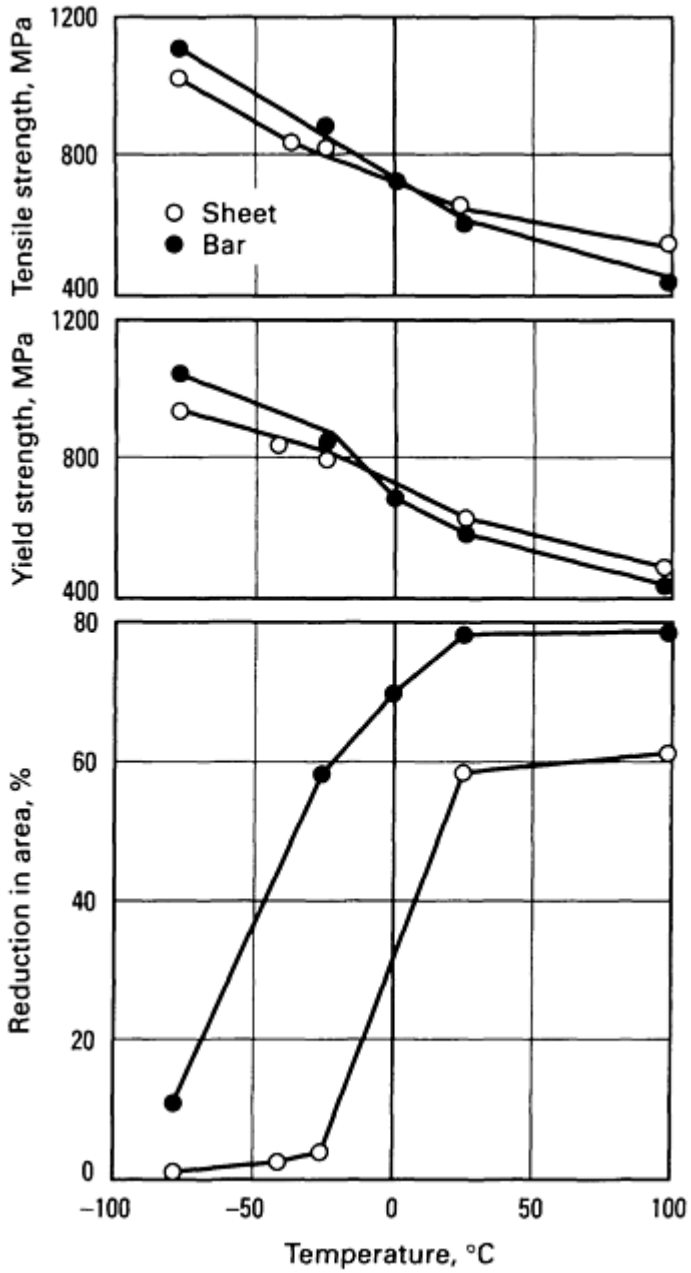

Fig. 75 Effect of product form on the tensile properties of molybdenum

Shear properties. See Fig. 76.

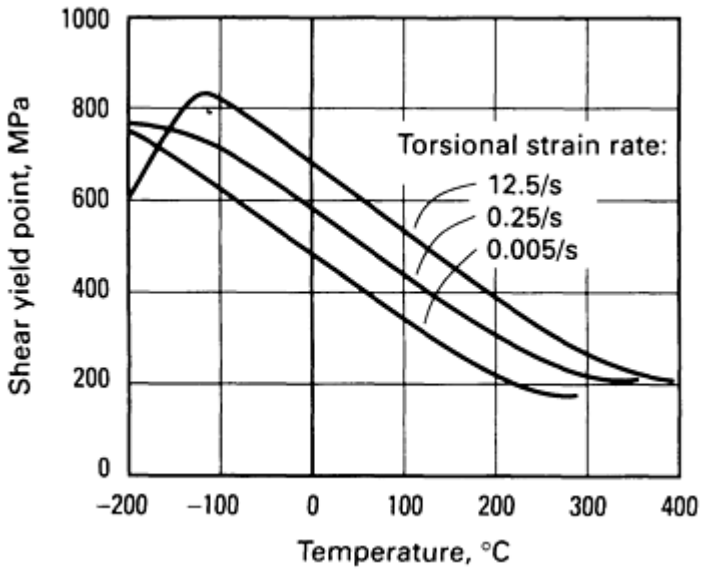

Fig. 76 Temperature dependence of the upper yield point in shear for molybdenum

Hardness. See Fig. 77.

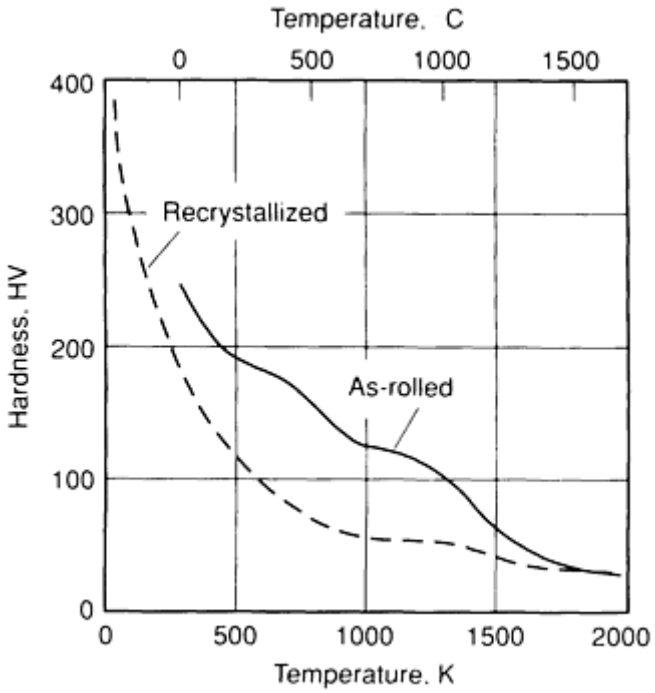

Fig. 77 Temperature dependence of the hardness of molybdenum

Elastic modulus. See Fig. 78.

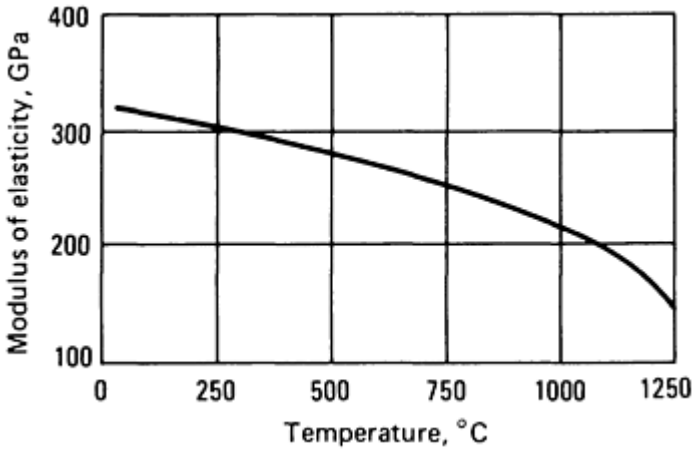

Fig. 78 Temperature dependence of the static modulus of elasticity of molybdenum

Impact strength. See Fig. 79.

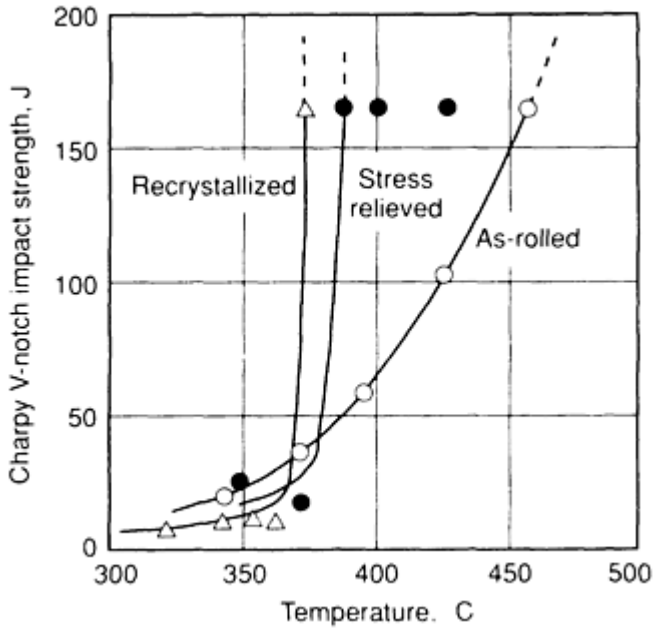

Fig. 79 Temperature dependence of the Charpy V-notch impact strength of molybdenum

Fatigue strength. See Fig. 80.

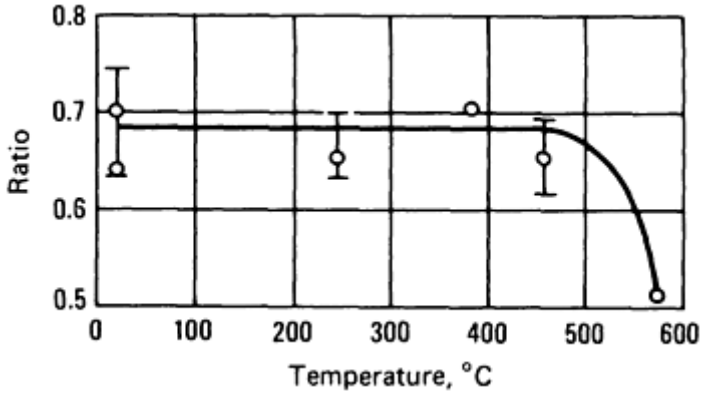

Fig. 80 Ratio at various temperatures of fatigue limit to tensile strength for molybdenum

Creep-rupture characteristics. See Fig. 81 and 82.

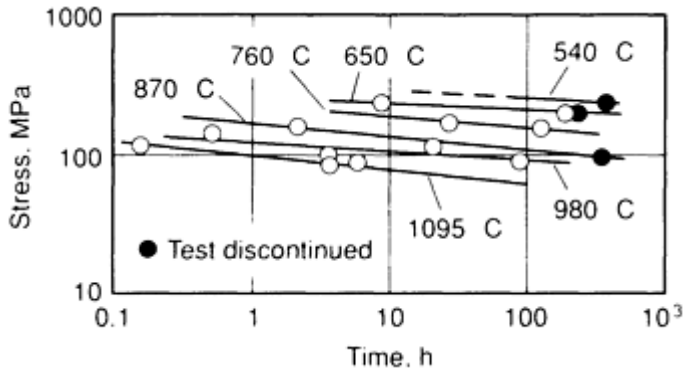

Fig. 81 Creep characteristics of recrystallized molybdenum

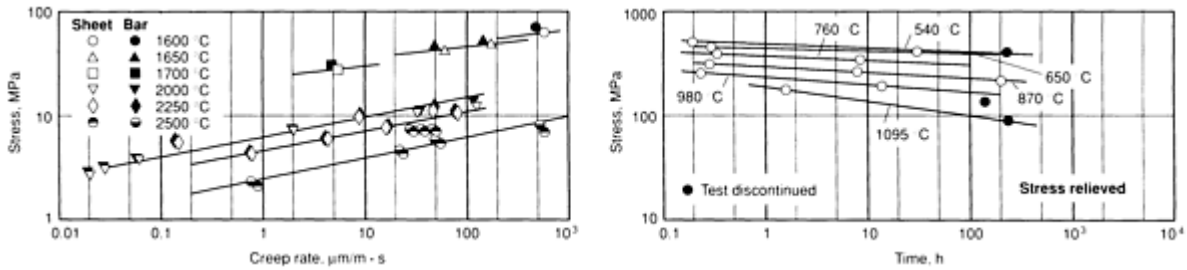

Fig. 82 Rupture strength of molybdenum

Directional properties. If not cross rolled, the tensile strength of molybdenum sheet can be as much as 20% greater in the direction of rolling than when the inclination of the direction of tension to that of rolling is between 45 and 90°.

Properties of single crystals. Tensile strength, 350 MPa

Velocity of sound. Longitudinal wave, 6370 m/s; shear wave, 3410 m/s; thin rod, 5500 m/s

Chemical Properties

General corrosion behavior. Molybdenum has particularly good resistance to corrosion by mineral acids, provided oxidizing agents are not present. It also resistant to many liquid metals and to most molten glasses. In inert atmospheres, it is unaffected up to 1760 °C by refractory oxides. Molybdenum is relatively inert in hydrogen, ammonia, and nitrogen up to about 1100 °C, but a superficial nitride case may be formed in ammonia or nitrogen.

Resistance to specific corroding agents:

Agent	Corrosion, mils/year
20% hydrochloric acid, boiling, unaerated	0.90
49% hydrochloric acid, room temperature, unaerated	0.14
85% phosphoric acid, 100 °C, unaerated	0.29
40% sulfuric acid, boiling, unaerated	1.5
Liquid lithium, sodium, and sodium-potassium, up to 900 °C	<1
Liquid bismuth, 980 °C	nil

Fabrication Characteristics

Consolidation. In most instances, molybdenum is consolidated from powder by compacting under pressure followed by sintering in the range from 1650 to 1900 °C. Some molybdenum is consolidated by a vacuum arc casting method in which a performed electrode is melted by arc formation in a water-cooled mold.

Hot-working temperature. Generally forged between 1180 and 1290 °C down to 930 °C

Annealing temperature. Normal stress-relieving temperature is 870 to 980 °C.

Recrystallization temperature. Depends on prior working and condition; 1180 °C for full recrystallization in h 1 of a 16 mm ($\frac{5}{8}$ in.) bar reduced 97% by rolling

Suitable forming methods. Conventional methods

Formability. See Fig. 83 and 84.

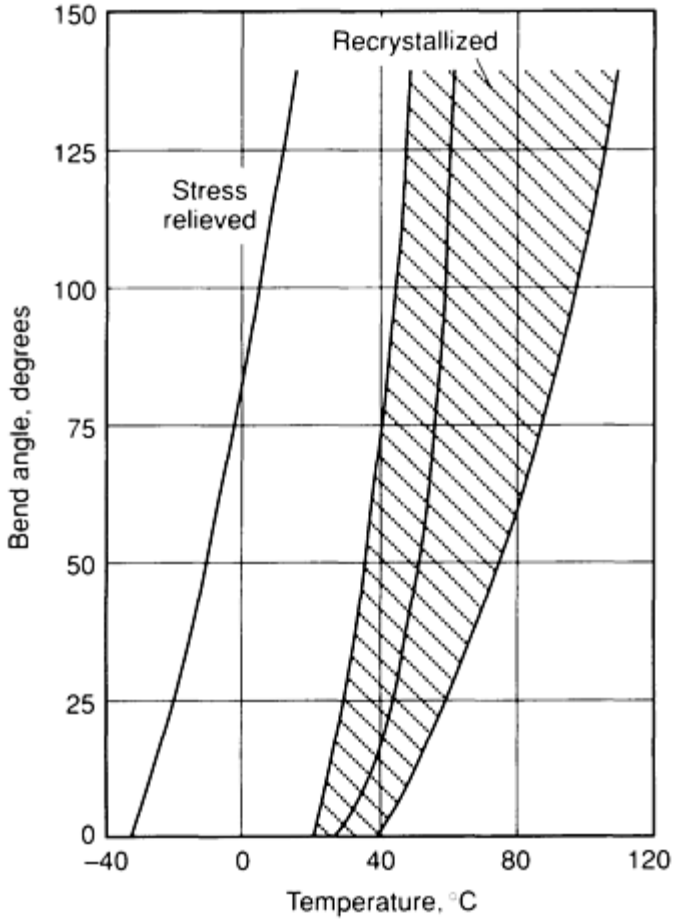

Fig. 83 Temperature dependence of the bend angle to fracture of molybdenum

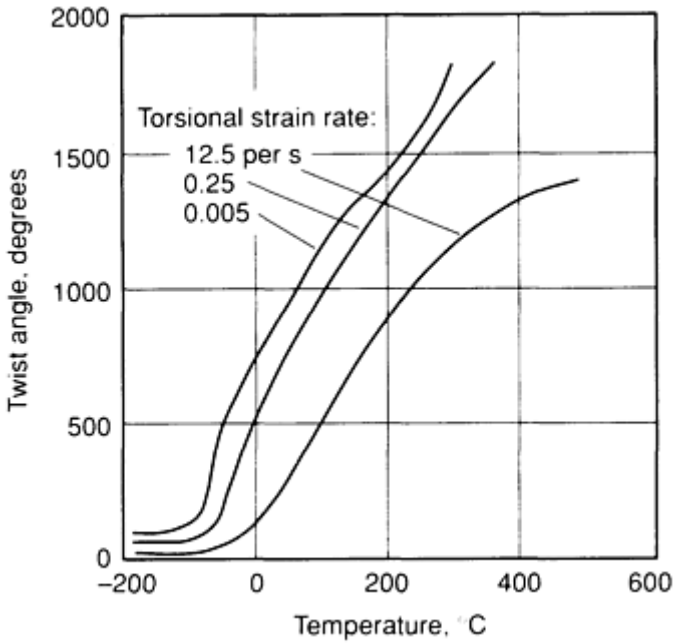

Fig. 84 Temperature dependence of the twist angle to fracture of molybdenum

Precautions in forming. Must be heated to the proper temperature relative to its thickness and forming speed

Heat treatment. Not hardenable by heat treatment but only by work hardening

Suitable joining methods. Can be brazed or joined mechanically, as well as welded by arc, resistance, percussion, flash, and electron beam methods. Arc cast molybdenum is preferred to a powder metallurgy product for welding. Absolute cleanliness of surface is essential. Fusion welding must be carried out in closely controlled inert atmosphere.

Nickel (Ni)

Compiled by INCO Alloys International, Inc.

Structure

Crystal structure. Face-centered cubic; a = 0.35167 nm at 20 °C

Mass Characteristics

Atomic weight. 58.71

Density. 8.902 g/cm^3 at 25 °C

Thermal Properties

Melting point. 1453 °C

Boiling point. Approximately 2730 °C

Coefficient of linear thermal expansion. 13.3 μm/m · K at 0 to 100 °C

Specific heat. 0.471 kJ/kg · K at 100 °C

Recrystallization temperature. 370 °C

Thermal conductivity. 82.9 W/m · K at 100 °C

Electrical Properties

Electrical conductivity. Volumetric, 25.2% IACS at 20 °C

Electrical resistivity. 68.44 nΩ · m at 20 °C; temperature coefficient, 69.2 nΩ · m per K at 0 to 100 °C

Magnetic Properties

Magnetic susceptibility. Ferromagnetic

Magnetic permeability. μ_{max} = 1240 at B = 1900 G

Coercive force. 167 A · m^{-1} from H = 4 kA · m^{-1}

Saturation magnetization. 0.616 T at 20 °C

Residual induction. 0.300 T

Hysteresis loss. 685 J/m^3 at B = 0.6 T

Curie temperature. 358 °C

Optical Properties

Color. Grayish white

Spectral reflectance. 41.3% for λ= 0.30 μm

Nuclear Properties

Effect of neutron irradiation. Results in small increase in tensile strength but large increase in yield strength

Chemical Properties

General corrosion behavior. Nickel is not an active element chemically and does not readily evolve hydrogen from acid solutions; the presence of an oxidizing agent is usually required for significant corrosion to occur. Generally, reducing conditions retard corrosion, whereas oxidizing conditions accelerate corrosion of nickel in chemical solutions. However, nickel may also form a protective corrosion-resistant, or passive, oxide film on exposure to some oxidizing conditions. Additional information is available in the articke "Corrosion of Nickel-Base Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Mechanical Properties

Tensile properties. Typical: tensile strength, 317 MPa; 0.2% offset yield strength, 59 MPa; elongation, 30% in 50 mm

Hardness. 64 HV (annealed)

Poisson's ratio. 0.31 at 25 °C

Elastic modulus. Tension, 207 GPa; shear, 76 GPa; compression, 207 GPa

Velocity of sound. 4.7 km/s at 40 °C

Fabrication

Because of its excellent ductility, nickel can be readily hot and cold worked. After forming, the fabrication characteristics of a workpiece can be recovered through annealing. Additional information is available in the article "Machining of Nickel and Nickel Alloys" in *Machining,* Volume 16 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Niobium (Nb)

Compiled by E.S. Bartlett, Battelle Memorial Institute; Revised by R.E. Droegkamp, Fansteel Metals

---

Niobium is used as an alloying element in nickel- and cobalt-base superalloys as well as in some grades of stainless and low-alloy steels. It is also used as an alloy base for various combinations with zirconium, hafnium, tungsten, tantalum, and molybdenum to increase high-temperature mechanical properties. These alloys have found use in aerospace applications, but they invariably have to be coated, usually with a silicide, for elevated-temperature service. Corrosion/abrasion applications are being found for niobium alloyed with Group IV (titanium, zirconium, and hafnium) and Group VI (molybdenum and tungsten) elements wherein the subsequent reaction with carbon, oxygen, and nitrogen is such that a very hard surface keyed to the substrate is formed. Niobium, niobium-titanium alloys, and niobium-tin alloys are used as superconductors.

Niobium oxidizes and rapidly becomes contaminated with absorbed oxygen above about 400 °C in oxygen-containing atmospheres, including atmospheres normally considered neutral or reducing; it absorbs hydrogen at temperatures between about 250 and 950 °C from hydrogen-containing atmospheres. Contamination by interstitial elements results in a loss of ductility at ambient temperature. Consequences of high impurity levels include impaired fabricability, increased ductile-to-brittle transition temperature, considerable low-temperature strengthening with an attendant loss in ductility, intensified strain-aging effects at slightly elevated temperature, and slight strengthening at higher temperature.

Structure

Crystal structure. Body-centered cubic; a = 0.3294 nm; atomic diameter, 0.294 nm

Slip plane. 110

Metallography. (1) Grind through 000 emery; (2) rough polish with coarse diamond in kerosine; (3) standard finish polish with alumina; (4) etchant (all acids in parts by volume of laboratory reagent grades): 30 lactic--10 nitric--5 hydrofluoric acid solution (more HF for alloys); (5) chemical polish (for freedom) of distortion, if required): 30 lactic--30 nitric--1 to 2 hydrofluoric; (6) electrolytic etch (for particularly uniform grain-boundary definition): $90H_2SO_4$-10HF at 2 V

Chemical Properties

General corrosion behavior. Niobium is moderately to highly resistant to corrosion in most aqueous mediums that are usually considered highly corrosive, such as dilute mineral acids, organic acids, and organic liquids. Notable exceptions are dilute strong alkalis, hot concentrated mineral acids, and hydrofluoric acid, all of which attack the metal rapidly. Gaseous atmospheres at high temperatures attack niobium rapidly, primarily by oxidation, although oxygen contents may be very low.

Niobium and its alloys are remarkably resistant to corrosion by certain liquid metals, notably lithium metal and sodium-potassium alloys, and to high temperatures (900 to 1010 °C). This resistance coupled with a low-capture cross section for thermal neutrons renders niobium materials most attractive for reactor applications. Additional information is available in the article "Corrosion of Niobium and Niobium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Mechanical Properties

Tensile properties. Highly dependent on purity, particularly the content of interstitial elements. Values listed are for material of good commercial purity (only 100 to 200 ppm interstitial contaminants):

- Wrought: tensile strength, 585 MPa; elongation, 5%
- Annealed: tensile strength, 275 MPa; yield strength, 207 MPa; elongation, 30%; reduction in area, 80%

See also Fig. 89.

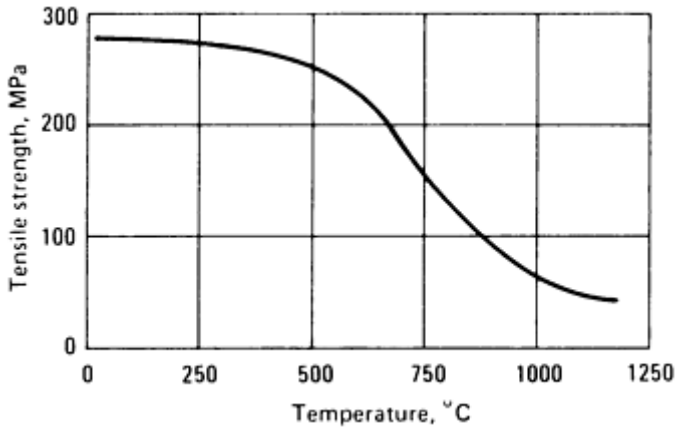

Fig. 89 Temperature dependence of the tensile strength of niobium

Hardness. Annealed: 80 HV. Wrought: 160 HV

Poisson's ratio. At 25 °C: 0.38

Strain-hardening exponent. 0.24; similar to that of low-carbon steel

Elastic modulus. At 25 °C: tension, 103 GPa; shear, 37.5 GPa. At 870 °C: tension, 90 GPa

Ductile-to-brittle transition temperature. <147 K; increases sharply with lower purity

Creep-rupture characteristics. See Table 32.

Table 32 Creep and creep-rupture behavior of wrought niobium at various temperatures

Temperature, °C	Stress for rupture in 1 h, MPa	10-h stress, MPa, for				100-h stress, MPa for				1000-h stress, MPa, for		
		0.05% creep	0.1% creep	0.2% creep	Rupture	0.05% creep	0.1% creep	0.2% creep	Rupture	0.05% creep	0.1% creep	0.2% creep
400	. . .	160	276	360	. . .	83	140	200	. . .	45	66	107

980	48	. . .	. . .	. . .	45	. . .	. . .	. . .	42	. . .	. . .	. . .
1200	35.8	. . .	. . .	. . .	32	. . .	. . .	. . .	28	. . .	. . .	. . .

Fabrication Characteristics

Alloying practice. High-vacuum powder metallurgy techniques can be utilized effectively. Consumable electrode vacuum arc melting and electron beam furnace melting can be used for alloying purposes. High-vacuum techniques purify niobium at temperatures above 1980 °C through volatilization of NbO_2.

Precautions in melting. Exclude atmospheric contaminants as completely as possible. Cold hearth techniques are required to prevent crucible reaction.

Recrystallization temperature. Material cold reduced 70 to 80% completely recrystallizes in 1 h at 1090 °C.

Hot-working temperature. 800 to 1100 °C may be necessary to break down the ingot structure of niobium. This process requires conditioning of the breakdown product to remove the contaminated surface layer. Subsequent working is done cold.

Maximum reduction between anneals. Virtually unlimited

Precautions in forming. Because of the high probability of seizure and galling, selection of lubricant and die material is important in extreme-pressure methods. Carbon-tetrachloride (for machining) or sulfonated tallow or proprietary waxes (for spinning and drawing) are preferred lubricants. Polished aluminum bronze has been recommended as a die material for extreme-pressure processes.

Suitable joining methods. Welding processes capable of excluding interstitial contaminants from the hot zone are satisfactory.

Osmium (Os)

Compiled by H.J. Albert, Engelhard Corporation; Reviewed for this Volume by Louis Toth, Engelhard Corporation

Osmium and its alloys are useful for their hardness and resistance to wear and corrosion. The resistance to rubbing wear is greater than would be expected on the basis of hardness; alloys of equal hardness have less resistance than osmium. Osmium is used in fountain nibs, phonograph needles, electrical contacts, and instrument pivots. Osmium should not be heated in the presence of oxygen because the toxic oxide OsO_4 boils off at 130 °C.

Structure

Crystal structure. Close-packed hexagonal, a = 0.27341 nm and c = 0.43197 nm at 26 °C (Ref 248). The space group is $C6/mmc$ D_{6h}^4 (Ref 249)

Mass Characteristics

Atomic weight. 190.2

Density. At 26 °C, calculated from lattice constants: 22.583 g/cm^3 (Ref 248); 22.57 g/cm^3 obtained directly on an arc melted button of osmium

Thermal Properties

Melting point. Approximately 2700 °C

Boiling point. Approximately 5500 °C (Ref 250)

Coefficient of thermal expansion. 3.2 μm/m · K at 50 °C parallel to c axis; 2.2 μm/m · K at 50 °C parallel to a axis (Ref 251); mean value, 2.6 μm/m · K at 50 °C

Specific heat. At 0 °C, 0.12973 kJ/kg · K; at 100 °C, 0.131 kJ/kg · K; at 1600 °C, 0.161 kJ/kg · K. From 25 to 2727 °C: C_p = 0.125 + 0.0190 T, where T is in K and C_p is in kJ/kg · K (Ref 252)

Electrical Properties

Electrical resistivity. Approximately 95 nΩ · at 20 °C (Ref 253). Temperature coefficient, 0 to 100 °C: 0.0042 nΩ · m per K (Ref 254)

Magnetic Properties

Magnetic susceptibility. Approximately 0.93×10^{-6} mks (Ref 255)

Chemical Properties

Resistance to specific corroding agents. Easily oxidized and forms a tetroxide boiling at 130 °C. It is rapidly attacked by HNO_3 and aqua regia at room temperature. It is not attacked by H_2SO_4 at room temperature or 100 °C, nor by 36% HCl or 40% HF at 20 °C (Ref 256).

Fabrication Characteristics

Working data. Completely unworkable. Can be shaped by melting, powder metallurgy, and grinding

Mechanical Properties

Hardness. Approximately 800 HV, arc melted button

Elastic modulus. 560 GPa (estimated) (Ref 257)

Optical Properties

Reflectance. 62.8% in white light; increases slightly in going from blue to red

Emittance. At $\lambda = 0.65$ μm: solid, 0.33; liquid, 0.37 (Ref 269)

General Properties

General corrosion behavior. At room temperature, palladium is resistant to corrosion by hydrofluoric, perchloric, phosphoric, and acetic acids. It is attacked slightly by sulfuric, hydrochloric, and hydrobromic acids, especially in the presence of air; it is attacked readily by nitric acid, ferric chloride, hypochlorites, moist chlorine, bromine, and iodine. In ordinary atmospheres palladium is resistant to tarnish, but some discoloration may occur during exposure to moist industrial atmospheres that contain sulfur dioxide. Adding palladium to gold or silver alloys improves the tarnish resistance. Platinum (Pt)

Compiled by Edward D. Zysk (deceased), Engelhard Corporation; Reviewed for this Volume by Lisa A. Dodson and James J. Klinzing, Johnson Matthey, Inc.

Structure

Crystal structure. Face-centered cubic, a = 0.39231 nm at 25 °C (Ref 270)

Mass Characteristics

Atomic weight. 195.09

Density. 21.45 g/cm^3 at 20 °C, calculated from lattice parameter (Ref 270). 21.46 g/cm^3 at 25 °C (measured)

Thermal Properties

Melting point. 1769 °C (Ref 271)

Boiling point. 3800 °C (Ref 272)

Coefficient of linear thermal expansion. 9.1 μm/m · K from 20 to 100 °C (Ref 273)

Specific heat. 0.132 kJ/kg · K at 0 °C (Ref 274)

Latent heat of fusion. 113 kJ/kg

Thermal conductivity. 71.1 W/m · K at 0 °C (Ref 275)

Vapor pressure. For 1377 to 1767 °C: p = 11.767 - 27,575/t, where t is in °C and p is in Pa (Ref 272, 276). See also Ref 274.

Oxide evaporation rate. Platinum has exceptional resistance to oxidation. Upon heating in air at all temperatures to the melting point, it remains untarnished. At temperatures above about 750 °C, slight weight loss occurs due to volatilization of the metal itself and the formation of a volatile oxide of platinum. This oxide is essentially PtO_2, although the presence of both PtO_2 and PtO has been noted (Ref 277); mass spectrometric techniques indicate that the main oxide molecules are PtO_2 and PtO_3 (Ref 278). As higher temperatures are reached, loss to volatilization of the oxide species becomes greater than that of the metal.

In determining weight loss of platinum at elevated temperatures, it is important that some consideration be given not only to the kinetic aspects of oxide formation, but also to the equilibrium between the metal and oxide species. The loss due to oxide formation is influenced by such factors as oxygen pressure, rate of gas flow over the metal surface, degree of saturation of the surrounding area with the oxide species and the geometry of the system. Should the evaporating species be removed, the evaporation rate is increased (Ref 279).

Equilibrium vapor pressures of the six platinum group metal oxides are dealt with in Ref 280; rate of evaporation of platinum in vacuum in low-pressure oxygen or air is covered in Ref 281, 282, 283; evaporation in air only covered in Ref 284, 285, 286; evaporation in air, nitrogen, argon, hydrogen, and oxygen is covered in Ref 287. As indicated in the cited references, care should be taken in applying research data relating to oxide vaporization in actual commercial applications because operating conditions may not be similar to those in the experiments.

Electrical Properties

Electrical resistivity. 98.5 nΩ · m at 0 °C; 106 nΩ · m at 20 °C. Temperature coefficient: 0.003927 K from 0 to 100 °C; see also Fig. 92.

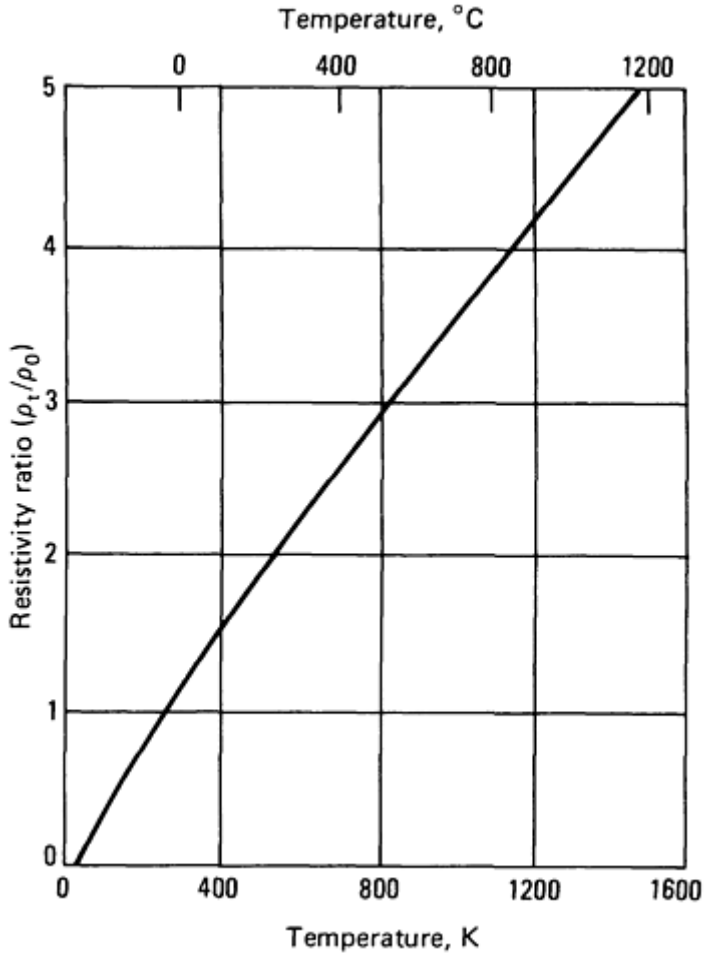

Fig. 92 Ratio of electrical resistivity at various temperatures to resistivity at 0 °C for platinum. *t* is in degrees Centigrade. Source: Ref 288

A laboratory standard platinum resistance thermometer is the standard instrument used on the International Practical Temperature Scale of 1968 from 13.81 K to 630.74 °C. The thermometer resistor must be strain-free annealed pure platinum (at least 99.998% Pt) to achieve a mandated temperature coefficient of at least 0.03925 nΩ · per K. Below 0 °C, the resistance temperature relation of the thermometer is determined by a reference function and specified deviation equations. From 0 to 630.74 °C, two polynomial equations provide the resistance temperature relation (see Ref 271). For data on the effect of trace impurities on the temperature coefficient of electrical resistivity, see Ref 289.

Thermal electromotive force. Very pure platinum, U.S. Thermometric Standard Pt 67 (supplied as a standard reference material by the U.S. National Bureau of Standards), is used as the reference electrode in comparing the thermoelectric behavior of individual metals and alloys. Measurements of the thermal electromotive force of samples of platinum (with the joined hot end at 1200 °C and two free ends at 0 °C) against Pt 67 are useful for estimating the purity of different lots of platinum. Small amounts of impurities (except gold) in solid solution in platinum make the slightly impure platinum

thermoelectrically positive to the platinum without the additions. Iron is troublesome in this respect. For data on the effect of trace impurities on the thermal electromotive force of platinum, see Ref 289.

Work function. 0.852 to 0.876 aJ (5.32 to 5.47 eV) (Ref 290)

Optical Properties

Color. Silver-white

Reflectance. Bulk: 70% at 589 nm. Electrodeposited: 58.4% at 441 nm; 59.1% at 589 nm; 59.4% at 668 nm (Ref 292, 293, 294)

Spectral emittance. At 650 nm: solid, 0.30; liquid, 0.38 (Ref 295)

Total hemispherical emittance. From Ref 296:

°C	Emittance
25	0.037
100	0.047
500	0.096
1000	0.152
1500	0.191

Chemical Properties

General corrosion behavior. See the articles "Precious Metals" and "Properties of Precious Metals" in this Volume and "Corrosion of the Nobles Metals" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Resistance to specific corroding agents. Platinum is resistant to ferric chloride at room temperature. It is attacked by hydrobromic acid plus bromine at room temperature. All of the free halogens attack platinum at elevated temperatures; however, hydrochloric acid in the absence of oxidizing agents does not attack it, and platinum is useful against this normally active gas up to 2000 °F. Sulfur dioxide does not attack platinum even at 2000 °F (Ref 297).

As an anode, platinum is outstanding and is used commercially in sulfuric and persulfuric acids, various sulfate chloride plating electrolytes and in chlorates with very little corrosion. If electrolyzed with alternating current, chlorides may attack, and this is a characteristic exploited in etching platinum and platinum alloys.

Platinum is quite resistant to acid, to potassium sulfate and sodium carbonate, to potassium nitrate at moderate temperatures, and to sodium carbonate at 1475 to 1650 °F under nonoxidizing conditions. Although it is attacked vigorously by molten alkali cyanides and polysulfides, it is quite resistant to the normal sulfides plus alkali. Certain

phosphates attack it at high temperatures, and care must be taken to avoid reducing conditions, particularly when compounds of arsenic, phosphorus, tin, lead, or iron are present. Platinum is resistant to molten glasses, especially to those low in lead and arsenic.

Platinum, even in the form of thin leaf, is resistant to corrosion and tarnishing on exposure to the atmosphere, including urban sulfur-bearing atmospheres.

Potassium (K)

Compiled by J.R. Keiser, Oak Ridge National Laboratory, and Keith R. Willson, Geneva College

Few uses have been found for potassium metal, although an alloy of sodium and potassium is used as a heat transfer medium. Because potassium is an essential element in plant growth, potassium or K_2O is a main component of plant fertilizer. Potassium is also used as the supper oxide KO_2 to produce oxygen in gas masks. Potassium is highly reactive and must be handled with great care. Use of a dry and oxygen-free inert-gas atmosphere is essential if reactions are to be avoided.

Structure

Crystal structure. Body-centered cubic, type *A*2; a = 0.5344 nm at 20 °C

Mass Characteristics

Atomic weight. 39.09

Density. (Ref 298):

°C	g/cm^3
-273	0.909
-173	0.894
-73	0.873
20	0.855
100	0.820
200	0.797
300	0.774
400	0.751
600	0.702
800	0.653

1000	0.602

Volume change on freezing. 2.41% contraction (Ref 299)

Thermal Properties

Melting point. 63.2 °C (Ref 298)

Boiling point. 756.5 °C (Ref 298)

Coefficient of thermal expansion. Linear: 83 μm/m · K for 0 to 95 °C. Volumetric, (liquid): $V/V_0 = 1 + 2.58 \times 10^{-4}\ T + 13.08 \times 10^{-8}\ T^2 + 1.98 \times 10^{-12}\ T^3$ for 63.2 to 1250 °C, where T is in °C (Ref 298)

Specific heat. 0.770 kJ/kg · K at 20 °C

Specific heat versus temperature. Solid, from -173 to 63.2 °C: $C_p = 538.07 + 0.8004\ T$ J/kg · K, where T is in K. Liquid, from 63.2 to 1150 °C: $C_p = 839.14 - 0.3675\ T + 4.594 \times 10^{-4}\ T^2$ J/kg · K, where T is in °C (Ref 298)

Enthalpy. Where T is in °C and H_{0c} is the enthalpy of the solid at 0 °C: solid, $H_c - H_{0c} = 710.62\ T + 1.0388\ T^2$ J/kg; liquid, $H_1 - H_{0c} = 56{,}178 + 841.01\ T - 0.1585\ T^2 + 1.0502 \times 10^{-4}\ T^3$ J/kg (Ref 298)

Entropy. Where T is in K and S_{0c} is the entropy of the solid at 0 °C. Solid, from 0 to 63.2 °C: $S_c - S_{0c} = 329.47 \log T + 2.0776\ T - 13{,}703$ J/kg · K. Liquid, from 63.2 to 800 °C: $S_1 - S_{0c} = 2189.9 \log T + 0.4864\ T + 1.5723 \times 10^{-4}\ T^2 - 50{,}481$ J/kg · K (Ref 298)

Latent heat of fusion. 59.45 kJ/kg (Ref 298)

Latent heat of vaporization. 1985 kJ/kg (Ref 298)

Thermal conductivity. 108.3 W/m · K at 293 K (Ref 298)

Thermal conductivity versus temperature. Solid: $k = 1.26 \times 10^2 - 6.03 \times 10^{-2}\ T$ W/m · K. Liquid:

$$k = 43.8 - 2.22 \times 10^{-2} T + \frac{3950}{T + 273.2}$$

where k is in W/m · K and T is in °C (Ref 298)

Vapor pressure:

$$\log \frac{p}{p_0} = \frac{-4625.3}{T} + 6.59817 - 0.700643 \log T$$

where T is in K and $p_0 = 101.325$ kPa = 1 atm; $p = 3.95$ kPa at 773 K; $p = 6.24$ kPa at 1273 K (Ref 298)

From Ref 300:

Temperature, °C	Pressure, kPa
590	15
710	50
770	100
850	200
950	500
1110	1000
1240	2000
1420	4000

Critical temperature and pressure. T_c = 2220 ± 25 K; P_c = 16.39 ± 0.02 MPa (Ref 300)

Diffusion characteristics:

Solute	Temperature range, °C	Activation energy, kJ/kg	Frequency factor, mm^2/s
^{198}Au	5.6 to 52.5	345.89	0.129
^{42}K	-52.0 to 61.0	1002.3	16
^{22}Na	0 to 62.0	797.80	5.8
^{86}Rb	0.1 to 59.9	940.21	9.0

(a) p, proton; EC, electron capture.

Chemical Properties

General corrosion behavior. Potassium is a highly reactive metal and consequently is found only in a combined state. It reacts vigorously with water to form the hydroxide and for this reason must be kept in a moisture-free environment. Potassium reacts with many other materials, including hydrogen, oxygen, sulfur, nitrogen, bromine, and graphite. It also forms alloys with many metals.

Mechanical Properties

Elastic constants. At 295 °C: C_{11}, 3.715 GPa; C_{12}, 3.153 GPa; C_{44}, 1.88 GPa (Ref 304)

Kinematic liquid viscosity. 0.00628 mm^2/s at 69.6 °C; 0.00328 mm^2/s at 250 °C; 0.00254 mm^2/s at 400 °C (Ref 305)

Liquid surface tension. $\sigma = 0.1157 - 6.4 \times 10^{-5} T$, where T is in °C and σ is in N/m (Ref 298)

Speed of sound. In liquid: speed of sound at melting point, 1880 m/s. Speed of sound over liquid range: $v = 1880 - 0.53 (T - T_m)$, where T_m is the melting point (Ref 306)

Silicon (Si)

Compiled by H.M. Liaw, Motorola Inc., Semiconductor Product Sector

Silicon used in industry can be classified into metallurgical and semiconductor grades. Metallurgical-grade silicon is produced by the reduction of sand (SiO_2) in an electric arc furnace. It contains approximately 98% Si. Major impurities include aluminum, calcium, and iron (Ref 333). Metallurgical-grade silicon is used primarily in the aluminum, steel, and silicone industries. Metallurgical-grade silicon is also used for the production of chlorosilanes or fluorosilanes.

Polycrystalline semiconductor-grade silicon is produced from pure silane or chlorosilanes by the chemical vapor deposition (CVD) technique. Total impurity content of the semiconductor-grade silicon is generally less than 0.1 ppm. Single-crystal semiconductor-grade silicon ingots are grown by pulling them from the melt of polycrystalline semiconductor-grade silicon either by the floating-zone or Czochralski technique (Ref 334). The silicon ingots pulled from the melt in a quartz crucible (that is, in the Czochralski method) are unintentionally doped with oxygen and carbon at concentrations of approximately 10 ppm O_2 and 0.5 ppm C. Thin films of epitaxial silicon grown on silicon substrates have also been widely used for the fabrication of solid-state devices. They are primarily grown from vapor phase by the CVD technique (Ref 335).

Amorphous silicon can be produced from plasma-enhanced pyrolysis of silane at a low temperature (<550 °C) on the surface of a dielectric material such as silicon dioxide. Because the properties of amorphous silicon can be changed by a high-temperature treatment, the properties listed below are of crystalline silicon.

Structure

Crystal structure. At a pressure from 0 to 12.5 GPa: diamond cubic structure containing 8 atoms per unit cell. Lattice constant at 25 °C: a = 0.54310626 ± 0.00000008 nm at 1 atm; a = 0.54310644 ± 0.00000008 nm under vacuum (Ref 336, 337, 338)

The lattice constant can be changed by the presence of impurities. For example, the presence of carbon in silicon causes the contraction of lattice constant Δa according to the empirical equation: $\Delta a/a = -6.5 \times 10^{-24} \times N_c$, where N_c is the carbon concentration in atoms per cm^3 (Ref 339).

The structure of silicon can be changed by applying pressure (Ref 340). The high-pressure phases observed include body-centered tetragonal, body-centered cubic, primitive hexagonal, hexagonal close-packed, and face-centered cubic.

Mass Characteristics

Atomic weight. 28.08

Density. Variation of density with temperature (Ref 341, 342):

Temperature, °C	Density, g/cm^3
25	2.3290
127	2.3269
427	2.3192
627	2.3136
827	2.3077
1027	2.3016

Thermal Properties

Melting point. 1414 °C (Ref 343)

Boiling point. 2355 °C at reduced pressure (10^{-3} atm); 3145 °C at 1 atm (Ref 344)

Thermal expansion coefficient. From Ref 345:

Temperature, K	Coefficient, µm/m · K

Latent heat of vaporization. 10 606 kJ/kg (Ref 347)

Heat of combustion. 31 350 kJ/kg Si (Ref 348)

Thermal conductivity. At temperatures below 150 K, silicon is very sensitive to variations in sample size, impurity level, orientation, and surface quality. The values listed below include typical data obtained in the 2 to 150 K range (Ref 349, 350):

Temperature, K	**Conductivity, W/m · K**
2	44
4	311
6	899
8	1640

10	2400
20	4770
30	4420
40	3660
50	2800
100	913
150	410
200	266
300	156
400	105
500	80
600	64
700	52
800	43
900	36
1000	31
1100	28
1200	26
1300	25
1400	24
1500	23

Electrical Properties (Ref 351)

Energy band gap. At 300 K: 1.12 eV

Intrinsic carrier concentration. 1.38×10^{10} cm^{-3}

Intrinsic Debye length. 28.7 μm

Intrinsic resistivity. At 300 K: 2.3×10^{5} Ω· cm

Extrinsic resistivity. At 300 K, extrinsic resistivity is a function of impurity concentration. Figure 94 shows the plot of resistivity versus doping concentration for *p*- and *n*-doped silicon.

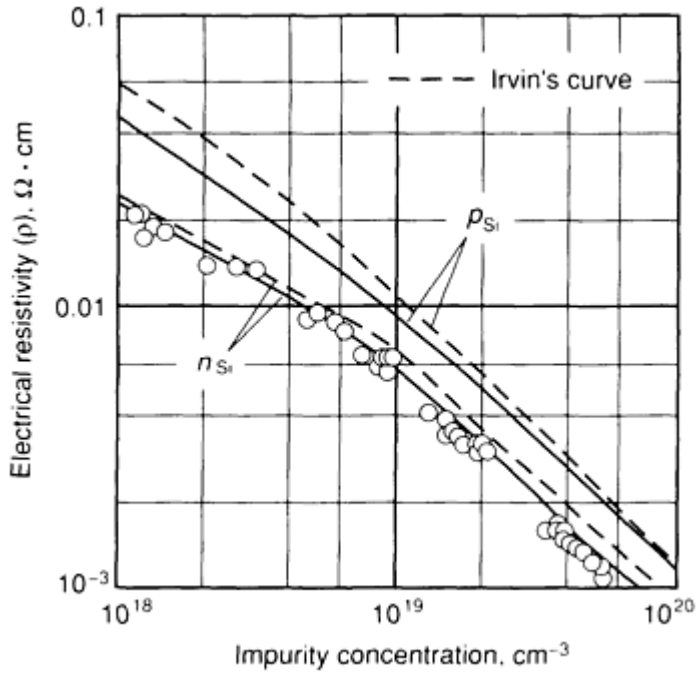

Fig. 94 Resistivity versus impurity concentration for *p*- and *n*-type silicon at 300 K

Electron mobility. The measured mean electron mobility in bulk silicon at 300 K is 1439 $cm^2/V \cdot s$.

Temperature dependence of electron mobility. Mobility (T) = 1439 $(T/300)^{-2.26}$ (Ref 352, 353)

Hole mobility. The measured mean hole mobility in bulk silicon at 300 K is 484 $cm^2/V \cdot s$.

Temperature dependence of hole mobility. Mobility (T) = 484 $(T/300)^{2.21}$ (Ref 352, 353)

Electrochemical equivalent. 0.07269 mg/°C (Ref 354)

Electrolytic solution potential. Versus H_2: -0.453 V (Ref 355)

Hydrogen overvoltage. Versus platinum: 0.192 ± 0.002 V (Ref 356)

Hall effect. 4100 V · m/A · T at 20 °C (Ref 357)

Dielectric constant. 11.695 ± 0.03 (Ref 358)

Magnetic Properties

Magnetic susceptibility. Volume: -1.63×10^{-6} mks (Ref 357)

Optical Properties (Ref 358)

Color. Dark steel gray

Refractive index. As a function of optical energy, see Fig. 95.

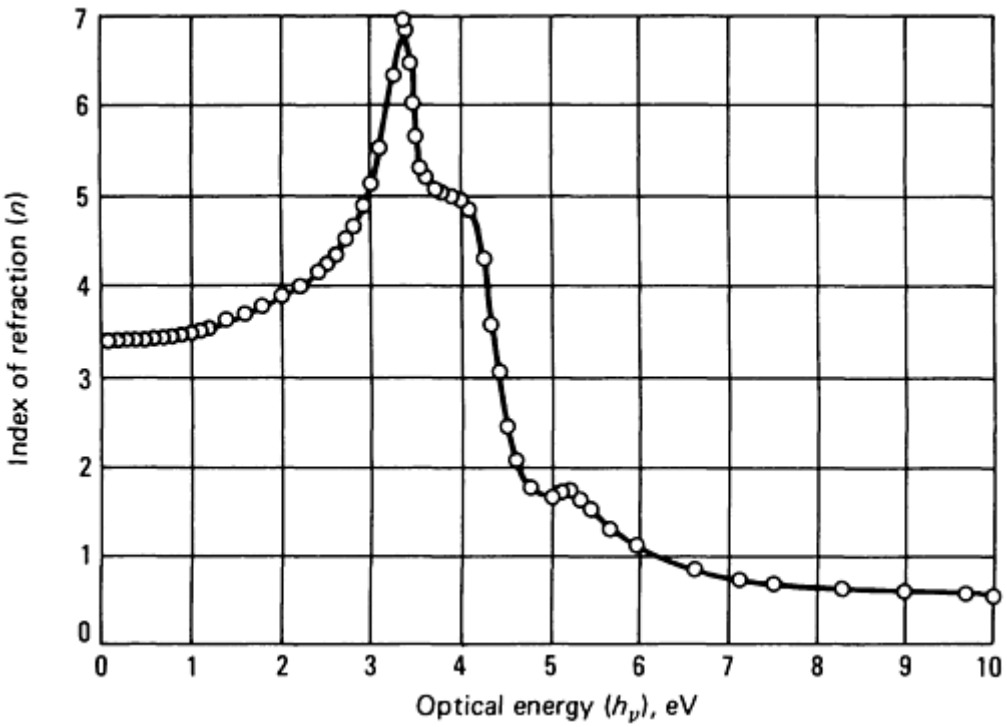

Fig. 95 Real part of the index of refraction versus energy for silicon. Source: Ref 359

Extinction coefficient. As a function of optical energy, see Fig. 96.

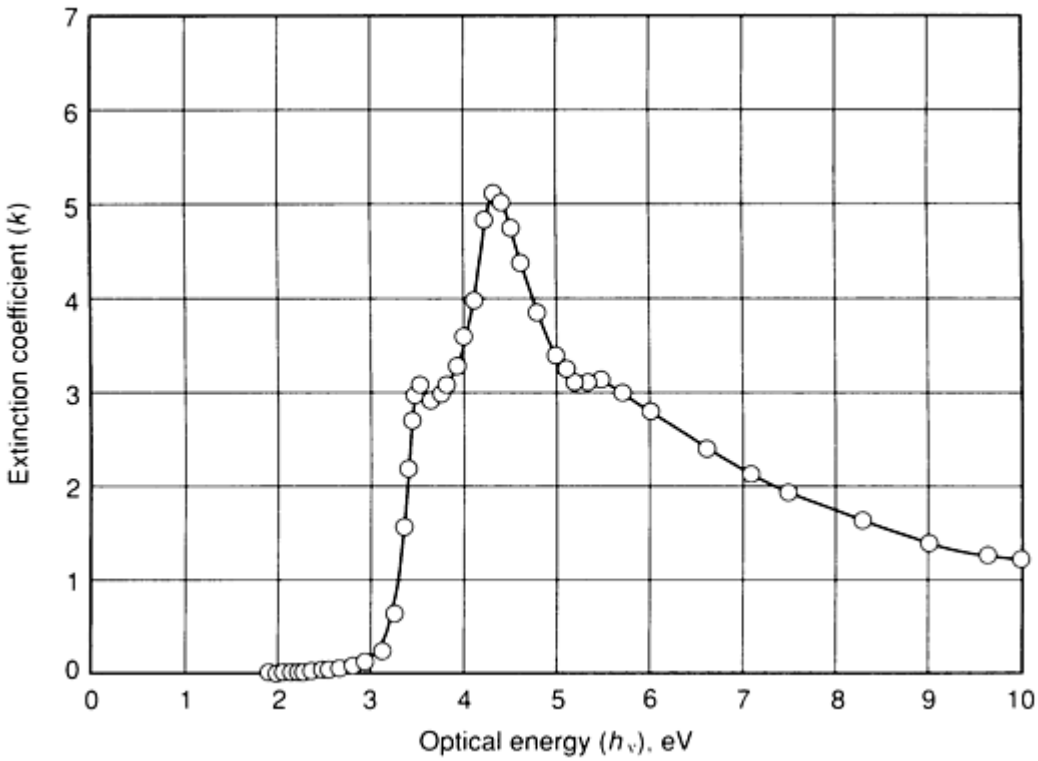

Fig. 96 Extinction coefficient (the imaginary part of the index of refraction) versus optical energy for silicon. Source: Ref 359

Absorption coefficient. As a function of optical energy, see Fig. 97.

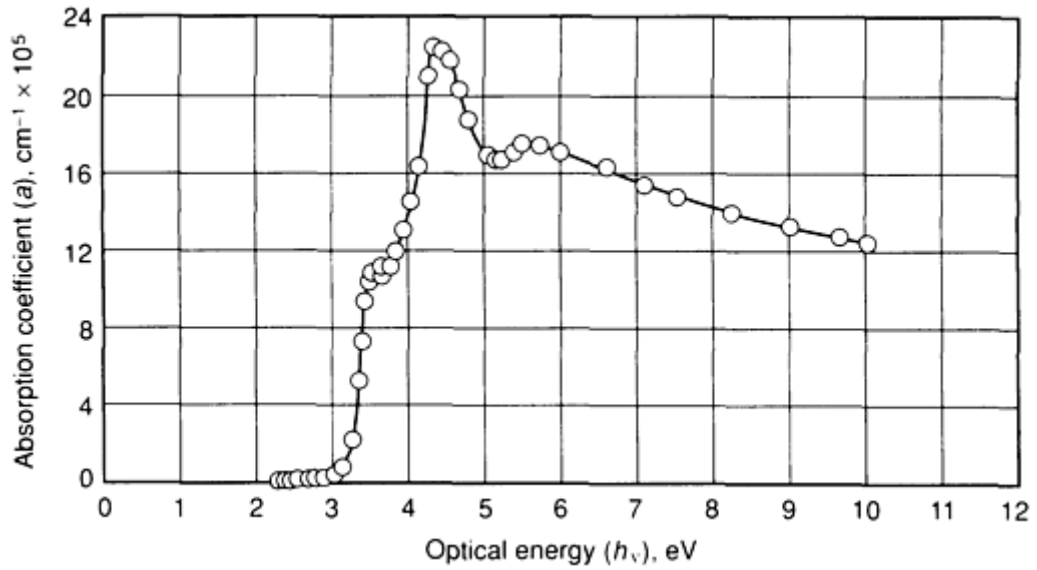

Fig. 97 Spectral dependence of the absorption coefficient of silicon as a function of optical energy. Source: Ref 359

Reflectance. As a function of optical energy, see Fig. 98.

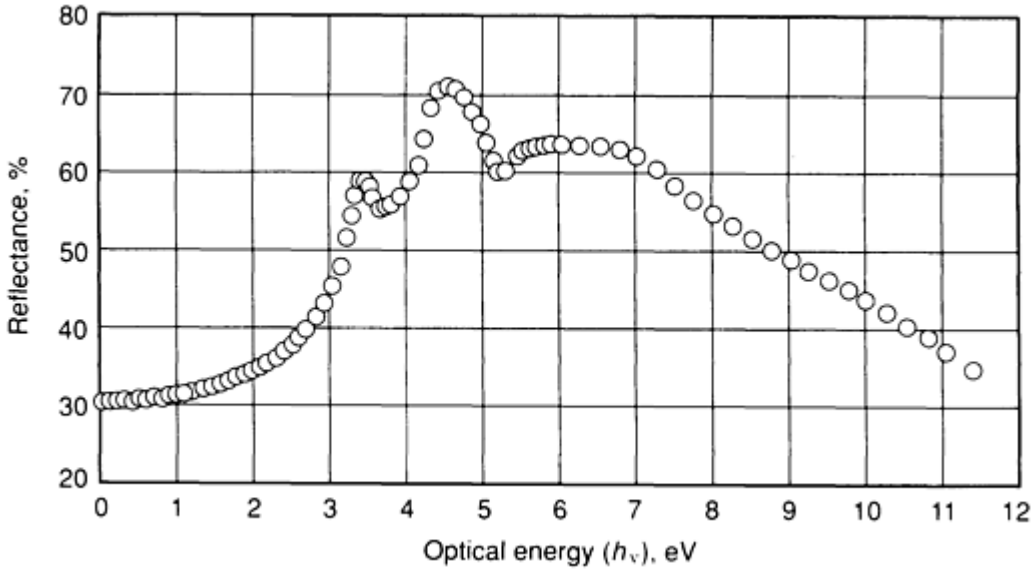

Fig. 98 Spectral dependence of the reflectance of silicon as a function of optical energy. Source: Ref 359

Effect of energy variations on optical parameters. A table of the refractive index extinction coefficient and the absorption coefficient versus energy (0 to 400 eV) has been compiled (Ref 360). Table 40 lists values from this table at selected energy levels.

Table 40 Effect of 0 to 10 eV energy on selected optical index and coefficient parameters

Energy, eV	Refractive index (*n*)	Extinction coefficient (*k*)	Absorption coefficient (*a*)
0.20	3.4236	7.4×10^{-7}	0.015
1.15	3.550	8.1×10^{-5}	9.4
1.20	3.565	4.5×10^{-4}	5.4×10^{1}
2.00	3.906	0.022	4.5×10^{3}
3.00	5.222	0.269	8.2×10^{4}
4.00	5.010	3.587	1.45×10^{6}
5.00	1.57	3.565	1.81×10^{6}
10.0	0.306	1.38	1.4×10^{6}

Source: Ref 360

Infrared refractive index. n as a function of wavelength (λ) (in μm) can be calculated with the empirical equation $n = A + BL + CL^2 + D\lambda^2 + E\lambda^4$, where $L = 1/(\lambda^2 - 0.028)$, A = 3.41983, B = 1.59906×10^{-1}, C = -1.23109×10^{-1}, D = 1.26878×10^{-6}, and E = 1.95104×10^{-9} (Ref 361).

Chemical Properties

Resistance to specific corroding agents. See Table 41.

Table 41 Resistance of silicon to specific corroding agents

Corrosive agent	Resistance
Air	Resistant
Ammonia	Resistant; reacts with vapors at bright red heat
Bromine	Resistant; burns at 500 °C
Carbon dioxide	Resistant
Chlorine	Resistant; burns at 340 °C
Copper sulfate	Resistant (10% solution)
Ferric chloride	Resistant (10% solution)
Hydrochloric acid	Resistant (dilute or concentrate, cold or boiling)
Hydrofluoric acid	Resistant (dilute or concentrate, cold or boiling)
Hydrogen sulfide	Resistant
Iodine	Resistant
Nitric acid	Resistant (dilute or concentrate, cold or boiling)
Oxygen	Resistant
Potassium hydroxide	Attacked
Sodium hydroxide	Attacked
Sulfur	Resistant; reacts at elevated temperatures

Sulfur dioxide	Resistant
Sulfuric acid	Resistant (dilute or concentrate, cold or boiling)
Water, distilled	Resistant
Water, rain	Resistant

***Mechanical Properties**[*]*

Hardness. 10^9 kg/m^2 (Ref 362)

Bulk modulus. 98.74 GPa (Ref 363)

Modulus of rupture in bending. 7×10^6 to 35×10^6 kg/m^2 (Ref 364)

Breaking strength in compression. 4.9×10^7 to 5.6×10^7 kg/m^2 (Ref 364)

Silver (Ag)

Compiled by S.C Carapella, Jr., ASARCO Inc., and D.A. Corrigan, Handy & Harman; Revised by G.M. Wityak, Handy & Harman

Silver is used in a very broad range of applications, including, but not limited to, jewelry, coinage, electrical and electronic devices, and photographic compounds. In some of these applications, silver is alloyed to improve its hardness. The primary alloying element is copper, which, in proportions of 7.5% and 10%, forms the recognized standards for sterling and coin silver, respectively.

The intrinsic qualities of silver (that is, excellent electrical and thermal conductivity, high reflectivity, good corrosion resistance, and ductility) make it a good material choice for a wide range of industrial applications. These applications include contact rivets, capacitor components, fuse links, thin-film coatings for optically and thermally efficient glass, conductive inks, plating anodes, and photographic emulsions.

Silver is also the primary ingredient in many brazing alloys, and many of these have historically been characterized as silver solders. The biological compatibility with human tissue of silver-base dental amalgams accounts, at least in part, for the long-term successful use of these compounds.

Structure

Crystal structure. Face-centered cubic at 25 °C, a = 0.408621 nm

Mass Characteristics

Atomic weight. 107.868

Density. At 20 °C: 10.49 g/cm^3. Liquid:

°C	g/cm^3
960.5	9.30
1000	9.26
1092	9.20
1195	9.10
1300	9.00

Volume change on freezing. 5% contraction

Thermal Properties

Melting point. 961.9 °C. Freezing point in approximate equilibrium with the oxygen in the atmosphere (partial pressure of oxygen 20 kPa) is about 950 °C (Ref 365, 366). Freezing point is not lowered by carbon.

Boiling point. 2163 °C (Ref 367)

Coefficient of linear thermal expansion. At 20 °C, 19.0 μm/m · K; -190 to 0 °C, 17.0 μm/m · K (Ref 368, 369, 370); 0 to 900 °C, $L_t = L_0 (1 + 19.494 \times 10^{-6}\, t + 1.0379 \times 10^{-6}\, t^2 + 2.375 \times 10^{-12}\, t^3$, where t is in °C (Ref 371); 0 to 100 °C, 19.68 μm/m · K (Ref 372); 0 to 500 °C, 20.61 μm/m · K

Specific heat. Solid: at 25 °C, 0.235 kJ/kg · K; 127 °C, 0.239 kJ/kg · K; 527 °C, 0.262 kJ/kg · K; 961 °C, 0.297 kJ/kg · K (Ref 367). Liquid: 961 to 2227 °C, 0.310 kJ/kg · K (Ref 367)

Latent heat of fusion. 104.2 kJ/kg (Ref 367)

Latent heat of vaporization. 2.63 MJ/kg (Ref 367)

Recrystallization temperature. 20 to 200 °C (68 to 392 °F), depending on purity and amount of cold work (Ref 373)

Thermal conductivity. 428 W/m · K at 20 °C; 356 W/m · K at 450 °C (Ref 374)

Vapor pressure. Liquid (Ref 367):

°C	kPa
1304	1.013×10^2
1510	1.013×10^3

1783	1.013×10^4
2163	1.013×10^5

Liquid (Ref 375):

$$\log p = \frac{-13350}{T} + 10.486$$

Solid (Ref 376):

$$\log p = \frac{-14020}{T} + 11.012$$

where T is in K and p is in Pa. High rate of volatilization at high temperatures and with oxidizing gases rather than under reducing gases (Ref 377)

Electrical Properties

Electrical conductivity. 108.4% IACS for extremely pure silver (105% referred to very pure oxygen)

Electrical resistivity. 14.7 nΩ · m at 0 °C. Temperature coefficient: from 0 to 100 °C, 0.0041 per K. Temperature dependence: see Fig. 99.

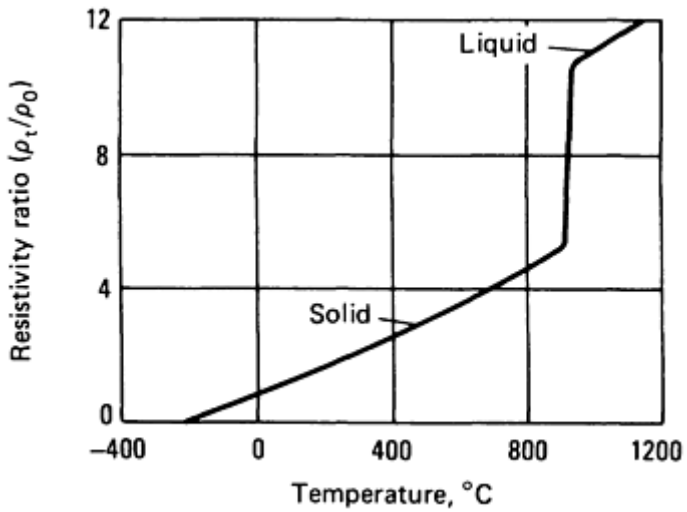

Fig. 99 Temperature dependence of the electrical resistivity ratio of silver. The ratio ρ_t/ρ_0 is about 0.10 at 20.4 K and 0.0068 at 1.3 K. Sources: Ref 378, 379, 380

Cold working of silver considerably increases resistivity: 5% for 90% reduction (Ref 381). Annealing commercially pure silver successively in air and hydrogen disrupts grain boundaries and increases resistance.

Tension reduces resistivity slightly as does hydrostatic pressure: 12,000 kg/cm^2 causes 4% reduction (Ref 382).

Thermal electromotive force. Versus platinum, +0.74 mV; cold junction at 0 °C, hot junction at 100 °C (Ref 383)

Magnetic Properties

Magnetic susceptibility. Volume: -2.27×10^{-6} mks

Optical Properties

Color. As a result of the high and fairly uniform reflectance in the visible range, silver is considered white, but if human eyes were sensitive to a slightly shorter wavelength region, silver would appear to have color.

Reflectance. For clean silver, high in the visible and infrared but low in near-ultraviolet; see Fig. 100.

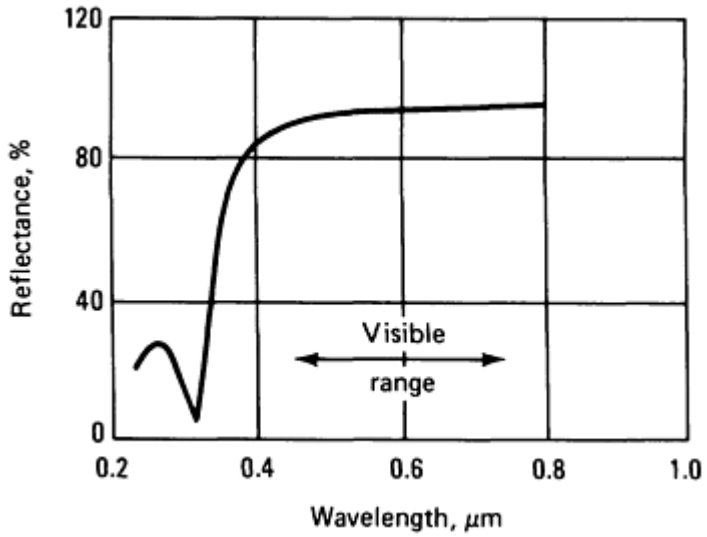

Fig. 100 Reflectance of silver as a function of wavelength. Sources: Ref 383, 384

Emittance. Solid silver at 0.65 μm: extremely low and not known accurately; values of 0.044 μm at 940 °C and 0.072 μm at 980 °C have been observed for liquid silver (Ref 385). Other experiments showed no discontinuity at the melting point of silver, the emissivity being about 0.055 at about 700 °C (Ref 386).

Mechanical Properties

Tensile properties. Considerable spread in values for tensile strength and hardness of high-purity silver. Average tensile strength, 125 MPa for 5 mm wire annealed at 600 °C (Ref 387)

Hardness. High-purity silver; hydrogen anneal 650 °C, 25 HV; air anneal at 650 °C, 27 HV; electrodeposited silver (higher electrical resistivity than wrought silver), 100 HV

Elastic modulus. Strained 5%, then heated 0.5 h at 350 °C, 71.0 GPa (Ref 388)

Poisson's ratio. Annealed: 0.37; hard drawn, 0.39

Liquid surface tension. 0.923 N/m at 995 °C

Sodium (Na)

Compiled by J.R. Keiser and J.H. DeVan, Oak Ridge National Laboratory, and Keith R. Willson, Geneva College

Sodium is used as a liquid metal heat transfer medium, a working fluid for evaporative heat pipes, and an electrical conductor in homopolar generators. It is also used in vapor lamps for highway lighting; as an alloying addition for lead, zinc, and aluminum; and as a reactant for deoxidation of metals and for reduction of metal fluorides.

Sodium is highly reactive with water; hydrogen released by the reaction is potentially explosive. Molten sodium will burn in ambient air. Iron-base alloys are usually selected as containers for the transport of liquid sodium. Argon, helium, and nitrogen are used as cover gases to minimize sodium oxidation.

Sodium fires are best extinguished by closing off air accesses or by blanketing with either nitrogen or inert solids such as carbon granules. Commercial extinguishing media include sodium chloride, sodium carbonate, and calcium phosphate. Carbon tetrachloride and solid carbon dioxide extinguishers should not be used on sodium fires.

Structure

Crystal structure. βphase, body-centered cubic, type *A*2; a = 0.42906 nm at 20 °C. On cooling below 36 K, sodium partially transforms to α phase, close-packed hexagonal, type *A*3; a = 0.3767 nm at 5 K (Ref 389)

Mass Characteristics

Atomic weight. 22.9898

Density. 0.9674 g/cm^3 at 25 °C; 0.9270 g/cm^3 at 100 °C; 0.7113 g/cm^3 at 1000 °C (Ref 390, 391)

Density versus temperature. Density at melting point: 0.927 g/cm^3. Density in the liquid range: $\rho = 0.927 - 2.35(T - T_m)$, where T_m is the melting point in K and density (ρ) is in g/cm^3 (Ref 392)

Volume change on melting. +2.71% (Ref 393)

Thermal Properties

Melting point. 97.82 °C (Ref 393)

Boiling point. 881.4 °C (Ref 393)

Phase transformation temperature. Incomplete transformation to α phase occurs on cooling (below 36 K) or on deforming (below 51 K) (Ref 394)

Coefficient of thermal expansion. Linear: 68.93 μm/m · K; at 0 to 96.6 °C, $l/l_0 = 1 + 6.893 \times 10^{-5}\ T + 0.63 \times 10^{-7}\ T^2$, where T is in 0 °C (Ref 392). Volumetric: 2.418 × 10^{-4}/°C; at 97.83 to 1350 °C, $V/V_0 = 1 + 2.4183 \times 10^{-4}\ T + 7.385 \times 10^{-8}\ T^2 + 15.64 \times 10^{-12}\ T^3$, where T is in °C (Ref 393)

Specific heat. C_p = 1.2220 kJ/kg · K at 25 °C (solid); C_p = 1.3210 kJ/kg · K at 250 °C (liquid); C_p = 2.5100 kJ/kg · K at 1000 °C (vapor) (Ref 395, 396)

Specific heat versus temperature. Solid: $C_p = 1198.72 + 0.64894\ T + 0.010527\ T^2$ J/kg · K for 0 to 97.8 °C (T is in °C); Liquid: $C_p = 1436.1 - 0.58026\ T + 4.6208 \times 10^{-4}\ T^2$ J/kg · K for 97.8 to 900 °C (T is in °C) (Ref 393)

Enthalpy. Where H_{0c} is enthalpy of the solid state at 0 °C: solid, $H_c - H_{0c} = 1199.26\ T + 0.3247\ T^2 + 3.510 \times 10^{-3}\ T^3$ J/kg for 0 to 97.8 °C (T is in °C); liquid, $H_1 - H_{0c} = 98{,}960 + 1436.7\ T - 0.29025\ T^2 + 1.5410 \times 10^{-4}\ T^3 + 2.400 \times 10^7 \times e^{-13600/(T + 273)}$ J/kg (for 97.8 to 900 °C; T is in °C) (Ref 393)

Entropy. Solid at 0 to 97.8 °C: $S_c - S_{0c} = 4162.42 \log(T) - 5.1036\ T + 0.0052658\ T^2 - 9140.2$ J/kg · K, where S_{0c} is entropy at 0 °C and T is in K. Liquid at 97.8 to 900 °C: $S_1 - S_{0c} = 3752.6 \log(T) - 0.8330\ T + 2.3112 \times 10^{-4}\ T^2 - 8673.9$ J/kg · K, where T is in K (Ref 393)

Latent heat of fusion. 113 kJ/kg (Ref 393)

Latent heat of vaporization. 3.874 MJ/kg (Ref 393)

Thermal conductivity. 131.4 W/m · K at 25 °C; 79.6 W/m · K at 250 °C (Ref 393)

Thermal conductivity versus temperature. For 0 to 95% °C: $k = 135.6 - 0.167\ T$, where k is in W/m · K and T is in °C. For 104 to 832 °C: $k = 91.8 - 0.049T$, where k is in W/m · K and T is in °C (Ref 393)

Vapor pressure. From Ref 393 and 397:

°C	Pa
100	1.43 × 10^{-5}

200	1.81×10^{-2}
300	1.85
500	5.19×10^{2}
700	1.40×10^{4}
900	1.20×10^{5}
980	2.0×10^{5}
1120	5.1×10^{5}
1230	1.0×10^{6}
1370	2.0×10^{6}

Also, log P = -5780/T - 1.18 log T + 13.625, where P is in Pa and T is in K. Valid range: 298 K to boiling point

Diffusion characteristics. See Table 42.

Table 42 Diffusion characteristics of sodium

Solute	Temperature range, °C	Activation energy, kJ/mol	Frequency factor, $m^2/s \times 10^{-8}$
^{198}Au	1-77	9.25	3.34
^{42}K	0-91	35.3	0.08
^{22}Na	0-98	42.2	0.145
^{86}Rb	0-85	35.5	0.15

(a) β^-, negative beta emission; β^+, positron emission; EC, orbital electron capture; IT, isomeric transition from upper to lower isomeric state; n, neutron emission; p, proton emission.

Chemical Properties

Resistance to specific corroding agents. At 25 °C, sodium passivates in dry O_2 but oxidizes in moist air to form Na_2O, NaOH, and finally Na_2CO_3. Sodium is highly pyrophoric in air at or above 125 °C. Sodium reacts with CO_2 above 200 °C to form Na_2O, C, and possibly $Na_2C_2O_4$. Below 320 °C, water (gas or liquid) reacts with liquid sodium to produce NaOH (solid) and H_2. (H_2 is potentially explosive if O_2 is present.) Above 320 °C, products of the H_2O reaction include NaOH (liquid), NaH, Na_2O, and H_2. A useful technique for removing sodium residues is by reaction with water vapor in nitrogen or noble gas at 70 °C followed by water rinsing. Sodium undergoes metallic dissolution in anhydrous liquid ammonia, the solution ultimately converting to sodium amide. Sodium reacts with alcohols to form sodium alcoholates and hydrogen. *N*-butyl alcohol can be used to slowly dissolve sodium at 25 °C. Ethyl alcohol is much more reactive and can be ignited if sodium comes in contact with air. Solid sodium is relatively inert toward dry hydrocarbons that do not have an active hydrogen or acetylene hydrogen component. In contact with molten sodium, alkyne hydrogen atoms are liberated, and aryl hydrocarbons can be polymerized or decomposed.

Mechanical Properties

Kinematic liquid viscosity. From Ref 393:

°C	**mm^2/s**
100	0.7338
200	0.5001
300	0.3921
400	0.3323
500	0.2955
600	0.2568
700	0.2313

800	0.2134

Liquid surface tension. 0.192 N/m at 97.8 °C; 0.161 N/m at 400 °C; 0.146 N/m at 550 °C; 0.113 N/m at 881.4 °C; also, for 97.8 to 881.4 °C, $\sigma = 0.2067 - 1 \times 10^{-4} T$, where σ is in N/m and *T* is in °C (Ref 393)

Velocity of sound. $V = 2577.25 - 0.524 T$, where *V* is in m/s and *T* is in °C (Ref 390)

Tantalum (Ta)

Compiled by Mortimer Schussler, Fansteel, Inc.; Revised by R.E. Droegkamp, Fansteel Metals

Tantalum provides a combination of properties not found in many refractory metals: excellent fabricability, a low ductile-to-brittle transition temperature, and a high melting point.

Figure 101 shows a breakdown of tantalum consumption by industry. The largest use of tantalum at this time is in electrolytic capacitors. Sizeable quantities of tantalum also are used in chemical process equipment (such as heat exchangers, condensers, thermowells, and lined vessels), notably for handling nitric, hydrochloric, bromic, and sulfuric acids, or combinations of these acids with many other chemical. Spinnerettes for extruding man-made fibers constitute another important application of tantalum.

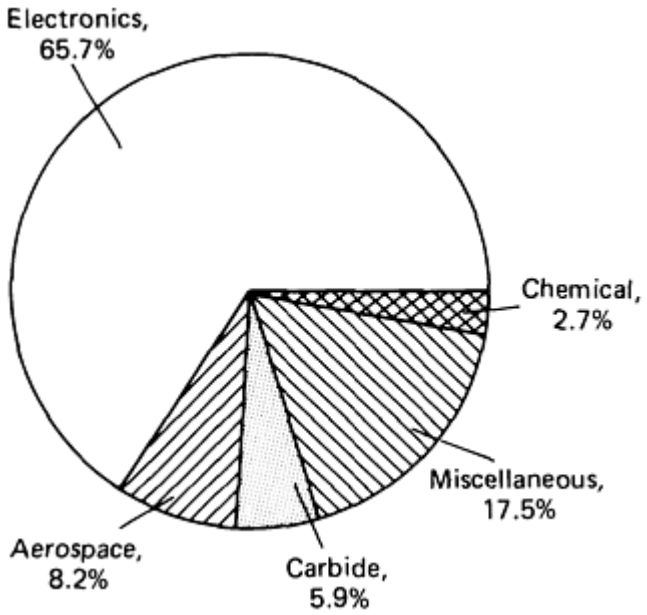

Fig. 101 1988 consumption of tantalum by specific industries. Source: Tantalum Producers Association

Because of its high melting point, tantalum is used for heating elements, heat shields, and other components of vacuum furnaces. Tantalum has been used in specialized aerospace and nuclear applications. Tantalum also is used in prosthetic devices in contact with body fluids and as an alloy component in superalloys. Tantalum carbide is an important constituent of cemented carbide cutting tools made from mixtures of titanium, tungsten, and tantalum carbides.

A new and important military application is evolving wherein tantalum is used as an armor penetrator. Also, emerging corrosion abrasion applications are being found for tantalum alloyed with Group IV elements (titanium, zirconium, and hafnium) and Group VI elements (molybdenum and tungsten); in these alloying combinations, the subsequent reaction with carbon, oxygen, and nitrogen is such that a very hard surface keyed to the substrate is formed.

Yield and ultimate strengths of tantalum are increased, and ductility is reduced, by increases in the amount of interstitial elements (oxygen, nitrogen, carbon, and hydrogen). Embrittlement of tantalum can occur if contamination by these elements is sufficiently severe. Maximum impurity limits (in ppm) for commercially available high-purity tantalum (99.90% min) are 500 Nb, 300 W, 100 to 200 O_2, 100 Fe, 100 Mo, 50 to 75 C, 50 to 75 N, 50 Ni, 50 Si, 50 Ti, and 10 H_2.

Nuclear Properties

Natural isotopes. ^{181}Ta, 99.988% natural abundance

Thermal neutron cross section. 21.3 b

Chemical Properties

General corrosion behavior. Tantalum oxidizes in air above 300 °C. It has excellent resistance to corrosion by a large number of acids, by most aqueous solutions of salts, by organic chemicals, and by various combinations and mixtures of these agents. Also, tantalum exhibits good resistance to many corrosive and common gases and to many liquid metals.

Resistance to specific corroding agents. Tantalum is attacked by hydrofluoric acid, fuming sulfuric acid, and strong alkalis. The presence of salts that hydrolyze to form hydrofluoric acid or strong alkalis can also lead to attack of tantalum. Tantalum can become embrittled by hydrogen if it is the cathode in a galvanic couple exposed to an acid environment or to a hydrogen-containing atmosphere at elevated temperature. Halogen gases can attack tantalum: Fluorine causes attack at both room and elevated temperatures, chlorine at and above 250 °C, bromine at and above 300 °C, and iodine at somewhat higher temperatures. Bromine plus methanol also attacks tantalum.

Fabrication Characteristics

Precautions in melting. Exclude oxygen, hydrogen, nitrogen, and carbon. Melt in vacuum or inert atmosphere.

Hot-working temperature. None; tantalum is worked cold.

Annealing temperature. Above 1050 °C in high vacuum for complete recrystallization, with resulting grain size as given below. Material was cold rolled 75% after intermediate annealing, then annealed 1 h at the indicated temperature. The average ASTM grain size No. was determined by comparison with the ASTM grain size chart at a magnification of 100×:

Final annealing temperature, °C	Average ASTM grain size No.
1200	5-6
1300	4
1400	3-4
1425	3-4
1600	2

1700	1
1800	0-1

Maximum reduction between anneals. Greater than 95

Suitable forming methods. Tantalum can be formed by spinning, deep drawing, bulging, bending, blanking, punching, and stretch forming using conventional methods, and using equipment and tooling normally found in shops that fabricate heat-resistant alloys.

Compacting pressure. 10 to 85 MPa, depending on the physical properties of the powder

Sintering temperature. Sintering at 2300 to 2600 °C in high vacuum will essentially remove all detrimental impurities contained in the powder.

Machinability. Fully recrystallized unalloyed tantalum has a machinability similar to that of soft copper. Use chlorinated hydrocarbons, light oil, or water-soluble oil as a cutting fluid, and high-speed tool steel or cemented carbide tools. Tantalum can be successfully turned, bored, drilled, tapped, reamed, shaped, milled sawed, and ground to desired tolerances and surface finishes.

Joining. Gas tungsten arc, gas metal arc, resistance, and electron beam welding techniques can be used for joining tantalum. High-purity inert gas (argon or helium) or vacuum must be used in fusion welding. Resistance spot and seam welding can be done in air or under water with proper precautions. Silver brazing alloys, copper, and several specially developed refractory metal brazing alloys can be used to braze tantalum to itself or to dissimilar metals such as stainless steels. Brazing is done in vacuum or under an inert atmosphere (high-purity argon or helium). Tantalum also can be bonded to dissimilar metals by explosive cladding and, in some instances, by roll bonding.

Cleaning. To avoid contamination of tantalum by interstitial elements and metallic impurities, it is mandatory that the material be chemically cleaned before any heating operation (such as annealing or welding). Such cleaning involves thorough degreasing with a detergent or solvent; chemical etching in 20 vol% HF, 20 vol% H_2SO_4, and 60 vol% HNO_3; rinsing with hot and cold water (deionized water recommended); and spot-free drying. The etching solution can be strengthened by adding HF or weakened by adding water to achieve the amount of stock removal necessary to ensure cleanness.

Mechanical Properties

Tensile properties. See Fig. 106, 107, and 108.

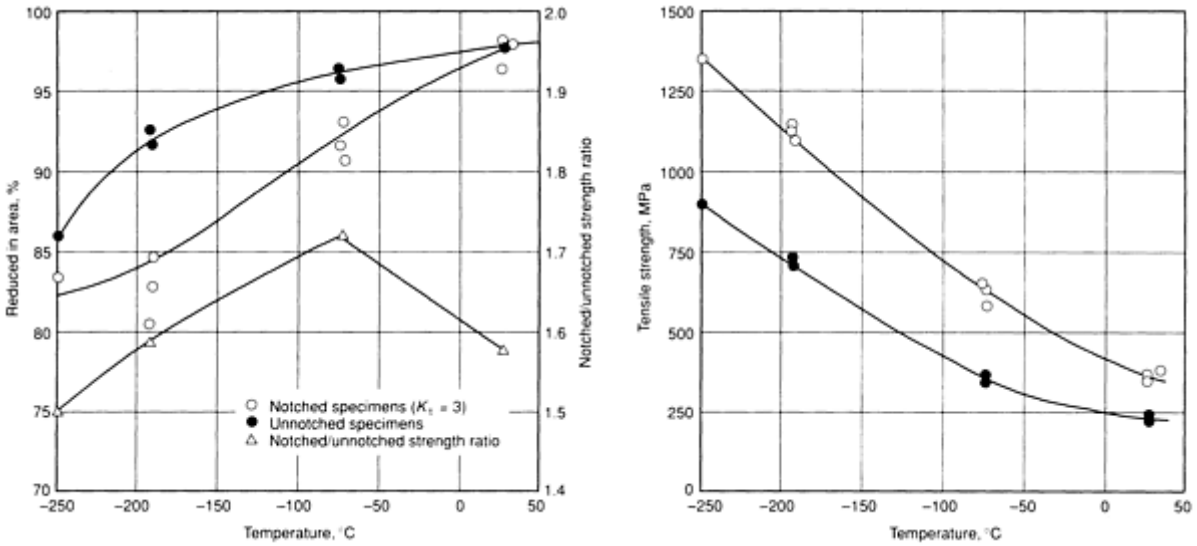

Fig. 106 Low-temperature tensile properties of electron-beam-melted tantalum bar. Sample impurities: <0.003% C, <0.003% O_2, 0.0008% N_2, <0.08% other. Bar was annealed for 3 h at 1200 °C: hardness, 83 HV; grain size, ASTM No. 5. Crosshead speed: unnotched specimens, 0.5 mm/min; notched specimens, 0.13 mm/min

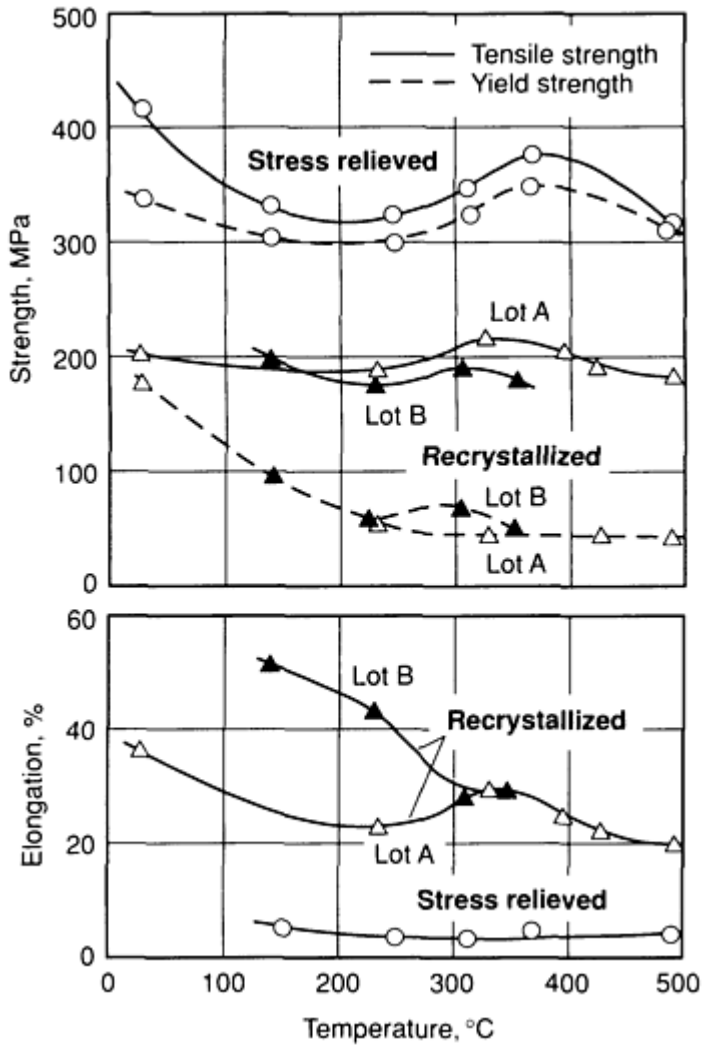

Fig. 107 Elevated-temperature tensile properties of 1 mm thick electron-beam-melted tantalum sheet. Sample impurities (both lots): 0.0030%

C, 0.0016% O_2, 0.0010% N_2, <0.040% other. Stress-relieved sheet was cold rolled 95% and stress-relieved for $\frac{1}{4}$ h at 730 °C; recrystallized sheet was cold rolled 75% and recrystallized by heating for 1 h at 1200 °C. Crosshead speed, 1.3 mm/min

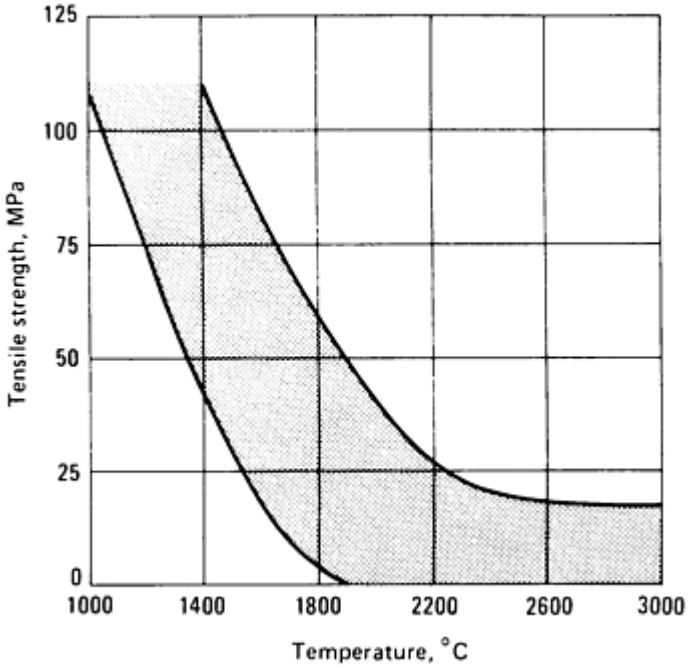

Fig. 108 High-temperature tensile strength of tantalum. The upper portion of the curve is characterized by high strain rates and high interstitial content, whereas the lower portion of the curve is characterized by low strain rates and low interstitial content.

Hardness. Electron beam melted, 110 HV; P/M compact, 120 HV

Poisson's ratio. 0.35 at 20 °C

Elastic modulus. Tension: 186 GPa at 20 °C; 159 GPa at 750 °C. Shear: 69 GPa at 20 °C. Compressibility:

Impact strength. See Fig. 109.

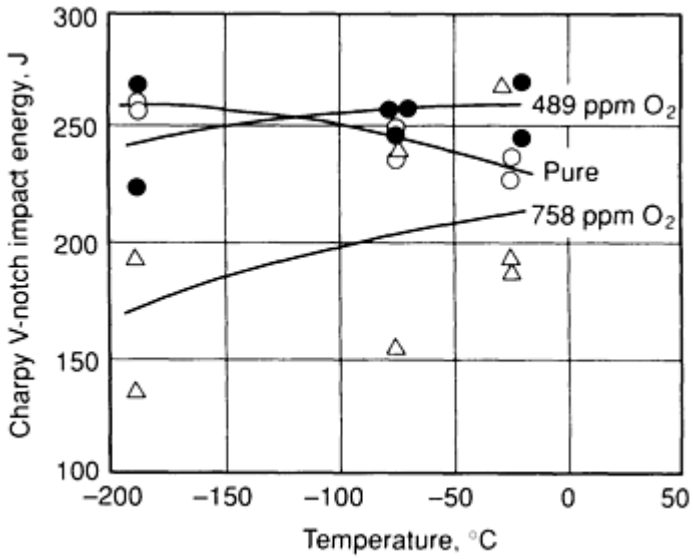

Fig. 109 Effects of temperature and oxygen content on the Charpy V-notch impact energy of wrought electron-beam-melted tantalum. Sample impurities: <44 ppm C + N_2. Temperature, °C

Fatigue strength. See Fig. 110.

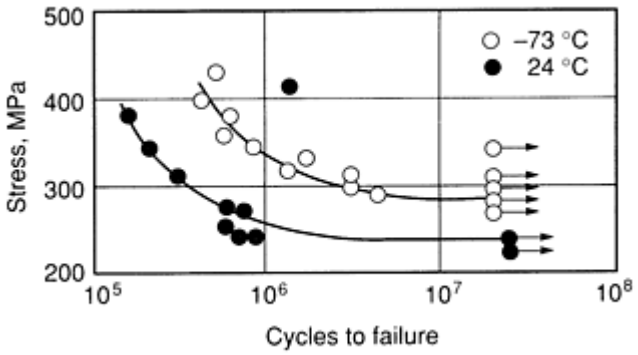

Fig. 110 Rotating-beam fatigue strength of wrought electron-beam-melted tantalum. Sample impurities: <44 ppm C + N_2

Creep-rupture characteristics. See Fig. 111

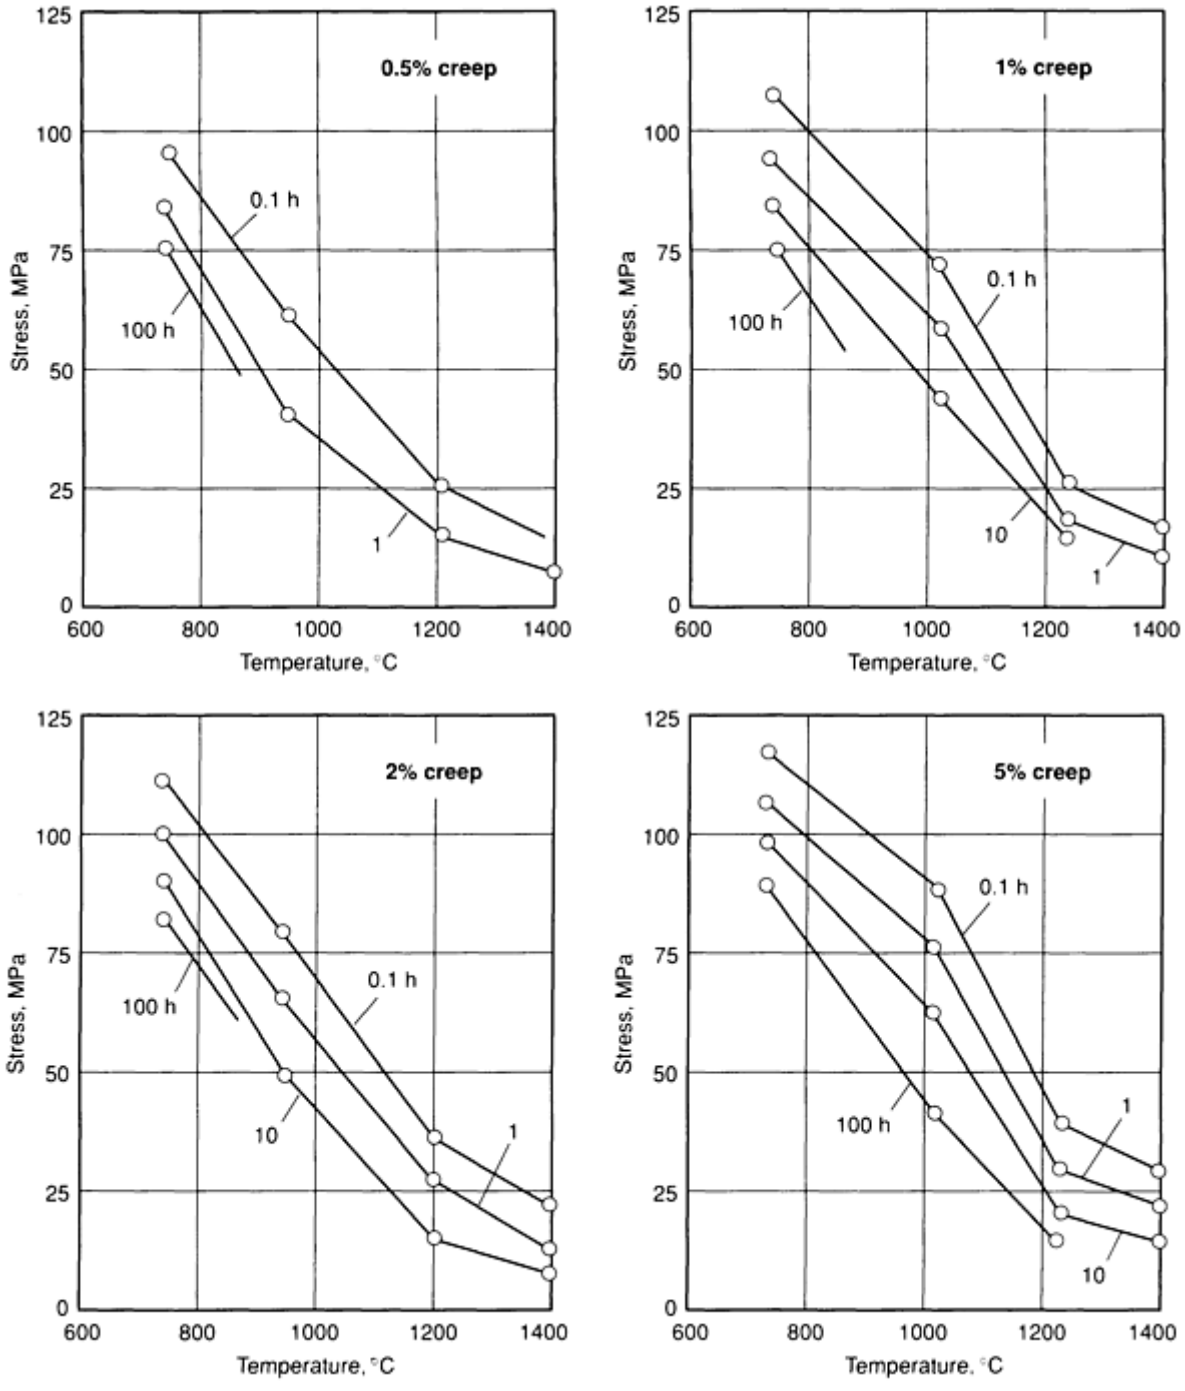

Fig. 111 Creep characteristics of 1 mm thick electron-beam-melted tantalum sheet. Sample impurities: 0.0030% C, 0.0016% O_2, 0.0010% N_2, <0.040% other. Sheet was cold rolled 75% and recrystallized by heating for 1 h at 1200 °C.

Damping characteristics. In polycrystalline sheet vibrated at a frequency of 0.65 Hz, maximum damping occurs at 1100 °C.

Friction characteristics. Tantalum galls against itself and against type 18-8 stainless steel.

Technetium (Tc)

Compiled by C.C. Koch, North Carolina State University

Technetium is used as a radioactive tracer in medicine and has potential uses arising from its favorable corrosion-inhibiting properties and catalytic behavior, and its high elemental superconducting transition temperature. There is contamination hazard from technetium due to its radioactivity, and the element is classed as moderately toxic. All processes such as sample preparation that could result in the dispersal of solid ^{99}Tc must be carried out in glove box facilities. The data that follow are for ^{99}Tc only.

Structure

Crystal structure. Close-packed hexagonal; *A*3; a = 0.27407 nm, c = 0.43980 nm, c/a = 1.6048 at 25 °C; a = 0.27364 nm, c = 0.43908 nm, c/a = 1.6046, at 4.2 K

Mass Characteristics

Atomic weight. 99.0000

Density. 11.5 g/cm^3 at 25 °C

Thermal Properties

Melting temperature. 2200 °C (Ref 409)

Coefficient of thermal expansion. Linear, from 150 K to 25 °C. Polycrystalline: 7.05 μm/m · K. Along crystal axes: 7.04 μm/m · K along *a* axis; 7.06 μm/m · K along *c* axis (Ref 410)

Thermal conductivity. 50.2 W/m · K at 25 °C (Ref 411)

Recrystallization temperature. 700 to 800 °C

Enthalpy of sublimation. 6.68 kJ/kg (Ref 412)

Vapor pressure. See Fig. 112.

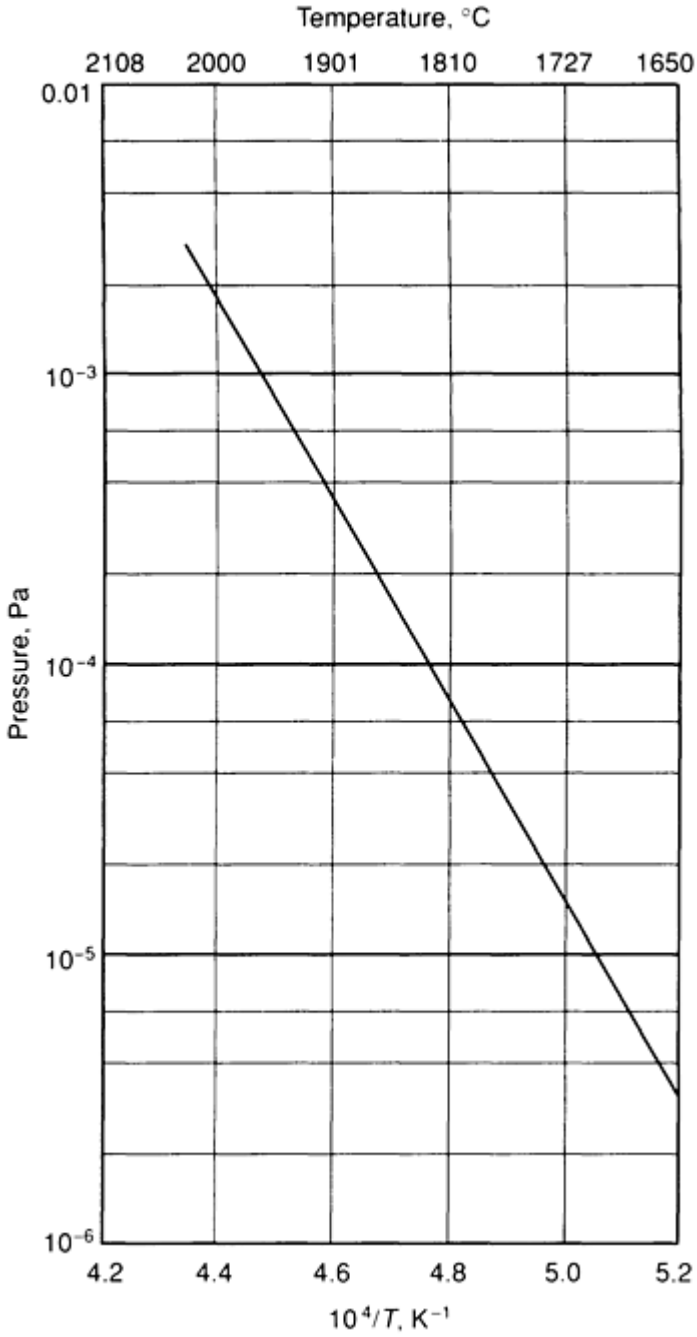

Fig. 112 Vapor pressure of ^{99}Tc. Source: Ref 412

Electrical Properties

Electrical resistivity. 185.0 nΩ · m at 25 °C (Ref 413). See also Fig. 113.

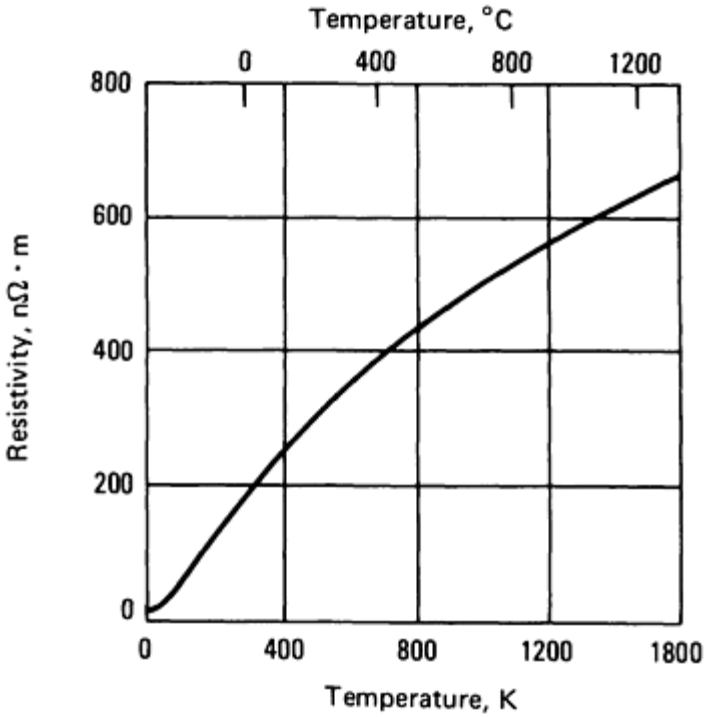

Fig. 113 Temperature dependence of the electrical resistivity of ^{99}Tc

Temperature of superconductivity. 7.8 K (Ref 414)

Work function. 0.782 aJ (4.88 eV) (Ref 415)

Magnetic Properties

Magnetic susceptibility. Volume: 1.63×10^{-4} mks units (Ref 416)

Nuclear Properties

Isotopes. See Table 44

Table 44 Isotopes of technetium

Isotope	Half-life	Decay	Energy	
			J × 10^{13}	MeV
^{92}Tc	4.4 min	β^-, ε	3.96	2.47
^{93}Tc	2.7 h	ε, β^-	1.31	0.82
^{94}Tc	293 min	ε, β^+	1.31	0.816
^{95}Tc	20 h	ε	. . .	. . .

^{96}Tc	4.3 days	ε	. . .	. . .
^{97}Tc	2.6×10^6 years	ε	. . .	. . .
^{98}Tc	1.5×10^6 years	β^-	0.48	0.30
^{99}Tc	2.14×10^5 years	β^-	0.468	0.292
^{100}Tc	17 s	β^-	5.41	3.38
^{101}Tc	14.0 min	β^-	2.11	1.32
^{102}Tc	4.5 min	β^-	3.5	2.2
^{103}Tc	50 s	β^-	3.5	2.2
^{104}Tc	18 min	β^-	7.4	4.6
^{105}Tc	7.7 min	β^-	5.4	3.4
^{106}Tc	37 s	β^-	~10	~6.5

Thermal neutron cross section. 22 b at 2200 m/s

Chemical Properties

General corrosion behavior. Technetium metal tarnishes slowly in air and burns in oxygen. At 400 °C it reacts with fluorine to form the hexafluoride and with chlorine to form a mixture of the hexachloride and tetrachloride. Technetium dissolves in oxidizing acids such as nitric, sulfuric, and aqua regia but not in hydrochloric acid. The pertechnetate ion has been shown to be an efficient anticorrosion agent in solution.

Mechanical Properties

Tensile properties. Tensile strength: 1510 MPa as-rolled (46% reduction); 800 MPa after annealing 10 min at 950 °C. 0.2% offset yield strength: 1290 MPa as-rolled (46% reduction); 320 MPa after annealing 10 min at 950 °C (fully recrystallized). Elongation in 25 mm: 4% as-rolled (46% reduction); 30% after annealing 10 min at 950 °C (Ref 412)

Hardness. 46% cold worked: 394 HV, 442 HB. Annealed at 950 °C: 151 HV, 112 HB (Ref 417)

Poisson's ratio. 0.31 (Ref 418)

Elastic modulus. Tension, 322 GPa; shear, 123 GPa; bulk, 281 GPa (Ref 418)

Velocity of sound. At 25 °C; longitudinal velocity, 6220 m/s; shear velocity, 3270 m/s

Tellurium (Te)

Compiled by S.C. Carapella, Jr., ASARCO Inc.; Reviewed for this Volume by, Douglas Hayduk, ASARCO Inc.

Tellurium was not widely used until after World War II, when it found a modest usage in some nonferrous alloys and as a secondary vulcanizing agent in the natural rubber industry. In 1958, interest developed in the potentialities of tellurium as a thermoelectric material in the form of bismuth telluride and lead telluride; however, this interest has not continued to develop (Ref 419).

The metallurgical industry consumes about 80% of the tellurium produced. It is used as a carbide-stabilizing agent in the production of white cast iron and malleable iron castings, as an additive to low-carbon steels and stainless steels, and as an additive to copper to improve machinability. It is also used as an additive to improve the corrosion resistance of lead alloys (Ref 419).

Numerous other applications requiring small amounts of tellurium have been found. The principal uses are (Ref 419):

- *Chemicals:* for catalytic reactions; as an element of salts and other compounds
- *Electronics:* as a component in thermoelectric materials
- *Explosives:* as an ingredient in blasting caps
- *Metallurgy:* as an additive to copper to increase machinability without materially decreasing conductivity; to produce free-machining steels; added to lead to improve resistance to vibration and fatigue; as an additive to cast iron to help control the depth of chill; and as a carbide stabilizer for the production of malleable iron
- *Pigments:* in production of various colored glasses and ceramics
- *Rubber:* as a secondary vulcanizing agent

Table 45 lists impurity level for various grades of elemental tellurium.

Table 45 Nominal composition of selected grades of tellurium

Grade designation	Composition, wt%								
	Te	Se	Pb	Fe	Cu	As	Zn	Other impurities	Impurities max

Commercial or refined	99.0-99.4	0.5	0.3	0.1	0.02	. . .	. . .	. . .	. . .

Thallium (Tl)

Compiled by S.C. Carapella, Jr., ASARCO, Inc.; Reviewed for this Volume by Douglas Hayduk, ASARCO, Inc.

Thallium is used in alloying to lower the freezing point of certain metals, such as mercury in arctic thermometers and low-temperature mercury switches. It is also a component of fusible alloys and glass, and can be used as an additive in the counter-electrode metal for selenium rectifiers. Compounds of thallium are used for catalysts and semiconductor applications.

Because of the high toxicity of thallium, skin contact and inhalation of dust and fumes are to be avoided. Impervious gloves and aprons should be worn and dust and fumes in work areas must be controlled by exhaust ventilation.

Structure

Crystal structure. Close-packed hexagonal below 230 °C; a = 0.34560 nm, c = 0.55248 nm. Body-centered cubic above 230 °C; a = 0.3874 nm

Mass Characteristics

Atomic weight. 204.37

Density. 11.872 g/cm^3 at 20 °C

Volume change on freezing. 3.23% contraction

Thermal Properties

Melting point. 303 °C

Boiling point. 1473 °C

Coefficient of linear thermal expansion. 28 μm/m · K at 20 °C

Specific heat. 0.150 kJ/kg · K for liquid, 0.130 kJ/kg · K for solid

Mechanical Properties

Tensile strength. 8.9 MPa

Elongation. 40% in 125 mm

Hardness. 2 HB

Liquid surface tension. 467 mN/m at 303 °C, 450 mN/m at 450 °C

Tin (Sn)

Compiled by Joseph B. Long, Tin Research Institute, Inc.; Reviewed for this Volume by William Hampshire, Tin Information Center

Under certain specific conditions at low temperature, tin can transform from the normal tetragonal metal (β tin or white tin) to a cubic form (α tin or gray tin) that has entirely different properties. Because this transformation is accompanied by an increase in volume, the resultant expansion causes disintegration of the metal to coarse powder or to local warts. The equilibrium temperature of transformation is 13.2 °C. In practice, it is extremely difficult to initiate the change, and the rate is slow even after transformation has started. Moreover, common impurities such as bismuth, antimony, and lead inhibit the change. The fear that fabricated products made of tin or high-tin alloys will fail at low temperatures or that tin in storage will disintegrate is largely unfounded.

The existence of γ tin, a brittle modification that is sometimes mentioned in technical literature, has been disproved (Ref 422). Abrupt changes in some properties at elevated temperatures, such as high-temperature ductility, are ascribed more accurately to impurities. Many of the properties listed here were determined on tin of 99.95% purity. Additional information is available in the article "Tin and Tin Alloys" in this Volume.

Structure

Crystal structure. α phase: face-centered cubic, *A*4, *cF*8 (*Fd*3*m*); *a* = 0.64912 nm (Ref 423, 424). β phase: body-centered tetragonal, *A*5, *tI*4 (*I*4*t*/*amd*); *a* = 0.58314 nm, *c* = 0.31815 nm (Ref 425, 426, 427, 428, 429, 430)

α tin	0.279	4
	0.456	8
β tin	0.302	4
	0.318	2
	0.376	4

Liquid tin (250 °C)	0.338	10

Source: Ref 433

Microstructure. Because tin is an extremely soft metal, it is often difficult to obtain an unworked surface free from scratches, and the low crystallization temperature of tin can result in false structure if distortion occurs during polishing. To overcome these difficulties, it is necessary to take special precautions during both mounting and polishing.

Fracture behavior. Ductile

Mass Characteristics

Hall effect. -0.02 nV · m/A · T at 0.4 T and room temperature (Ref 470, 471, 472)

Temperature of superconductivity. 3.73 K (Ref 472)

Photoelectric work function. 464 eV (Ref 473)

Magnetic Properties

Magnetic susceptibility. Mass: α phase, -39×10^{-11} mks; β phase at 18 °C, $+34 \times 10^{-11}$ mks; liquid phase at 250 °C, -45×10^{-11} mks

Optical Properties

Color. White with bluish tinge

Reflectance. Refractive and absorption indices. See Table 47.

Table 47 Optical properties of tin at λ= 546.1 nm

Surface	Reflectance	Refractive index	Absorptive index
Film, 42-200 nm thick[(a)]	0.70	2.4	1.9
Film, 2.5 nm thick[(a)]	. . .	3.0	0.17
Bulk solid	0.80	1.0	4.2
Liquid	0.80	1.7	3.1

Sources: Ref 474, 475, 476, 477

(a) Vacuum-evaporated film.

Emittance. 0.04 at 50 °C (Ref 435)

Nuclear Properties

Stable isotopes. Results from three measurements (Ref 478):

Mass number	Abundance, %
112	1.01, 0.90, 0.94
114	0.68, 0.61, 0.65
115	0.35, 0.33, ?
116	14.28, 14.07, 14.36
117	7.67, 7.54, 7.51

118	23.84, 23.98, 24.21
119	8.68, 8.62, 8.45
120	32.75, 33.03, 33.11
122	4.74, 4.78, 4.61
124	6.01, 6.11, 5.83

Unstable (radioactive) isotopes. See Table 48.

Table 48 Unstable (radioactive) isotopes of tin

Isotope	**Half-life**	**Energy of radiation, MeV**	
		Particles	**γ rays**
^{109}Sn	18 min	β^+: ~1.6	. . .
^{110}Sn	4 h	. . .	. . .

Mechanical Properties

Poisson's ratio. 0.33

Elastic modulus. At room temperature (Ref 479): as-cast (coarse grain), 41.6 GPa; self-annealed (fine grain), 44.3 GPa. For effect of temperature:

°C	Percentage of value at 16 °C	
	Polycrystalline	**Single crystals**
25	98	99
50	92	96
75	86	93
100	79	90
125	72	87

Source: Ref 480

Elastic modulus along crystal axes. Room temperature: 84.7 GPa along (001) plane (maximum value), 26.3 GPa along (110) plane (minimum value). Effect of temperature (Ref 481, 482, 483): 53.9 MPa/K at -180 to 0 °C, 75.5 MPa/K at 0 to 100 °C, 121.6 MPa/K at 100 to 200 °C

Dynamic liquid viscosity. From Ref 484, 485, 486, 487, 488, 489:

°C	mPa · s
232	2.71
250	1.88
300	1.66
400	1.38
500	1.18
600	1.05
700	0.95
800	0.87

Liquid surface tension. From 400 to 800 °C: $\sigma = 700 - 0.17 \times T + (25 + 0.015 \times T)$, where σ is in mN/m and T is temperature in K (Ref 490)

Velocity of sound. In solid, 2.60 km/s at 18 °C (Ref 424); in liquid, 2.27 km/s at 232 °C and 12 MHz (Ref 491)

Titanium (Ti)

Compiled by W. Stuart Lyman, Copper Development Association, Inc. (formerly with Battelle Memorial Institute); Reviewed for this Volume by Titanium Development Association

Designations

Common name. Iodide titanium, electrolytic titanium. See Table 49 for impurity limits.

Table 49 Impurity limits of electrolytic titanium and iodide titanium

Impurity element	Typical concentration, %	
	Electrolytic	Iodide crystal bar
Fe	0.009	0.002
Si	0.002	0.005
Ca	. . .	0.003
Cu	0.007	<0.001
Mg	<0.001	0.003
Mn	<0.001	0.003

Sn	<0.020	0.001
Zr	<0.001	0.050
C	0.008	0.001
O	0.037	0.03-0.06
N	0.004	0.002
Cl	0.073	0.002
Ti (by difference)	99.837	99.90-99.87

Typical uses. Experimentation and research; commercial applications requiring freedom from interstitial alloying elements (oxygen, nitrogen, carbon, and hydrogen)

Structure

Crystal structure. α phase: close-packed hexagonal; a = 0.295030 nm, c = 0.468312, c/a = 1.5873. β phase: body-centered cubic, a = 0.332 nm at 900 °C

Mass Characteristics

Atomic weight. 47.9

Density. α phase: 4.507 g/cm^3 at 20 °C. β phase: 4.35 g/cm^3 at 885 °C (from indirect measurements)

Thermal Properties

Melting temperature, 1668 ± 10 °C

Boiling point. 3260 °C (estimated)

Vapor pressure. From 1587 to 1698 K:

$$\log P = 7.7960 - \frac{24\,644}{T} - 0.000227\,T$$

where P is in Pa and T is in K

Phase transformation temperature. α to β, 882.5 °C

Coefficient of thermal expansion. At 20 °C, 8.41 × 10^{-6}/°C at 1000, 10.1 × 10^{-8}/°C (estimated)

Thermal expansion in crystallographic direction. Calculated from lattice parameters:

Temperature, °C	Direction	Expansion, µm/m · K
20-400	Perpendicular to *c* axis	10.2
20-700	Perpendicular to *c* axis	11.0
20-700	Along *c* axis	12.8

Specific heat. Below 13 K, $C_p = 0.0706 + 5.43 \times 10^{-4}\ T^3$; above room temperature, $C_p = 669.0 - 0.037188\ T - 1.080 \times 10^7\ T^2$, where C_p is in J/kg · K and T is in K:

Temperature, K	C_p, kJ/kg · K
50	0.0993
75	0.2100
100	0.3002
125	0.3632
150	0.4094
175	0.4408
200	0.4651
225	0.4841
250	0.4994
275	0.5126
298.15	0.5223

300	0.5378
350	0.5678
400	0.5866
450	0.5989
500	0.6072
550	0.6128
600	0.6167
650	0.6193
700	0.6209
750	0.6219
800	0.6224
850	0.6224
900	0.6223
950	0.6217
1000	0.6210
1050	0.6202
1100	0.6192
1150	0.6181

Latent heat of fusion. 440 kJ/kg (estimated)

Latent heat of transformation. 91.8 kJ/kg (estimated)

Latent heat of vaporization. 9.83 MJ/kg (estimated)

Thermal conductivity. 11.4 W/m · K at -240 °C

Electrical Properties

Electrical resistivity. 420 nΩ · m at 20 °C. See also Fig. 114.

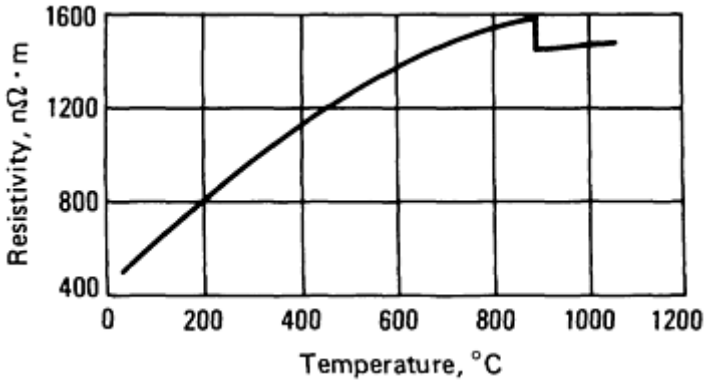

Fig. 114 Electrical resistivity of 99.9% pure titanium

Superconductivity. Critical temperature: 0.37 to 0.56 K

Magnetic Properties

Magnetic susceptibility. Volume, at room temperature: 180 (±1.7) × 10^{-6} mks

Optical Properties

Total hemispherical emittance. 0.30 at 710 °C

Nuclear Properties

Stable isotopes:

Isotope	Natural abundance, %	Cross section, b[(a)]
^{46}Ti	7.95	0.6
^{47}Ti	7.75	1.6
^{48}Ti	73.43	8.0
^{49}Ti	5.51	1.8
^{50}Ti	5.34	0.2

(a) b, barns

Chemical Properties

General corrosion behavior. Greater resistance than that of commercial grades of unalloyed titanium. See the article "Corrosion of Titanium and Titanium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Mechanical Properties

Tensile properties. Typical, at room temperature: tensile strength, 235 MPa; 0.2% yield strength, 140 MPa; elongation in 50 mm, 54%. See also Fig. 115.

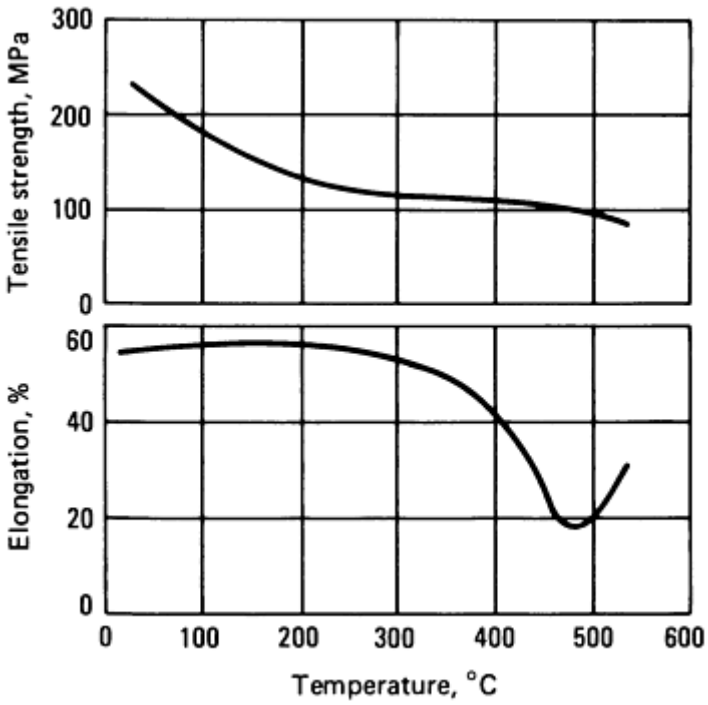

Fig. 115 Typical tensile properties of 99.9% pure titanium

Minimum bend radius. <1*t*

Hardness. Ingot melted from: electrolytic titanium, 70 to 74 HB; iodide titanium, 65 to 72 HB

Velocity of sound. 4970 m/s

Additional information is available in the articles "Introduction to Titanium and Titanium Alloys," "Wrought Titanium and Titanium Alloys," "Titanium and Titanium Alloy Castings," and "Titanium Powder Metallurgy Products" in this Volume.

Tungsten (W)

Compiled by Stephen W.H. Yih, Consultant; Reviewed for this Volume by Toni Grobstein, NASA Lewis Research Center

Structure

Crystal structure. α phase: body-centered cubic, *cI*2 (*Im*3*m*); a = 0.316522 ± 0.00009 nm at 25 °C. β phase occurs only in the presence of oxygen and is probably W_3O; it is stable below 630 °C and of type *A*15 or *cP*8 (*Pm*3*n*); a = 0.5046 nm at 25 °C

Minimum interatomic distance. α phase, 0.274116 nm; β phase, 0.252 nm

Mass Characteristics

Atomic weight. 183.85

Density. 19.254 g/cm^3

Thermal Properties

Melting point. 3410 ± 20 °C (Ref 492)

Boiling point. 5700 ± 200 °C (Ref 493)

Coefficient of thermal expansion. Linear at low temperatures:

Temperature		Coefficient, μm/m	
K	**°C**	**X-ray spacing data**	**Extensometer data**
180	-93	3.7	3.9
140	-133	3.2	3.4
100	-173	2.3	2.7
80	-193	1.8	2.2
60	-213	1.1	1.5
40	-233	0.4	0.6

Source: Ref 494, 495, 496

Thermal expansion. From 25 to 2500 °C:

$$\frac{L - L_{25°C}}{L_{25°C}} x100 = A_0 + A_1T + A_2T_2$$

where T is the Celsius temperature and the values of coefficients A_0, A_1, and A_2 are shown in Table 50

Table 50 Values of coefficients for calculation of the thermal expansion of tungsten from 25 to 2500 °C

Material	Coefficient		
	A_0	A_1	A_2
Powder metallurgy rod	-8.69×10^{-3}	3.83×10^{-4}	7.92×10^{-8}
Powder metallurgy sheet	-4.58×10^{-3}	3.65×10^{-4}	9.81×10^{-8}
Arc cast sheet	-6.76×10^{-3}	3.91×10^{-4}	8.98×10^{-8}

Source: Ref 497

Specific heat. From 0 to 3000 °C (Ref 498):

$$C_p = 135.76\left(1 - \frac{4805}{T^2}\right) + (9.1159x10^{-3})T + (2.3134x10^{-9})T^3$$

where C_p is in J/kg · K and T is in K

Enthalpy. From 935 to 2975 °C (derived from specific heat equation):

$$H_T - H_{298} = 135.76\left(T + \frac{26.14}{T}\right) - 4.266x10^{-3} + (4.5569x10^{-3})T^2 + (5.78205x10^{-10})T^4$$

where H is in J/kg and T is in K

Entropy. At 25 °C (Ref 499): 178.3 J/kg · K. Change with temperature (Ref 500):

°C	J/kg · K
25	0
127	37
727	163
1627	262

Latent heat of fusion. 220 ± 36 kJ/kg (Ref 493)

Latent heat of sublimation. 4680 ± 25 kJ/kg (Ref 501)

Thermal conductivity. See Fig. 116.

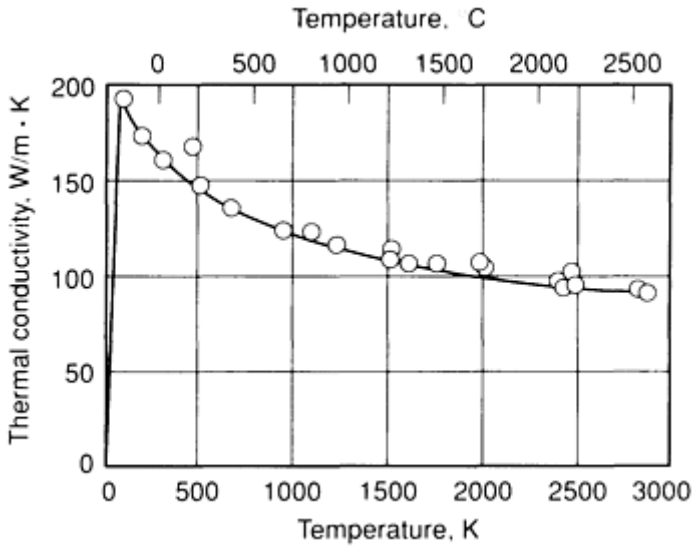

Fig. 116 Temperature dependence of the thermal conductivity of tungsten. Sources: Ref 502, 503, 504, 505, and 506

Vapor pressure. From 2327 to 2827 °C (Ref 501):

$$\log_{10} P = \frac{-45385}{T} + 2.865$$

where P is in Pa and T is in K

Electrical Properties

Electrical resistivity. 53 nΩ · m at 27 °C. From 27 to 967 °C (Ref 506): $\rho = (4.33471 \times 10^{-14}) T^2 + (2.19691 \times 10^{-10}) T -$ $(1.64011 \times 10^{-8}$, where ρ is in Ω· m and T is in K

Hall constant. 10.55 μV · m/A · T (Ref 493)

Temperature of superconductivity. 0.016 K (Ref 507)

Magnetic Properties

Magnetic susceptibility. See Fig. 117.

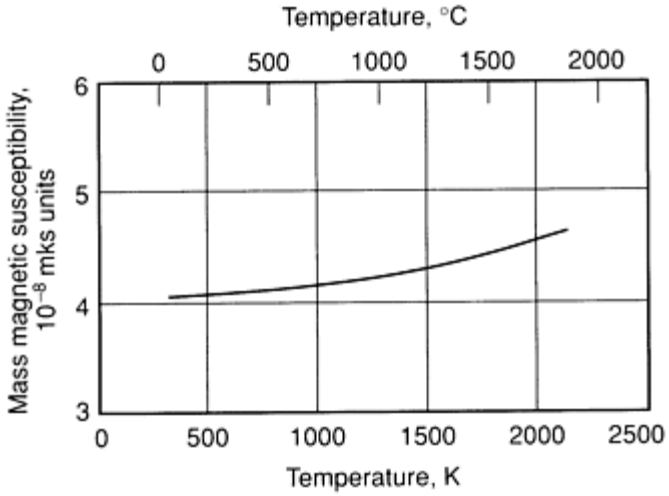

Fig. 117 Temperature dependence of the mass magnetic susceptibility (χ_m) of tungsten. Source: Ref 508

Optical Properties

Total emissivity. From Ref 509:

°C	Total emissivity
127	0.042
527	0.088
1327	0.207
1727	0.260

Vanadium (V)

Revised by F.H. Perfect, Reading Alloys, Inc.

Elemental vanadium is finding use in commercial quantities in a titanium-base alloy. The nuclear industry is a major consumer of unalloyed vanadium; lesser amounts are used in the superconductor and electronics industries. U.S. consumption of vanadium in steel, usually in the form of ferrovanadium, is about 3605 tons annually (see Fig. 124). This constitutes 84% of the entire U.S. vanadium market. The titanium industry uses aluminum-vanadium, the most common nonferrous master alloy of vanadium; this use accounts for 15% of total U.S. consumption. The remaining 1% is used by the catalyst chemical industry (Ref 526).

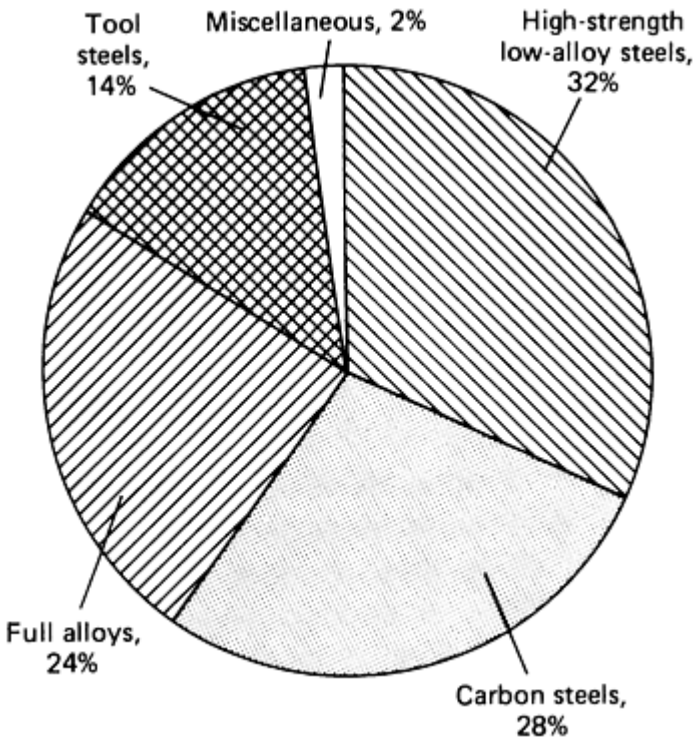

Fig. 124 Breakdown of unalloyed vanadium metal used in the ferrous industry in 1987. Miscellaneous includes vanadium used for stainless and heat-resistant steels, cast irons, superalloys, welding, and hardfacing. Source: Ref 526

At present, most vanadium metal is produced by electron beam remelting of aluminothermic aluminum-vanadium. The former process, calcium reduction of vanadium oxide, was used when ultrapurity was required (Ref 527). Currently, the less-pure metal is refined by a variation of the van Arkel-DeBore process (Ref 528).

The purity of the vanadium obtained by these processes depends on the initial purity of the oxide and reductant that are used. A typical nominal composition of vanadium metal produced by the electron beam remelting of aluminothermic aluminum-vanadium (a process that yields several tons of vanadium metal product) is listed below:

Element	**Wt%**
Aluminum	0.090
Carbon	0.017
Iron	0.025
Nitrogen	0.031
Oxygen	0.093

Silicon	0.190
Sulfur	0.006
Vanadium	99.52

Increased impurity levels, particularly of silicon, oxygen, nickel, carbon, and hydrogen, have an adverse effect on hardness and ductility.

Structure

Crystal structure. Body-centered cubic. Lattice parameters: calcium reduced, 0.30278 nm; iodide, 0.30258 nm

Mass Characteristics

Atomic weight. 50.941

Density. 6.16 g/cm^3 at 20 °C (Ref 529); 5.55 g/cm^3 at melting point (Ref 530)

Thermal Properties

Melting point. 1910 °C (Ref 531, 532)

Boiling point. 3350 to 3400 °C (Ref 533)

Coefficient of linear thermal expansion:

Temperature range, °C	**Average coefficient, µm/m · K**
23-100	8.3
23-500	9.6
23-900	10.4
23-1100	10.9

Latent heat of fusion. 314 kJ/kg

Latent heat of vaporization. 9002 kJ/kg

Vapor pressure. From 1666 to 1882 K: $R \ln (P) = 1.21950 \times 10^5 T^{-1} - 5.123 \times 10^{-4} T + 38.3$, where R is gas constant, P is pressure in kPa, T is in K, and ln is logarithm to base e

Specific heat. 498 kJ/kg · K at 0 to 100 °C (Ref 534, 535, 536)

Thermal conductivity. 31.0 W/m · K at 100 °C (Ref 537, 538, 539)

Electrical Properties

Electrical resistivity. 248 to 260 nΩ · m at 20 °C (Ref 529, 534)

Nuclear Properties

Thermal neutron cross section. 4.7 ± 0.02 b; 5.06 ± 0.06 b (Ref 540); 5.1 ± 0.2 b (Ref 541)

Chemical Properties

Resistance to specific corroding agents. At room temperature, vanadium and its alloys have excellent resistance to corrosion in salt water and dilute hydrochloric acid; good corrosion resistance in sodium hydroxide solutions; and poor corrosion resistance in nitric acid solutions. Resistance to attack by liquid alkali metals is good.

Mechanical Properties

Tensile properties. Typical at 1025 °C: tensile strength, 53 MPa; elongation, 37% in 25 mm

Hardness. 72 HB, electron beam ingot. See also Table 51.

Table 51 Typical mechanical properties for vanadium metal at room temperature

Condition	Tensile strength, MPa	Yield strength, MPa	Elongation in 50 mm, %	Reduction in area, %	Hardness		Cold bend
					HRA	HRB	
Bar, 25.4 mm in diameter[(a)]							
Hot rolled	472	439	27.0	54.4	. . .	85	. . .
Wire, 3.9 mm in diameter[(b)]							
Vacuum annealed	538	463	25.0	87.5	48	. . .	180°
Cold drawn 80%	910.8	765	6.8	76.5	54	. . .	180°
Sheet, 1.9 mm thick[(c)]							
Vacuum annealed	536	454	20.0	53.0	. . .	83	180°

(a) Specimen size: 12.8 mm diameter × 51 mm.

(b) Specimen size: 3.9 mm diameter × 51 mm.

(c) Specimen size: 1.9 mm × 12.7 mm × 51 mm

Poisson's ratio. 0.36

Elastic modulus. Tension, 124 to 137 GPa; shear, 46.4 GPa

Creep-rupture characteristics. Limiting creep stress, 4.63 MPa for 1% deformation in 24 h at 1000 °C. Stress/density ratio at 1000 °C, 110

Fabrication Characteristics

Recrystallization temperature. 800 to 1010 °C

Standard finishes. The machining of vanadium metal is similar to that of stainless steel and presents no special problem except where the metal surface has been severely contaminated with oxygen and nitrogen.

Suitable joining methods. Satisfactory electric welding of vanadium requires adequate protection of the weld pool and heat-affected zone with a neutral gas, such as argon or helium, to prevent or minimize contamination with oxygen, hydrogen, and nitrogen. Flame welding is not practical because of the reactivity of any combustion gas mixture with molten vanadium. Vanadium can be joined by welding to ferritic austenitic stainless steels, to titanium and titanium alloys, and to low-carbon steel.

Zirconium (Zr)

Compiled by R.T. Webster, Teledyne Wah Chang Albany

Zirconium is principally used as a corrosion-resistant cladding for uranium in nuclear reactors. It is also used as a corrosion-resistant structural material in chemical processing equipment such as pressure vessels, heat exchangers, pumps, and valves.

Zirconium is nontoxic and, consequently, does not require serious limitations on its use because of health hazards (Ref 562).

Zirconium is pyrophoric because of its heat-producing reaction with oxidizing elements such as oxygen. Large pieces of sheet, plate, bar, tube, and ingot can be heated to high temperatures without excessive oxidation or burning, but small pieces with a high ratio of surface area to mass, such as machine chips and turnings, are easily ignited and burn at extremely high temperatures. It is recommended that large accumulations of chips and other finely divided material be avoided. Also, in storing the chips and turnings, care should be taken to place the material in nonflammable containers and isolated areas. One storage method that works quite well is to keep the material covered with water in the containers and use oil on the water to keep it from evaporating.

If a fire accidentally starts in zirconium, do not attempt to put it out with water or ordinary fire extinguishers, but use dry sand, powdered graphite, or commercially available Met-L-X powder. Large quantities of water can be used to control and extinguish fires in other flammables in the vicinity of a zirconium fire.

When zirconium is exposed to highly corrosive attack by a concentrated acid such as red fuming nitric acid, it is possible than in time the exposed surfaces of the zirconium will be converted to a finely divided powder. This powder can ignite, possibly with explosive force. If the proper balance between water vapor and nitrogen dioxide above the liquid is maintained, this hazard can be eliminated.

Structure

Crystal structure. α phase, close-packed hexagonal: at 20 °C, a = 0.323115 nm, c = 0.51477 nm, c/a = 1.5931. β phase, body-centered cubic: at 862 °C, a = 0.36090 nm (Ref 563)

Slip planes. $\{10\bar{1}0\}$ at 20 °C

Twinning planes. $\{10\bar{1}2\}$ $\{11\bar{2}1\}$ $\{11\bar{2}2\}$ $\{11\bar{2}3\}$ at 20 °C

Cleavage planes. α phase, {1000}. β phase, {100}

Minimum interatomic distance. α phase at 20 °C: d_1 = 0.316 nm, d_2 = 0.312 nm. β phase, d_1 = 0.322 nm

Microstructure. Polishing and etching zirconium to observe the microstructure is not difficult when the proper techniques are used. Due to the tendency of zirconium to smear during polishing, an attack-polish technique is used. A solution of alumina is used in conjunction with a dilute acid solution to attack the sample surface chemically at about the same rate that is being removed by abrasion. The right combination of wheel speed, hand pressure, acid solution, and abrasive will result in a true undisturbed microstructure.

The sample is first sanded on abrasive cloth down to a 3/0 grit. It is then polished on a wheel using nylon cloth over Metcloth (the nylon is fairly acid resistant), according to the following procedure:

1. Apply abrasive solution (5 g of 3 μm alumina/150 mL H_2O) to wheel
2. Apply acid solution (250 mL H_2O/22 mL HNO_3/3 mL HF) to wheel
3. Spin for several seconds (approximately 1000 rev/min) to allow an even film to form on the cloth
4. Reduce speed to approximately 550 rev/min and polish sample with light-to-moderate pressure between the wheel and the sample. When the sample is removed from the wheel, wash immediately with H_2O (squirt bottle works well) or overetching will occur. Repeat above polishing as necessary to obtain a surface with no disturbed metal

To maintain the proper acid concentration on the wheel, the polishing cloth should be thoroughly rinsed with water after using for 1 to 2 min. New alumina and acid should be applied to continue polishing.

For etching, the sample surface is swabbed with acid solution (22 mL H_2O/22 mL HNO_3/3 mL HF) for 5 to 10 s, then rinsed in water to prevent overetching.

Mass Characteristics

Atomic weight. 91.22

Density. α phase, 6.505 g/cm^3 (low in hafnium) to 6.574 g/cm^3 (high in hafnium); β phase at 979 °C, 6.046 g/cm^3 (high-purity crystal bar zirconium)

Thermal Properties

Melting point. 1852 ± 2 °C

Boiling point. 4377 °C

Phase transformation temperature. 862 ± 5 °C

Coefficient of thermal expansion. Linear: 5.85 μm/m · K at 20 °C for heterogeneously oriented polycrystals; temperature dependence, see Fig. 132; along crystal axes, 5.65 μm/m · K perpendicular to *c* axis and 6.96 μm/m · K parallel to *c* axis. Volumetric: 17.68 μm/m · K for 0.005 at.% Hf; 17.47 μm/m · K for 1.2 at.% Hf

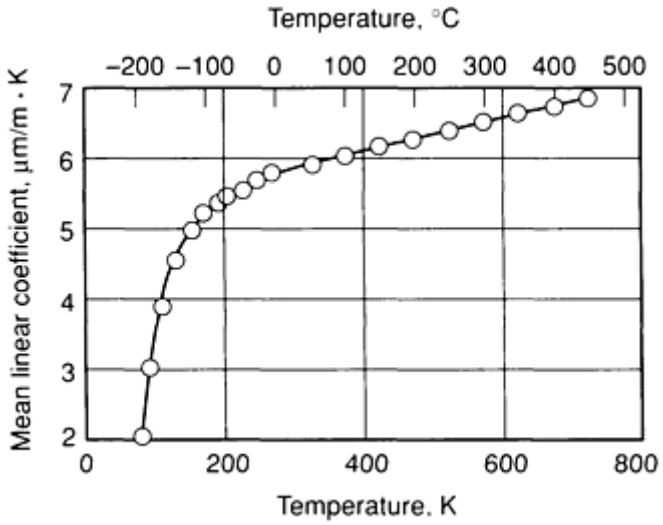

Fig. 132 Temperature dependence of the mean coefficient of linear thermal expansion for zirconium. Source: Ref 564

Specific heat. See Fig. 133.

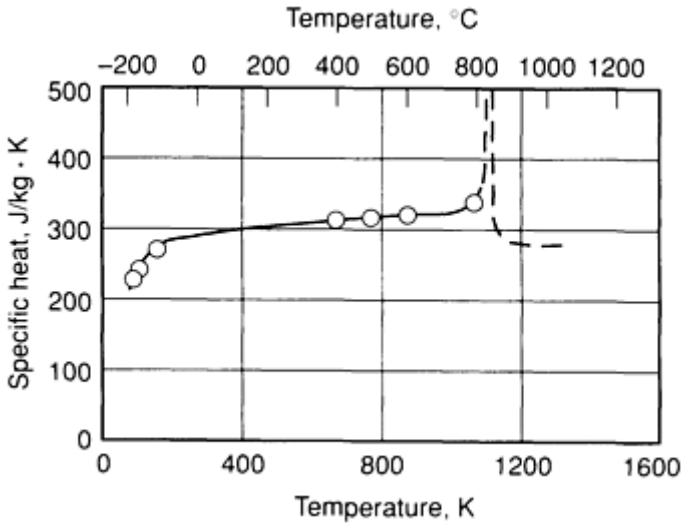

Fig. 133 Temperature dependence of the specific heat of zirconium. Source: Ref 564

Enthalpy. $H_T - H_{298}$:

°C	kJ/kg · K

100	23.1
200	52.2
300	80.3
400	112.6
500	146.4
600	182.0

Entropy. 426.1 J/kg · K at 25 °C

Latent heat of fusion. 25 kJ/kg

Latent heat of phase transformation. 42.2 kJ/kg

Latent heat of vaporization. 6520 kJ/kg

Heat of combustion. Heat of formation of ZrO_2, 5940 kJ/kg Zr

Thermal conductivity. From Ref 564: at 25 °C, 21.1 W/m · K; 100 °C, 20.4 W/m · K; 200 °C, 19.6 W/m · K. Temperature dependence: $k = 30.8 (\sigma - 0.000327) T + 3.81$, where k is thermal conductivity in W/m · K, σ is electrical conductivity in reciprocal nΩ · m, and T is temperature in K (see also Fig. 134).

(d) e^-, internal conversion electron.

Effect of irradiation on properties. See Fig. 137 and 138.

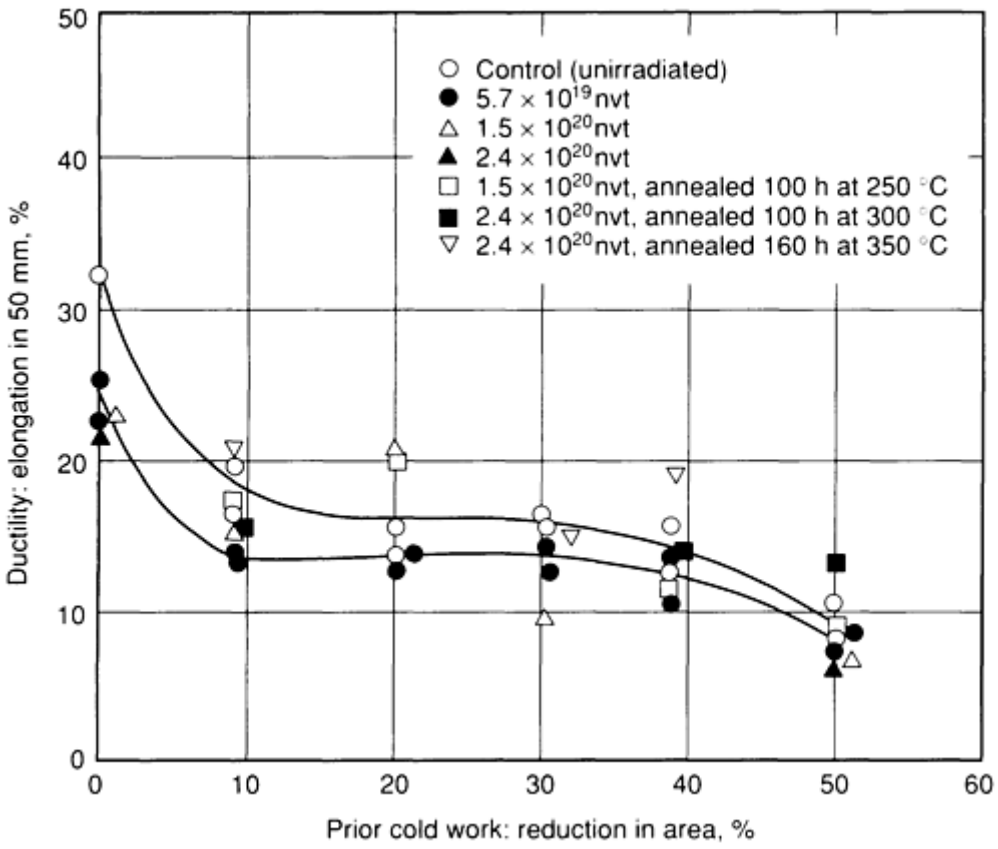

Fig. 137 Effect of irradiation and subsequent annealing on the ductility of sponge zirconium. Source: Ref 568

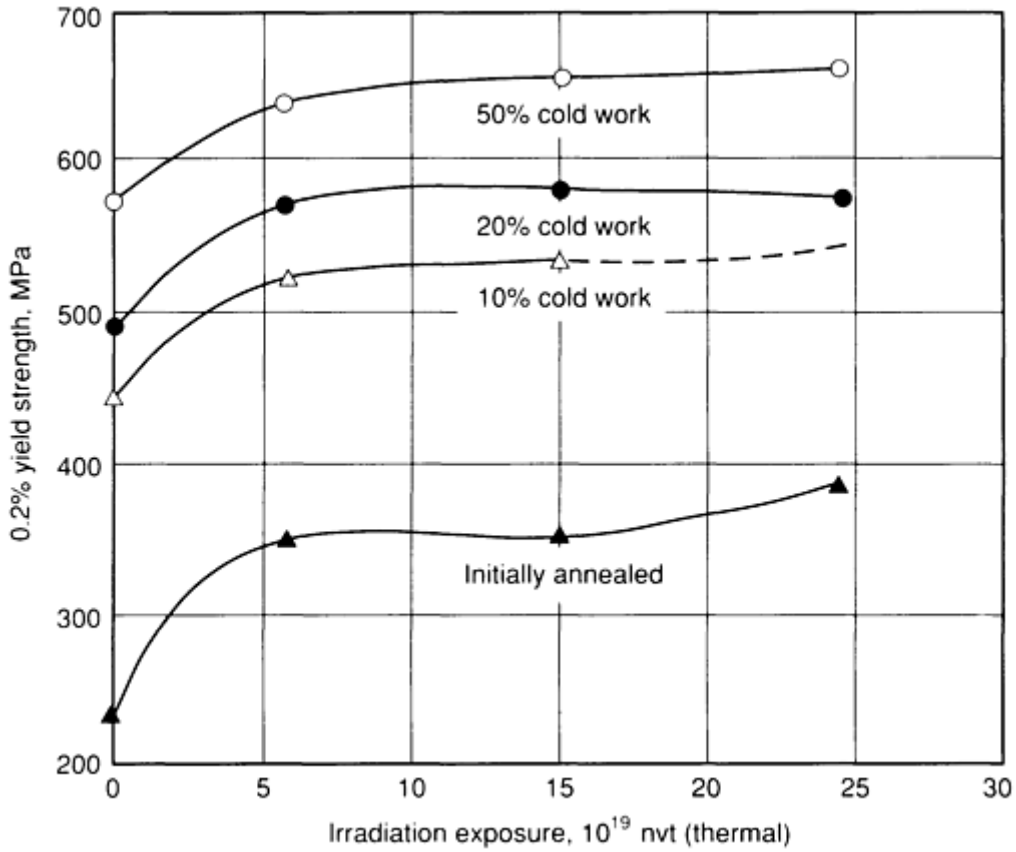

Fig. 138 Effect of irradiation on the yield strength of sponge zirconium. Exposure temperature was 50 to 60 °C. Source: Ref 568

Chemical Properties

Resistance to specific agents. Zirconium is able to maintain a bright surface permanently at room temperature. It is also able to form a stable oxide to high melting point and (possibly) to form a continuous oxide surface. However, its oxidation resistance in air or oxygen at moderately high temperatures is poor (Fig. 139).

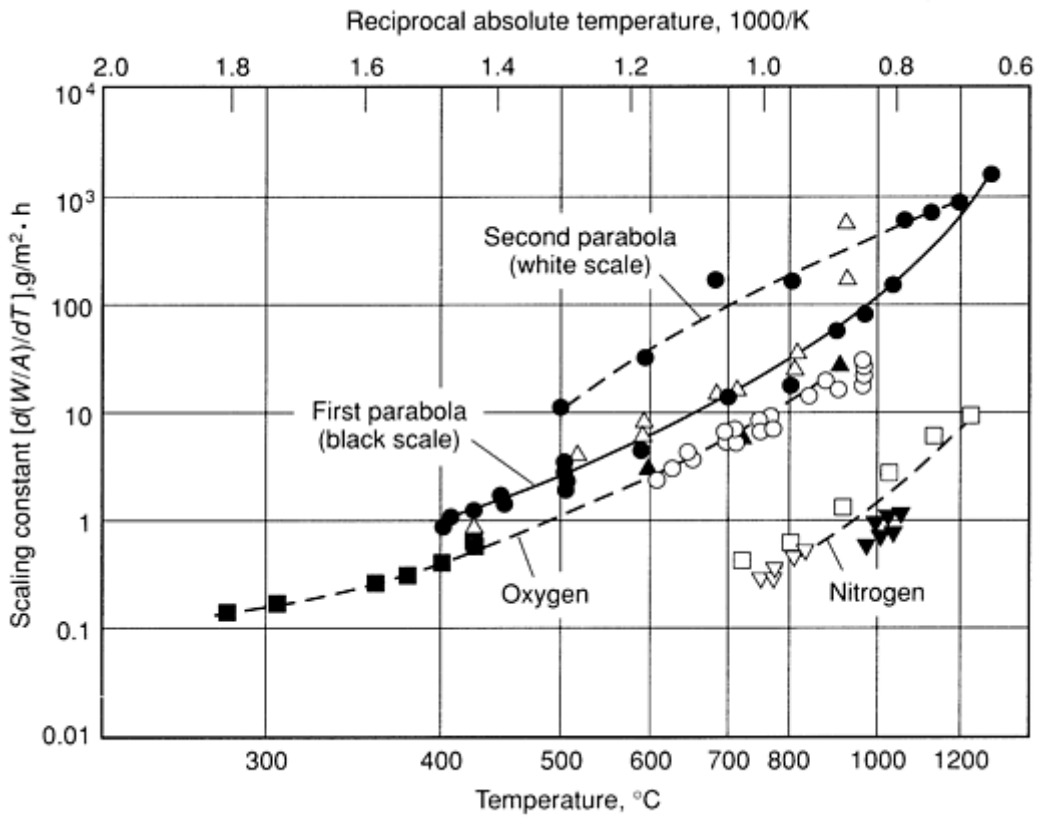

Fig. 139 Scaling rate of zirconium at elevated temperature. Source: Ref 568

Mechanical Properties

Tensile Properties. See Fig. 137 and 138.

Poisson's ratio. 0.35 at room temperature

Elastic properties. Tension, 99.284 GPa. Pressure dependency of specific volume (compressibility) (Ref 569):

Pressure, MPa	Relative specific volume
0.10	1.000
2940	0.967
3920	0.956
5880	0.937
6860	0.929

7850	0.922
8830	0.916
9810	0.910

Specific damping capacity. 17×10^{-4} at 25 °C, decreasing to 6.2×10^{-4} at 260 °C with a sharp increase to 1×10^{-2} at 610 °C

Coefficient of friction. For zirconium sliding on zirconium, 0.42 at 20 °C (Ref 570)

Velocity of sound. 4.62 km/s

Properties of the Rare Earth Metals

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, lowa State University

Cerium (Ce)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, lowa State University

Cerium, as a component (~50%) of mischmetal, is used as an alloying additive to ferrous alloys to scavenge impurities such as sulfur and oxygen, to nodulize cast iron, and to strengthen magnesium. It improves the high-temperature oxidation resistance of superalloys. It is also used in glass-polishing compounds, petroleum cracking catalysts, catalytic converters, lighter flints, glass-decolorizing agents, carbon arc lights, ceramic capacitors, $CeCo_5$ permanent magnets, and pyrophoric ordnance devices.

Cerium readily oxidizes at room temperature in air. It should be stored in vacuum or an inert atmosphere; storage in oil is not recommended. Turnings can be ignited easily and burn white hot. Finely divided cerium should not be handled in air.

Structure

Crystal structure. α phase, face-centered cubic, $Fm3m$ O_5^h; a = 0.485 nm at 77 K. β phase, double close-packed hexagonal, $P6_3/mmc$ D_4^{6h}; a = 0.36810 nm, c = 1.1857 nm at 24 °C. γ phase, face-centered cubic, $Fm3m$ O_5^h; a = 0.51610 nm at 24 °C. δ phase, body-centered cubic, $Im3m$ O_h; a = 0.412 nm at 757 °C

Minimum interatomic distance. γ phase, 0.172 nm at 77 K; β phase, r_a = 0.18405 nm, r_c = 0.18237 nm, radius CN_{12} = 0.18321 nm at 24 °C, where CN_{12} indicates a coordination number of 12; γ phase, 0.18247 nm at 24 °C

Mass Characteristics

Atomic weight. 140.115

Density. α phase, 8.16 g/cm^3 at 77 K; β phase, 6.689 g/cm^3 at 24 °C; γ phase, 6.770 g/cm^3 at 24 °C; δ phase, 6.65 g/cm^3 at 768 °C; liquid, 6.68 g/cm^3 at 800 °C

Volume change on freezing. 1.1% expansion

Volume change on phase transformation. γ to α phase, 16.0% volume contraction on cooling at 110 K; γ to β phase, 1.2% volume expansion on cooling at 273 K; δ to γ phase, 0.3% volume expansion on cooling

Thermal Properties

Melting point. 798 °C

Boiling point. 3443 °C

Phase transformation temperature. γ to δ phase: 726 °C; γ to β phase: M_s = 237 to 278 K, M_f = ?. β to γ phase: A_s = 373 to 451 K, A_f = 420 to >451 K. γ to α phase: M_s = 89 to 116 K, $M_f \cong$ 4.2 K. α to γ + β phases: A_s = 158 to 180 K, A_f = 190 to 210 K, β to α phase: M_s = 45 K, M_f = 15K; α to β phase: A_s = 125 K, A_f = 200 K

Coefficient of thermal expansion. At 24 °C. Linear: γ phase, 6.3 μm/m · K. Linear along crystal axes: γ phase, 6.3 μm/m · K along a axis. Volumetric: γ phase, 18.9 × 10^{-6} per K

Latent heat of fusion. 38.97 kJ/kg

Latent heat of transformation. γ to δphase, 21.34 kJ/kg

Latent heat of vaporization. 3.016 MJ/kg at 25 °C

Heat of combustion. For cubic CeO_2 at 25 °C: ΔH_c° = 777 MJ/kg Ce; ΔG°_f = -732 MJ/kg Ce

Recrystallization temperature. About 325 °C

Thermal conductivity. γ phase, 11.3 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 1290 °C; 0.101 Pa at 1554 °C; 10.1 Pa at 1926 °C; 1013 Pa at 2487 °C

Electrical Properties

Electrical resistivity. β phase, 828 nΩ · m at 25 °C; 41 nΩ · m at 2 K. γ phase, 744 nΩ · m at 25 °C. Liquid, 1300 nΩ · m at 800 °C

Ionization potential. Cel(I), 5.466 eV; Ce(II), 10.85 eV; Ce(III), 20. 198 eV; Ce(IV), 36.758 eV

Hall coefficient. +0.181 nV · m/A · T at 15 °C

Temperature of superconductivity. Bulk cerium not superconducting down to 0.25 K at atmospheric pressure. α phase becomes superconducting at 0.022 K at 2.2 GPa.

Magnetic Properties

Magnetic susceptibility. Volume, mks units. β phase: 1.50×10^{-3} at 25 °C; obeys Curie-Weiss law from 50 to 320 K with an effective moment of 2.61 μ_B (Bohr magnetons) and θ= -41 K, where θ is the Curie temperature. γ phase: 1.38×10^{-3} at 25 °C; obeys Curie-Weiss law above 0 °C with an effective moment of 2.52 μ_B and θ= -50 K.

Magnetic transformation temperature. β phase: Néel temperatures at 12.5 K (cubic sites) and 13.7 K (hexagonal sites)

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. 32.2% for λ= 645 nm at 877 to 1547 °C

Nuclear Properties

Thermal neutron cross section. 0.7 b

Chemical Properties

General corrosion behavior. Cerium oxidizers readily in air at room temperature. Oxidation rates increase with temperature and humidity. Interstitial impurities increase the oxidation rate, whereas some solid-solution additives, such as scandium, decrease the oxidation rate. Hydrogen will react with cerium at room temperature.

Resistance to specific corroding agents. Cerium reacts vigorously with dilute acids. Cold water slowly attacks cerium; hot water reacts faster. The presence of the fluoride ion retards acid attack by the formation of CeF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. β phase: tensile strength, 138 MPa; yield strength, 86 MPa; reduction in area, 24% at 24 °C, γ phase: tensile strength, 117 MPa; yield strength, 28 MPa; elongation, 22%; reduction in area, 30% at 24 °C

Hardness. 22 HV

Poisson's ratio. γ , 0.24

Dysprosium (Dy)

Compiled by K.A. Gschneidner, Jr. and, B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Dysprosium is used as a control rod in nuclear reactors; it is also used in magnetostrictive materials ($Tb_{0.3}Dy_{0.7}Fe_2$), Nd-Fe-B permanent magnets (to raise the magnetic ordering temperature), phosphors, catalysts, and garnet microwave devices. In addition, it is used to measure neutron fluxes. Dysprosium will remain shiny in air at room temperature. However, turnings can be ignited and will burn white hot. Finely divided metal should not be handled in air.

Structure

Crystal structure. α' phase, orthorhombic, *Cmcm* D_{17}^{2h}; a = 0.3595 nm; b = 0.6184 nm; c = 0.5678 nm at 86 K. α phase, close-packed hexagonal, $P6_3/mmc$ D_4^{6h}; a = 0.35915 nm; c = 0.56501 nm at 24 °C. β phase, body-centered cubic, $Im3m$ O_9^h; a = 0.403 nm at 1381 °C

Slip planes. At 24 °C: primary $\{10\bar{1}0\}$, secondary {0002}

Twinning planes. At 24 °C: primary $\{11\mathbf{2}1\}$, secondary $\{10\ \bar{1}\ 2\}$

Minimum interatomic distance. r_a = 0.17958 nm; r_c = 0.17522 nm; radius CN_{12} = 0.17740 nm at 24 °C

Mass Characteristics

Atomic weight. 162.50

Density. α phase, 8.551 g/cm^3 at 24 °C; β phase, 8.23 g/cm^3 at 1381 °C; liquid, 8.2 g/cm^3 at 1415 °C

Volume change on freezing. 4.5% contraction

Thermal Properties

Melting point. 1412 °C

Boiling point. 2567 °C

Phase transformation temperature. α to α' phase, 86 K; α to β phase, 1381 °C

Coefficient of thermal expansion. At 24 °C. Linear: 9.9 μm/m · K. Linear along crystal axes: 7.1 μm/m · K along a axis, 15.6 μm/m · K along c axis. Volumetric: 29.8 × 10^{-6} per K

Specific heat. 0.1705 kJ/kg · K at 25 °C

Entropy. 465.2 J/kg · K at 25 °C

Latent heat of fusion. 68.1 kJ/kg

Latent heat of phase transformation. α to β phase, 25.62 kJ/kg

Latent heat of vaporization. 1.787 MJ/kg at 25 °C

Heat of combustion. For cubic Dy_2O_3 at 25 °C: ΔH_c° = -5.73 MJ/kg Dy; ΔG_f° = -5.46 MJ/kg Dy

Recrystallization temperature. About 550 °C

Thermal conductivity. 10.7 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 804 °C; 0.101 Pa at 988 °C; 10.1 Pa at 1252 °C; 1013 Pa at 1685 °C

Electrical Properties

Electrical resistivity. 926 nΩ · m at 25 °C; 24 nΩ · m at 4 K. Along crystal axes at 25 °C: 1110 nΩ · m along *a* axis, 766 nΩ · m along *c* axis. Liquid: 2100 nΩ · m at 1414 °C

Ionization potentials. Dy(I), 5.927 eV; Dy(II), 11.67 eV; Dy(III), 22.8 eV; Dy(IV), 41.47 eV

Hall coefficient. Along crystal axes at 20 °C: -0.03 nV · m/A · T along *b* axis; -0.37 nV · m/A · T along *c* axis

Temperature of superconductivity. Bulk dysprosium is not superconducting down to 0.45 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume (mks units) at 27 °C: χ_a = 0.0717 and χ_c = 0.0511; obeys Curie-Weiss law above 250 K with an effective moment of 10.83 μ_B, θ_a = 169 K and θ_c = 121 K

Saturation magnetization. 3.71 T at 0 K along $<11\bar{2}0>$

Magnetic transformation temperature. Curie temperature 89 K, Néel temperature 179 K

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Liquid, 29.7% for λ= 645 nm at 1413 to 1437 °C

Nuclear Properties

Thermal neutron cross section. 1100 b

Chemical Properties

General corrosion behavior. Remains shiny in air at room temperature. The rate of oxidation is slow even at 1000 °C due to the formation of a dark, tightly adhering oxide on the surface. The presence of water vapor increases the rate of oxidation.

Resistance to specific corroding agents. Dysprosium does not react with cold or hot water, but it will react vigorously with dilute acids. It is attacked slowly by concentrated sulfuric acid. The presence of the fluoride ion retards acid attack due to the formation of DyF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. Tensile strength, 139 MPa; yield strength, 43 MPa; elongation, 30%; reduction in area, 30%

Hardness. 44 HV

Poisson's ratio. 0.237

Liquid surface tension. 0.648 N/m at 1415 °C

Europium (Eu)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Europium is used as control rods in nuclear reactors and as phosphors, especially those that make up the red component in color television screens. Europium oxidizes rapidly in air at room temperature and should be handled and stored under an inert atmosphere; storage in oil is not recommended. Finely divided europium can ignite spontaneously in air.

Structure

Crystal structure. Body-centered cubic: $Im3m$ O_9^h; a_0 = 0.45827 nm at 24 °C

Minimum interatomic distance. 0.19844 nm at 24 °C; radius CN_{12} = 0.20418 nm

Mass Characteristics

Atomic weight. 151.96

Density. 5.244 g/cm^3 at 24 °C; liquid, 4.87 g/cm^3 at 825 °C

Volume change on freezing. 4.8% contraction

Thermal Properties

Melting point. 822 °C

Boiling point. 1529 °C

Coefficient of thermal expansion. At 24 °C. Linear: 35.0 μm/m · K. Volumetric: 105 × 10^{-6} K

Specific heat. 0.1823 kJ/kg · K

Entropy. At 25 °C: 512.0 J/kg · K

Latent heat of fusion. 60.6 kJ/kg

Latent heat of vaporization. 1.154 MJ/kg at 25 °C

Latent heat of combustion. For monoclinic Eu_2O_3 at 25 °C: ΔH_c° = -5.43 MJ/kg Eu; ΔG_f° = -5.12 MJ/kg Eu

Recrystallization temperature. 300 °C

Thermal conductivity. 13.9 W/m · K at 25 °C (estimated)

Vapor pressure. 0.001 Pa at 399 °C; 0.101 Pa at 515 °C; 10.1 Pa at 685 °C; 1013 Pa at 964 °C

Electrical Properties

Electrical resistivity. 900 nΩ · m at 25 °C; 6 nΩ · m at 4 K; liquid, 2420 nΩ · m at 822 °C

Ionization potential. Eu(I): 5.666 eV; Eu(II): 11.241 eV; Eu(III): 24.92 eV; Eu(IV): 42.6 eV

Hall coefficient. +2.44 nV · m/A · T

Temperature of superconductivity. Bulk europium is not superconducting down to 0.03 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume: 0.0134 mks at 25 °C; obeys Curie-Weiss law above 100 K with an effective moment of 8.48 μ_B

Saturation magnetization. >6T at 4 K

Magnetic transformation temperature. Néel temperature, 90.4 K

Optical Properties

Color. Metallic silver when free from surface contamination

Nuclear Properties

Thermal neutron cross section. 4300 b

Chemical Properties

General corrosion behavior. Europium is the most air reactive of the rare earth metals, especially in moist air. In dry air, a dark coating is formed that retards oxidation. Hydrogen reacts with europium at about 250 °C.

Resistance to specific corroding agents. Europium reacts vigorously with cold water and dilute acids.

Mechanical Properties

Hardness. 17 HV

Poisson's ratio. 0.152

Elastic modulus. Tension, 18.2 GPa; shear, 7.9 GPa; bulk, 8.3 GPa at 27 °C

Liquid surface tension. 0.264 N/m at 825 °C

Erbium (Er)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Erbium is used in lasers, phosphors, garnet microwave devices, ferrite bubble devices, and catalysts. Erbium will remain shiny in air at room temperature. However, turnings can be ignited and will burn white hot. Finely divided erbium metal should not be handled in air.

Structure

Crystal structure. Close-packed hexagonal: $P6_3/mmc$ D_4^{6h} ; a = 0.35592 nm; c = 0.55850 nm at 24 °C

Slip planes. Primary $\{10\bar{1}0\}$, secondary {0002} at 24 °C

Twinning planes. Primary $\{11\bar{2}1\}$, secondary $\{10\bar{1}2\}$ at 24 °C

Minimum interatomic distance. r_a = 0.17796 nm; r_c = 0.17335 nm; radius CN_{12} = 0.17566 nm at 24 °C

Mass Characteristics

Atomic weight. 167.26

Density. 9.066 g/cm^3 at 24 °C; liquid, 8.6 g/cm^3 at 1530 °C

Volume change of freezing. 9.0% contraction

Thermal Properties

Melting point. 1529 °C

Boiling point. 2868 °C

Coefficient of thermal expansion. At 24 °C. Linear: 12.2 μm/m · K. Along crystal axes: 7.9 μm/m · K along *a* axis, 20.9 μm/m · K along *c* axis. Volumetric: 36.7 × 10^{-6} per K

Specific heat. 0.1680 kJ/kg · K at 25 °C

Entropy. 437.6 J/kg · K at 25 °C

Latent heat of fusion. 119.0 kJ/kg

Latent heat of vaporization. 1.896 MJ/kg

Heat of combustion. For cubic Er_2O_3 at 25 °C: ΔH_c° = -5.67 MJ/kg Er; ΔG_f° = -5.41 MJ/kg Er

Recrystallization temperature. About 520 °C

Thermal conductivity. 14.5 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 908 °C; 0.101 Pa at 1113 °C; 10.1 Pa at 1405 °C; 1013 Pa at 1896 °C

Electrical Properties

Electrical resistivity. 860 nΩ · m at 25 °C; 47 nΩ · m at 4 K. Along crystal axes at 25 °C: 945 nΩ · m along *a* axis, 603 nΩ · m along *c* axis. Liquid: 2260 nΩ · m at 1531 °C

Ionization potentials. Er(I), 6.101 eV; Er(II), 11.93 eV; Er(III), 22.74 eV; Er(IV), 42.65 eV

Hall coefficient. Along crystal axes at 20 °C: +0.03 nV · m/A · T along *b* axis; $R_{H,c}$ = -0.36 nV · m/A · T along *c* axis

Temperature of superconductivity. Bulk erbium is not superconducting down to 0.03 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume (mks units): χ_a = 0.0314 and χ_c = 0.0353 at 25 °C; obeys Curie-Weiss law above 195 K with an effective moment of 9.9 μ_B, θ_a = 32.5 K and θ_c = 61.7 K

Saturation magnetization. >3.33 T at 4.2 K along <10 $\bar{1}$ 0> and <11 $\bar{2}$ 0> 3.33 T at 4.2 K along <0001>

Magnetic transformation temperatures. Curie temperature, 20 K; a spin rearrangement at 53 K; Néel temperature, 85 K

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Solid and liquid, 37.2% for λ= 645 nm from 1027 to 1587 °C

Nuclear Properties

Thermal neutron cross section. 170 b

Chemical Properties

General corrosion behavior. Erbium stays shiny in air at room temperature. The rate of oxidation is slow even at 1000 °C due to the formation of a dark, tightly adhering oxide on the surface of the metal.

Resistance to specific corroding agents. Erbium does not react with cold or hot water, but it will react vigorously with dilute acids. The attack by concentrated sulfuric acid is slow. The presence of the fluoride ion retards acid attack due to the formation of ErF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. Tensile strength, 136 MPa; yield strength, 60 MPa; elongation, 11.5%; reduction in area, 11.9%

Hardness. 42 HV

Poisson's ratio. 0.237

Strain-hardening exponent. 0.25

Elastic modulus. At 27 °C: tension, 69.9 GPa; shear, 28.3 GPa; bulk, 44.4 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 83.67 GPa; c_{12} = 29.29 GPa; c_{13} = 22.22 GPa; c_{33} = 84.45 GPa; c_{44} = 27.53 GPa

Liquid surface tension. 0.637 N/m at 1530 °C

Gadolinium (Gd)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Gadolinium is used as a burnable poison in shields and control rods in nuclear reactors; it is also used in host materials for rare earth phosphors, catalysts, and garnet microwave devices. Amorphous Gd-Co alloys are used as magnetooptic storage devices and gadolinium intermetallic compounds are used as magnetic refrigeration materials. Gadolinium will tarnish slightly in air. Turnings can be ignited and burn white hot. Finely divided gadolinium should not be handled in air.

Structure

Crystal structure. α phase, close-packed hexagonal, $P6_3/mmc$ D_4^{6h}; a = 0.36336 nm, c = 0.57810 nm at 24 °C. β phase, body-centered cubic, $Im3m$ O_9^h; a = 0.406 nm at 1265 °C

Slip planes. At 24 °C: primary $\{10\bar{1}0\}$, secondary {0002}

Twinning planes. At 24 °C: primary $\{11\bar{2}1\}$, secondary $\{10\bar{1}2\}$

Minimum interatomic distance. At 24 °C: r_a = 0.18168 nm; r_c = 0.17858 nm; radius CN_{12} = 0.18013 nm

Mass Characteristics

Atomic weight. 157.25

Density. α phase, 7.901 g/cm^3 at 24 °C; β phase, 7.80 g/cm^3 at 1265 °C; liquid, 7.4 g/cm^3 at 1315 °C

Volume change on freezing. 2.0% contraction

Thermal Properties

Melting point. 1313 °C

Boiling point. 3273 °C

Phase transformation temperature. α to β phase, 1235 °C

Coefficient of thermal expansion. At 100 °C. Linear: 9.4 μm/m · K at 100 °C. Linear along crystal axes: 9.1 μm/m · K along *a* axis, 10.0 μm/m · K along *c* axis. Volumetric: 28.2 × 10^{-6} per K

Specific heat. 235.9 kJ/kg · K at 25 °C

Entropy. 431.8 J/kg · K at 25 °C

Latent heat of fusion. 63.6 kJ/kg

Latent heat of transformation. 24.9 kJ/kg

Latent heat of vaporization. 2.528 MJ/kg at 25 °C

Heat of combustion. For monoclinic Gd_2O_3 at 25 °C: ΔH_c° = -5.77 MJ/kg Gd; ΔG_f° = -5.50 MJ/kg Gd

Recrystallization temperature. About 500 °C

Thermal conductivity. 10.5 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 1167 °C; 0.101 Pa at 1408 °C; 10.1 Pa at 1760 °C; 1013 Pa at 2306 °C

Electrical Properties

Electrical resistivity. Solid: 1310 nΩ · m at 25 °C; 24 nΩ · m at 4 K. Liquid: 1950 nΩ · m at 1315 °C. Along crystal axes at 25 °C: 1351 nΩ · m along *a* axis, 1217 nΩ · m along *c* axis

Ionization potentials. Gd(I), 6.14 eV; Gd(II), 12.09 eV; Gd(III), 20.63 eV; Gd(IV), 44.0 eV

Hall coefficient. -0.448 nV · m/A · T at 77 °C. Along crystal axes at 20 °C: -1.0 nV · m/A · T along *a* axis; -5.4 nV · m/A · T along *c* axis

Temperature of superconductivity. Bulk gadolinium is not superconducting down to 0.37 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume: 0.117 mks at 77 °C; obeys Curie-Weiss law above 77 °C with an effective moment of 7.98 μ_B and $\theta_a = \theta_c$ = 317 K

Saturation magnetization. 2.63 T at 0 K

Magnetic transformation temperatures. Curie temperature, 293.4 K

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Solid: 33.7% for λ= 645 nm at 1025 to 1313 °C. Liquid: 34.2% for λ= 645 nm at 1313 to 1600 °C

Nuclear Properties

Thermal neutron cross section. 40,000 b

Chemical Properties

General corrosion behavior. Gadolinium tarnishes slightly in air at room temperature. Even at 1000 °C the oxidation rate is slow because of the formation of a dark, tightly adhering oxide on the surface. The presence of water vapor increases the rate of oxidation. After heating to 550 °C in vacuum, hydrogen will react at 250 °C.

Resistance to specific corroding agents. Gadolinium does not react with cold or hot water, but it will react vigorously with dilute acids. It is attacked slowly by concentrated sulfuric acid. The presence of the fluoride ion retards acid attack due to the formation of GdF_3.

Mechanical Properties

Tensile properties. Tensile strength, 118 MPa; yield strength, 15 MPa; elongation, 37%; reduction in area, 56%

Hardness. 37 HV for polycrystalline; 23 HV for $\{10\bar{1}0\}$ prismatic face; 69 HV for {0001} basal plane

Poisson's ratio. 0.259

Strain-hardening exponent. 0.37

Elastic modulus. At 27 °C: tension, 54.8 GPa; shear, 21.8 GPa; bulk, 37.9 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 67.83 GPa; c_{12} = 25.59 GPa; c_{13} = 20.73 GPa; c_{33} = 71.23 GPa; c_{44} = 20.77 GPa

Liquid surface tension. 0.664 N/m^2 at 1315 °C

Holmium (Ho)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

---

Holmium is used in phosphors and ferrite bubble devices. It will remain shiny in air at room temperature. Turnings can be ignited and will burn white hot. Finely divided holmium should not be handled in air.

Structure

Crystal structure. Close-packed hexagonal: $P6_3/mmc$ D_4^{6h} ; a = 0.35778 nm, c = 0.56178 nm at 24 °C

Slip planes. At 24 °C: primary $\{10\bar{1}0\}$, secondary {0002}

Twinning planes. At 24 °C: primary $\{11\bar{2}1\}$, secondary $\{10\bar{1}2\}$

Minimum interatomic distance. At 24 °C: r_a = 0.17889 nm; r_c = 17,433 nm; radius CN_{12} = 0.17661 nm

Mass Characteristics

Atomic weight. 164.93032

Density. 8.795 g/cm^3 at 24 °C; liquid, 8.34 g/cm^3 at 1480 °C

Volume change on freezing. 7.4% contraction

Thermal Properties

Melting point. 1474 °C

Boiling point. 2700 °C

Coefficient of thermal expansion. At 24 °C. Linear: 11.2 μm/m · K. Linear along crystal axes: 7.0 μm/m · K along *a* axis, 19.5 μm/m · K along *c* axis. Volumetric: 33.6 × 10^{-6} per K

Specific heat. 0.1649 kJ/kg · K at 25 °C

Entropy. At 25 °C: 454.7 J/kg · K

Latent heat of fusion. 103 kJ/kg (estimated)

Latent heat of vaporization. 1.824 MJ/kg at 25 °C

Latent heat of combustion. For cubic Ho_2O_3 at 25 °C: ΔH_c° = -5.70 MJ/kg Ho ΔG_f° = -5.43 MJ/kg Ho

Thermal conductivity. 16.2 W/m · K at 25 °C

Recrystallization temperature. About 520 °C

Vapor pressure. 0.001 Pa at 845 °C; 0.101 Pa at 1036 °C; 10.1 Pa at 1313 °C; 1013 Pa at 1771 °C

Electrical Properties

Liquid surface tension. 0.650 N/m at 1475 °C

Lanthanum (La)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Lanthanum, as a component (~25%) of mischmetal, is used as an alloying additive to ferrous alloys to scavenge impurities such as sulfur and oxygen and to strengthen magnesium. It improves the high-temperature oxidation resistance of superalloys. Lanthanum is also used in optical lenses, petroleum cracking catalysts, carbon arc lights, lighter flints, hydrogen storage alloys, optical fibers, and ceramic capacitors.

Lanthanum readily oxidizes at room temperature in air. It should be stored in vacuum or an inert atmosphere; storage under oil is not recommended. Turnings can be ignited easily and burn white hot. Finely divided lanthanum should not be handled in air.

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_{6h}^4. At 24 °C: a = 0.37740 nm; c = 1.2171 nm. β phase, face-centered cubic, $Fm3m$ O_h^5; a = 0.5303 nm at 325 °C. γ phase, body-centered cubic, $Im3m$ O_h^9; a = 0.426 nm at 887 °C

Minimum interatomic distance. At 24 °C: r_a = 0.18870 nm; r_c = 0.18711 nm; radius CN_{12} = 0.18791 nm

Mass Characteristics

Atomic weight. 138.9055

Density. α phase, 6.146 g/cm^3 at 24 °C; β phase, 6.187 g/cm^3 at 325 °C; γ phase, 5.97 g/cm^3 at 865 °C; liquid, 5.96 g/cm^3 at 920 °C

Volume change on freezing. 0.6% contraction

Volume change on phase transformation. α to β phase, 0.5% volume contraction on heating; β to γ phase, 1.3% volume expansion on heating

Thermal Properties

Melting point. 918 °C

Boiling point. 3464 °C

Phase transformation temperature. α to β phase: A_s = 330 °C, A_f = 336 °C. β to α phase: M_s = 251 °C, M_f = 247 °C. β to γ phase: 865 °C

Coefficient of thermal expansion. At 24 °C. Linear: 12.1 μm/m · K. Linear along crystal axes: 4.5 μm/m · K along *a* axis; 27.2 μm/m · K along *c* axis. Volumetric: 36.2 × 10^{-6} per K

Specific heat. 0.1951 kJ/kg · K at 25 °C

Entropy. At 298.15 K: 409.6 J/kg · K

Mischmetal (MM)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Mischmetal is used as an alloying additive in ferrous alloys to scavenge sulfur, oxygen, and other substances. Mischmetal is also added to magnesium-base alloys to improve high-temperature strength and to ductile irons to nodularize graphite. It is used as a reductant to produce the volatile rare earth metals (samarium, europium, and ytterbium) from their oxides. Other uses of mischmetal include lighter flints, galvanizing alloys, and mischmetal cobalt (cerium-free mischmetal-nickel alloys are used as hydrogen storage alloys), and permanent magnets.

Mischmetal oxidizes at room temperature in air. Turnings can be ignited easily and burn white hot. Finely divided mischmetal should not be handled in air.

Because mischmetal is an indefinite mixture of rare earth metals, the properties of a particular mischmetal depend on its composition, which in turn depends on the mineral source for the mixture. Listed below are the properties of two of the most common high-purity mischmetal mixtures. Because most commercial mischmetals contain several atomic percent of iron and magnesium (about 1 wt%), their properties may differ somewhat from those listed below. Many values are estimated and are marked as such.

Bastnasite-Derived Mischmetal

Specifications

UNS number. E21000

Chemical Composition

Composition limits. Total mixed rare earths: 99.0 min; mixture consists of 39 La, 38 Ce, 16 Nd, 6 Pr, 1 other rare earth

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_4^{6h} ; a = 0.3718 nm, c = 1.1978 nm at 24 °C. β phase, body-centered cubic

Minimum interatomic distance. At 24 °C: r_a = 0.1859 nm; r_c = 0.1842 nm; radius CN_{12} = 0.1851

Mass Characteristics

Atomic weight. 140.1

Density. 6.490 g/cm^3 at 24 °C;

Volume change on freezing. 0.1% expansion (estimated)

Thermal Properties

Melting point. Melts over a range of temperatures from 888 to 895 °C

Boiling point. Expected to evaporate incongruently with the initial loss of a major constituent (neodymium) by boiling at ~3100 °C

Phase transformation temperature. α to β phase, 801 °C

Coefficient of thermal expansion. At 24 °C. Linear: 8.7 μm/m · K. Volumetric: 26 × 10^{-6} per K (both estimated)

Specific heat. 0.193 kJ/kg · K at 25 °C

Entropy. 467 J/kg · K at 25 °C (estimated)

Latent heat of fusion. 47 kJ/kg

Latent heat of transformation. 22 kJ/mol (estimated)

Latent heat of combustion. For hexagonal R_2O_3 at 25 °C: ΔH_c° = -6.4 MJ/kg MM (estimated); ΔG_f° = -6.0 MJ/kg MM (estimated)

Recrystallization temperature. ~350 °C (estimated)

Thermal conductivity. 13 W/m · K at 25 °C (estimated)

Electrical Properties

Electrical resistivity. Solid: 800 nΩ · m at 25 °C (estimated). Liquid: 1300 nΩ · m at 900 °C (estimated)

Magnetic Properties

Magnetic susceptibility. Volume, 1.6 × 10^{-3} mks at 25 °C (estimated)

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Liquid, 30% (estimated)

Chemical Properties

General corrosion behavior. Commercial mischmetal is stable in air at room temperature due to presence of magnesium. Vacuum-melted mischmetal oxidizes in air at room temperature. Oxidation rates increase with increasing temperature and humidity.

Resistance to specific corroding agents. Mischmetal reacts vigorously with dilute acids. The presence of the fluoride ion retards acid attack by the formation of rare earth fluoride (RF_3) on the surface of the metal.

Mechanical Properties

Tensile properties. At 24 °C: tensile strength, 138 MPa; yield strength, 48 MPa; elongation, 25%; reduction in area, 50% (all estimated)

Hardness. 27 DPH

Poisson's ratio. 0.27 (estimated)

Elastic modulus. At 27 °C: tension, 35 GPa; shear, 14 GPa; bulk, 25 GPa (all estimated)

Kinematic liquid viscosity. 0.46 mm^2/s at 900 °C (estimated)

Liquid surface tension. 0.70 N/m at 900 °C (estimated)

Monazite-Derived Mischmetal

Specifications

UNS number. E31000

Chemical Composition

Composition limits. Total mixed rare earths, 99.0 min; mixture consists of 50 Ce, 20 La, 20 Nd, 6 Pr, 2 Gd, 1.6 Y, <1 other rare earths

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_{6h}^4 ; a = 0.3695 nm; c = 1.1900 nm at 24 °C. β phase, probably body-centered cubic; a = 0.415 nm (estimated)

Minimum interatomic distance. At 24 °C: r_a = 0.1848 nm; r_c = 0.1830 nm; radius CN_{12} = 0.1839 nm

Mass Characteristics

Atomic weight. 140.1

Density. 6.612 g/cm^3 at 24 °C

Volume change on freezing. 0.1% expansion (estimated)

Thermal Properties

Melting point. Melts over a range of temperatures from 899 to 913 °C

Boiling point. Expected to evaporate incongruently with the initial loss of a major constituent (neodymium) by boiling at ~3100 °C

Phase transformation temperature. α to β phase, 782 °C

Coefficient of thermal expansion. At 24 °C. Linear: 8.6 μm/m · K. Volumetric: 26×10^{-6} per K (both estimated)

Specific heat. 0.195 kJ/kg · K at 25 °C (estimated)

Entropy. At 298.15 K, 477 J/kg · K (estimated)

Latent heat of fusion. 46 kJ/kg (estimated)

Latent heat of transformation. 22 kJ/kg (estimated)

Latent heat of combustion. For hexagonal R_2O_3 at 25 °C: ΔH_c° = -6.4 MJ/kg MM (estimated); ΔG_f° = -6.0 MJ/kg MM (estimated)

Recrystallization temperature. ~350 °C (estimated)

Thermal conductivity. 13 W/m · K at 25 °C (estimated)

Electrical Properties

Electrical resistivity. Solid, 800 nΩ · m at 25 °C (estimated); liquid, 1300 nΩ · m at 925 °C (estimated)

Magnetic Properties

Magnetic susceptibility. Volume: 5.2×10^{-3} mks at 25 °C (estimated)

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Liquid, 30% (estimated)

Chemical Properties

General corrosion behavior. Commercial mischmetal is stable in air at room temperature due to the presence of magnesium. Vacuum-melted mischmetal oxidizes in air at room temperature. Oxidation rates increase with increasing temperature and humidity.

Resistance to specific corroding agents. Mischmetal reacts vigorously with dilute acids. The presence of the fluoride ion retards acid attack by the formation of rare earth fluoride (RF_3) on the surface of the metal.

Mechanical Properties

Tensile properties. At 24 °C: tensile strength, 138 MPa; yield strength, 48 MPa; elongation, 25%; reduction in area, 50% (all estimated)

Hardness. 28 HV

Poisson's ratio. 0.27 (estimated)

Elastic modulus. At 27 °C: tension, 37 GPa; shear, 15 GPa; bulk, 27 GPa (all estimated)

Kinematic liquid viscosity. 0.47 mm^2/s at 920 °C (estimated)

Liquid surface tension. 0.71 N/m at 920 °C (estimated)

Neodymium (Nd)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

The major use of neodymium is in high-strength Nd-Fe-B permanent magnets, which are the strongest magnets known. Neodymium, as a component (~20%) of mischmetal, is used as an alloying additive in ferrous alloys to scavenge sulfur, oxygen, and other elements, and to strengthen magnesium alloys. It is also used as a laser material and glass-coloring agent, and in petroleum cracking catalysts, carbon arc lights, lighter flints, and ceramic capacitors.

Neodymium oxidizes at room temperature in air. It should be stored in a vacuum or inert atmosphere; storage in oil is not recommended. Turnings can be ignited easily and will burn white hot. Finely divided neodymium should not be handled in air.

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_4^{6h} ; a = 0.36582 nm, c = 1.17966 nm at 24 °C. β phase, body-centered cubic, $Im3m$ O_9^h; a = 0.413 nm at 883 °C

Minimum interatomic distance. At 24 °C: r_a = 0.18291 nm; r_c = 0.18137 nm; radius CN_{12} = 0.18214 nm

Mass Characteristics

Atomic weight. 144.24

Density. α phase, 7.008 g/cm^3 at 24 °C; β phase, 6.80 g/cm^3 at 883 °C; liquid, 6.72 g/cm^3 at 1025 °C;

Volume change on freezing. 0.9% contraction

Volume change on phase transformation. α to β phase, 0.1% volume expansion on heating

Thermal Properties

Melting point. 1021 °C

Boiling point. 3074 °C

Phase transformation temperature. α to β phase, 863 °C

Coefficient of thermal expansion. At 24 °C. Linear: 9.6 μm/m · K. Linear along crystal axes: 7.6 μm/m · K along a axis, 13.5 μm/m · K along c axis. Volumetric: 28.7 × 10^{-6} per K

Specific heat. 0.1900 kJ/kg · K at 25 °C

Entropy. At 25 °C: 492.9 J/kg · K

Latent heat of fusion. 49.5 kJ/kg

Latent heat of transformation. 21.0 kJ/kg

Latent heat of vaporization. 2.271 MJ/kg at 25 °C

Thermal conductivity. 16.5 W/m · K at 25 °C

Heat of combustion. Hexagonal Nd_2O_3 at 25 °C: ΔH_c° = -6.27 MJ/kg Nd; ΔG_f° = -5.96 MJ/kg Nd

Recrystallization temperature. 400 °C

Vapor pressure. 0.001 Pa at 955 °C; 0.101 Pa at 1175 °C; 10.1 Pa at 1500 °C; 1013 Pa at 2029 °C

Electrical Properties

Electrical resistivity. 643 nΩ · m at 25 °C; 68 nΩ · m at 4K. Liquid: 1510 nΩ · m at 1022 °C

Ionization potential. Nd(I), 5.499 eV; Nd(II), 10.73, eV; Nd(III), 22.1 eV; Nd(IV), 40.41 eV

Hall coefficient. +0.0971 nV · m/A · T at 25 °C

Temperature of superconductivity. Bulk neodymium is not superconducting down to 0.25 K atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume: 3.62×10^{-3} mks at 25 °C; obeys Curie-Weiss law above 35 K with an effective moment of 3.45 μ_B, $\theta_a = 5$ K and $\theta_c = 0$ K

Saturation magnetization. >35T at 2 K along $<11\bar{2}0>$

Magnetic transformation temperature. Néel temperatures at 7.5 K (cubic sites) and 19.9 K (hexagonal sites)

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. 39.4% for λ= 645 nm from 1021 to 1567 °C

Nuclear Properties

Thermal neutron cross section. 48 b

Chemical Properties

General corrosion behavior. Neodymium oxidizes in air at room temperature, but at a slower rate than lanthanum or cerium. Oxidation rates increase with increasing temperature and humidity; interstitial impurities increase the rate of oxidation. Hydrogen will react with neodymium at room temperature.

Resistance to specific corroding agents. Neodymium reacts vigorously with dilute acids and slowly with concentrated sulfuric acid. The presence of the fluoride ion retards acid attack due to the formation of NdF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. Tensile strength, 164 MPa; yield strength, 71 MPa; elongation, 25%; reduction in area, 72%

Hardness. 18 HV

Poisson's ratio. 0.281

Strain-hardening exponent. 0.28

Elastic modulus. At 27 °C: tension, 41.4 GPa; shear, 16.3 GPa; bulk, 31.8 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 54.77 GPa; c_{12} = 24.60 GPa; c_{13} = 16.56 GPa; c_{33} = 60.80 GPa; c_{44} = 15.01 GPa

Liquid surface tension. 0.687 N/m at 1021 °C

Praseodymium (Pr)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Praseodymium, as a component (~5%) of mischmetal, is used as an alloying additive to ferrous alloys to scavenge impurities such as sulfur and oxygen, and to strengthen magnesium. It is also used as a glass-and ceramic-coloring agent, and in petroleum cracking-coloring catalysts, carbon arc lights, and $PrCo_5$ permanent magnets. $PrNi_5$ is used in adiabatic demagnetization refrigerators to attain ultralow temperatures (<1 mK).

Praseodymium oxidizes at room temperature in air. It should be stored in vacuum or inert atmosphere; storage in oil is not recommended. Turnings can be ignited easily and will burn white hot. Finely divided praseodymium should not be handled in air.

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_4^{6h} ; a = 0.36721 nm, c = 1.18326 nm at 24 °C. β phase, body-centered cubic, $Im3m$ O_9^h ; a = 0.1413 nm at 821 °C

Minimum interatomic distance. At 24 °C: r_a = 0.18360 nm; r_c = 0.18197 nm; radius CN_{12} = 0.18279 nm

Mass Characteristics

Atomic weight. 140.90765

Density. α phase, 6.773 g/cm^3 at 24 °C; β phase, 6.64 g/cm^3 at 821 °C; liquid, 6.59 g/cm^3 at 935 °C

Volume change on freezing. 0.02% contraction

Volume change on phase transformation. α to β phase, 0.5% volume expansion on heating

Thermal Properties

Melting point. 931 °C

Boiling point. 3520 °C

Phase transformation temperature. α to β phase, 795 °C

Coefficient of thermal expansion. α phase at 24 °C. Linear: 6.7 μm/m · K. Linear along crystal axes: 4.5 μm/m · K along a axis, 11.2 μm/m · K along c axis. Volumetric: 20.2 × 10^{-6} per K

Specific heat. 0.1946 kJ/kg · K at 25 °C

Entropy. At 25 °C, 524.5 J/kg · K

Latent heat of fusion. 48.9 kJ/kg

Latent heat of transformation. 22.5 kJ/kg

Latent heat of vaporization. 2.524 MJ/kg at 25 °C

Heat of combustion. For cubic Pr_6O_{11} at 25 °C: ΔH_c° = -6.73 MJ/kg Pr; ΔG_f° = -6.34 MJ/kg Pr

Recrystallization temperature. About 400 °C

Thermal conductivity. 12.5 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 1083 °C; 0.101 Pa at 1333 °C; 10.1 Pa at 1701 °C; 1013 Pa at 2305 °C

Electrical Properties

Electrical resistivity. 700 nΩ · m at 25 °C; 22 nΩ · m at 4 K. Liquid: 1390 nΩ · m at 932 °C

Ionization potential. Pr(I), 5.422 eV; Pr(II), 10.55 eV; Pr(III), 21.624 eV; Pr(IV), 38.98 eV; Pr(V), 57.45 eV

Hall coefficient. +0.0709 nV · m/A · T at 25 °C

Temperature of superconductivity. Bulk praseodymium is not superconducting down to 0.25 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume: 3.34 × 10-3 mks at 25 °C; obeys Curie-Weiss law above 100 K with an effective moment of 3.56 μ_B and $\theta \cong 0$ K

Saturation magnetization. >35 T at 4 K along <11 $\bar{2}$ 0>

Magnetic transformation temperature. Single-crystal strain-free praseodymium does not order magnetically; most polycrystalline samples order at various temperatures below 25 K.

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. 28.4% for λ= 645 nm from 931 to 1537 °C

Nuclear Properties

Thermal neutron cross section. 11 b

Chemical Properties

Corrosion behavior. Praseodymium oxidizes in air at room temperature, but at a lower rate than lanthanum or cerium. Oxidation rates increase with temperature and humidity. Interstitial impurities in the metal increase the rate of corrosion in air. Hydrogen will react with praseodymium at room temperature.

Resistance to specify corroding agents. Praseodymium reacts vigorously with dilute acids. It reacts slowly with concentrated sulfuric acid. The presence of the fluoride ion retards acid attack due to the formation of PrF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. At 24 °C: tensile strength, 147 MPa; yield strength, 73 MPa; elongation, 15.4%; reduction in area, 67%

Hardness. 20 HV

Poisson's ratio. 0.281

Elastic modulus. At 27 °C: tension, 37.3 GPa; shear, 14.8 GPa; bulk, 28.8 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 49.35 GPa; c_{12} = 22.95 GPa; c_{13} = 14.3 GPa; c_{33} = 57.40 GPa; c_{44} = 13.59 GPa

Kinematic liquid viscosity. 0.432 mm^2/s at 935 °C

Liquid surface tension. 0.707 N/m at 935 °C

Promethium (Pm)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Promethium is used in luminous watch dials and as a lightly shielded radioisotope power source. It is also a highly radioactive β emitter (^{147}Pm).

Structure

Crystal structure. α phase, double close-packed hexagonal, $P6_3/mmc$ D_4^{6h} ; a = 0.365 nm, c = 1.165 at 24 °C. β phase, probably body-centered cubic, a = 0.410 nm (estimated) at 890 °C

Minimum interatomic distance. At 24 °C: r_a = 0.1825 nm; r_c = 0.1797 nm; radius CN_{12} = 0.1811

Mass Characteristics

Atomic weight. 145

Density. α phase, 7.264 g/cm^3 at 24 °C; β phase, 6.99 g/cm^3 (estimated) at 890 °C; liquid, 6.9 g/cm^3 (estimated) at 1050 °C

Thermal Properties

Melting point. 1042 °C

Boiling point. 3000 °C (estimated)

Phase transformation temperature. 890 °C

Coefficient of thermal expansion. At 24 °C. Linear (estimated): 11 μm/m · K. Linear along crystal axes 9 μm/m · K along a axis, 16 μm/m · K along c axis. Volumetric: 34×10^{-6} per K

Specific heat. 0.188 kJ/kg · K at 25 °C (estimated)

Entropy. At 25 °C: 494 J/kg · K (estimated)

Latent heat of fusion. 53 kJ/kg (estimated)

Latent heat of transformation. 21 kJ/kg (estimated)

Latent heat of vaporization. 2.4 MJ/kg at 25 °C (estimated)

Thermal conductivity. 15 W/m · K at 27 °C (estimated)

Heat of combustion. For monoclinic Pm_2O_3 at 25 °C: ΔH_c° = -6.3 MJ/kg Pr; ΔG_f° = -6.0 MJ/kg Pm (estimated)

Recrystallization temperature. 400 °C (estimated)

Electrical Properties

Electrical resistivity. 750 nΩ · m at 25 °C (estimated)

Ionization potential. Pm(I), 5.554 eV; Pm(II), 10.90 eV; Pm(III), 22.3 eV; Pm(IV), 41.1 eV

Magnetic Properties

Magnetic susceptibility. Probably strongly paramagnetic with a susceptibility somewhat greater than that of cerium at 24 °C

Magnetic transformation temperature. Probably exhibits two Néel temperatures that fall between those observed in neodymium and samarium

Optical Properties

Color. Metallic silver

Chemical Properties

General corrosion behavior. About the same as that of neodymium

Resistance to specific corroding agents. About the same as that of neodymium

Mechanical Properties

Tensile properties. About the same as that of neodymium

Hardness. 63 HK

Poisson's ratio. 0.28 (estimated)

Elastic modulus. At 27 °C: tension, 46 GPa (estimated); shear, 18 GPa; bulk, 33 GPa

Liquid surface tension. 0.68 N/m (estimated) at 1045 °C

Samarium (Sm)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

---

Alloyed with cobalt, samarium is used as a permanent magnet, Sm_2Co_{17}-$SmCo_5$. Samarium is also used as a burnable poison in nuclear reactors, as a phosphor, and in catalysts and ceramic capacitors.

Samarium oxidizes slowly in air at room temperature. Storage in an inert atmosphere or vacuum is recommended. Turnings can be ignited easily. Finely divided samarium should not be handled in air.

Structure

Crystal structure. α phase, rhombohedral, $R3m$ D_5^{3d}; a = 0.89834 nm, a = 23.311° (hexagonal parameters, a = 0.36290 nm, c = 2.6207 nm at 24 °C). α phase, close-packed hexagonal, $P6_3/mmc$ D_4^{6h}; a = 0.36630 nm; c = 0.58448 nm at 450 °C. γ phase, body-centered cubic, $Im3m$ O_9^h; a = 0.410 nm (estimated) at 922 °C

Minimum interatomic distance. At 24 °C: r_a = 0.18145 nm; r_c = 0.17937 nm; radius CN_{12} = 0.18041 nm

Mass Characteristics

Atomic weight. 150.4

Density. α phase, 7.520 g/cm^3 at 24 °C β phase, 7.353 g/cm^3 at 450 °C; γ phase, 7.25 g/cm^3 (estimated) at 922 °C liquid, 7.16 g/cm^3 at 1075 °C

Volume change on freezing. 3.6% contraction

Thermal Properties

Melting point. 1074 °C

Boiling point. 1794 °C

Phase transformation temperature. α to β phase, 734 °C; β to α phase, 727 °C; β to γ phase, 922 °C

Coefficient of thermal expansion. At 24 °C. Linear: 12.7 μm/m · K. Linear along crystal axes: 9.6 μm/m · K along a axis; 19.0 μm/m · K along c axis. Volumetric, 38.1 × 10^{-6} per K

Specific heat. 0.1962 kJ/kg · K at 25 °C

Entropy. At 25 °C: 462.2 J/kg · K

Latent heat of fusion. 57.3 KJ/kg

Latent heat of transformation. β to γ phase, 20.7 kJ/kg

Latent heat of vaporization. 1.375 MJ/kg at 25 °C

Heat of combustion. For monoclinic Sm_2O_3 at 25 °C: ΔH_c° = -6.06 MJ/kg Sm; ΔG_f° = -5.77 MJ/kg Sm

Recrystallization temperature. About 440 °C

Thermal conductivity. 13.3 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 508 °C; 0.101 Pa at 642 °C; 10.1 Pa at 835 °C; 1013 Pa at 1150 °C

Electrical Properties

Electrical resistivity. 940 nΩ · m at 25 °C, 67 nΩ · m at 4 K. Liquid: 1820 nΩ · m at 1075 °C

Ionization potential. Sm(I), 5.631 eV; Sm(II), 11.07 eV; Sm(III), 23.4 eV; Sm(IV), 41.4 eV

Hall coefficient. -0.021 nV · m/A · T at 25 °C

Temperature of superconductivity. Bulk samarium is not superconducting down to 0.37 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume: 8.03×10^{-4} mks at 17 °C; does not obey Curie-Weiss law

Saturation magnetization. >35 T at 4 K along <0001> and >30 T at 4 K along $<11\bar{2}0>$

Magnetic transformation temperature. Ordering temperatures at 14 K (cubic sites) and 106 K (hexagonal sites)

Optical Properties

Color. Metallic silver

Spectral hemispherical emittance. Solid, 43.7% for λ= 645 nm from 852 to 1074 °C; liquid, 43.7% for λ= 645 nm at 1075 °C

Nuclear Properties

Thermal neutron cross section. 5600 b

Chemical Properties

General corrosion behavior. Samarium oxidizes slowly at room temperature in air. The rate of oxidation increases with temperature. Hydrogen will react at about 250 °C with samarium metal.

Resistance to specific corroding agents. Samarium reacts vigorously with dilute acids but only slowly with concentrated sulfuric acid. The presence of fluoride ion retards acid attack due to the formation of SmF_3 on the surface of the metal.

Mechanical Properties

Tensile properties. Tensile strength, 156 MPa; yield strength, 68 MPa; elongation, 17%; reduction in area, 29.5%

Hardness. 39 HV

Poisson's ratio. 0.274

Strain-hardening exponent. 0.23

Elastic modulus. At 27 °C: tension, 49.7 GPa; shear, 19.5 GPa, bulk, 37.8 GPa

Liquid surface tension. 0.431 N/m at 1075 °C

Scandium (Sc)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Scandium is used as a neutron window or filter in reactors. It is also used in high-intensity lamps because of the multilined spectrum of incandescent scandium vapor. Turning of scandium can be ignited and will burn white hot. Finely divided scandium should not be handled in air. Ingots of pure scandium can be stored in air.

Structure

Crystal structure. α phase, close-packed hexagonal, $P6_3/mmc$ D_4^{6h} ; a = 0.33088 nm ; c = 0.52680 nm at 24 °C. β phase, body-centered cubic, $Im3m$; a = 0.373 nm (estimated) at 1337 °C

Minimum interatomic distance. At 24 °C: r_a = 0.16544 nm; r_c = 0.16269 nm; radius CN_{12} = 0.16407 nm

Mass Characteristics

Atomic weight. 44.95591

Density. α phase, 2.989 g/cm^3 at 24 °C; β phase, 2.88 g/cm^3 at 1337 °C; liquid, 2.80 g/cm^3 at 1550 °C

Thermal Properties

Melting point. 1541 °C

Boiling point. 2836 °C

Phase transformation temperature. α to β phase, 1337 °C

Coefficient of thermal expansion. At 24 °C. Linear: 10.2 μm/m · K. Linear along crystal axis: 7.6 μm/m · K along *a* axis; 15.3 μm/m · K along *c* axis. Volumetric: 30.5×10^{-6} per K

Specific heat. 0.5674 kJ/kg · K at 25 °C

Entropy. 769.6 kJ/kg · K at 25 °C

Latent heat of fusion. 313.6 kJ/kg

Latent heat of transformation. 89.0 kJ/kg

Latent heat of vaporization. 8.404 MJ/kg at 25 °C

Heat of combustion. For cubic Sc_2O_3 at 25 °C: ΔH_c° = -21.23 MJ/kg Sc; ΔG_f° = -20.23 MJ/kg Sc

Recrystallization temperature. About 550 °C

Thermal conductivity. 15.8 W/m · K at 25 °C

Vapor pressure. 0.0010 Pa at 1036 °C; 0.101 Pa at 1243 °C; 10.1 Pa at 1533 °C; 1013 Pa at 1999 °C

Electrical Properties

Electrical resistivity. 562 nΩ · m at 25 °C; 1.6 nΩ · m at 4 K. Along crystal axes at 25 °C: 709 nΩ · m along *a* axis; 269 nΩ · m along *c* axis

Ionization potential. Sc(I), 6.54 eV; Sc(II), 12.80 eV; Sc(III), 24.76 eV; Sc(IV), 73.47 eV; Sc(V), 91.66 eV; Sc(VI), 111.1 eV

Hall coefficient. -0.013 nV · m/A · T at 25 °C

Temperature of superconductivity. Bulk scandium is not superconducting down to 0.032 K at atmospheric pressure; however, it is superconducting at 0.050 and 18.6 GPa.

Magnetic Properties

Magnetic susceptibility. Volume (mks units) at 24 °C: 2.466×10^{-4}. Along crystal axes: 2.490×10^{-4} along *a* axis; 2.419×10^{-4} along *c* axis

Optical Properties

Color. Metallic silver

Nuclear Properties

Thermal neutron cross section. 24 b

Chemical Properties

General corrosion behavior. Scandium remains shiny in air at room temperature; discoloration starts at about 300 °C. Oxidation proceeds slowly to completion at 1000 °C.

Resistance to specific corroding agents. Scandium reacts readily with most acids. The presence of fluoride ions causes the formation of ScF_3, which retards attack by nitric, hydrochloric, and other acids.

Mechanical Properties

Tensile properties. Tensile strength, 255 MPa; yield strength, 173 MPa; elongation, 5%; reduction in area, 8%

Hardness. Anisotropic: 132 HV (0001) and 36 HV $(10\bar{1}0)$

Poisson's ratio. 0.279

Elastic modulus. At 27 °C: Tension, 74.4 GPa; shear, 29.1 GPa; bulk, 56.6 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 98.1 GPa; c_{12} = 45.7 GPa; c_{13} = 29.4 GPa; c_{33} = 105.1 GPa; c_{44} = 27.2 GPa

Liquid surface tension. 0.954 N/m at 1545 °C

Terbium (Tb)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

---

Terbium is used as a phosphor and in magnetostrictive materials ($Tb_{0.3}Dy_{0.7}Fe_2$) and catalysts. Amorphous Tb-Co alloys are used as magnetooptic storage devices. Terbium will remain shiny in air at room temperature. Turnings can be ignited and will burn white hot. Finely, divided terbium should not be handled in air.

Structure

Crystal structure. α' phase, orthorhombic, *Cmcm* D_{27}^{2h}; a = 0.3605 nm, b = 0.6244 nm, c = 0.5706 nm at -53 °C. α phase, close-packed hexagonal, $P6_3/mmc$ D_4^{6h}; a = 0.36055 nm, c = 0.56966 nm at 24 °C. β phase, body-centered cubic, $Im3m$ O_9^h; a = 0.407 nm at 1289 °C

Minimum interatomic distance. r_a = 0.18028; r_c = 0.17639; radius CN_{12} = 0.17833 nm

Mass Characteristics

Atomic weight. 158.92534

Density. α phase, 8.230 g/cm^3 at 24 °C; β phase, 7.82 g/cm^3 at 1289 °C; liquid, 765 g/cm^3 at 1360 °C

Volume change on freezing. 3.1% contraction

Thermal Properties

Melting point. 1356 °C

Boiling point. 3230 °C

Phase transformation temperature. α to α' phase, -53 °C; α to β phase, 1289 °C

Coefficient of thermal expansion. At 24 °C. Linear: 10.3 μm/m · K. Linear along crystal axes: 9.3 μm/m · K along *a* axis, 12.4 μm/m · K along *c* axis. Volumetric: 31.0×10^{-6} per K

Specific heat. 0.1818 kJ/kg · K at 25 °C

Entropy. 461.2 J/kg · K at 25 °C

Latent heat of fusion. 67.9 kJ/kg

Latent heat of transformation. 31.6 kJ/kg

Latent heat of vaporization. 2.446 MJ/kg at 25 °C

Heat of combustion. For cubic Tb_2O_3 at 25 °C: ΔH_c° = -5.87 MJ/kg Tb; ΔG_f° = -5.59 MJ/kg Tb

Recrystallization temperature. 500 °C

Thermal conductivity. 11.1 W/m · K at 25 °C

Vapor pressure. 0.001 Pa at 1124 °C; 0.101 Pa at 1354 °C; 10.1 Pa at 1698 °C; 1013 Pa at 2237 °C

Electrical Properties

Electrical resistivity. 1150 nΩ · m at 25 °C; 35 nΩ · m at 4 K. Along crystal axes at 25 °C: 1235 nΩ · m along *a* axis, 1015 nΩ · m along *c* axis. Liquid: 1930 nΩ · m at 1358 °C

Ionization potentials. Tb(I), 5.842 eV; Tb(II), 11.52 eV; Tb(III), 21.91 eV; Tb(IV), 39.79 eV

Hall coefficient. Along crystal axes at 20 °C: -0.10 nV · m/A · T along *b* axis; -0.37 nV · m/A · T along *c* axis

Temperature of superconductivity. Bulk terbium is not superconducting down to 0.37 K at atmospheric pressure.

Magnetic Properties

Magnetic susceptibility. Volume (mks units): χ_a = 0.129 and χ_c = 0.0738 at 27 °C; obeys Curie-Weiss law above 240 K with an effective moment of 9.77 μ_B, θ_a = 239 K and θ_c = 195 K

Saturation magnetization. 13 T at 4.2 K along $<11\bar{2}0>$

Magnetic transformation temperatures. Curie temperature, 219.5 K; Néel temperature, 230 K

Optical Properties

Color. Metallic silver

Nuclear Properties

Thermal neutron cross section. 45 b

Chemical Properties

General corrosion behavior. Terbium stays shiny in air at room temperature. The rate of oxidation is slow even at 1000 °C due to the formation of a dark, tightly adhering oxide on the surface. Water vapor increases the rate of oxidation. After heating to 550 °C in vacuum, hydrogen will react at 250 °C.

Resistance to specific corroding agents. Terbium does not react with cold or hot water, but it will react vigorously with dilute acids. It is slowly attacked by concentrated sulfuric acid. The presence of the fluoride ion retards acid attack due to the formation of TbF_3.

Mechanical Properties

Tensile properties. About the same as those of gadolinium

Hardness. 38 HV for polycrystalline; 30 HV for $\{10\bar{1}0\}$ prismatic face; 80 HV for {0001} basal plane

Poisson's ratio. 0.261

Elastic modulus. At 27 °C: tension, 55.7 GPa; shear, 22.1 GPa; bulk, 38.7 GPa

Elastic constants along crystal axes. At 27 °C: c_{11} = 69.24 GPa; c_{12} = 24.98 GPa; c_{13} = 21.79 GPa; c_{33} = 74.39 GPa; c_{44} = 21.75 GPa

Liquid surface tension. 0.669 N/m at 1360 °C

Thulium (Tm)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

---

Thulium is used in phosphors, ferrite bubble devices, and catalysts. Irradiated thulium (^{169}Tm) is used as a portable radiographic source. Thulium will remain shiny in air at room temperature. Turnings can be ignited and will burn white hot. Finely divided thulium should not be handled in air. Because of its high vapor pressure at its melting point, thulium should not be arc melted.

Structure

Crystal structure. Close-packed hexagonal: $P6_3/mmc$ D_4^{6h} ; a = 0.35375 nm, c = 0.55540 nm at 25 °C

Minimum interatomic distance. At 24 °C: r_a = 0.17688 nm; r_c = 0.17236 nm; radius CN_{12} = 0.17462 nm

Mass Characteristics

Atomic weight. 168.93421

Density. 9.321 g/cm^3 at 24 °C; liquid, 9.0 g/cm^3 (estimated) at 1550 °C

Volume change on freezing. 6.9% contraction

Thermal Properties

Melting point. 1545 °C

Boiling Point. 1950 °C

Coefficient of thermal expansion. At 24 °C. Linear: 13.3 μm/m · K. Linear along crystal axes: 8.8 μm/m · K along *a* axis, 22.2 μm/m · K along *c* axis. Volumetric: 39.8 × 10^{-6} per K

Specific heat. 0.1598 kJ/kg · K at 25 °C

Entropy. At 25 °C: 438.0 J/kg · K

Latent heat of fusion. 99.4 kJ/kg

Ytterbium (Yb)

Compiled by K.A Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory, U.S. Department of Energy, Iowa State University

Ytterbium is used in phosphors, ceramic capacitors, ferrite devices, and catalysts. Ytterbium (^{170}Yb), which has been formed by neutron irradiation of thulium (^{169}Tm), is used as a portable radiograph source; ytterbium foils are used to measure pressure and as stress transducers. Ytterbium will tarnish slightly at room temperature in air. Massive ytterbium can be handled in air, but should be stored in an inert atmosphere or vacuum. Finely divided ytterbium should not be handled in air.

Structure

Crystal structure. α phase, close-packed hexagonal, $P6_3/mmc$ D_4^h; a = 0.38799 nm, c = 0.63859 nm at 24 °C. β phase, face-centered cubic, $Fm3m$ O_5^h; a = 0.54848 nm at 24 °C. γ phase, body-centered cubic, $Im3m$ O_9^h; a = 0.444 nm at 763 °C

Minimum interatomic distance. 0.19392 nm at 24 °C

Mass Characteristics

Atomic weight. 173.04

Yttrium (Y)

Compiled by K.A. Gschneidner, Jr. and B.J. Beaudry, Ames Laboratory U.S. Department of Energy, Iowa State University

Yttrium is used in magnesium alloys and oxidation-resistant alloys; it is also used in garnets and ferrites for electronic components. Yttrium is a host material for rare earth phosphors, including the red color (Eu) in color television screens. Yttrium oxide is used to stabilize cubic zirconia for structural and electronic ceramics, and as an oxide dispersant in superalloys; it is a major component in the high-temperature oxide superconductors ($YBa_2Cu_3O_{7-x}$).

Yttrium tarnishes slowly in air at room temperature. Turnings can be ignited quite easily and burn with great evolution of heat. Finely divided yttrium should be handled with great care and should be kept away from air and oxidizing agents.

Structure

Crystal structure. α phase, close-packed hexagonal, $P6_3/mmc$; a = 0.36428 nm, c = 0.57318 nm at 25 °C. β phase, body-centered cubic, $Im3m$; a = 0.410 nm above 1478 °C

Slip planes. $[10\bar{1}0]<[1\bar{2}10]>$ from -196 to 224 °C; $[0002]<[1\bar{2}10]>$ from -196 to 224 °C

Twinning planes. $[11\bar{2}1]<\bar{1}\bar{1}26>$ at 25 °C

Minimum interatomic distance. At 24 °C: r_a = 1.824 nm; r_c = 1.7783 nm; radius CN_{12} = 1.8012 nm

Fracture behavior. Primarily ductile

Mass Characteristics

Atomic weight. 88.90585

Density. α phase, 4.469 g/cm^3 at 24 °C; β phase, 4.28 g/cm^3 at 1478 °C; liquid, 4.24 g/cm^3 at 1525 °C

Thermal Properties

Melting point. 1522 °C

Boiling point. 3345 °C

Phase transformation temperature. 1478 °C

Coefficient of thermal expansion. Linear: 10.6 μm/m · K. Linear along crystal axes: 6.0 μm/m · K along a axis; 19.7 μm/m · K along c axis. Volumetric 31.7 × 10^{-6} per K

Specific heat. 0.2981 kJ/kg · K at 25 °C

Entropy. At 298.15 K: 499.4 J/kg · K

Radioactive isotopes. All isotopes (^{209}Ac through ^{232}Ac) are radioactive. The longest-lived isotope, ^{227}Ac, has a half-life of 21.773 years and decays by β^- emission (98.62%) and α emission (1.38%). It is the most abundant isotope, and has been recovered in milligram quantities from uranium ores and produced in gram quantities by thermal neutron irradiation of ^{226}Ra:

$$^{226}\text{Ra (n, }\gamma\text{) }^{227}\text{Ra (}\beta^-\text{, 41.2 min) }^{227}\text{Ac}$$

This reaction can also be expressed as the end product of two separate equations:

$$^{226}\text{Ra} + \text{n} \rightarrow {}^{227}\text{Ra} + \gamma$$

and

$$^{227}Ra \xrightarrow{b^-,41,2} {}^{227}Ac$$

Effect of neutron irradiation : Unknown

Thermal neutron cross sections. $\sigma_c = 900 \pm 150$ b; $\sigma_f = 3.5 \times 10^{-4}$ b

Chemical Properties

Oxidizes rapidly in moist air. Oxide coating somewhat inhibits further attack.

Neptunium (Np)

Compiled by J.A. Fahey, Bronx Community College, City University of New York

Neptunium was the first artificial element to be discovered. It was produced by the bombardment of uranium with slow neutrons. Many isotopes of neptunium are known, and all are radioactive. ^{237}Np is the most stable isotope, with an α decay half-life of 2.14×10^6 years. The 59.6 keV γ ray associated with the α decay of ^{237}Np to an excited state of ^{233}Pa makes it important in the investigation of the electronic, structural, and magnetic properties of the solid compounds and metallic phases of neptunium by Mössbauer spectroscopy. The isotope ^{237}Np is used for most studies because of its long half-life and its relative availability. ^{237}Np and ^{239}Np are produced, along with ^{239}Pu, in the operation of conventional nuclear reactors. ^{237}Np is also important because it is the source material for the production of ^{238}Pu for use in atomic-powered batteries. Most of the health concerns associated with neptunium are related to the possible presence of residual amounts (0.5%) of ^{239}Pu, a strong carcinogen, due to incomplete separation in the purification process.

Structure

Crystal structure. α phase: orthorhombic (*Pnma*); a = 0.4723 nm, b = 0.4887 nm, c = 0.6663 nm at 25 °C. β phase: tetragonal, *P*4/*nmm*; a = 0.4897 nm, c = 0.3388 nm at 313 °C. γ phase: bcc *Im*3*m*; a = 0.3518 nm at 600 °C

The unit cell of α neptunium contains eight atoms. Half the atoms are in a site with the seven nearest neighbors at an average distance of 0.2968 nm (2.968 Å), and the other half are in a site with the five nearest neighbors at an average distance of 0.2854 nm (2.854 Å).

The unit cell of β neptunium contains four atoms. Half the atoms are in a site with the four nearest neighbors at an average distance of 0.3206 nm (3.206 Å), and the other half are in a site with the four nearest neighbors at an average distance of 0.3232 nm (3.232 Å).

The unit cell of γ neptunium contains two atoms. Each atom has its eight nearest neighbors at a distance of 0.297 nm (2.97 Å) when extrapolated to 20 °C

Mass Characteristics

Atomic weight. ^{237}Np, 237.0482

Density. α phase: 20.48 g/cm^3 at 25 °C (x-ray); 20.25 g/cm^3 at 25 °C (measured). β phase: 19.38 g/cm^3 at 313 °C (x-ray); 19.31 g/cm^3 at 25 °C (measured). γ phase: 18.08 g/cm^3 at 600 °C (x-ray)

Thermal Properties

Melting point. 637 °C

Boiling point. ~3902 °C

Phase transformation temperatures. At 1 atm pressure: α to β, 280 °C; β to γ, 577 °C; γ to liquid, 637 °C

Coefficient of thermal expansion. Volumetric, as determined by x-ray diffraction. α neptunium between 20 and 275 °C: $\alpha_{100} = 24 \times 10^{-6}$ per K; $\alpha_{010} = 25 \times 10^{-6}$ per K; $\alpha_{001} = 34 \times 10^{-6}$ per K. β neptunium between 278 and 530 °C: $\alpha_{100} = \alpha_{010} = 64 \times 10^{-6}$ per K; $\alpha_{001} \cong 0.0$.

The thermal expansion of neptunium metal has been measured by dilatometry. A typical dilatometric run is shown in Fig. 140. The values of the coefficient of linear expansion were found to be 27.5×10^{-6} per °C for the α phase (40 to 240 °C) and 41×10^{-6} °C for the β phase (300 to 540 °C). The dilatometric behavior also shows a discontinuous change of slope at the phase transitions.

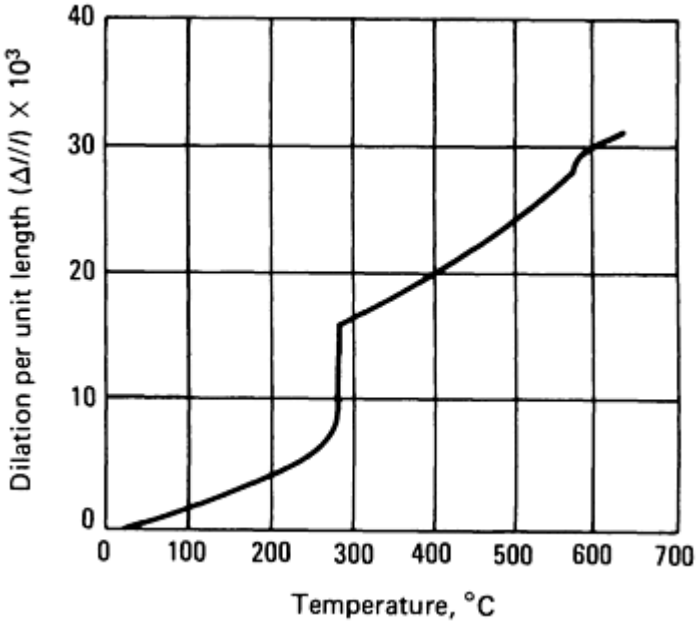

Fig. 140 Thermal expansion of neptunium metal. Source: Ref 571

Specific heat. The heat capacity of pure neptunium metal reaches the Dulong-Petit value of 3*R* (where *R* is the universal gas constant) at 140 °C and 29.68 J · K^{-1} at 300 K. Measuring the specific heat of neptunium metal between 7.4 and 300 K yields a γ(coefficient of the electronic term in the specific heat) of 14 mJ/mol · K^2. The specific heat of neptunium metal is a smooth function over this temperature range. The Debye temperature of neptunium metal is calculated to be 240 ± 4 K.

Latent heat of phase transformation. α to β, 5607 J/mol; β to γ, 5272 J/mol

Latent heat of fusion. 5230 J/mol

Enthalpy of solution. Neptunium metal in 1.5 *M* HCl: -165.7 ± 0.2 kcal/mol at 25 °C

Enthalpy of oxide formation. NpO_2, -1074 ± 3 kJ/mol

Free energy of oxide formation. NpO_2, -1022 ± 3 kJ/mol

Vapor pressure. Liquid: log *P* = -(20,610 ± 1280)/*T* + (5.10 ± 0.70), where *P* is in atm and *T* is in K. See Fig. 141.

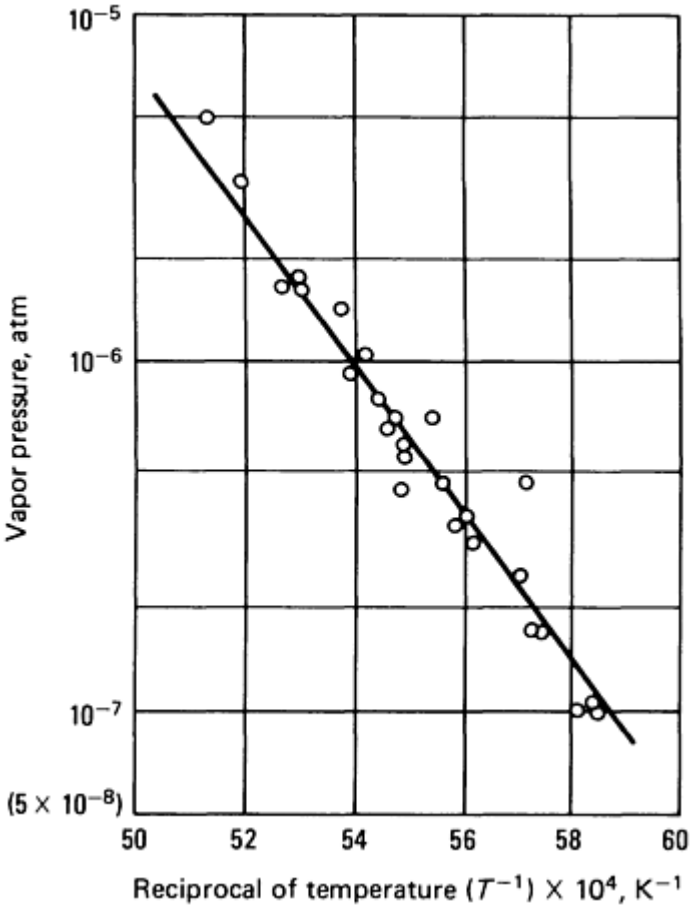

Fig. 141 Plot of vapor pressure versus temperature for neptunium metal. Source: Ref 572

Heat of vaporization. At 1800 K: 94.3 ± 5.9 kcal/mol

Entropy of vaporization. At 1800 K: 23.3 ± 3.2 cal/mol · K

Phase diagram and compressibility. The compressibility of neptunium metal is similar to that of neighboring actinides such as uranium and plutonium. The phase diagram shown in Fig. 142 has one triple point (tetragonal body-centered cubic/liquid) at a temperature of 1000 K (725 °C) and a pressure of 3.2 GPa. A pressure-volume study at room temperature of neptunium metal established the bulk modulus to be 118 GPa and the pressure derivative to be 6.6 in the pressure range up to 52 GPa. At 1 atm pressure, the α phase is stable up to 280 °C, the β phase is stable up to 577 °C, and the γ phase is stable up to the melting point of 637 °C.

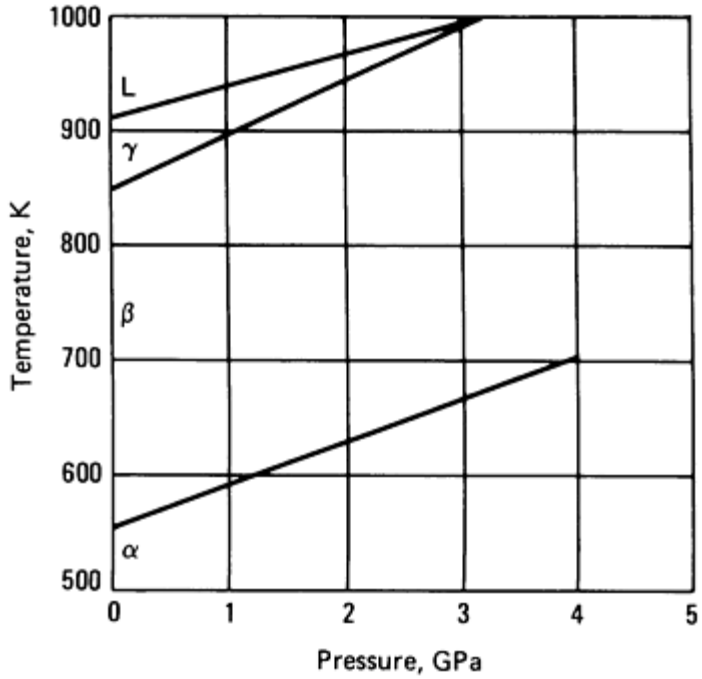

Fig. 142 Pressure versus temperature phase diagram for neptunium metal. Source: Ref 573

Electrical Properties

Temperature coefficients of resistivity. The resistivity of neptunium metal has been measured by standard potentiometric methods; the results are represented in Fig. 143 and Table 55. Table 55 also gives the variation of the temperature coefficient of resistivity with temperature in the three allotropes.

Table 55 Effect of phase and temperature variation on the resistivity of neptunium

Magnetic Properties

The susceptibility of α-Np metal when measured on very pure samples has a room-temperature value of 560×10^{-6} emu/mol and is almost independent of temperature (Ref 575).

Nuclear Properties

Isotopes from ^{227}Np to ^{242}Np are known; all are radioactive and have half-life periods ranging from ~60 s to 2.14×10^6 years. The latter half-life is associated with ^{237}Np, and accounts for the use of this isotope in most studies. The half-life of ^{237}Np is relatively short when compared with the estimated age of the earth; therefore, any primordial ^{237}Np would long since have decayed. However, small amounts of ^{239}Np are expected to occur in uranium minerals by continual formation from ^{238}U through the capture of neutrons from the spontaneous fission of ^{238}U.

Chemical Properties

Neptunium metal is silvery in appearance, about as malleable as uranium metal, and becomes covered with only a thin oxide layer when exposed to air for short periods. It reacts rapidly to form NpO_2 in air at high temperatures. NpO has been reported to form in vacuum at high temperature on the surface of the partially oxidized metal.

Direct reaction between hydrogen and neptunium metal results in the formation of at least two hydrides, NpH_2 and NpH_3. Neptunium hydride decomposes when heated in vacuum above 300 °C, yielding finely divided pyrophoric neptunium metal.

Phase diagrams for the Np-Pu and Np-U alloys all exhibit a common feature: the complete miscibility between γ neptunium and γ uranium and between γ neptunium and ε plutonium.

Several intermetallic compounds of neptunium with noble metals have been prepared by the reduction of NpO_2 with very pure hydrogen at 1300 °C in the presence of the noble metal. The intermetallics $NpAl_2$, $NpAl_3$, $NpBe_{13}$, NpB_6, $NpCd_6$, $NpCd_{11}$, and $NpPd_3$ have been prepared in this fashion (Ref 572).

Plutonium (Pu)

Compiled by M.B. Brodsky, Argonne National Laboratory; Revised for this Volume by Dr. Brodsky and Michael Stevens, Los Alamos National Laboratory

The term plutonium usually implies ^{239}Pu of at least 95% purity (generally 99.7 to 99.99 wt%). Small amounts of δ-phase stabilizers, such as 0.1 wt% Al, may cause retention of the δ phase at room temperature. The term plutonium, however, also implies ^{239}Pu sufficiently free of δ-phase stabilizers so that only the α phase is present at room temperature.

Typical uses of plutonium include nuclear weapons, nuclear fuel, neutron sources, heat sources for thermoelectric generators (especially ^{238}Pu), and production of higher isotopes and transplutonic elements. Plutonium is a highly radioactive α emitter, extremely poisonous, and is properly handled in glove boxes. It is about twice as poisonous as radium to the human system. The maximum permissible body burden is 0.6 μg. When handling quantities in excess of 300 g, the possibility of nuclear criticality must be considered.

Structure

Crystal structure. See Table 56.

Table 56 Crystal structure and density of various phases of plutonium

Phase	Lattice symmetry	Lattice constants, nm	Interaxial angle β	Density, g/cm^3	Atoms per unit cell

		a_0	b_0	c_0	angle β	g/cm^3	unit cell
α	Monoclinic	0.6183 (21 °C)	0.4822	1.0963	101.79°	19.86	16
β	Monoclinic	0.9284 (190 °C)	1.0463	0.7859	92.13°	17.70	34

Phase	Minimum distance, nm
α	0.25
β	0.297
γ	0.3026
δ	0.3279
δ'	0.3249
ε	0.3149

Metallography. Standard grinding procedures using kerosene or carbon tetrachloride as a lubricant are used. Polishing is done on microcloth charged with γ alumina or 1 μm diamond. Suitable etches contain tetraphosphoric acid, water, and 2-ethoxyethanol in the following proportions: 7:36:57 for low-temperature phases; 12:33:55 for δ phase; 2:3:5 for long etching. Tetraphosphoric acid can be replaced by orthophosphoric acid and less water. Additional etches include dimethylformamide and HNO_3 in an 80:20 mixture. This electrolyte can be used on α metal for electrolytic polishing and

etching at room temperature and 10 to 12 V_{dc}. A 90:10 mixture of ethylene glycol and HNO_3 may be used on δ metal at 10 V_{dc}. Residual powders must be collected regularly to prevent the buildup of potentially critical amounts.

Fracture behavior. The metal exhibits little toughness ($K_{Ic} \cong 11.8$ MPa $\sqrt{m}$) (Ref 582); however, the fracture micromechanism is microvoid coalescence.

Mass Characteristics

Atomic weight. 239.052

Density. See Table 56.

Compressibility. α plutonium: approximately 0.2 per Pa at atmospheric pressure to 0.05 per Pa at 10 GPa; the volume at 10 GPa is about 90% of the volume at atmospheric pressure (Ref 576, 578). β plutonium at 200 °C: 0.23 ± 0.10/Pa in the range from 0 to 200 MPa

Volume change on transformation. See Table 57.

239	2.4×10^4	α (5.15 MeV), γ	315	746
240	6.6×10^3	α (5.16 MeV), γ	250	0.03
241	13.2	β^- (0.021 MeV), γ	390	1010

Thermal neutron cross section. See Table 62.

Chemical Properties

General corrosion behavior. Plutonium is a highly reactive metal, similar in reactivity to the rare earths.

Resistance to specific corroding agents. Relatively inert to dry air but corrodes rapidly if traces of moisture are present (Ref 576). Reacts slowly with water at room temperature

Fabrication Characteristics

Machinability. Similar to that of 3003 Al

Recrystallization temperature. Approximately 120 °C

Casting temperature. In vacuum: 800 to 900 °C

Alloying practice. Low-melting elements are commonly added as pure metals to the molten bath. Alloys of refractory metals are added as master alloys.

Deoxidizers. Cerium and calcium have been used in deoxidizing plutonium. Plutonium melts have been made under potassium chloride-sodium chloride covers.

Melting practice. High-vacuum furnaces are commonly used to melt plutonium alloys. Magnesia and coated graphite crucibles are used to 1200 °C, and thoria crucibles are used to 1500 °C. Tantalum can be used to 1000 °C to contain molten plutonium. Magnesia, graphite, and copper are suitable mold materials.

Hot-working temperature. Can be worked readily in the δ (fcc) temperature range, 312 to 458 °C. β plutonium is ductile and can be worked (Ref 583).

Heat treatment. Plutonium is given a cold treatment at -23 °C to complete the β to α transformation (Ref 576).

Mechanical Properties

The mechanical properties of plutonium depend heavily on microstructure. They are especially sensitive to the presence of microcracks caused by the large volume change associated with the β-to-α phase transformation.

Tensile properties. Typical for cast α at 25 °C (Ref 576, 579, 584): tensile strength, 415 MPa; yield strength, 275 MPa; elongation, 0.2 to 0.5%; proportional limit, 160 MPa

Compressive properties. Typical for cast α at 25 °C (Ref 576, 579, 584): compressive strength, 830 MPa; compressive yield strength, 415 MPa

Hardness. 250 to 283 HV, 10 kg load (Ref 579)

Poisson's ratio. 0.15 to 0.21

Elastic modulus. Tension, 107 GPa; shear, 45 GPa

Fatigue strength. Typical, rotating beam: 90 MPa at 10^8 cycles

Liquid surface tension. 0.5 N/m

Viscosity. Dynamic, molten Pu: 7.4 mPa · s at 650 °C; 6.2 mPa · s at 750 °C

Protactinium (Pa)

Compiled by Lester R. Morss, Chemistry Division, Argonne National Laboratory, and Barbara Cort, Los Alamos National Laboratory

Only in recent years has protactinium been available in sufficient amounts to characterize. It is radioactive and must be handled in a glove box. Although ^{231}Pa is an α emitter, daughters emit both α and β radiation. Protactinium is also chemically reactive and oxidizes easily in air; it should be stored in an inert atmosphere.

Structure

Crystal structure. α phase: body-centered tetragonal (*I*4/*mmm*); a_0 = 0.3921 ± 0.0001 nm, c_0 = 0.3235 ± 0.001 nm at 300 K. β phase: face-centered cubic (*Fm*3*m*), a_0 = 0.5018 ± 0.0001 nm at 1775 K (Ref 585)

Mass Characteristics

Atomic weight. ^{231}Pa, 231.0359

Density. 15.43 g/cm^3 at 300 K (Ref 586)

Volume change on freezing. Unknown

Thermal Properties

Melting point. 1845 ± 20 K (Ref 586)

Boiling point. 4300 K (Ref 587)

Phase transformation temperature. 1438 K

Coefficient of thermal expansion. Volume, 303 to 773 K: 18 × 10^{-6}/K. Linear, 303 to 973 K, 9.9 × 10^{-6}/K

Specific heat. 60 mJ/mol · K at 5 K, 2550 mJ/mol · K at 17 K; = 5 mJ/mol · K^2; Debye temperature, 185 ± 5 K; density of states = 1.54 states/eV/atom (solid) (Ref 588)

Entropy. $S°_{298K}$ = 51.8 J/mol · K (estimated)

Enthalpy. Unknown

Heat of fusion. 12.3 kJ/mol (Ref 586)

Heat of vaporization. 569 kJ/mol (Ref 586)

Latent heat of phase transition. Unknown

Enthalpy of oxide formation. PaO_2, -1109 kJ/mol (solid, 298 K) (estimated); Pa_2O_5, unknown

Free energy of oxide formation. -1044 kJ/mol (estimated); Pa_2O_5, unknown. For PaO_2(s): $\Delta G°$ = -1087 - 0.166 *T*, where $\Delta G°$ is in kJ/mol and *T* is in K

Thermal conductivity of metal. 0.47 W/cm · K (estimated)

Thermal conductivity versus temperature. Unknown

Vapor pressure. Estimated as 1×10^{-8} atm at 2300 K. Over protactinium (liquid) in the temperature region 2500 to 2900 K: $\log_{10}P = [(31328 \pm 375)/T] + (10.83 \pm 0.13)$, where P is in Pa and T is in K

Diffusion coefficient. Unknown

Electrical Properties

Electrical resistivity. 15 μΩ· cm at 300 K (Ref 589)

Superconducting transition temperature. 0.43 K (Ref 590)

Magnetic Properties

Magnetic susceptibility. 190 emu/mol from 20 to 298 K; property is independent of temperature.

Magnetic permeability. Unknown

Optical Properties

Color. Golden cast

Emissivity. Unknown

Nuclear Properties

Radioactive isotopes. All isotopes (^{215}Pa through ^{238}Pa) are radioactive. The longest-lived isotope, ^{231}Pa, has a half-life of 32 760 years and decays by α emission. It is the most abundant isotope, having been recovered in gram quantities from uranium ores.

Thermal neutron cross sections. $\sigma_c = 210 \pm 20$ b; $\sigma_f = 0.010 \pm 0.005$ b. Effect of thermal neutron irradiation is unknown.

Chemical Properties

Little or no tarnishing in air for several months; oxidation at 300 °C. Attacked by 8 *M* HCl, 2.5 *M* H_2SO_4, and 12 *M* HF, but reaction ceases. Best solvents are 8 *M* HCl-1 *M* HF and 12 *M* HCl-1-0.05 *M* HF.

Fabrication Characteristics

Malleable and ductile

Mechanical Properties

Tensile properties. Unknown

Compressive properties. Unknown

Hardness. Malleable and ductile

Poisson's ratio. Unknown

Elastic modulus. Bulk modulus, 157 ± 5 GPa (Ref 591)

Thorium (Th)

Compiled by J.F. Smith, Ames Laboratory, U.S. Department of Energy, Iowa State University

Thorium, as a solid or fluid in elemental, intermetallic, or oxide form, is used as a fuel for nuclear reactors because it is a fertile material for the generation of fissionable ^{233}U. The oxide form of thorium is used for gas mantles. Thorium oxide additions control grain size in tungsten filaments. Thoria-dispersed nickel alloys (TD nickel) contain thorium oxide additions for increased strength. Thorium metals is used as an alloying addition in magnesium technology and as a deoxidant for molybdenum, iron, and other metals. Thorium has a variety of applications in electronic technology.

Thorium is radioactive. Pure, fresh thorium is a weak α emitter, but old thorium, with accumulated decay products, also emits β particles and penetrating γ rays. Thorium is chemically quite reactive. In finely divided form, thorium can be pyrophoric; in dust form, it may be explosive. Chemical toxicity of thorium and its compounds is generally low.

Structure

Crystal structure. α phase: face-centered cubic, Al, *cF*4 (*Fm*3*m*); a = 0.5086 nm at 25 °C. β phase: body-centered cubic, *A*2, *cI*2 (*Im*3*m*); a = 0.411 nm at 1450 °C

Slip planes. Deformation textures imply that {111} slip planes are active throughout the temperature range of study, -196 to 900 °C.

Minimum interatomic distance. 0.3596 nm at 25 °C

Microstructure. Common inclusions in thorium metal are gray ThO_2, a so-called white phase of debated identity that often surrounds cast grains of calcium-reduced thorium, gold-colored nitrides, and an occasional massive particle of tungsten in arc melted material. A fine Widmanstätten-like microstructure with cream-colored needles and angular inclusions, which turn deep blue after exposure to air for 1 day, can be produced by melting in graphite crucibles.

Mass Characteristics

Atomic weight. 232.038

Density. Solid: 11.8 g/cm^3 at -273 °C; 11.72 g/cm^3 at 25 °C; 10.89 g/cm^3 at 1755 °C. Liquid: 10.35 g/cm^3 at 1755 °C

Density versus temperature. $\Delta d/d_0 \cdot K = -34.2 \times 10^{-6}$ at 25 °C

Volume change on freezing. -5%

Thermal Properties

Melting point. 1755 °C

Boiling point. ~4800 °C

Phase transformation temperature. β to α phase (cooling), 1345 °C

Coefficient of thermal expansion. Linear: 10.9 μm/m · K at -193 °C; 11.4 μm/m · K at 25 °C; 12.6 μm/m · K at 600 °C; 13.3 μm/m · K at 750 °C; 14.0 μm/m · K at 850 °C; 14.9 μm/m · K at 950 °C

Specific heat. 0.11308 kJ/kg · K at 25 °C

Specific heat versus temperature:

°C	J/kg · K
-193	92.61
-173	97.79
-153	101.58
-113	106.1
-73	108.9
-23	110.8
27	113.17
127	116.7
227	120.2
327	123.9
427	127.8
527	132.0

627	136.4
727	141.0

Enthalpy. $H_{298} - H_0$ = 25.16 kJ/kg at 25 °C

Entropy. S_{298} = 226.9 J/kg · K at 25 °C

Latent heat of fusion. 59.50 kJ/kg

Latent heat of phase transformation. 15.6 kJ/kg

Latent heat of sublimation. 2.539 MJ/kg at 25 °C

Enthalpy of oxide formation. ThO_2: -4.6460 MJ/kg at 25 °C

Free energy of oxide formation. ThO_2: -4.4274 MJ/kg at 25 °C

Thermal conductivity. 77 W/m · K at 25 °C

Thermal conductivity versus temperature. See Fig. 147

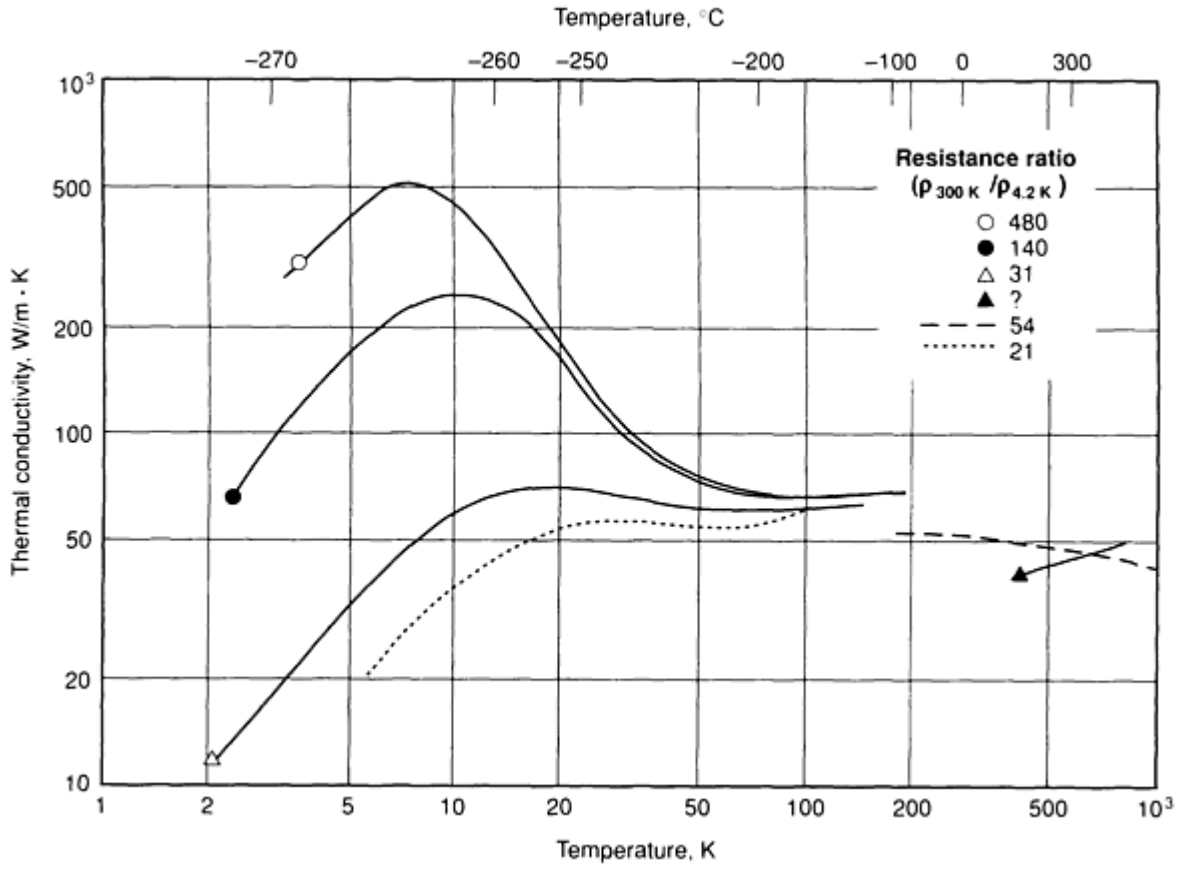

Fig. 147 Thermal conductivity of thorium

Vapor pressure. Solid, log P = -(28,780 ± 620)/T + 10.997 ± 0.333 at 1484 to 1683 °C; liquid, log P = -(29,770 ± 220)/T + 11.030 ± 0.098 at 1747 to 2187 °C, where P is in Pa and T is in K

Diffusion coefficient. Where D is in m^2/s, activation energy is in kJ/mol, T is in K. Self-diffusion: $D = 1.7 \times 10^{-4}$ exp (-327/RT) for α phase; $D = 0.5 \times 10^{-4}$ exp (-230/RT) for β phase. Hydrogen in α phase: $D = 2.92 \times 10^{-7}$ exp (-40.8/RT) at infinite dilution. Carbon in β phase: $D = 2.2 \times 10^{-6}$ exp (-113RT). Nitrogen in β phase: $D = 3.2 \times 10^{-7}$ exp (-71/RT). Oxygen in βphase: $D = 1.3 \times 10^{-7}$ exp (-94.1/RT)

Electrical Properties

Electrical conductivity. Volumetric, 11% IACS

Electrical resistivity. 157 nΩ · m at 25 °C

Temperature coefficient of electrical resistivity. 0.560 nΩ · m per K

Pressure coefficient of electrical resistivity. 5.7 aΩ · m per GPa

Thermoelectric potential. See Fig. 148.

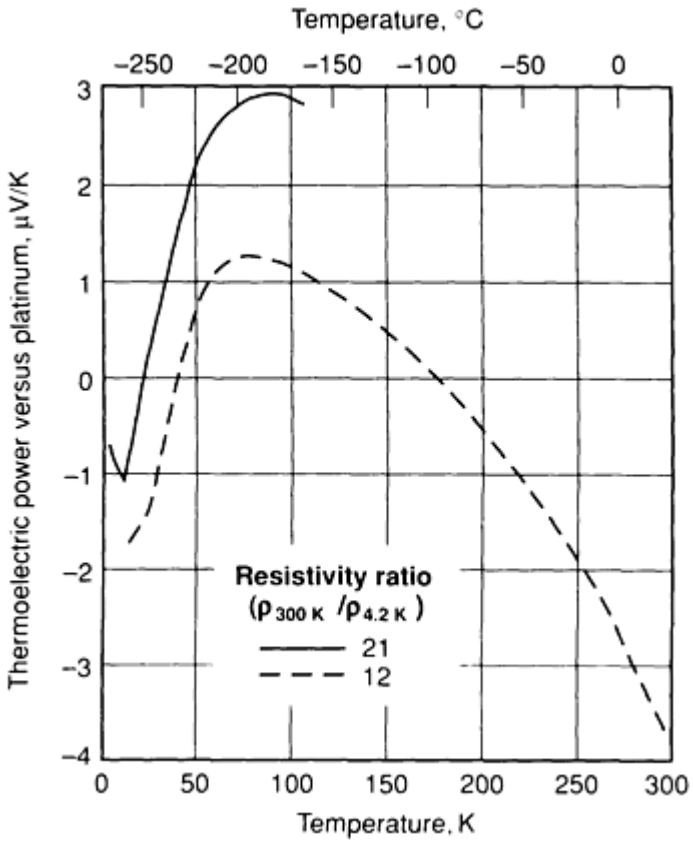

Fig. 148 Thermoelectric potential of thorium

First ionization potential. 6.08 eV

Hall coefficient. -0.088 to -0.13 nV · m/A · T at 25 °C

Temperature of superconductivity. 1.390 K at zero field

Increase of electrical resistivity with carbon addition. 55 pΩ · m/ppm C by weight

Work function. 0.559 aJ

Magnetic Properties

Magnetic susceptibility. Volume: 60.7×10^{-6} mks at 25 °C

Magnetic permeability. 1.0000607 at 25 °C

Optical Properties

Color. At fresh surface exhibits a bright silvery luster; the surface darkens after prolonged exposure to air.

Emissivity. Total: 30% at 1127 °C; 30.5% at 1227 °C; 31% at 1327 °C; 32% at 1427 °C; 34% at 1527 °C. Change in emissivity at the α -β transition, <0.5%

Nuclear Properties

Unstable isotopes. Isotopes from ^{223}Th through ^{235}Th are known; all are radioactive, with half-life periods ranging from 0.9 s to 1.4×10^{10} years. This latter half-life is associated with ^{232}Th, which is the isotope constituting essentially 100% of the natural abundance; ^{232}Th emits α particles with energies of 6.38×10^{-13} J.

Effect of neutron irradiation. Dimensional changes in irradiated thorium are essentially isotropic and relatively small. They are associated with the increase in volume from the accumulation of fission products in the material. Tensile strength has been found to increase 75% after a neutron exposure of 10^{19} nvt (where nvt is the neutron dose equivalent to the number of neutrons per square centimeter) and an additional 30% at double that exposure.

Chemical Properties

Resistance to specific corroding agents. In air between 100 and 900 °C, corrosion is principally oxidation and follows a linear reaction rate; at 800 °C, a weight gain of 2.88 kg/m^2 per day in air is typical. Above 850 °C, reaction with oxygen follows the parabolic law. Reaction with nitrogen also follows the parabolic law in the range of 671 to 1490 °C; in purified nitrogen, typical weight gain at 800 °C is 0.96 kg/m^2 per day. Thorium corrodes in water to form thorium oxide and hydrogen, and it loses weight by spallation; typical weight loss of unalloyed thorium in high-purity water at 178 °C is 0.109 kg/m^2 per day.

Fabrication Characteristics

Machinability. Thorium is readily machined. However, high-purity thorium tends to be gummy; its softness causes continuous turnings. Lower-purity material contains abrasive oxides, which cause rapid tool wear. It is advisable to use a water-soluble coolant when machining thorium.

Recrystallization temperature. ~650 °C (depends upon purity and amount of prior cold work)

Sintering temperature. 1100 to 1200 °C

Annealing temperature. Initial recovery: 525 °C. Recrystallization: 650 °C

Hot-working temperature. 750 to 900 °C

Mechanical Properties

Tensile properties. As-cast thorium (0.02 to 0.08 wt% C): tensile strength, 219 MPa; yield strength at 0.2% offset, 144 MPa; elongation, 34%; reduction in area, 35%. See also Fig. 149 and 150.

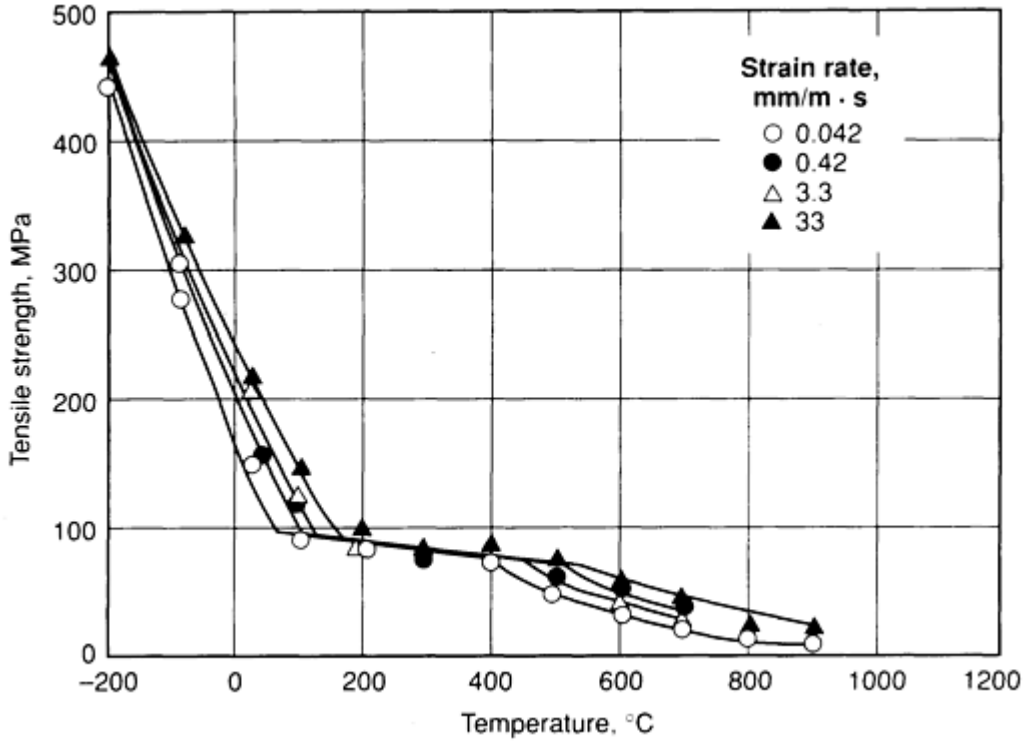

Fig. 149 Temperature dependence of the tensile strength of thorium

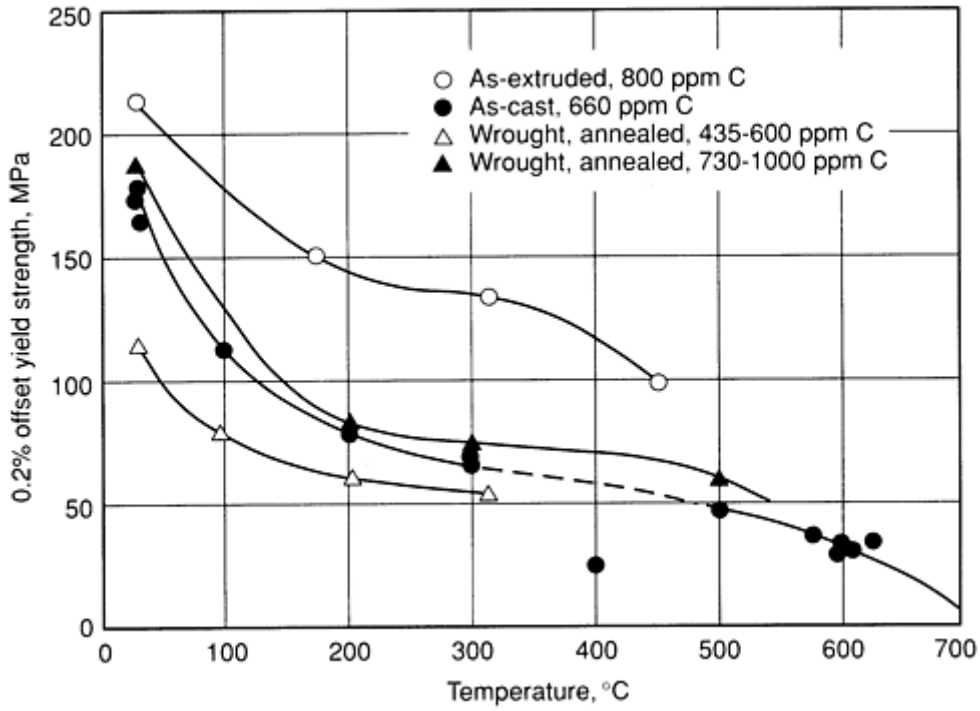

Fig. 150 Temperature dependence of the yield strength of thorium

Compressive properties. Values closely comparable to tensile values

Hardness. 56 to 114 HV with 20 kg load; see also Fig. 151.

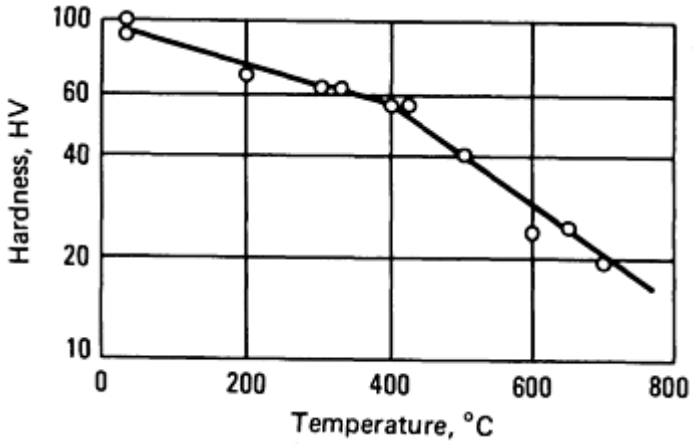

Fig. 151 Temperature dependence of the hardness of thorium

Poisson's ratio. 0.27

Strain-hardening exponent. 0.18 at 25 °C

Elastic modulus. Tension, 72.4 GPa; shear, 27.6 GPa; bulk, 57.7 GPa

Elastic properties along [100] crystal axis. Tension modulus, 60.1 GPa; shear modulus, 47.8 GPa; Poisson's ratio, 0.394

Impact strength. ~13 J for calcium-reduced thorium at 25 °C

Fatigue strength. Endurance limit: ~97 MPa for calcium-reduced thorium, reversed bending test

Specific damping capacity. 3×10^{-3} in 0 to 300 °C temperature range

Uranium (U)

Compiled by Paul S. Dunn, Los Alamos National Laboratory

Uranium can exist as a number of different isotopes. Natural uranium nominally contains 0.006% ^{234}U, 0.71% ^{235}U, and a balance of ^{238}U. The term enriched uranium designates uranium containing higher-than-natural ^{235}U; depleted uranium designates lower-than-natural ^{235}U; normal uranium contains the naturally occurring amount of ^{235}U. Other designations include α uranium, β uranium, and γ uranium for the three allotropic forms.

The most common use of uranium is in the nuclear and defense industries. Enriched uranium is used in nuclear reactor fuel elements and is usually a mixture of uranium oxide and plutonium dioxide. Enriched uranium is also used as a nuclear explosive. Depleted uranium is commonly used as a shielding material in particle accelerators and as a projectile material in conventional ordnance.

Massive depleted uranium offers no substantial problem in handling and storage. It oxidizes slowly in dry air and forms an adherent oxide. However, oxidation in moist air will result in a flaky oxide crust.

Finely divided uranium metal is pyrophoric, and care must be exercised to prevent fires. Uranium is a heavy-metal contaminant and must be processed under controlled conditions to avoid ingestion of fumes or dust.

Structure

Crystal structure. α: orthorhombic (*Cmcm*; *oC*4); a = 0.2854 nm, b = 0.5869 nm, c = 0.4856 nm at 298 K. β: complex tetragonal ($P4_2/mnm$; *tP*30); a = 1.0748 nm, c = 0.5652 nm at 950 K. γ: body-centered cubic (*Im*3*m*; *cI*2); a = 0.3535 nm at 1100 K

Slip planes. At 300 to 875 K, primary slip in α uranium is (010) [100], which cross slips onto (001).

Twinning planes. The most frequently observed type of twinning occurs on (130) and is operative as high as 873 K. The (172) twin is the second most frequently observed system in α uranium.

Mass Characteristics

Atomic weight. 238.029

Density. α: 19.05 g/cm^3 at 298 K (from x-ray data); 18.7 to 19.0 g/cm^3 for wrought metal. β: 18.3 g/cm^3 at 973 K. γ: 17.91 g/cm^3 at 1173 K. Liquid: 17.25 g/cm^3 at 1410 K. Temperature coefficients: α, 0.001 g/cm^3 · K; β, 0.0009 g/cm^3 · K; γ, 0.0012 g/cm^3 · K; liquid, 0.0016 g/cm^3 · K

Volume change on melting. 2.2% expansion

Volume change on phase transformation. On cooling: β to α, 1.0% contraction; γ to β, 0.6% contraction

Thermal Properties

Melting point. 1406 K

Boiling point. 4091 K

Phase transformation temperature. α to β, 934 K; β to γ, 1042 K

Coefficient of thermal expansion. The thermal expansion of wrought α uranium is highly anisotropic and depends on fabrication history and the resultant preferred orientation. Linear: quenched α phase, 12 μm/m · K at 298 K and 28 μm/m · K at 900 K; β phase, 28 μm/m · K at 1000 K; γ phase, 20 μm/m · K between 1175 and 1400 K

Coefficients of linear thermal expansion (α) along crystal axes. α phase between 50 and 923 K: $\alpha_{[100]} = 2.422 \times 10^{-5} - 9.83 \times 10^{-9}\,T + 4.602 \times 10^{-11}\,T^2$; $\alpha_{[010]} = 3.07 \times 10^{-6} + 3.47 \times 10^{-9}\,T - 3.845 \times 10^{-11}\,T^2$; $\alpha_{[001]} = 8.72 \times 10^{-6} + 3.704 \times 10^{-8}\,T + 9.08 \times 10^{-12}\,T^2$, where T is in K. βphase: $\alpha_{[100]}$, 25 μm/m · K: $\alpha_{[001]}$, 5 μm/m · K

Specific heat versus temperature:

Temperature, K	Specific heat, J/kg · K
α phase	
300	117
600	145
800	172

900	190
β phase	
940	179
1040	179
γ phase	
1050	160
1300	160

The equation for specific heat of α uranium versus temperature is $C_p = 103.6 + 0.0180\ T + 8.49 \times 10^{-5}\ T^2$, where C_p is in J/kg · K and T is in K.

Latent heat of fusion. 38.72 kJ/kg at 1406 K

Latent heat of phase transformation. α to β, 12.3 kJ/kg at 943 K; β to γ, 20.1 kJ/kg at 1042 K

Latent heat of vaporization. 2.069 kJ/kg at 1406 K

Thermal conductivity:

Temperature, K	Thermal conductivity, W/m · K
α phase	
10	9.8
20	15.8
100	2.17
300	27.6
600	31.7

900	41.3
βphase	
1000	43.9
γphase	
1100	46.3

Recrystallization temperature. Generally between 650 and 750 K, but highly dependent on purity and fabrication history

Vapor pressure. 1 μPa at 1500 K; 17.5 mPa at 2000 K

Enthalpy. At 298 K: 26.74 kJ/kg

Entropy. 211 J/kg · K at 298 K

Electrical Properties

Electrical resistivity. α phase, 300 nΩ · m at 300 K; βphase, 560 nΩ · m at 1000 K; γphase, 540 nΩ · m at 1100 K; liquid, 66 nΩ · m at 1200 K. Temperature coefficient: α phase, 0.021 per K at 300 K, 0.039 per K at 900 K. Along crystal axes, α phase at 273 K: $\rho_{[100]}$, 390 nΩ · m; $\rho_{[010]}$, 240 nΩ · m; $\rho_{[001]}$, 262 nΩ · m

Hall coefficient. 380 nV · m/A · T at 300 K

Temperature of superconductivity. <0.5 K

Work function. 0.58 aJ

Magnetic Properties

Magnetic susceptibility. Volume: 390×10^{-6} mks at 300 K

Optical Properties

Spectral reflectance. 73.5% for λ= 660 nm

Spectral hemispherical emittance. 26.5% for λ= 660 nm

Nuclear Properties

Unstable isotopes. Table 63 lists data for α-particle emission.

Table 63 Properties of unstable uranium isotopes with α-particle emission

Isotope	Abundance, %	Half-life ($t_{1/2}$), years	Energy, MeV

^{234}U	0.0055	2.47×10^5	4.77, 4.72, 4.58, 4.47,
^{235}U	0.720	7.1×10^6	4.40, 4.2
^{238}U	99.274	4.51×10^9	4.18

Thermal neutron cross section. For 0.025 eV neutrons:

Isotope	Thermal neutron cross section, b	
	Capture (σ_c)	Fission (σ_f)
Natural uranium	6.7	. . .
^{238}U	1.6	. . .

Mechanical Properties

Wide variations exist in all mechanical properties of α uranium, and these properties depend markedly on a large number of parameters, most notably preferred orientation, grain size, fabrication history, heat treatment, and type and distribution of impurities. For example, fracture stress decreases from approximately 600 MPa for a grain size of 1 μm to 130 MPa for a grain size of 10 μm.

Tensile properties. At ~293 K. As-cast: tensile strength, 400 MPa; 2% offset yield strength, 200 MPa; elongation, 4%; reduction in area, 10%. β annealed (grain size, 500 μm): tensile strength, 615 MPa. Wrought α uranium: tensile strength 1150 MPa; yield strength, 740 MPa; elongation, 7%; reduction in area, 14%

Hardness. Coarse-grain: α uranium, 185 HV at 300 K. Fine-grain: α uranium, 250 HV at 300 K; β uranium, 30 HV at 950 K; γ uranium, 1 HV at 1100 K

Poisson's ratio. See Table 64.

Table 64 Elastic properties of α uranium at room temperature

Condition	Modulus of elasticity[(a)]		Poisson's ratio
	GPa	10^6 psi	
Swaged and annealed	201	29.1	0.22

Extruded	202	29.3	0.21
Cast	203	29.5	0.22
Hot-rolled	203	29.5	0.20

Elastic modulus. See Table 64.

Properties of the Transplutonium Actinide Metals (Am-Fm)

Compiled by R.G. Haire, Transuranium Research Laboratory, Oak Ridge National Laboratory

Availability and Nuclear Properties

The first six transplutonium metals, americium (Am), curium (Cm), berkelium (Bk), californium (Cf), einsteinium (Es), and fermium (Fm), are treated as a group rather than as individual elements because of the similarities in their physical properties and the limited amount of information available about them. All six are man-made radioactive elements with isotopes that decay mainly by α emission (5 to 7 MeV α particles); ^{249}Bk is an exception; it decays by β emission.

Beyond plutonium in the actinide series, the availability of each subsequent element diminishes rapidly. Einsteinium is the last element for which weighable (microgram) quantities are available. The low availability precludes obtaining solid-state properties for higher elements. The largest quantities of these six elements are produced using a neutron capture scheme in nuclear reactors; this method then governs the isotopes that are generated. Other isotopes of these elements can be produced in much smaller quantities using accelerators.

A limited summary of the commonly available isotopes, their availability, and other pertinent data are given in Table 65. Thermal neutron cross sections for selected transplutonium isotopes are listed in Table 66.

Table 65 Nuclear properties for isotopes of the first six transplutonium elements

Isotope	Half-life	Available quantity	Specific heat, W/g
Am_{95}^{241}	433 years	kg	0.10
Am_{95}^{241}	7.38×10^{3}years	g	6×10^{-3}
Cm_{96}^{244}	18.1 years	g	2.7

(a) Total.

(b) Estimated

Applications and Basic Properties

Currently, the practical applications for these elements are limited, with most involving their radioactive nature. The ionizing radiation of ^{241}Am has been used in smoke detectors, and thermoelectric generators have employed the decay heat of curium isotopes. Also, the neutrons emitted (spontaneous fission decay branch) from ^{252}Cf have found use in cancer therapy, neutron radiography, and neutron activation analysis of remote areas (for example; the ocean floor).

In contrast to the earlier members of the actinide series, these six transplutonium elements tend to be more like the lanthanide elements in their properties and behavior. The tendency is for these six elements to be true *f* elements, formed

by regularly adding a localized 5*f* electron in progression across the series. They differ from the lanthanide elements in their increased tendency toward being divalent metals when progressing to the higher members; divalency first occurs in the series at einsteinium. This latter tendency arises in the actinide series because of the increasing magnitude of the promotion energy ($f^n s^2$ to $f^{n-1} d s^2$) required to make a third electron available for bonding.

Some of the basic properties of these six metals are given in Table 67. Enthalpy of vaporization, which is a measure of cohesive energies, is plotted for each of the six transplutonium metals in Fig. 152; the enthalpy of each of their lanthanide homologs is plotted for comparison. The lower values for the actinides reflect this trend toward divalency. The lower enthalpy for the lanthanide europium is in accordance with its divalency. The vapor pressure over the solid phase of these transplutonium metals can be calculated from the relationships given in Table 68. The calculated boiling points of these metals are also listed in Table 68.

Table 67 Physical properties of the first six transplutonium actinide metals

Element	Crystal structure at 298 K	Density, g/cm^3	Melting point, K	Enthalpy of vaporization at 298 K, kJ/mol	Entropy, ($S°$), J/mol · K[(a)]	Bulk modulus, GPa
Americium	dhcp	13.61	1446	284	55.4	45

Table 68 Vapor pressure (*P*) relationships for the solid phases and the calculated boiling points of the first six transplutonium actinide metals

P is obtained from the equation $\log_{10} P = a - b/T$, where *P* is in atm, *T* is in K, and *a* and *b* are coefficients listed in this table.

Element	*a*	*b*	Boiling point, K
Americium	6.578	14315	2340
Curium	6.082	19618	3383
Berkelium	5.78	15718	3173

Californium	5.675	9895	2018
Einsteinium[(a)]	5.642	7112	1269
Fermium[(b)]	5.474	7090	1350

(a) Calculated using data obtained from einsteinium-ytterbium alloys and assuming an ideal alloy behavior.

(b) Calculated using data obtained from fermium-ytterbium alloys and assuming an ideal alloy behavior

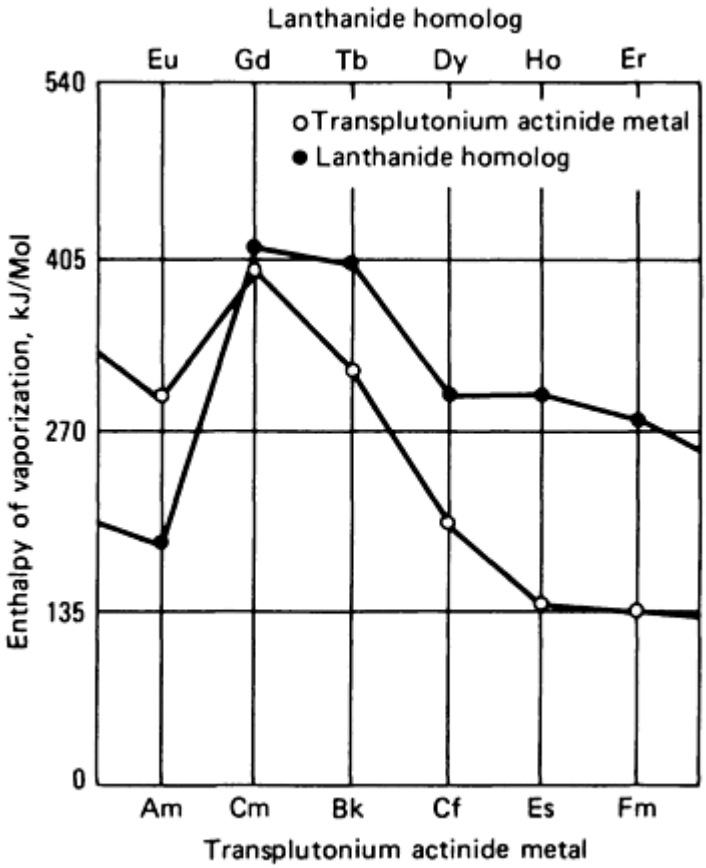

Fig. 152 Enthalpy of vaporization for the first six transplutonium actinide metals and their lanthanide homologs

Crystal Structures

The first four transplutonium elements are trivalent metals; that is, they have three bonding or conduction electrons. They have a low-temperature phase with a double-hexagonal close-packed (dhcp) structure. These metals are isostructural with some of the light lanthanide metals. Many of the lanthanide metals have a body-centered cubic (bcc) high-temperature phase; however, these transplutonium metals have a high-temperature fcc (β) phase. There is some evidence from dilatometry and differential thermal analysis to suggest that the fcc forms of americum and curium may transform to a bcc form just prior to melting, but x-ray confirmation of these bcc forms has not been obtained.

Einsteinium is the first divalent actinide metal, and it displays an fcc structure with a much larger lattice parameter than the fcc phases of the first four (Am, Cm, Bk, Cf) transplutonium metals. Structural data do no exist for fermium metal, although it is also a divalent metal (based on the magnitude of its enthalpy of vaporization), and it is likely to be

isostructural with einsteinium metal. Both einsteinium and fermium metals are best compared to the divalent lanthanide metals europium and ytterbium. The lattice constants, atomic volumes, and metallic radii for these transplutonium metals are provided in Table 69. The phase and melting-point behaviors of the first six transplutonium actinide metals are illustrated in Fig. 153.

Table 69 Structural properties of the first six transplutonium metals

Element	Structure	Lattice constants, nm		Atomic volume, $nm^3 \times 10^3$	Metallic radius, nm[(a)]
		a_0	c_0		
Americium	dhcp	0.3468	1.1241	29.27	0.1725
	fcc	0.4894	. . .	29.30	0.1730
Curium	dhcp	0.3496	1.1331	29.98	0.1739
	fcc	0.493	. . .	30.0	0.174
Berkelium	dhcp	0.3416	1.1069	27.96	0.1699
	fcc	0.482	. . .	28.0	0.170
Californium	dhcp	0.3384	1.1040	27.37	0.1691
	fcc	0.478	. . .	27.3	0.169
Einsteinium[(b)]	fcc	0.575	. . .	47.5	0.203

(b) Divalent actinide metals; comparable to divalent europium and ytterbium metal in the lanthanide series.

(c) Estimated

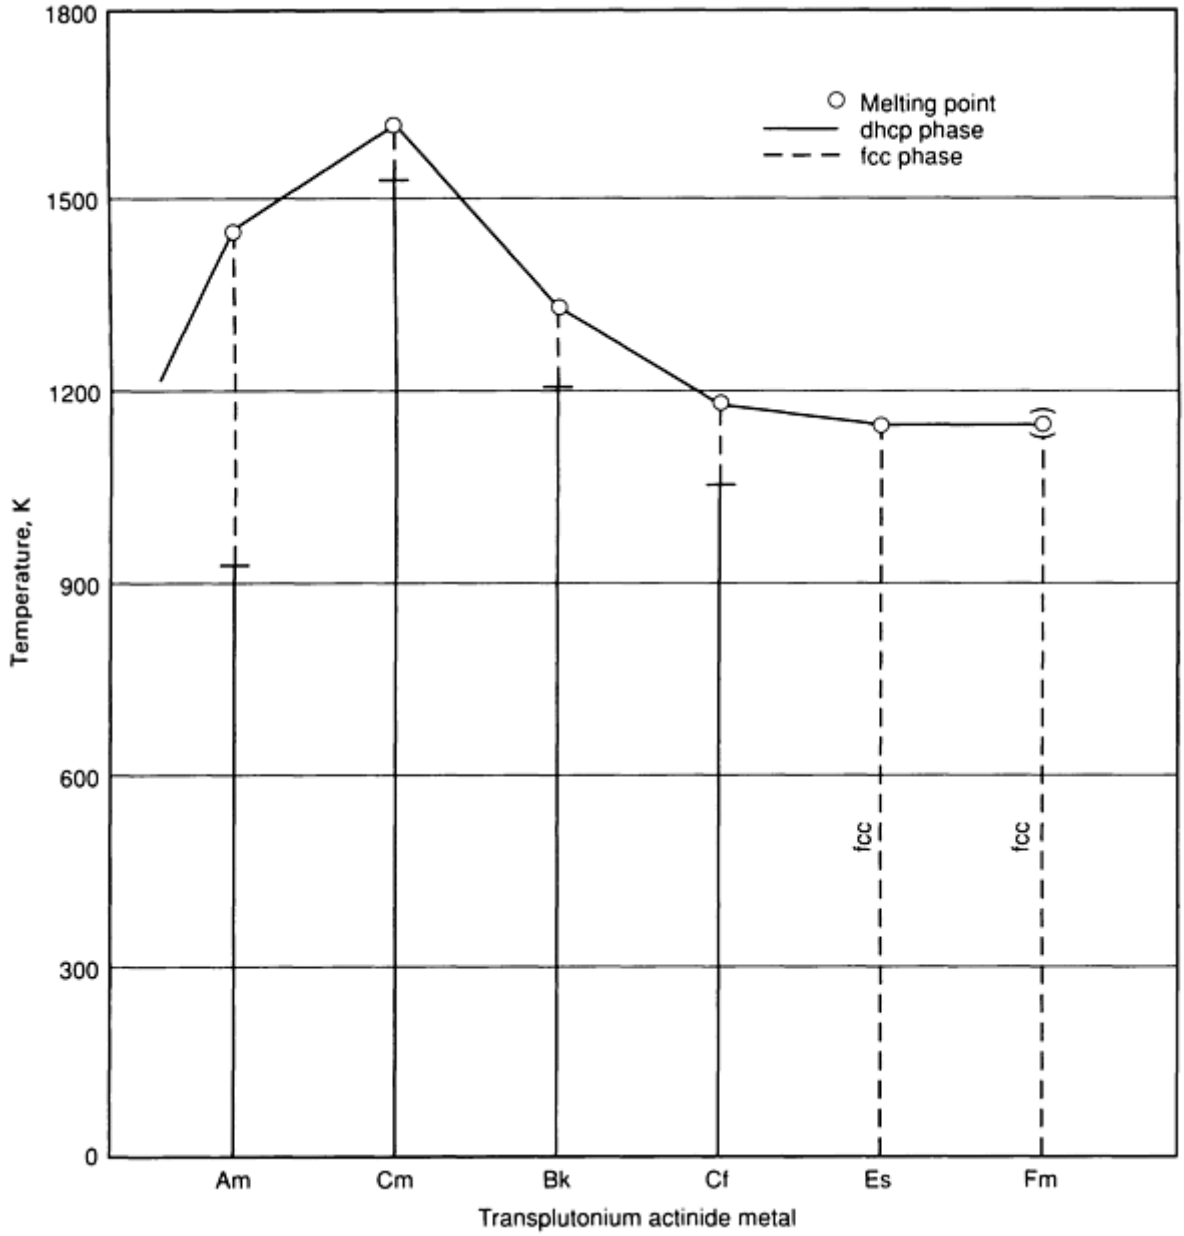

Fig. 153 Phase behavior and melting points of the first six transplutonium actinide metals

Under pressure, the first four transplutonium metals undergo two or three phase transitions and ultimately form the α-uranium-type, orthorhombic structure. The structural sequence is dhcp to fcc to distorted fcc (fcc') to orthorhombic. Both americium and californium form this distorted fcc structure, whereas curium and berkelium metals do not. The formation of the α uranium structure has been interpreted to signify the partial delocalization of the 5*f* electrons and their participation in the metallic bonding. After release of the applied pressure, the sequence is reversed, but some hysteresis may occur between the fcc-to-dhcp transition.

The pressure behavior of the first four transplutonium metals is summarized in the block diagram in Fig. 154; the dashed line indicates the variation of the delocalizationpressures for the metals. Data do not exist for einsteinium or fermium metals under pressure.

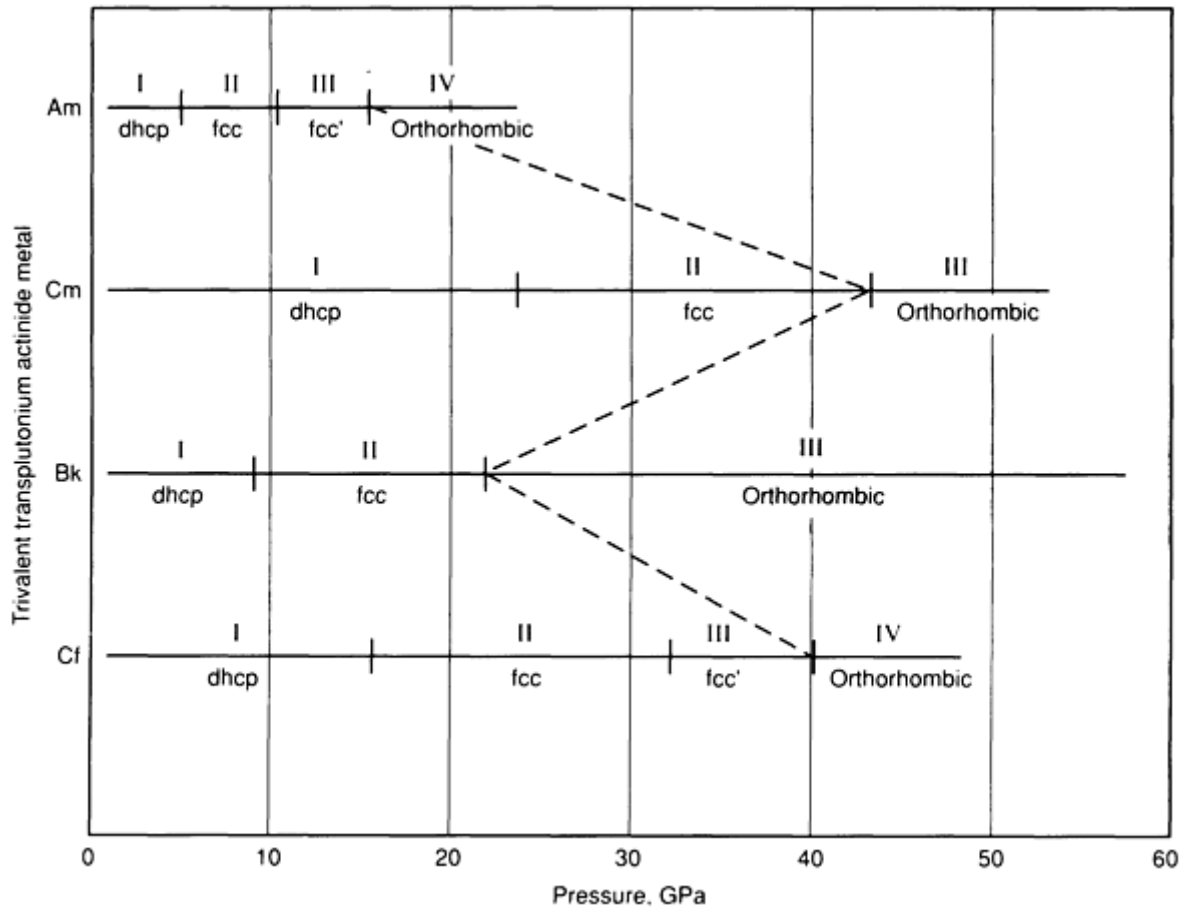

Fig. 154 Phase behavior of the first four transplutonium actinide metals under pressure. Dashed line indicates delocalization pressure variation of these trivalent transplutonium metals. Orthorhombic designation indicates an α-uranium structure (5*f* delocalization).

Chemical and Mechanical Properties

The first six transplutonium metals are electropositive metals that react with air and moisture to give oxides (sesquioxides or dioxides). They are usually prepared by the thermometallic reduction of their oxides with lanthanum or thorium metals, or by the reduction of their fluorides with lithium metal. At 25 °C, the rate of reaction for bulk forms of the first four metals (americium, curium, berkelium, and californium) with air is moderate and is comparable to that of the light lanthanide metals. The divalent metals, einsteinium and fermium, are more reactive, and their behavior is better compared to that of europium metal.

All of the first six transplutonium metals react rapidly with mineral acids to evolve hydrogen and yield trivalent ions (see Table 70 for thermodynamic values). They react with anhydrous hydrogen halides to yield the trihalides. The metals react slowly with dry nitrogen at room temperature to give mononitrides; at temperatures above 200 °C, they react with hydrogen to form-di- to trihydrides. At elevated temperatures, the metals are more reactive; for example, californium metal will react with glass containers at temperatures as low as 200 °C. At elevated temperatures, the metals combine with the excess pnictogen elements (any member of the nitrogen family of elements, group V in the periodic family) and chalcogen elements (the elements that form group VI of the periodic table, including sulfur, selenium, tellurium, and polonium) to yield the monopnictides or chalcogenides of higher stoichiometries.

Table 70 Thermodynamic values for An^{3+} ions at 298 K

Elements	Enthalpy ($\Delta H°_f$), kJ/mol	Entropy ($S°$), J/mol · K[(a)]	Gibbs free energy ($\Delta G°_f$), kJ/mol

Americium	-617	-201	-599
Curium	-615	-194	-593
Berkelium	-601	-194	-578[(a)]
Californium	-577	-197	-553[(a)]
Einsteinium	-603[(a)]	-206	-573[(a)]
Fermium	-632[(a)]	-215	-599[(a)]

(a) Calculated or estimated values

The pure metals are bright and metallic-looking, relatively ductile, and soft enough to be cut without much difficulty. Impurities tend to make the metals brittle. Coefficients of expansion have been determined for americium, curium, and berkelium metals:

Element	$\alpha_a \times 10^6$, K^{-1}	$\alpha_c \times 10^6$, K^{-1}
Americium	7.5	6.2
Curium	8.7	12.8
Berkelium	10.8	17.8

Note: Data for californium, einsteinium, and fermium are not available.

The molten metals are very reactive and difficult to contain; tungsten is the preferred container material, but tantalum is sometimes used. These transplutonium metals are known to form alloys with several other metals; their behavior in this respect is similar to that of the light trivalent lanthanide metals. The first four transplutonium metals appear to have only a limited solubility (estimated to be a few atomic percent) in the divalent lanthanide metals, europium and ytterbium.

The transplutonium elements are classified as toxic because they are heavy metals and because of their radioactivity. Ingestion or inhalation of the metals or their compounds are to be avoided. In mammals, these materials tend to deposit in the bones or the liver.

Magnetic Properties

The elements beyond plutonium are believed to have localized 5*f* electrons, in contrast to the earlier actinides. Magnetic data that support this assumption have been acquired for the first five transplutonium metals. The magnetic moments (in Bohr magnetons, μ_B) of these metals are comparable to values found for their lanthanide homologs when the same electronic configurations are present (for example, the same number of localized *f* electrons). The magnetic moment for

curium metal (8 μ_B; $5f^7 6d 7s^2$ configuration) is thus essentially the same as that for gadolinium metal ($4f^7 5d 6s^2$ configuration). In contrast, americium metal is a trivalent metal with a zero moment, whereas its homolog, europium, is divalent and has a moment of 7 μ_B. Magnetic data for these actinide metals is summarized in Table 71.

Table 71 Magnetic properties of the first six transplutonium actinide metals

Element	Metallic valence	Localized 5*f* electrons	Magnetic moment (μ_{eff}), μ_B		Transactions/ordering	
			Calculated[(a)]	Experimental[(b)]	Type[(c)]	Temperature, K
Americium	3	6	0	0	P	. . .
Curium	3	7	7.94	7.6-8.1	AF	65
Berkelium	3	8	9.72	8.8-9.8	AF	34
Californium	3	9	10.63	9.7-10.2	FM	57
Einsteinium	2	11	10.60	11.3[(d)]	. . .	. . .

(a) Moments calculated using the simple spin-orbit interaction (*L* + *S*, total angular momentum) model; μ_{eff} is expressed in Bohr magnetons (μ_B).

(b) Experimental moments (in Bohr magnetons, μ_B) for low-temperature phases: Am-Cf, dhcp; ES, fcc.

(c) P, paramagnetic; AF, antiferromagnetic; FM, ferromagnetic or ferrimagnetic.

(d) Preliminary data

It has been determined that americium metal becomes superconducting at temperatures as high as 0.8 K. Although americium metal has localized 5*f* electrons, this superconductivity occurs because of its nonmagnetic ground state. The remaining transplutonium metals through einsteinium are magnetic, and they are not expected to be superconducting at low temperature. Measurements above 4.2 K on the metals from curium through einsteinium have shown no evidence for superconductivity.

Although the 5*f* electrons of these six transplutonium metals are reasonably localized, they still communicate by a slight overlapping of their wave functions and/or by interactions with the conduction electrons. This communication leads to the occurrence of magnetic transitions (ferro-, ferri-, or antiferromagnetic) and low-temperature saturated magnetic moments. Curium, berkelium, and californium exhibit transitions to ordered structures at low temperatures; americium is paramagnetic (see Table 70). Preliminary measurements on einsteinium metal have indicated it exhibits paramagnetism and does not exhibit low-temperature ordering, contrary to what would be expected for it. Data have not been obtained for fermium metal.

Recycling of Nonferrous Alloys

Chairman: David V. Neff, Metaullics Systems

Recycling of Aluminum

Elwin L. Rooy, Aluminum Company of America; J.H.L. Van Linden, Alcoa Laboratories

ALUMINUM RECYCLING started less than 20 years after the commercialization of the Hall-Heroult process in 1888, driven by the high value and several unique properties of the metal. In the early days of the developing aluminum industry, the primary producers attempted to maximize new metal sales to reduce the unit price and make aluminum competitive with the traditional construction metals. They were not interested in scrap recycling, leaving that activity to others, who in time developed an independent secondary industry.

As both industries grew, their objectives changed. The primary producers started to use scrap of all forms and origins, and the secondary producers began producing more sophisticated end products, thus reducing the originally distinctive differences between the two industries. Similar developments occurred in the technology arena. The secondary producers were originally low-capital salvage operators. Some still operate in that mode, whereas others have grown into large corporations utilizing advanced technology. This latter group patterned its development after that of the primary industry, which has taken a more capital-intensive approach to solving recycling problems. This section will emphasize mainly these general technological trends and developments rather than the traditional methods and hardware.

Recyclability of Aluminum

Aluminum possesses many characteristics that make it highly compatible with recycling. It is resistant to corrosion, and a low ratio of energy is required to remelt aluminum compared with that required for its primary production. Also, the alloy versatility of aluminum has resulted in a large number of commercial compositions, many of which were designed to accommodate impurity contamination.

Aluminum is resistant to corrosion under most environment conditions, and thus retains a high level of metal value after use, exposure, or storage. Once produced, aluminum can be considered a permanent resource for recycling, preferably into similar products.

The energy requirements for the conversion of aluminum scrap are low when compared with the energy consumed in primary aluminum production. For example, the actual ratio of primary total energy to recycled total energy for used beverage cans is 28.5:1 (Ref 1).

The objective of recycling is to produce a salable commercial aluminum alloy product. Currently, more than 300 compositions covering wrought and cast alloys are registered with the Aluminum Association. Many of these alloys are designed to tolerate the variations in composition and ranges in impurity content that may be experienced in the recovery of scrap. Even widely varying scraps can be melted to produce alloys that are commonly used in die and gravity casting, extrusion, and sheet rolling.

In the early decades of this century, the output of the secondary aluminum industry was largely tied to the consumption of castings by the automotive industry. As shown in Fig. 1, the recycling of aluminum has increased steadily from 1950 until the present despite recessions and energy crises. This increase is the result of growth in the automotive market as well as the development of new and significant recycling applications, such as the consumption of used beverage cans (UBCs) in the manufacture of sheet for new cans.

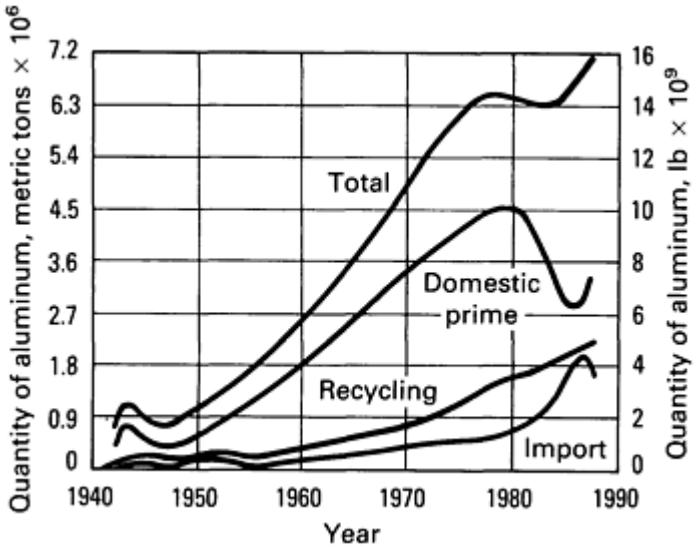

Fig. 1 U.S. aluminum supply distribution for the years 1940 to 1990. Source: Aluminum Association

In recent years, environmental concerns have contributed to an increased awareness of the importance of scrap recycling. Today, the recyclability of aluminum is a major advantage to the aluminum industry in materials competitions for major product markets. The current driving forces for aluminum recycling are:

- Regulatory actions taken by government agencies to encourage resource conservation, energy conservation, and waste reduction through mandatory segregation and deposit programs
- Consumer sensitivity to environmental issues and the solid-waste crisis
- Competitive pressures from other materials.
- Economic advantages based on the relative value and availability of aluminum scrap

The Recycling Loop

The reclamation of aluminum scrap is a complex interactive process involving collection centers, primary producers, secondary smelters, metal processors, and consumers. Figure 2 depicts the flow of metal originating in primary smelting operations through various recycling activities. The initial reprocessing of scrap takes place in the facilities of primary producers. In-process scrap, generated both in casting and fabricating, is reprocessed by melting and recasting. Increasingly, primary producers are purchasing scrap to supplement primary metal supply; an example of such activity is the purchase or toll conversion of UBCs by primary producers engaged in the production of rigid container stock.

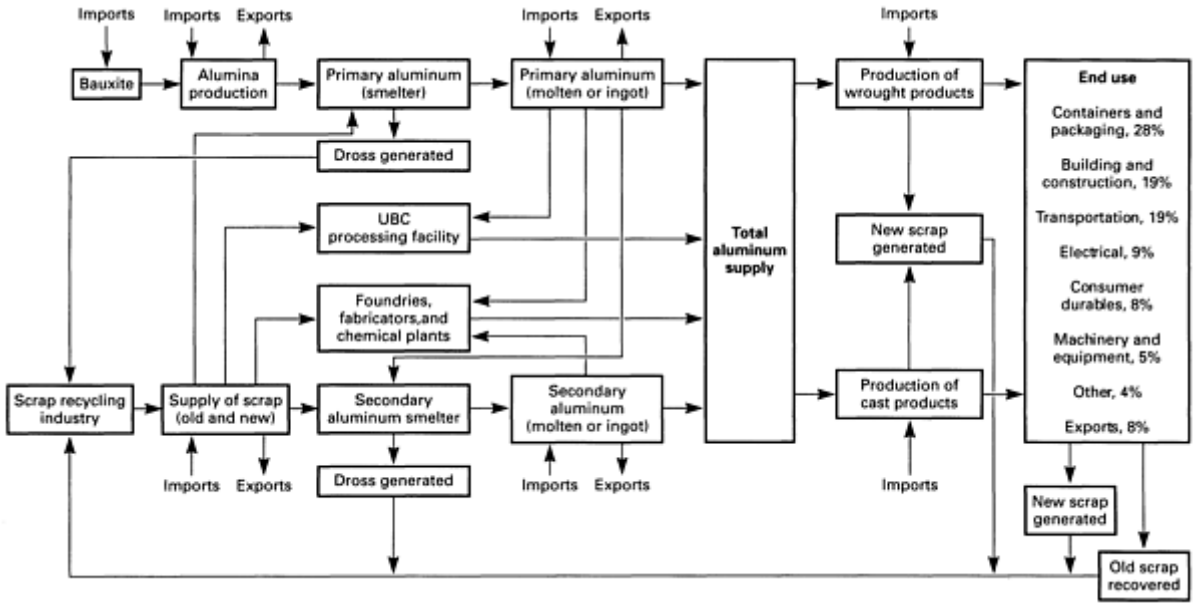

Fig. 2 Flow diagram for aluminum in the United States, showing the role of recycling in the industry. Scrap recycling (lower left) includes scrap collectors, processors, dealers and brokers, sweat furnace operators, and dross reclaimers. Source: U.S. Bureau Mines

Scrap incurred in the processing or fabrication of semifabricated aluminum products represents an additional source of recyclable aluminum. Traditionally, this form of new scrap has been returned to the supplier for recycling, or it has been disposed of through sale on the basis of competitive bidding by metal traders, primary producers, and secondary smelters.

Finished aluminum products, which include such items as consumer durable and nondurable goods; automotive, aerospace, and military products; machinery; miscellaneous transportation parts; and building and construction materials, have finite lives. In time, discarded aluminum becomes available for collection and recovery. So-called old scrap, metal product that has been discarded after use, can be segregated into classifications that facilitate recycling and recovery.

Scrap specifications have been developed that allow the convenient definition of scrap types for resale and subsequent reprocessing. Those developed by the Institute of Scrap Recycling Industries are in broad use (Ref 2). These specifications, however, are for the most part physical descriptions of scrap categories useful to dealers. Chemistry specifications and limits on harmful impurities are not defined, and treatment of extraneous contaminants is inconsistent. More comprehensive scrap specifications are being developed by the industry.

Recycling Trends

A number of industry segments are in competition for the available aluminum scrap, though not necessarily the same types of scrap. As shown in Fig. 3, the primary producers have experienced the largest increase in scrap consumption. The sporadic data available for the period prior to 1940 suggests that recycling of aluminum grew steadily to about 15% of total shipments. World War II disrupted the pattern drastically, but the stockpile reduction in the years following the war reduced the recycling rate to the prewar level (Fig. 4). Scrap consumption trends describing the relationship between the contributions of the primary and secondary industries to the recycling effort are illustrated in Fig. 5.

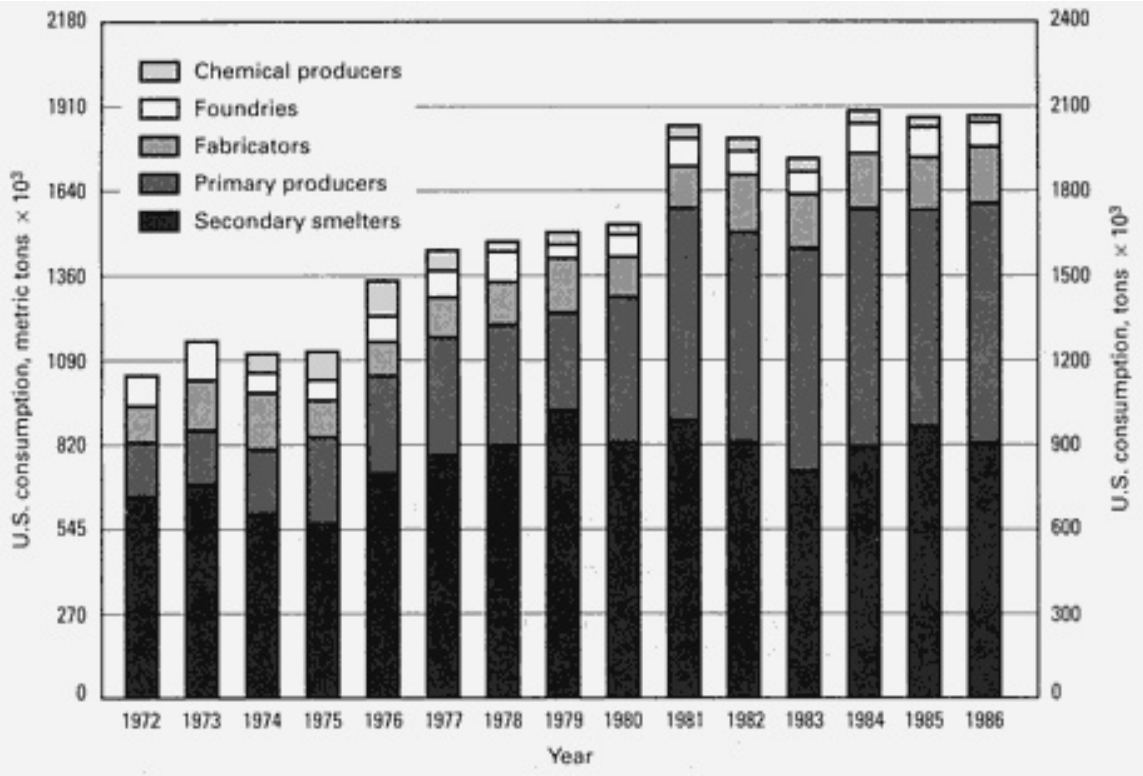

Fig. 3 U.S. aluminum scrap consumption by type of company for the years 1972 to 1986. Source: U.S. Bureau of Mines

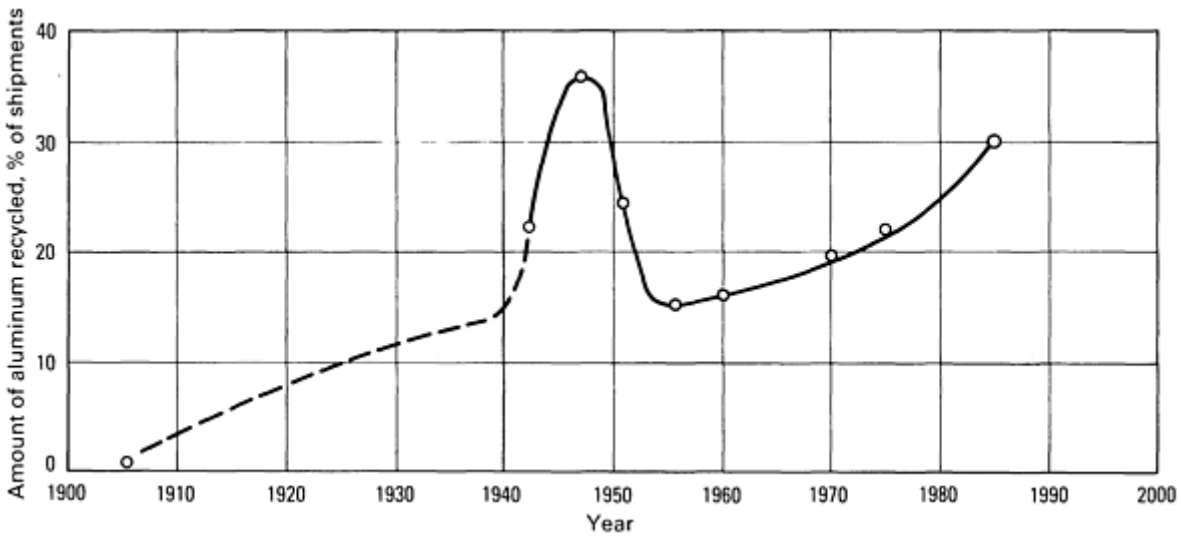

Fig. 4 Aluminum recycling trends in the United States. The percentage of shipments recycled is only now approaching the peak experienced during World War II.

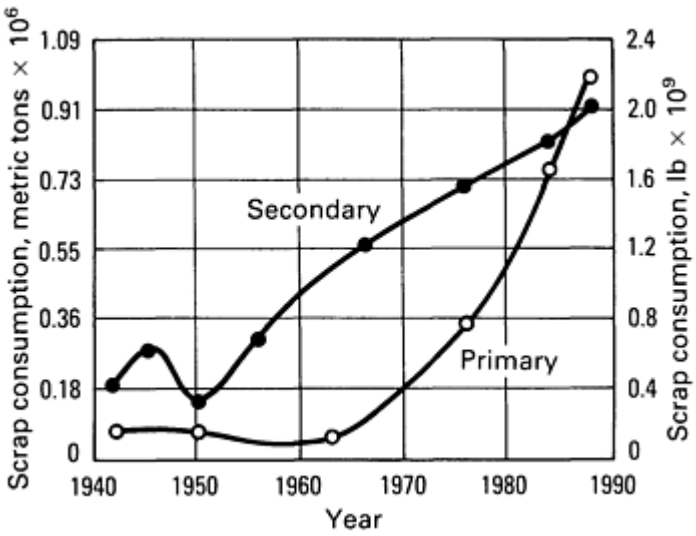

Fig. 5 U.S. aluminum recycling by industry type

The objective of all collection activities is the conversion of scrap forms to products having the highest commercial value. A growing trend is the consumption of scrap in secondary fabricating facilities. A number of extruders, foundries, and minimill operations are producing billet, castings, and common alloy sheet products directly from scrap. The die casting industry relies heavily on secondary compositions for the production of automotive and other parts, and the larger die casters have, in many cases, expanded metal supply through direct scrap purchases.

Aluminum Industry Trends. Recent developments have strongly influenced the rate at which scrap is recycled and the nature of the markets served by recycling activity. Several generalizations concerning the U.S. and world aluminum industries can be made:

- *The aluminum industry today is truly international.* Primary aluminum is produced in virtually every global region, and the metal produced competes in global markets. Aluminum alloy scrap is now traded internationally as well
- *Domestic primary aluminum production will not be expanded beyond the capacity of existing smelting facilities*. Energy costs and labor rates in the United States suggest that there will be substantial decreases in primary output in the absence of any forseeable new, more economical smelting technologies
- *New risks and uncertainties.* The European and, to a lesser but significant extent, the U.S. aluminum industries face new risks and uncertainties caused by the growing geographic separation of primary production from major fabricating and consuming markets
- *Aluminum is a U.S.-dollar-based commodity.* Exchange rate fluctuations represent a major complication in stabilizing prices and regulating international competition and metal supply
- *The world aluminum production capacity will expand,* but such expansion will take place in countries with low energy costs, such as Canada, Venezuela, Brazil, and Australia
- *Recycling will increase in importance.* For the United States, and ultimately for the rest of the aluminum-consuming world, recycling and resource recovery will play an increasingly important strategic role in ensuring a reliable and economical metal supply
- *The U.S will import aluminum.* On the basis of the best assumption, the United States will become an importing nation as aluminum requirements exceed domestic smelting capacity. Most imports will consist of unalloyed smelter ingot for remelting, casting, and fabrication in North American facilities. Some products will be imported, but only for specialty applications with unique and/or cost advantages over domestic products
- *Word competition for scrap units will intensify* based on the relative costs and availability of primary aluminum and scrap

Developing Scrap Streams

The traditional flow of scrap through the primary, consuming, and secondary industries is dominated by three major scrap streams: UBCs, automotive scrap, and municipal scrap.

Beverage Cans. The recycling of UBCs is a remarkable success story (Fig. 6). It is not an exaggeration to suggest that aluminum recycling has played a major role in the market growth of aluminum beverage cans and their penetration into a market previously dominated by competing materials. In 1976, the aluminum can accounted for 21% of the beverage container market; 46.4 billion containers were produced, of which 4.9 billion were recycled. In 1986, 72.9 billion cans were produced and 33.3 billion cans were recycled. It is projected that by 1991, the aluminum can market will have grown by 14% and the recycling rate may reach 60%. In 1988, 94% of all beverage can bodies were produced from aluminum and virtually 100% of all cans featured the aluminum easy-open end.

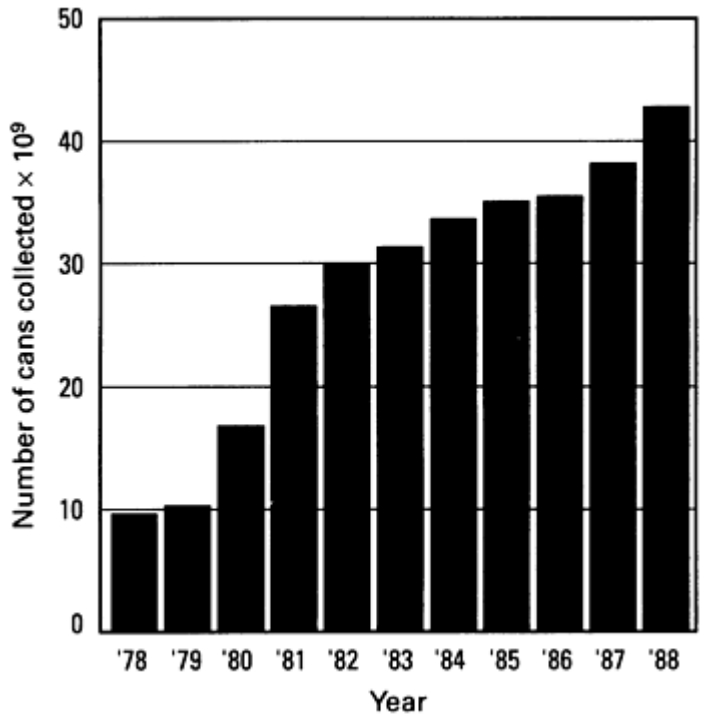

Fig. 6 Increase in recycling of aluminum UBCs from 1978 to 1988. The calculation for the number of cans collected is based on a can weight survey conducted by the Aluminum Association.

Aluminum producers, can makers, and the public have invested in the return system. Large-scale consumer advertising campaigns have emphasized energy savings and resource conservation. Under deposit legislation, cans have generally proven most convenient to handle by consumers, retailers, bottlers, and wholesalers. Collection activities include reverse vending machines, mobile return centers, and public information and educational campaigns. Recycling centers are active in the development of thematic programs to promote the concept of recycling; these programs often associate recycling with civic causes and medical programs, and encourage volunteer, service, and community groups and individuals to maximize the return of used beverage cans.

Recycling of UBCs is based on the inherently high scrap value of aluminum and its convertibility into new-can stock. For the most part, UBCs are consumed by primary producers of rigid-container sheet and are employed in the regeneration of can stock. The growth in markets such as Western Europe, coupled with high energy rates in some countries (Japan, for example), has also created an active market involving the export of UBCs and can scrap. The alloy compatibility of the components of the can makes the UBC uniquely suitable for the closed-loop recycling concept, and it is responsible for the consistent high value of UBCs as well as the ever-increasing volume of UBCs in new can sheet.

Automotive Scrap. Increased activity in the recycling of spent automobiles is based largely on new steel technologies that make scrap conversion economically attractive. However, the exceptional value of the nonferrous metals that are being

separated through the efforts of metal recyclers and the secondary industry also contributes significantly to this recycling activity.

Because the use of aluminum in automobiles is increasing (Fig. 7), the aluminum value recovered from shredded automobiles is of special importance to the metal castings industry. The potential for aluminum use in automobiles is limited only by how aggressively material advantages are pursued by the manufacturers. Common informed predictions indicated that there could be an average use of 90 to 125 kg (200 to 275 lb) of aluminum per automobile in the near future (Ref 3). Growth to the present level of aluminum use in the automotive industry has been largely associated with construction concepts emphasizing castings. Aluminum alloy forgings, sheet, and extrusions are presently being developed by international automobile manufacturers in cooperation with primary aluminum producers to enable the increased use of these materials.

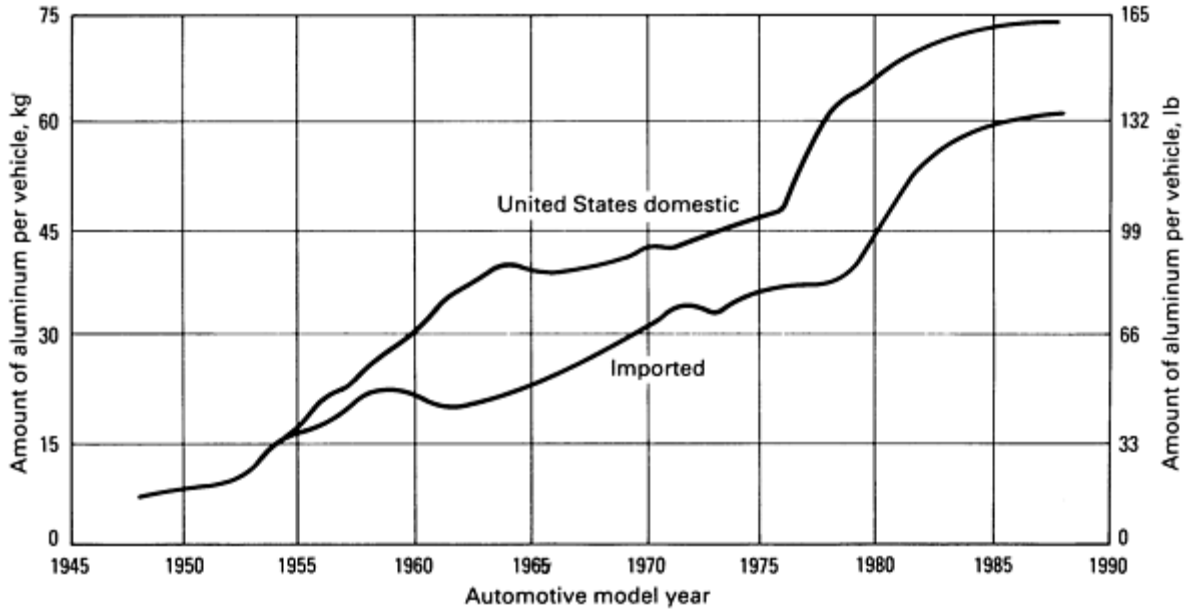

Fig. 7 Average use of aluminum in automobiles from 1946 to 1988. U.S. automakers have used more aluminum than world producers since the mid-1950s.

In 1990, 10 million retired automobiles may yield as much as 500,000 metric tons (550,000 tons) of aluminum; this figure is based on a recovery of 55 kg (120 lb) per vehicle, about the 1980 average. In 1995, because of the projected increase of the use of aluminum in automobiles, recoverable aluminum may increase to 820,000 metric tons (900,000 tons). Trucks and buses, in which aluminum is used more intensively, would add to these estimates.

Municipal Scrap. The separation of metals from municipal refuse has not grown as originally expected. The best available information indicates that more than 12 million metric tons (13.5 million tons) of metals are lost annually through refuse disposal in the United States. Metals make up only 9% of total refuse. Of the total metals available in metal municipal refuse, less than 1% is recovered. Because the cost of separating all components of the refuse stream must be based on the value of reusable materials and energy content, a logical conclusion is that municipal refuse processing has not yet become economically viable; future expansion of such processing will depend either on government subsidies or changes in energy costs and the availability of raw materials.

The solid waste crisis has exposed the need to increase all forms of recycling activity. In 1988, the United States generated 145 million metric tons (160 million tons) of waste. It is anticipated that it may produce more than 180 million metric tons (200 million tons) per year by the year 2000. In 1979, the nation had 18,500 landfills in operation. This number was reduced to 6500 by 1988, and the U.S. Environmental Protection Agency (EPA) estimates that 80% of existing landfills will close in the next twenty years. The EPA and other agencies have argued for responsible reductions in waste, increased emphasis on recycling, the use of incineration to generate energy and greatly reduce the reliance on landfill space. At present, only 10% of waste in the United States is recycled. A national goal established by EPA is to

increase recycling to 25% by 1992. The value of aluminum scrap can be expected to significantly affect the success of plans to increase the percentage of waste that is recycled.

Clearly, the recyclability of any material enhances its attractiveness in commercial applications relative to materials that are not recyclable, or that can be recycled only at an excessive cost. The inherent recyclability of aluminum and its value after recycling enable it to be used in a manner that is supportive of national environmental and waste reduction goals.

Technological Aspects of Aluminum Recycling

Although the term recycling suggests a closed loop, or a set of endless material/product cycles, the widely accepted territory of aluminum recycling includes scrap collection and preparation, remelting, refining, and the upgrading of molten metal to a ready-to-cast condition. Molten metal treatment processes such as demagging, degassing, filtering, composition adjustment, and fluxing play an extremely important role in enabling the reuse of often heavily contaminated scrap in the production of new products; these processes are well described in the literature. A comprehensive overview of molten metal processes for nonferrous metals is available in the article "Nonferrous Molten Metal Processes" in *Casting,* Volume 15 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.* The following discussion will concentrate on issues involving scrap preparation and melting.

In the early days of the aluminum industry, recycling consisted entirely of hand charging unused parts of castings (for example, risers or cut-to-fit scrap pieces) into an oil-fired vessel that resembled an oil drum on its side and that could be tilted for tapping. After the invention of the resealable taphole, the reverberatory, or open hearth, furnace evolved as the predominant remelting facility.

There are two reasons for the long-term success of the direct-firing method in which the combustion chamber and the scrap charge room are combined into one open hearth. First, aluminum oxidation progresses slowly due to the protective, flexible thin oxide film that forms instantaneously when a fresh aluminum surface is exposed to any oxygen-containing atmosphere. Second, the surface-to-volume ratio of scrap particles was generally small because the scrap usually consisted of large sections or parts and heavy-gage sheet. Therefore, the penalty for direct exposure to the melting environment was acceptable when the scrap was generally coarse and the alloys were low in magnesium content.

The open hearth furnace was the mainstay of the scrap-remelting business for over 50 years, but as the application of aluminum became more widespread and diverse, the need for effective and efficient recycling technology grew rapidly. The corresponding growth and diversification of the scrap-recycling industry have been driven by several factors, including increased production requirements, alloy development, scarcity of energy and resources, and increased availability of mixed scrap.

Increased Production Requirements. Large modern casting stations may use up to 114 metric tons (125 tons) of metal per production cycle. This requires not only a high melt rate in large melt furnaces, but also a minimal charge time. The present rectangular open hearth furnace construction is practically limited in size to about a 30 m^2 (320 ft^2) bath area. Cylindrical furnace construction allows for hearth areas of up to 75 m^2 (800 ft^2) and features a removable lid. This configuration allows for very fast, well-distributed overhead charging with preloaded dump buckets. The old design relies on cumbersome door charging, which requires a special machine to push relatively small amounts of scrap as far back into the furnace as practically possible.

Alloy Developments. The use of aluminum-magnesium alloys in light-gage sheet for automotive and container products and aluminum-magnesium-zinc alloys for aerospace and extrusion applications results in large amounts of high-surface-area scrap that has a significantly higher oxidation rate at elevated temperatures than pure aluminum, aluminum-copper, or aluminum-silicon alloys. The prevalence of this type of scrap has stimulated the development and use of methods that minimize the exposure of the scrap to the hostile furnace atmosphere; these methods include continuous melting for large volumes and induction melting for more modest volumes.

Energy and Resource Scarcity. The energy crisis of 1973 highlighted the enormous energy advantage of using scrap rather than new metal and exposed the corresponding need to minimize melt losses. The primary producers started to keep more-difficult-to-melt scrap (using their newly developed continuous melters or induction furnaces), forcing the

secondary producers to deal with even less-desirable scrap types. This scrap was processed mostly in rotary salt melters, which were already popular for skim and dross reclamation.

Increased Availability of Mixed Scrap. Since the early 1960s, the volume of scrap from discarded long-life-cycle products such as home construction materials, trailers, household goods, and so on--often inseparably mixed with other metals--increased steadily. Substantial amounts of otherwise lost aluminum are recovered from such scrap by sweat melting. This is a selective process that involves melting the scrap in a hearth with a sloped bottom; it works by exploiting the melt temperature differences of the metals present, melting, draining, and collecting at the base the metal with the lowest melt point first, followed by the metal with the next-lowest melt point, and so on.

Alloy Integrity. In addition to preservation and melt loss reduction, a key factor in successful recycling is the maintenance of alloy integrity. Obviously, the ideal way of reusing scrap is to recycle it into similar products, or in other words, process used cans into new-can sheet, auto scrap into new car parts, and so on. Melting UBCs, removing the magnesium by chlorination, and adding silicon to produce a casting alloy can be profitable at times and is technically less challenging than making new-can sheet, but the metal units involved will be permanently degraded by such an approach.

In primary aluminum production plants, a great effort is made to keep the scrap identified and segregated. This so-called turn-around scrap is pedigreed and therefore of of the highest value. However, at the production stations of part fabrication (for example, a machining operation in an aircraft manufacturing plant), it is considered impractical and uneconomical to keep scrap segregated by alloy. Furthermore, in end-product fabrication, permanent attachment of some aluminum to other metals or non-metals is inevitable. Therefore, no ideal process for recycling the latter two types of scrap material is readily available.

The greatest challenge for the recycling community is finding the most economical way to separate and prepare scrap for melting so that it can be used in the least-degraded form with the least number of postmelt treatments for alloy or quality adjustments. Each product has its own specific demands, which present obstacles and provide opportunities for meeting this challenge. A complete review of all possible paths would be impractical. Because the UBC and auto scrap loops are different in every aspect, this article will focus on several of the technological developments in preparation and melting in those loops. Municipal refuse and automotive recovery technologies are basically the same.

Can Recycling Technology

Considerable amounts of UBCs are either toll converted for primary producers or remelted by secondary operators, using open hearth or rotary salt furnaces for use in casting alloys. However, the majority (about 80%) of UBCs are returned directly to the primary industry, and UBC recycling is thus a prime example of closed-loop product recycling. The flow diagram in Fig. 8 shows the captive nature of the can manufacturing and recycling loop. The scrap preparation and melt technologies described in this section are considered the most advanced and should not be viewed as industry standards. However, many UBC converters are using similar, rather sophisticated technologies.

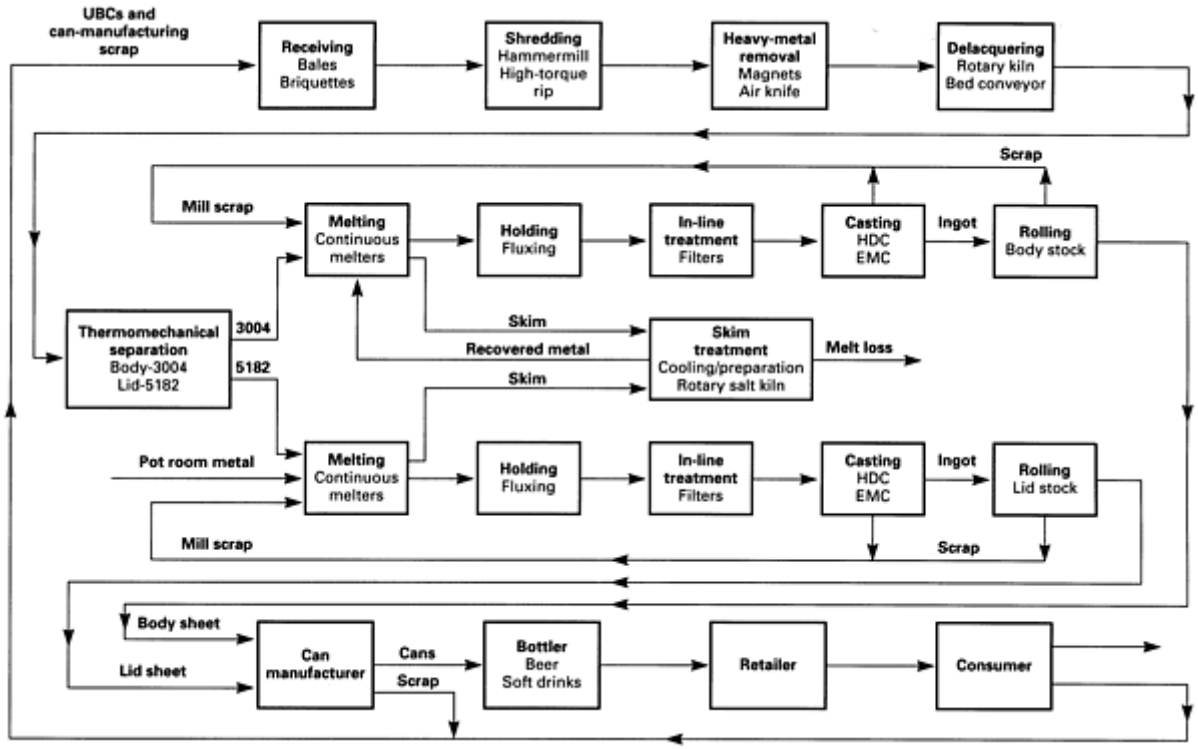

Fig. 8 Flow diagram of closed-loop UBC recycling and manufacturing. Source: Ref 4

Collection. UBCs are received from collection centers as bales weighing 400 kg (880 lb) or as briquettes with a maximum density of 500 kg/m^3 (31 lb/ft^3). The briquettes can be stacked on skids and offer storage advantages to the supplier, but they can be hard on the equipment of the receiver. In the shredding operation, bales and briquettes are broken apart and the cans shredded to ensure that no trapped liquid or extraneous material will reach the melters and cause serious damage or injuries. From the shredder, the material passes, via a magnetic separator that removes ferrous contaminants, through an air knife. In the air knife, heavy nonferrous materials such as lead, zinc, and stainless steel scrap drop out. The shredded aluminum cans then pass on to the delacquering units.

Delacquering. There are two basic approaches to continuous thermal delacquering. One is based on a relatively long exposure time at a safe temperature, and the other is based on staged temperature increases to just below melting for as short an exposure time as possible. The first approach uses a pan conveyor on which a bed of precrushed and shredded UBCs approximately 200 mm (8 in.) deep moves through a chamber held at about 520 °C (970 °F). The chamber contains products of combustion (POC) gases that are diluted with air to provide the proper atmosphere and temperature for the delacquering process (part pyrolysis, part combustion). The second approach employs a rotary kiln with a sophisticated recirculating system for POC gases at various entry points. The temperature in the last stage is near 615 °C (1140 °F), which is very close to the temperature at which incipient melting occurs in the aluminum-magnesium 5*xxx* series) alloys typically used in can lids and tabs.

Both systems present inherent control problems that may result in nonuniform delacquering. A temperature that is too low or exposure times at the proper temperatures that are too short will leave a tar-like coating on the UBCs. This coating causes premelt burning, which leads to increased metal losses upon melting. A temperature that is too high or exposure times at proper temperatures that are too long will cause considerable oxidation of the scrap, also resulting in increased melt losses.

In the pan delacquering system, large bed depths may result in temperature gradients that cause the above-mentioned problems. In the kiln method, gas flows are high and the UBC shreds are physically agitated, and these conditions lead to nonuniform residence times and the same problems. Proper operating controls for these delacquering units, which treat about 18 metric tons (20 tons) of scrap (~1.25 million UBCs) per hour, are vital for producing low-melt-loss feedstock.

Alloy Separation. The hot, delacquered UBCs then move into the thermomechanical separation chamber, which is held at a specific temperature and contains a nonoxidizing atmosphere. In this chamber, a gentle mechanical action breaks up the alloy 5182 lids into small fragments along grain boundaries, which have been weakened by the onset of incipient melting. An integrated screening action removes the fragments as soon as they can pass the screen to avoid overfragmentation. This process requires a very narrow operating control capability to avoid melting entire 5182 particles, which would then cluster with the still-solid alloy 3004 particles. The screened-out alloy 5182 particles are transported to the lid stock melters, and the large alloy 3004 particles continue directly into the body stock melters.

Melting, Preparation, and Casting. At present, most melting facilities for UBCs throughout the industry are dedicated units designed to handle the enormous volumes and to minimize the melt losses inherent in melting thin-walled material. Larger companies have developed their own processes, some of which are described later in this section. Significant amounts of skim--the mixture of metal, oxides, other contaminants, and trapped gas that floats on top of the melt--are removed and treated for metal recovery. A typical skin weight is 15% of the original charge. The recovered metal (6 to 8% of the original charge) from this skim will be used only in body stock manufacturing because of its high levels of manganese and contaminants.

The metal from these dedicated melters is often transferred to on-line melting furnaces, where additional bulky scrap is remelted and primary unalloyed metal is charged to create the desired volume of the proper alloy composition. From these melting furnaces, the metal is transferred to the holding furnaces, where minor composition adjustments are made and metal quality treatments are performed (for example, gas fluxing to remove hydrogen). Some metal treatment, for example, inclusion removal, can be done in so-called in-line treatment units; again, most major companies have developed their own preferred methods and technology. The clean and on-composition metal is cast into ingots weighing up to 13.5 metric tons (15 tons). During casting and rolling of the ingot to sheet, about 42% of the original melt weight may be shaved, cropped, or slit off in various stages. This metal is called the in-house, or turnaround, scrap, and it is directly returned to the remelters.

The body and lid sheet are shipped to a can manufacturer. As a result of can fabrication processes, about 20% of the sheet (or 13% of the original melt) is returned to the aluminum manufacturer as skeleton scrap. On a global basis, this means that 55% of a melt consists of new (production-related) scrap. If all cans were returned as UBCs and total melt losses were 7% of the melt, this 7% would be the only makeup metal required from primary smelters to close the loop (provided the market remained constant). Figure 9 illustrates this interrelationship.

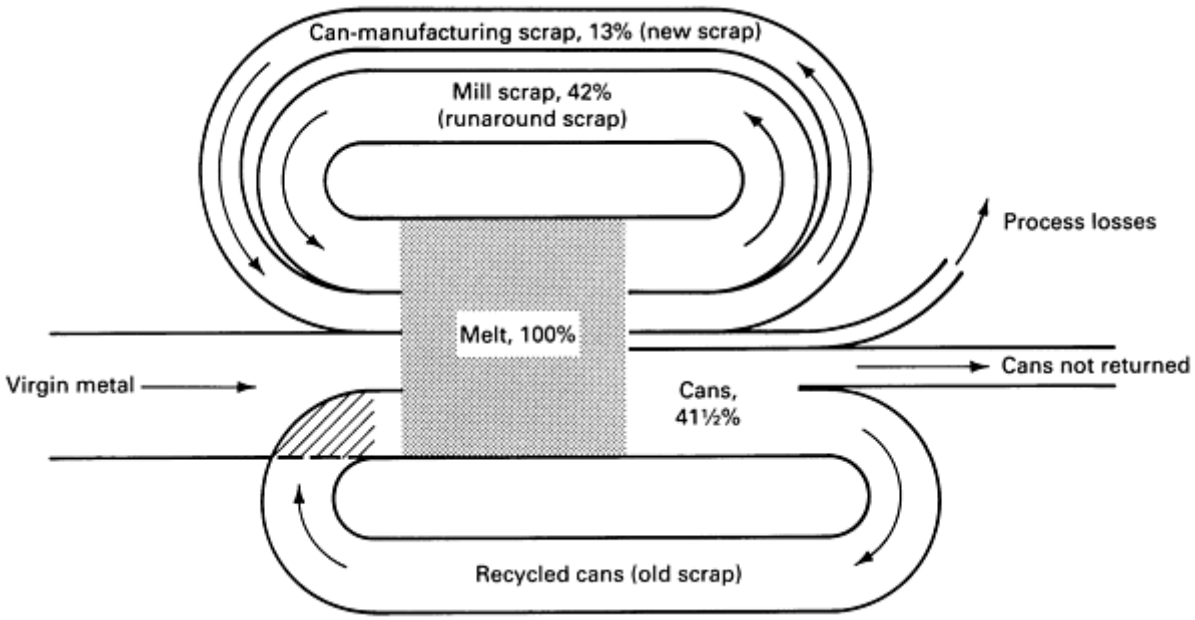

Fig. 9 Process by which recycled cans replace virgin metal in the beverage container market

As the recycling rate continues to increase, composition control and the corresponding contamination avoidance become technical challenges as important as melt loss reduction. These developments were predicted in a mathematical model of the recycling system (Ref 5). It appears that prudent use of salt fluxes may hold the key to improvements in these areas.

Process Developments

Although melt loss had become the major cost factor in ingot production, it was the soaring cost of energy during the 1973 energy crisis that triggered the search for more-efficient remelt processes. This effort also sought to develop process that were less labor intensive and more productive, specifically with respect to handling UBCs. It was recognized that the open hearth furnace was designed for remelting bulky scrap, which not only requires extensive charging time but also creates large amounts of skim. This layer of skim acts as an insulating blanket between the burners and the melt, severely reducing the thermal efficiency of the process. It became clear that the commitment to beverage can recycling necessitated a fundamental review of processing methods.

Excessive Skim Formation. The open hearth furnace consists of a relatively shallow molten metal container with a large surface area; the combustion chamber is located directly above the container. The scrap is piled up with this single chamber through a door in the front wall. The burners are aimed at the periphery of the solid charge. Because aluminum is a good heat conductor, the temperature of the scrap increases fairly uniformly, provided that the volume-to-surface-area ratio of the scrap is sufficiently high for conductive heat transfer. The protective nature of aluminum oxide films will, under these circumstances, prevent accelerated high-temperature oxidation, and the entire charge will melt at about the same time. The bath can then be skimmed. The clean surface facilitates rapid heating of the melt to the desired operating temperature.

The situation is vastly different however, when the scrap charge consists of shredded cans with a wall thickness of 0.13 mm (0.005 in.) and a heavy oxide layer acquired during thermal delacquering. The portion of the scrap contacted by the flame heats up and melts, but the unexposed metal remains cold, due to the poor heat transfer. The melting particles deform, breaking the oxide skin and exposing additional nascent metal to the harsh furnace environment. This metal immediately forms a new skin, while the particles solidify on the cold mass underneath. This melt/freeze cycle is repeated many times before the entire mass is melted. By then, a thick layer consisting of a mixture of oxide skins, trapped metal, and air covers the melt.

The Continuous Melting Concept. From the response of shredded can scrap melted in open hearth furnaces, it was reasoned that low-density scrap must not be exposed to the furnace atmosphere; this means that either the scrap must be submerged quickly in superheated molten metal inside the furnace, or molten metal has to be taken out of the furnace for external mixing with the scrap. The advantage of the latter procedure is that the inevitable skim (fortunately in much smaller amounts) can be captured outside the furnace as well. The resulting metal stream, cooled down but still molten, can be returned to the furnace for reheating by means of a molten metal pump. In this manner, a steady-state condition can be maintained if the heat required for melting a constant mass flow of scrap particles (plus makeup for heat losses) is equal to the net heat input into the furnace. The molten metal is mass balanced by equating metal overflow to the charge rate minus the skim generation rate times the oxidation constant (a correction for weight gain due to oxidation).

A few events can cause deviation from the steady-state conditions; for example, skim buildup on the metal in the furnace can change the heat transfer efficiency, and sludge buildup in the passageway can affect the circulation rate. Diagnostic sensors monitoring the process can detect the changes in the early stages and alert the operator.

Practical Applications. Several processes using continuous melting have been developed. For example, Alcoa developed three different methods (Ref 6, 7, 8) based on pump design variations; these designs create the scrap-ingesting vortex either in the pump bay itself or in an optimized adjacent charge bay (see Fig. 10). Although these methods differ in such areas as production capacity, scrap size tolerance, and hardware simplicity, the skim generation for a specific scrap type is equally low for all three methods. Several variations of this principle have been reported by other researchers (Ref 9, 10, 11), suggesting that the method is appealing to others in the industry who are also struggling to reduce melt losses.

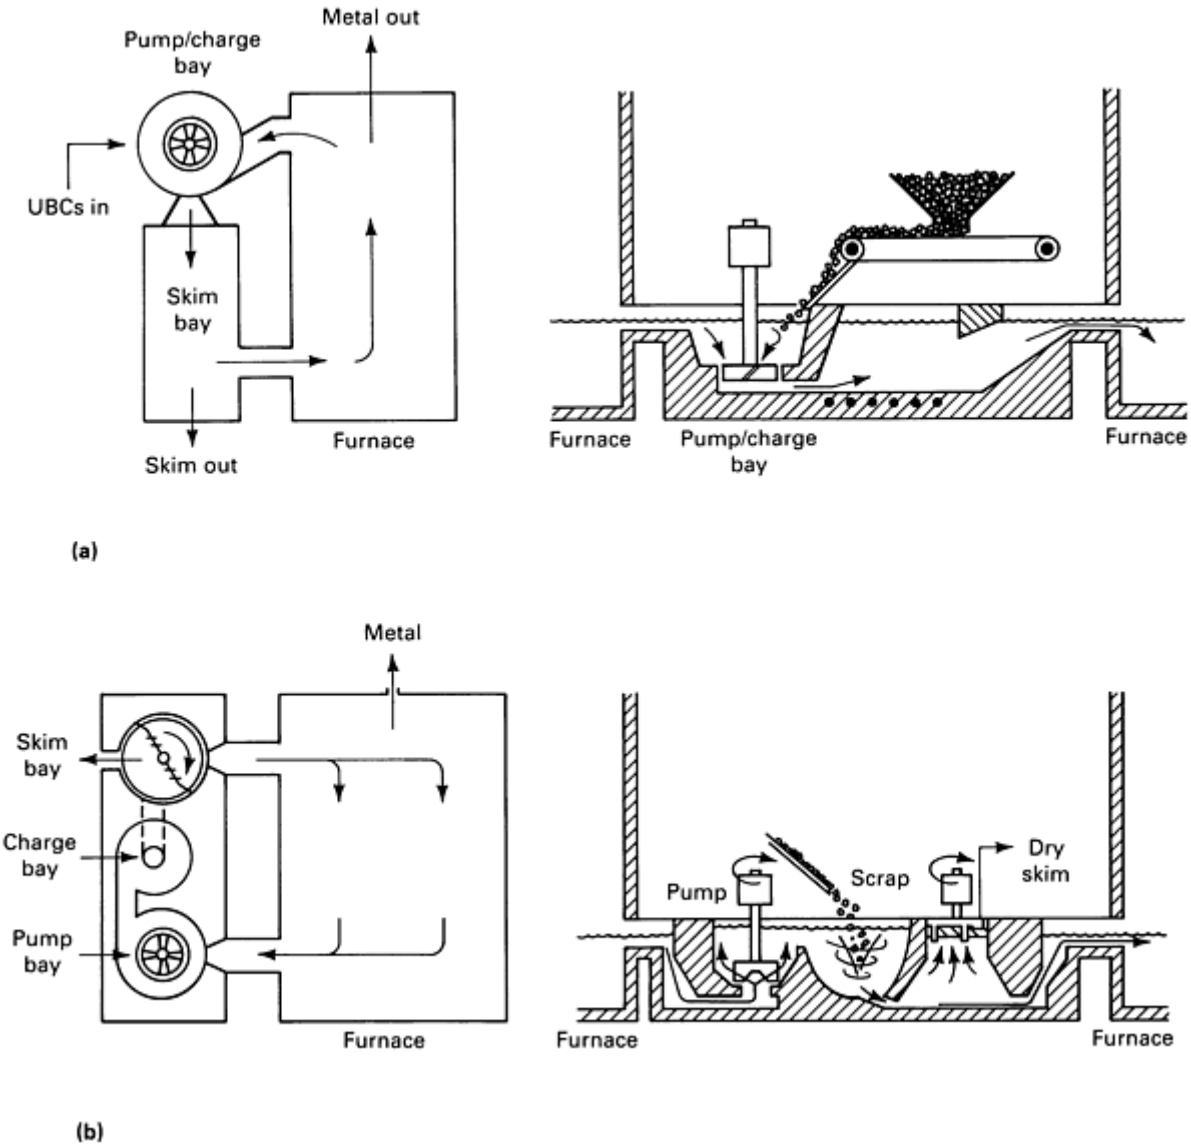

Fig. 10 Melting processes for UBC scrap. (a) Early can scrap melter. (b) More-advanced swirl scrap charge melter, which uses a continuous melting process

Another advantage of continuous melting is that the constant supply of waste heat can be utilized very effectively to preheat the constant flow of scrap and/or combustion air. In the batch process of the open hearth furnace, the supply and demand of waste heat for scrap preheating are essentially out of phase. The new melters improve fuel efficiency 12% on the basis of constant-waste heat utilization alone. Also,the fact that the skim is confined to a relatively small chamber outside the furnace offers an opportunity to maximize metal recovery from skim, without interfering with production.

Automobile Scrap Recycling Technology

In contrast with the explosive recent development of closed-loop can recycling, automobile recycling is an established industry, and it has traditionally been a multifaceted scavenging activity carried out by many independent entrepreneurs, without the focused objectives that prevail in can recycling. Material selection by car manufacturers is based on cost and performance; little consideration is given to what happens to the material at the end of the approximately 10-year life span of a car. Consumers are basically indifferent concerning material choice. Salvages and dismantlers take what they can get. They may have preferences, but they have no say in material selection.

Substantial amounts of aluminum had been applied in early car manufacturing, but between 1925 and 1946, its use was minimal. As mentioned before, the amount of aluminum in cars has steadily increased since 1946 (Fig. 6). Until 1975, most growth was in castings, but as a consequence of the energy crisis, more wrought alloy hang-on parts began to be used for weight reduction, and sheet metal panels and space frame constructions are now under development.

An average 1980 model can contains approximately 70 kg (155 lb) of aluminum, which accounts for only 5% of the total weight of the average car. Yet it is economically an important fraction. Figure 11 is a schematic showing one of several possible paths for the recovery of the majority of the materials presently used in cars. In alternative schemes, a water-based classification step (elutriation) is added to remove plastic and a portion of the rubber and glass. The aluminum fraction is usually sold to an automotive cast shop, which uses open hearth as well as induction furnaces and occasionally rotary salt kilns. The fraction of inseparable multimetallic particles must be treated in a sweat furnace. In some schemes, without heavy-medium or eddy current separation, the entire nonferrous fraction goes to the sweat melter. The chemical composition of this sweat pig metal can vary substantially, and this variation greatly affects the value of the product.

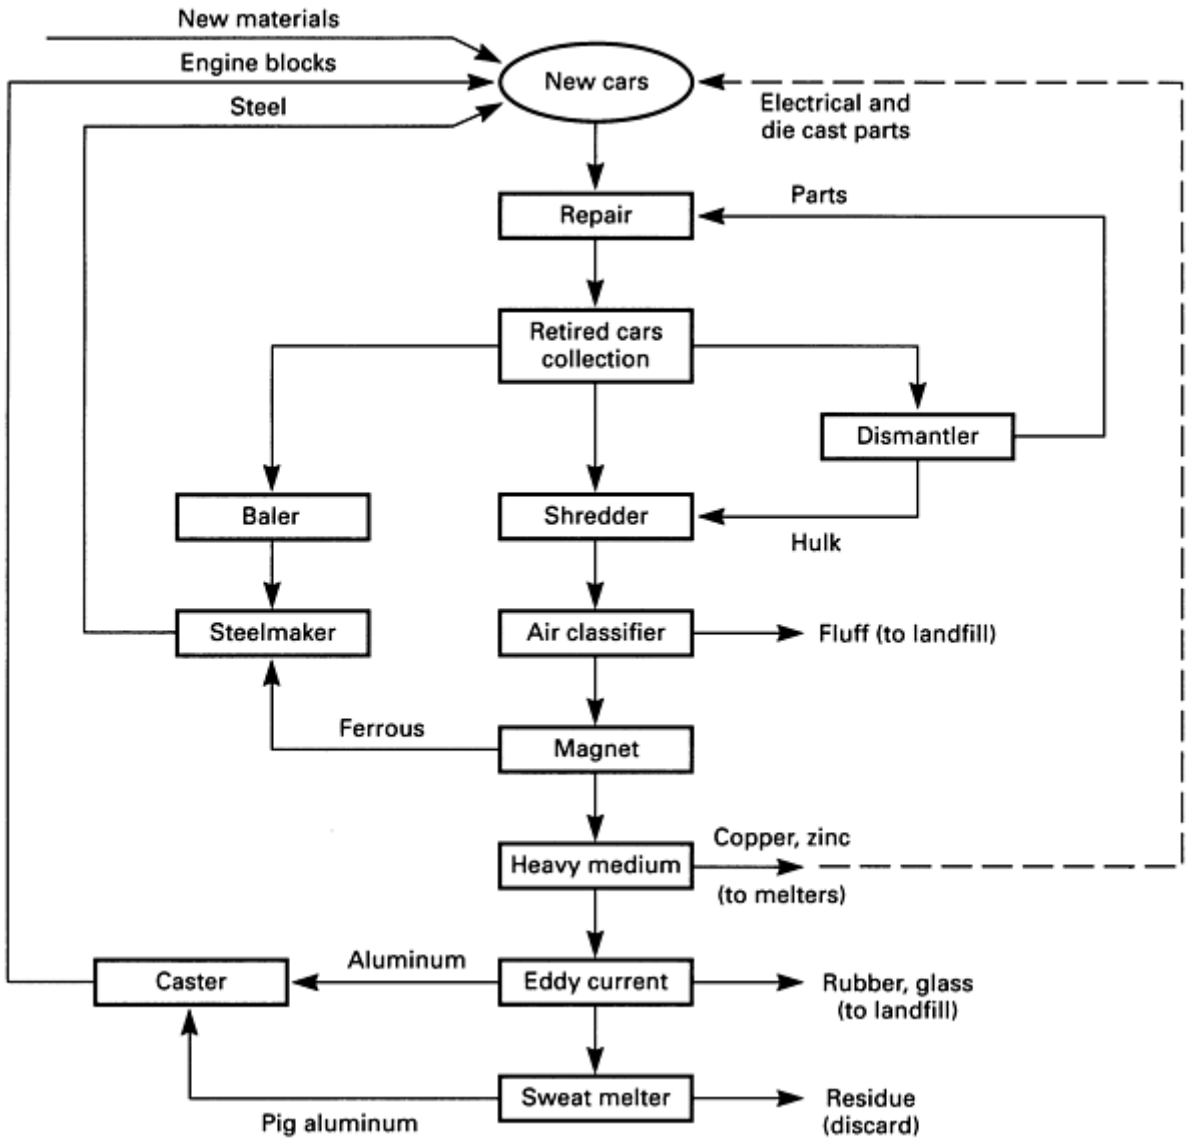

Fig. 11 Recycling loop for aluminum automotive components. Castings make up the bulk of aluminum automotive scrap.

The can recycling loop is totally dedicated to a single product of two compatible aluminum alloys. Automotive recyclers, on the other hand, must deal with a number of fractions with different destinations and relatively low values. These recyclers have not yet been driven to develop sophisticated technology to improve the quality and value of the fractions.

For automobile recycling to become as effective as can recycling, a cooperative effort is required by the scrap collectors, handlers, and manipulators to introduce advanced scrap separation and upgrading technology. A number of alternative scrap recovery methods have been developed for other mixed aluminum scrap sources, and these methods could be adapted for use in car recycling. They include improved pre-processing methods to concentrate aluminum fractions and mechanical, physical, and chemical separation processes for upgrading scrap mixtures and recovering aluminum from low-grade sources.

High-Temperature Process. Other processes, besides the delacquering processes for can scrap described earlier, have been developed for separating aluminum scrap. A fluid-bed rotary furnace has been developed in England to remove paint, plastic, and other combustibles from aluminum in a heated bed of inert material, such as alumina. Flights move the scrap through the drum furnace, and the evolving gases and fumes are led to an afterburner. Rubber and wood, which do not evaporate in this furnace, need to be removed in advance (Ref 12).

In Sweden, the so-called Granges box is in use. This is an oven consisting of two chambers, one for containing scrap, the other for combustion of gases and fumes released from the scrap. The scrap is heated in part by external sources and in part by recirculation of the hot POC from the combustion chamber. This batch process may be suitable for certain auto scrap fractions.

The U.S. Bureau of Mines has developed a hot crushing process for separating wrought and cast alloys. It works on the same principle as the thermomechanical alloy separation process for UBCs. This process appears to be tailor-made for automotive scrap, which contains increasing amounts of sheet and die cast alloys.

Low-Temperature Separation. Cryogenic separation has been performed commercially in Belgium on shredded automotive scrap. The method is based on the difference in ductility of nonferrous and ferrous metals at extremely low temperatures. Below -65 °C (-85 °F), ferrous metals become very brittle and can be fragmentized easily, whereas nonferrous metals remain ductile. Simple screening achieves separation. This method is expensive and should be used only for separation of mixed shredder fragments (of steel attached to aluminum, for example).

Gravity separation methods include the common-heavy-media/sink-float process mentioned earlier and a process developed in the Netherlands (Ref 13). The latter uses the same heavy medium (ferrite/water suspension), but it is not a passive sink-float method. Instead, the scrap is charged in a cyclone through which the heavy medium is pumped. In this manner, the sensitivity of the process is increased, and inaccuracies due to shape differences of the particles are decreased.

Other Processes. Several separation processes used in the mining industry deserve consideration for adaptation by processors of automotive scrap and municipal refuse. The U.S. Bureau of Mines has experimented with a jigging system in which gravity separation in a bed of shredded mixed scrap is obtained by pulsating liquid flows through the bed. A suspension is formed, and the less-dense material migrates to the top. A system of baffles, spigots, and screens is used to separate the fractions. The U.S. Bureau of Mines has also worked on a shaking-table process for recovering aluminum from municipal refuse incinerator residue. In this process, water flowing in a direction perpendicular to riffles on a slightly tilted vibrating table results in the less-dense material flowing over the riffles and washing downward, while the dense material travels upward between the riffles. This process could possibly be used for separating dirty, fine shredder fractions or dross.

A combined air classification/flotation process for separating wire and plastic insulation has been developed in Japan (Ref 12). After thorough shredding to detach the insulation from the wire and removing the larger metal pieces on a vibrating screen and air table, the light fraction (with up to 15% metal) is charged into a flotation separator to float off the plastic. If a method can be found to concentrate the substantial amount of wiring from the shredder output, this process could be useful for copper recovery, which, in turn would help prevent copper contamination of the aluminum fraction.

Physical separation methods already in use include electromagnetic, or eddy current, separators. These work by creating a force on a nonferrous particle that is traveling in a magnetic field; that created force is perpendicular to the direction of particle travel. The phenomenon is caused by induction of electrical currents when a conductor moves through a magnetic field, resulting in a Lorentz force. Equipment utilizing this phenomenon include the well-known scrap-carrying conveyor belt/electromagnet combination (Almag) and the lesser-known configuration of a sliding table with an array of permanent magnets mounted underneath to create an apparent alternating field for particles moving downward. These separators are presently used for separating nonferrous metal from nonmetallic particles. However, they can potentially be used for alloy separation, especially if shape differences are also characteristic, as in, for example, bulky cast alloy fragments mixed with light-gage wrought alloy sheet fragments (Ref 14).

Electrostatic separation methods, used in mineral separation, can be applied in metal/nonmetal particles separation. One possible application for these methods is the removal of glass, stones, and fiberglass from nonferrous and/or ferrous particles. Various other sorting systems are under study in various laboratories. One system is based on the color differences among copper, brass, and aluminum. Another uses x-ray fluorescence to detect specific elements. A third uses infrared thermal imaging. The success of these methods depends not only on the sensitivity and accuracy of the detection method, but also on coupling detection with a reliable removal method.

Recycling of Copper

David V. Neff, Metaullics Systems; Robert F. Schmidt, Colonial Metals Company

MANY DIFFERENT BRASSES, bronzes, and copper-base alloys exist in the world of scrap metals. Identification of these various grades can be by description, chemistry, a Copper Development Association (CDA) number, or a universal product code. The universal product code, developed by the Institute of Scrap Recycling Industries (ISRI), serves as an internationally accepted language and greatly facilitates the trading and marketing of scrap metals.

Scrap Classification

The grades discussed in this section are among the most common grades of copper alloy scrap. In an ever-changing industry where new alloys are introduced yearly and old standard grades become obsolete, an all-inclusive listing is impractical, and such a listing might be misleading in some instances. Solid scrap is most prevalent, but almost all grades are available as turnings. In some cases, skims, spills, and drosses are also available and desirable.

Red brass, or composition, has a typical chemistry of Cu-5Sn-5Pb-5Zn. The ISRI code name is ebony. It exists in the form of valves, fittings, pump impellers, plumbing items, and so on. This grade has been progressively replaced over the years by a number of semired brass alloys, and thus current red brass scrap might have a typical content of 80 to 83% Cu, 3 to 5% Sn, 3 to 6% Pb, and 5 to 8% Zn.

Yellow brass, or heavy brass, has a typical chemistry of 61 to 67% Cu, 1% Sn, 1 to 3% Pb, and 29 to 35% Zn. The ISRI code name for yellow brass scrap is honey. This scrap originates from lighting fixtures, valves, fittings, and other sources. Yellow brass should be free of automobile radiators and heater cores, as well as manganese and aluminum bronze.

Hard brass, or machinery brass, has a typical chemistry of Cu-10Sn-10Pb. Certain grades have higher lead contents; others contain a smaller percentage of zinc. The ISRI code name is engel. Hard brass scrap exists in the form of bearings, bushings, and other corrosion-resistant parts.

G metal, or high grade, has a typical chemistry of Cu-10Sn-2Zn. Some high grade contains a small percentage of lead or nickel. G metal scrap exists in the form of gears, pump bodies, fittings, and many naval applications.

M metal is a grade with a composition between those of red brass and G metal. Its typical chemistry is Cu-6Sn-1.5Pb-4Zn. M metal scrap exists in the form of fittings, pump bodies, high-pressure valves, and various naval applications.

Automobile radiators are very common and popular grade of scrap, with a typical chemistry of Cu-3Sn-9Pb-11Zn. The ISRI code name is ocean. Automobile radiators should be unsweated and free of iron, heater cores, shredded radiators, and aluminum radiators. Locomotive and diesel radiators are included in this category and are usually accepted.

Other Brasses. Admiralty brass (ISRI code, pales) has a typical chemistry of Cu-1Sn-29Zn. Aluminum brass (ISRI code, pallu) has a typical chemistry of Cu-1.5Al-24Zn. Both are generally used as condenser tubing and in heat exchangers. They should be unplated and free of sediment. Because of their original application, they should also be checked for possible residues. Various grades of aluminum brass are used in electronic and industrial applications; these are slightly higher in aluminum content and are usually referred to by their CDA numbers.

Nickel silver, or German silver, has a nickel content that spans at broad range: 7.5 to 18%. The copper content is 55 to 65%, and zinc makes up the balance. It exists in the form of hardware fittings, valve trim, ornamental applications, eyeglass frames, and other items.

Phosphor bronze, a copper-tin alloy, is found mostly in electrical and industrial applications. Grade A (C51000) has a typical chemistry of Cu-5Sn. Grade C (C52100) has a typical chemistry of Cu-8Sn.

Aluminum bronze has a typical chemistry of 78 to 90% Cu, 8.5 to 11.5% Al, and 1 to 5% Fe. Certain grades also contain 4 to 5% Ni. It exists in the form of marine applications, bushings, pump impellers, and other applications.

Manganese Bronze. Regular, or low-tensile, manganese bronze has a typical chemistry of 55 to 60% Cu, 1% Sn max, 4 to 2% Fe, 0.5 to 1.5% Al, 1.5% Mn max, and a balance of zinc. It exists as gears, valve stems, marine applications, and propellers. High-tensile manganese bronze exists in similar forms including bushings and cams. Typical chemistry of the high-tensile varieties is 60 to 68% Cu, 3 to 4% Fe, 3 to 7.5% Al, 2.5 to 5% Mn, and a balance of zinc.

70/30 Brass. Material consisting of 70% cu and 30% Zn is known simply as 70/30 brass (C26000). This grade is commonly found in the form of brass rifle shells (ISRI code, lake). They should be fired before shipment to a scrap consumer.

Free-Cutting Brass. Free-cutting rod brass solids (ISRI code, noble) and free-cutting rod brass turnings (ISRI code, night), like 70/30 brass, are popular brass mill items. The typical chemistry of rod brass is 60 to 63% Cu and 2.5 to 3.7% Pb, and a balance of zinc.

Other Scrap Grades. Other types of brass mill scrap include red brass pipe and yellow brass pipe (ISRI code, melon), with chemistries of Cu-15Zn and Cu-35Zn, respectively. Other nickel-bearing scrap items include Cu-10Ni, Cu-30Ni, and a variety of copper-nickel alloys. Also worth mentioning are lined railroad carbox journals (ISRI code, fence), silicon brass, low-brass house screen, paper mill screen, lined and unlined traction bearings, minnox metal, modine tubes, and a host of other grades that are usually identified by CDA numbers.

Pure Copper Scrap

There are three predominant grades of copper scrap: No. 1, No. 2, and light copper.

No. 1 copper (99+% Cu) consists of a number of categories including clean pipe and tubing, bare bright wire, burnt wire, green-line copper, busbar, and copper choppings. There are a number of ISRI codes (barley, berry, candy, and clover) that apply to this grade. All grades should be clean and free of any detrimental impurities; wire should have a minimum size of 16 gage. Certain grades of No. 1 copper, such as bare bright wire and heavy choppings, can command a premium price in the market place. Size and packaging are also factors in determining the price of the scrap.

No. 2 copper is usually sold with a minimum copper content of 96%. The ISRI codes for No. 2 copper are birch, cliff, and cobra. It should be free of excessively leaded, tinned, or soldered copper scrap; brass and bronze; excessive oil; iron; and ash and other nonmetallics.

Light Copper is sold with a minimum content of 92% Cu. It is also referred to as sheet copper or No. 3 copper, or by the ISRI code name dream. It usually consists of sheet copper, gutters, downspouts, kettles, boilers, and similar items.

Other grades of copper scrap are referred to as refinery or copper-bearing scrap. The value is determined by the percentage of copper recovered in a refinery process.

Recycling Technology

Collection Procedures. As shown in Table 1, huge amounts of copper-base scrap are recycled each year. Accumulating, processing, and preparing these amounts of scrap are not easy tasks. The peddlers and junkmen of yesterday have been replaced by the sophisticated and professional recyclers of today.

Table 1 U.S. consumption of copper scrap products from 1985 to 1988

Type of scrap	Consumption							
	1985		1986		1987		1988	
	Metric tons	Tons	Metric tons	Tons	Metric tons	Tons	Metric tons	Tons
No. 1 wire	348,087	383,694	389,198	429,010	410,636	452,641	416,655	459,275
No. 2 wire, mixed	278,047	306,489	338,031	409,870	383,862	423,128	409,332	451,204
Red brass	51,423	56,683	49,406	54,460	56,366	62,132	53,638	59,125

Source: U.S. Bureau of Mines

The material that finds its way to the scrap dealer comes from many sources. Obsolete scrap is perhaps the most common and abundant material. This category includes copper and brass from electrical and plumbing contractors, brass radiators from automobile wreckers and shredders, copper wire from telephone and power lines, railroad scrap, scrap from plant- and shopdismantling operations, and generally any copper-base item from homes, farms, industries, and municipal solid-waste operations.

Industrial scrap is another category that consists of large volumes of scrap material. Industrial scrap usually consists of new production material, for example, the skeleton or strip from a stamping operation, the turnings from a machining process, rod or tube ends, wire, or any item that a manufacturer would consider a reject because of chemistry, size, shape, or other parameters.

The last major source of copper-base scrap is the military. Most of this scrap is in the form of fired brass shell cases. There is, however, a good amount of obsolete and dismantling scrap generated throughout the various military bases.

After material has been scrapped, the scrap dealer must process, identify, and sort it into saleable commodities. Uniform industrial scrap is probably the easiest to market. Most brass and copper mills, as well as secondary smelters, consider it a premium item. Therefore, it is imperative that uniform scrap be free of impurities, and extra care must be taken to ensure its purity. Once contaminated, it becomes an entirely different grade with a lower value.

A large percentage of the scrap entering the recycling chain is mixed. This material must be graded or sorted into the correct scrap category. This is done in a number of ways. The quickest method for a trained, seasoned sorter is by color. Spot testing with acid is another method used to identify alloys. Magnets, files, grinders, and a host of commercial metal identification products also assist in making proper identification. If these procedures prove to be inconclusive, laboratory work, either by wet process or by x-ray method, can result in positive identification.

Once identified, the various grades of scrap are packaged for shipment. Boxed and drummed material is usually accepted at most mills. Bulky item such as automobile radiators, copper wire, and numerous sheets and strips are baled. Rod turnings, as well as some larger solids, should be shipped loose; this facilitates unloading by dumping or by a front-end loader.

Drosses, skims, and spills that result from secondary smelting can be handled in a number of ways. If the dross is high in metallic yield and does not contain any detrimental impurities, it can be reused directly into the rotary furnaces. Low-yield material is less likely to be used directly. The majority of this material is best suited for the copper refineries; these refineries can recover the copper fraction of the material, and they are less affected by impurities and low metallic yield.

Melt refining practices depend on the materials being recycled, that is, whether they are high coppers or copper-base alloys. Secondary, or recycling, practice for the high coppers usually involves remelting only; it is performed in small induction furnaces. An inert flux cover such as graphite is used to prevent oxidation loss. A reactive flux cover containing fluoride salts is also often used to provide some fluidity. The reactive cover prevents oxygen transfer into the melt and also helps strip oxide films that can form from reactive elements such as chromium.

For refining purposes, copper-base alloys can be divided into two groups; wide melting range alloys and narrow melting range alloys. The first group melts over a range of about 165 °C (300 °F) and includes such alloys as the red brasses and the tin bronzes. The second group melts over a range of 70 °C (125 °F) or less; some alloys in this group melt over a range as narrow as 16 °C (30 °F). Table 2 lists the current CDA designations and nominal compositions of selected alloys from both groups.

(a) All compositions contain a balance of copper.

Raw material for the first group usually consists of radiators, valves, fittings, bushings, bearings, machine turnings, grinding dust, and cupola slabs. Melting is done in reverberatory or rotary furnaces with capacities ranging from 13.5 to 63 metric tons (15 to 70 tons), depending on the monthly tonnage of the alloys sold. Refining is carried out by blowing air or oxygen into the molten charge and oxidizing all the lighter-element impurities. Impurities of sulfur, antimony, aluminum, iron, silicon, manganese, nickel, and phosphorus are usually present. Figure 12 shows the rate of reduction of the various impurities during the refining process.

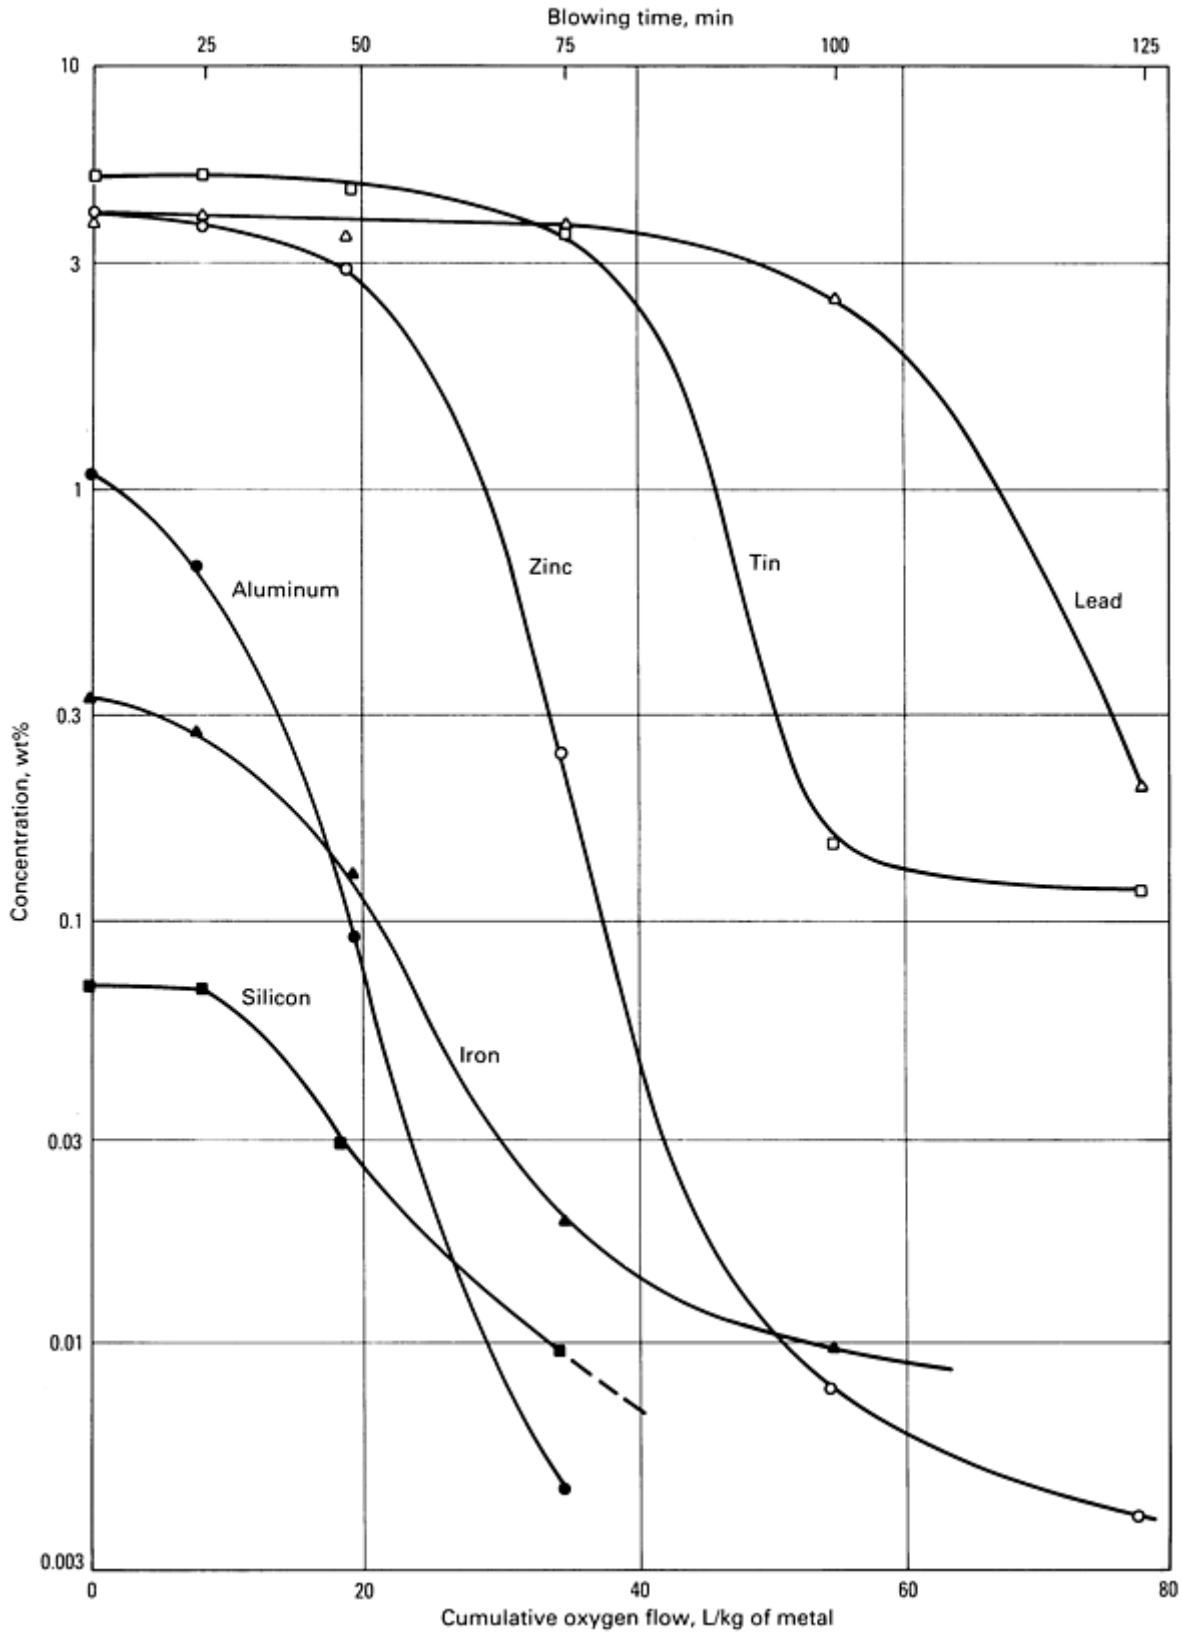

Fig. 12 Effect of fire refining on impurities in molten copper. Source: Ref 15

Aluminum is usually the first element to be oxidized out, followed by manganese, silicon, phosphorus, iron, and then zinc. Although zinc is oxidized out, it is usually a desired element. If too much is lost during smelting, additional zinc and tin must be added after refining to bring the specific alloy up to specification.

For the most part, lead, nickel, tin, and antimony cannot be refined out; they must be diluted out if the alloy is not within specification limits. Care must be taken to use known raw material for the charge so that these elements are not over the allowable maximum. Some success in refining lead and antimony has been achieved with soda ash fluxes (see the article "Nonferrous Molten Metal Processes" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.). Soda ash, borax, boron-containing mineral ores, silica sand, and coal screens are used as fluxes and covers to help with the refining processes and to control excess oxidation. During refining, continual chemical checks are used to monitor the removal of iron, aluminum, silicon, manganese, and phosphorus. These results can be obtained in less than 2 min with optical or x-ray spectrographs.

Alloys in the second group include the aluminum, manganese, silicon, and phosphor bronzes; copper-nickel; and nickel silver. Generally speaking, very close control is maintained over remelting these scrap materials, and contaminants and impurities are minimized in the charge materials. Consequently, alloys in this second group are generally not refined but are alloyed up from primary copper-base returns or virgin elements.

Because the total quantities of the second-group alloys are lower, they are usually made in smaller (4 to 22.5 metric ton, or 5 to 25 ton) rotary or high-frequency induction furnaces. Fluxes used include soda ash or borax, with fluoride salts to cut oxide skins. Virgin elements are usually used to produce aluminum bronze, high-strength manganese bronze, silicon bronze, brass, and copper-nickel alloys. Copper is melted first, and then manganese, iron, or silicon is added and worked in. Nickel, aluminum, or zinc is added next, depending on which alloy is being produced. All of these steps are checked as they occur by spectrographic analysis to ensure the right amount is added. The speed and accuracy of the chemical laboratory is an important factor in the production of these high-quality alloys.

Alloys sold on mechanical specifications are sand cast into test bars and checked to be sure they meet tensile property, yield strength, and elongation requirements. Many alloys in this second group have a wide range of acceptable compositions, but all of these may not meet certain restrictive mechanical property requirements. Consequently, mechanical testing is often mandatory.

Recycling of Magnesium

Michael Slovich, Garfield Alloys, Inc.

THE SECONDARY MAGNESIUM industry is quite small relative to other nonferrous recycling industries. There are two reasons for this: first, magnesium metal has not found the widespread acceptance of many other nonferrous metals, and second, approximately 80% of primary magnesium has historically been consumed by nonstructural uses for distributive and sacrificial purposes.

Scrap Sources

Magnesium scrap generally comes in forms similar to those of other nonferrous metals: new castings and the gates, runners, drippings, turnings, and drosses that result from such operations; and old scrap recovered at the end of the useful life of the magnesium-containing product. Since World War II, structural applications for magnesium have mainly been in the form of various wrought products and die and sand castings. Among the processes used to produce these products, die casting is the largest source of scrap magnesium.

Some forms of old scrap come from aircraft parts, such as wheels, fuselages, and control panels, and from military applications, such as incendiary bombs and tent support poles. Other significant sources of old scrap are discarded lawn mower decks, dock plates, chainsaws, and various hand tools.

By far, the single largest structural use of magnesium--and the largest source of magnesium scrap--has been Volkswagon Beetle die cast engine and transmission castings. When the use of magnesium in this application reached its peak in the mid-1970s, Volkswagon was consuming approximately 45,000 metric tons (50,000 tons) per year. Approximately 18 kg (40 lb) of magnesium was used in each vehicle.

Volkswagon continues to produce some magnesium engine blocks in Brazil and Mexico, but consumption in this application is significantly and permanently lowered. The main reason for the decrease in the use of magnesium in this application was the rapid price escalation of the metal that started in the mid-1970s; the price of magnesium quadrupled between 1973 and 1986. As a result, the secondary magnesium industry has seen a gradual reduction in the amount of old scrap available.

Because the supply of old magnesium scrap has come mainly from die cast and wrought products, it is useful to look at past consumption of primary magnesium by the producers of these items (Fig. 13). The data in Fig. 13 can be used to indicate the trend of the secondary magnesium industry because the amount of scrap generated is directly related to the amount of magnesium consumed in the production of these structural items. Although there are some rather large fluctuations in usage from year to year, Fig. 13(a) indicates an overall declining trend in die casting use. As shown in Fig. 13(b), wrought product consumption has virtually remained flat. All told, annual magnesium consumption has decreased by approximately 4500 metric tons (5000 tons) in recent years.

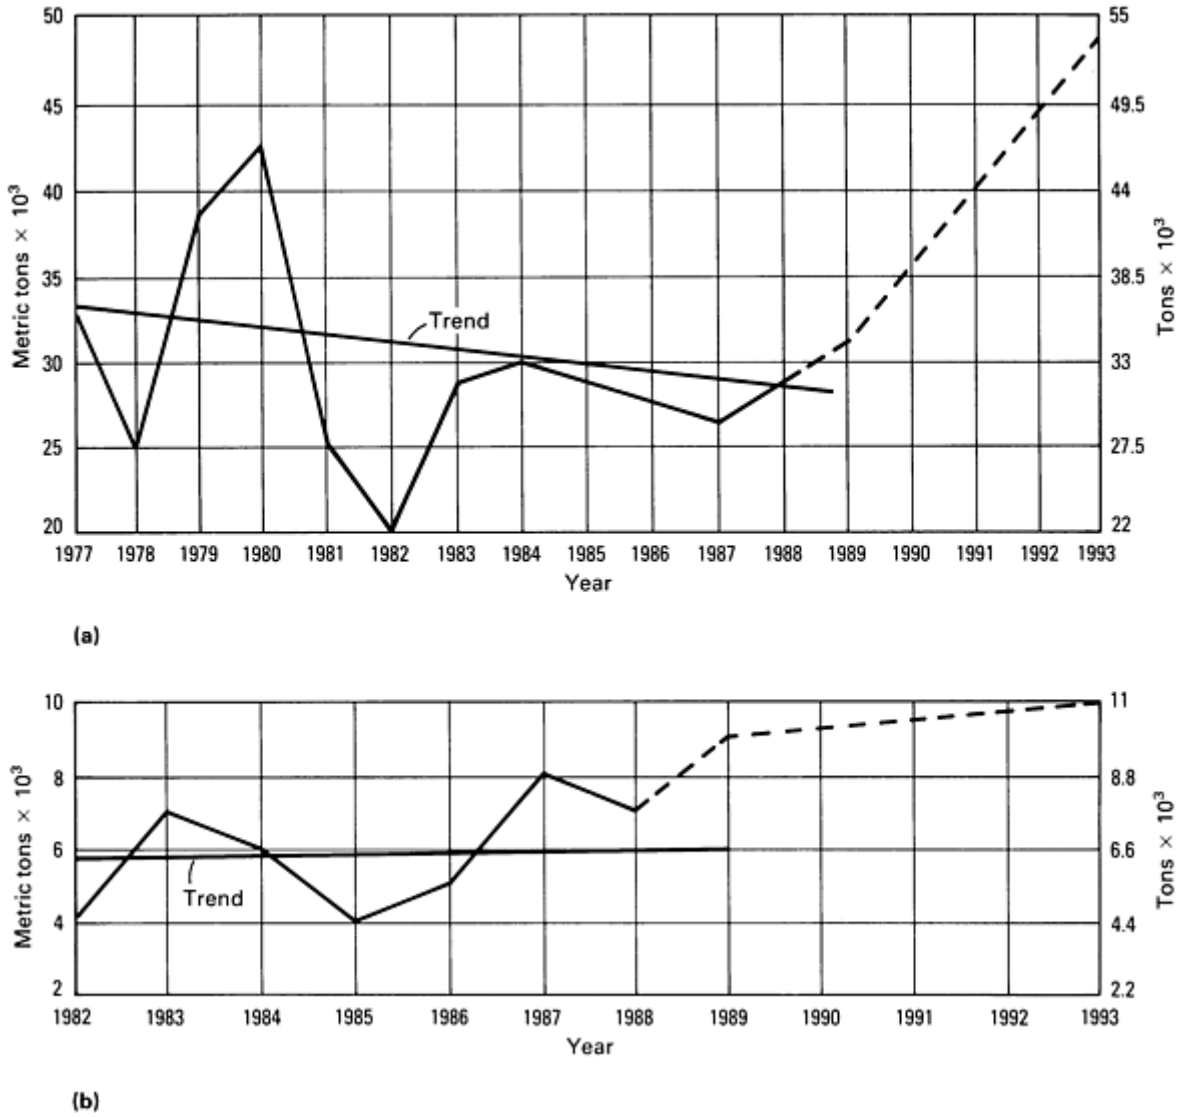

Fig. 13 Magnesium consumption in the United States. (a) Die castings. (b) Wrought products. Source: Ref 16

However, a recent resurgence in the use of die cast magnesium in the automotive industry has created additional sources of new magnesium scrap. As shown in Table 3, the amount of new magnesium base scrap processed annually more than tripled from 1987 to 1988. On the other hand, the amount of old magnesium-base scrap processed has generally been declining since 1984, and this trend will continue in the foreseeable future. Eventually, the parts currently being placed in automobiles will return to the secondary market as the cars are scrapped, but this will not happen for many years.

Table 3 Magnesium recovered from scrap processed in the United States

Kind of scrap	**Amount recovered**							
	1985		**1986**		**1987**		**1988**	
	Metric tons	**Tons**	**Metric tons**	**Tons**	**Metric tons**	**Tons**	**Metric tons**	**Tons**
New scrap								
Magnesium base	1,510	1,664	991	1,092	845	930	2,641	2,911
Aluminum base	16,252	17,914	17,822	19,645	20,868	23,000	19,926	21,964
Old scrap								
Magnesium base	4,630	5,104	3,958	4,363	3,857	4,251	3,882	4,279
Aluminum base	18,906	20,840	19,036	20,983	19,595	21,600	23,758	26,188
Total	**41,298**	**45,522**	**41,807**	**46,083**	**45,165**	**49,785**	**50,207**	**55,343**

At present, between 80 and 90% of recycled magnesium is used in recycled aluminum alloys, the most common of which are used to make aluminum beverage cans.

Recently, the price of magnesium die cast alloys has remained quite stable relative to the large fluctuations in the price of secondary aluminum alloys. The planned expansion of primary metal production will affect future pricing. The opening of two new facilities is expected to increase the free-world magnesium production capacity by approximately 20%. This projected new capacity should ensure stable or reduced prices for current and potential magnesium consumers.

On the technological front, the development of high-purity alloys that provide improved corrosion resistance has been a major factor in promoting the use of magnesium in applications where the metal is exposed to the elements. More information on these alloys is available in the articles "Selection and Application of Magnesium Alloys" and "Properties of Magnesium Alloys" in this Volume.

The two factors mentioned above--price stability and significant technological developments--coupled with the enlistment of new die casters to produce magnesium parts and continued market development by all participants, should provide the proper conditions for significant growth in the magnesium industry.

Magnesium Recycling Technology

Magnesium scrap is most often received loose on a dump trailer or in boxes on a van-type trailer. Because magnesium closely resembles aluminum, many suppliers have difficulty separating magnesium from aluminum. Consequently, a load of magnesium scrap will often contain a percentage of aluminum scrap. Therefore, it is imperative that the secondary magnesium facility have qualified personnel who can hand sort and identify foreign materials. The most-used method of separating aluminum from magnesium scrap involves scratching the metal with a sharp knife. Magnesium tends to flake, whereas aluminum will curl because of its relative softness. Once the extraneous materials have been removed, the remaining magnesium scrap must be sorted according to alloy. This process is absolutely critical in creating a product to specification.

Magnesium scrap storage piles, whether indoors or out, should have a width of at least 10 ft or one-half the pile height. For outdoor raw material storage, a pile should be no closer to any building than one-half the pile height. These practices help ensure safety as well as ease of access.

Melting. The sorted scrap is set up and charged into the furnace according to the type of alloy of the scrap relative to the desired composition for the finished metal. Once the scrap has been fully charged and melted, a sample is extracted for preliminary spectrographic analysis. If this analysis indicates a composition that does not meet desired specifications, adjustments are made by adding alloying elements such as aluminum, zinc, or manganese to the melt as needed. If the preliminary analysis indicates an excess of an alloying element or the presence of any tramp elements, the metal can be sweetened by adding pure magnesium to the melt to reduce the excess as a percentage of the whole.

Several proprietary techniques are involved in the economical and safe processing of fine magnesium turnings, borings, and powders. The same is true in processing magnesium dross for metal recovery. Drosses can be effectively recycled, assuming there is enough metal content in the dross itself. Generally, if the metal content is less than 15 to 20%, it is not economical to recover metal from magnesium dross. Anyone involved with such materials should be aware of the inherent dangers if they are mishandled. These materials pose the obvious danger of fire; in addition, they must be kept absolutely dry to avoid oxidation. Oxidation yields heat and hydrogen, which can result in spontaneous combustion. When handled properly, magnesium in both the solid or finely divided form is not dangerous. As with most other things, mishaps are usually the result of carelessness.

Magnesium scrap is melted in steel crucibles at a temperature of 675 °C (1250 °F). A fluxing agent is used to remove impurities such as oxides. The molten metal can then be handled in one of three ways; manual ladling, pumping, or tilt pouring. Because molten magnesium oxidizes rapidly, the metal should be cast immediately once the desired chemical specifications have been attained. Such a practice will minimize the danger of crucible failure and maximize metal recovery.

Overheating magnesium during melting causes several problems. First, even minor overheating will cause oxidation, thereby reducing metal recovery. Second, if the metal is at the appropriate temperature when alloying or sweetening materials are added, the alloying efficiency is increased and the danger of spit back is reduced. Third, significant overheating will cause the metal to burn, creating a potentially dangerous situation. Fourth, overheating, and the corresponding rise in the chamber temperature of the furnace, increases the oxidation of the crucible. As the crucible becomes heated to excess, pieces of the steel crucible begin to flake off in the form of iron oxide, increasing the possibility of leaking. If the crucible begins to leak, and if molten magnesium comes in contact with the iron oxide in the furnace chamber, a catastrophic thermic reaction could result.

Properties of Secondary Magnesium. The properties of secondary and primary magnesium die-cast alloy ingot are identical, assuming both are within chemical specification limits and all inclusions are removed from the metal. Any residual impurities left in the metal could cause a variety of problems for the die caster, depending on the type and amount of contamination. For example, flux inclusions in the ingot that are not removed in the die casting process will cause corrosion. Similarly, the presence of heavy metals (nickel, iron, copper, and silicon) in the alloy could cause premature oxidation.

The recent introduction of high-purity magnesium alloys has played a major role in gaining the attention of the worldwide automotive industry. However, these high-purity alloys are a double-edged sword for the die caster. The stringent specifications for these alloys have made it virtually impossible for the caster to recycle his own scrap in-house while maintaining high-purity specifications. Therefore, the die caster must sell the scrap to, or have it tolled by, a qualified secondary facility that can maintain quality by culling out any nonconforming materials. Indeed, such a facility is far more qualified to handle scrap and produce a quality metal alloy than a die caster; the die caster is geared toward producing castings of high integrity using source materials that meet chemical and physical specifications.

Recycling of Tin

William B. Hampshire, Tin Information Center

THE RECYCLING OF TIN is intimately interconnected with the recovery of metals other than tin. Even the briefest examination of the applications of metallic tin will reveal its ability to wet and coat a variety of base metals, including iron and copper. This property was the basis for the development of tinplate, which combines the strength and durability of steel with the nontoxic protection of a thin coating of tin to create the preeminent food container material. Soldering, the other substantial use for tin metal, also relies heavily on the ability of tin to wet a variety of metallic surfaces. In all cases, other metals must provide the required mechanical strength because tin itself is quite soft.

The cost of tin is relatively high compared with that of the more-common metals. Cost considerations keep the amount of tin used in its applications at a minimum. For example, bronze normally contains only a few percent of tin, perhaps up to 10%. Tinplate typically contains only 2 to 3 kg (4 to 6 lb) of tin per ton of steel (about 0.25% by weight). Because of this dilution of the tin content in so many of its major applications, it is very difficult to recover tin as tin metal, and it is often recycled as an alloy of the more-dominant metal.

Bronze and tin-containing brass are usually recycled by melting and realloying to produce alloys that are the same as, or similar to, the input metal. Tinplate is sometimes detinned, but the very low percentage of tin in the material makes the process less cost-effective than in earlier years, when tinplate was produced with a higher fraction of tin. Solders can be recycled; for example, solders from radiators (usually high-lead alloys), can be sweated out for recovery, but surface tension forces and alloying tend to severely limit the amount of solder that can be recovered in this way. In all these cases, tin is being recycled, but the larger proportion of recycled material consists of copper, steel, or lead.

Kinds of Scrap Tin Materials

Basically, two general types of tin-rich materials can serve as sources for secondary tin. The first type consists of mostly metallic tin that is usually fairly high in tin content. Prices for this type are quoted in *American Metal Market.* The specific scrap grades within this type--block tin, and high-tin babbitt and pewter--are consistent enough to identify and define.

Block Tin. Pure tin is widely preferred as the containing material for high-quality distilled water. Less than 1 ppb Sn is expected to dissolve in freshly distilled water contained in tin. Large pipes and conduits of pure tin metal are found in some stills, and the general term for these pieces is block tin. Because block tin is of commercial purity and easily melted down, it commands a high premium as a secondary material. For cost considerations, block tin has often been replaced by heavily tinned copper tube; of course, this material has a much lower value for recycling.

High-Tin Babbitt and Pewter. These related alloys typically consist of about 90% Sn, with antimony and copper added as hardeners. The tin babbitts would likely come from worn-out or damaged bearings. It seems unlikely that much pewter would find its way into the secondary market; it is more likely to be repaired.

The U.S. Bureau of Mines makes the following stipulations concerning the content of these materials (Ref 18):

- *Block tin* must contain a minimum of 98% Sn, and it must be free of liquids, solder, brass connections, pewter, pumps, pot pieces, and dirt
- *High-tin-base babbitt* must contain a minimum of 78% Sn, and it must be free of brass-like metals and high-zinc metals
- *Pewter* can consist of tableware and soda fountain boxes, and it must contain a minimum of 84% Sn. Siphon tops

should be accounted for separately. The material must be free of brass, zinc, and other foreign metals

Other Materials. The second general type of tin-rich secondary tin source material contains significant proportions of tin oxides. Drosses from hot-tinning posts or from soldering pots are examples of this type of material. The specific scrap grades lack any consistency and thus can be defined only by individual assay. The chemical stability of tin oxides makes these scrap forms more difficult to process for the recovery of the tin values. Therefore they are less popular as sources of secondary tin than materials from the first group, and they are usually resmelted with flue dusts and/or tin concentrates from ore.

Facts and Figures on Recycled Tin

Figure 14 shows data for annual tin consumption in the United States. The secondary tin market shows good stability, and this can be attributed to the relatively high cost of tin and the corresponding viability of tin recovery. The level of secondary tin consumption has remained fairly consistent at about 33% of primary tin consumption. In the 1970s, when tinplate accounted for a larger share of tin consumption, this percentage was about 25% because tinplate producers have always preferred to use primary tin for their products.

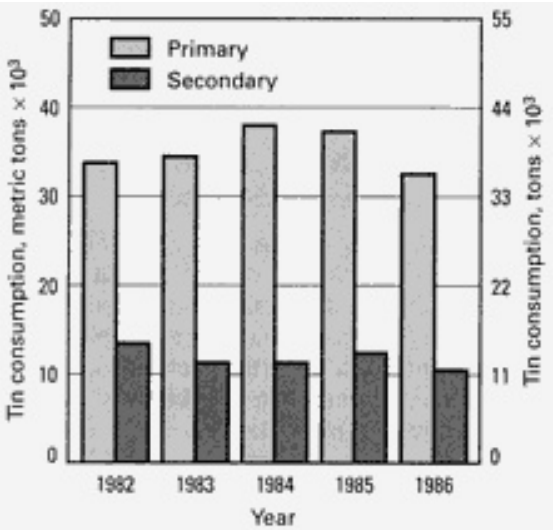

Fig. 14 Primary and secondary tin consumption in the United States from 1982 to 1986. Source: Ref 18

Figure 15 shows 1986 data for U.S. tin consumption by sector. These values are the latest complete set available at the time of publication. The solder market and the bronze and brass market consume substantial amounts of secondary tin. The "other" category includes tin chemicals, which are often made from secondary tin. In fact, in some detinning schemes tin is removed chemically from scrap tinplate and is converted into another chemical (often for use in tin-plating) without ever being recovered as tin metal.

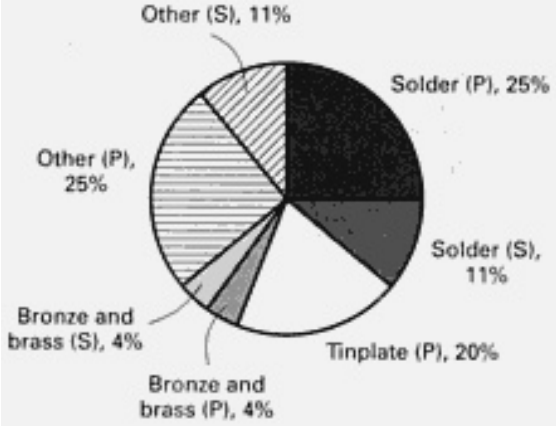

Fig. 15 U.S. primary and secondary tin consumption by sector for the year 1986. Consumption of secondary tin for tinplate withheld to avoid disclosing proprietary data; included in "Other (S)." P, primary; S, secondary. Source: Ref 18

Stott (Ref 19) divides the secondary tin industry into segments and provides estimates for the amount of tin recovered per year in each segment:

- Tinplate scrap processing, 1200 metric tons (1320 tons)
- Secondary copper industry, 6800 metric tons (7500 tons)
- Secondary lead industry, 6575 metric tons (7250 tons)
- Processing of clean tin residues and complex residues, 150 metric tons (165 tons)

The total is just under 15,000 metric tons (16,500 tons) per year, although, as Stott points out, statistics on this industry are subject to some variation.

The secondary copper and secondary lead segments are mentioned only briefly in the following section; they are covered in the sections "Recycling of Copper" and "Recycling of Lead" in this article. Processing of tinplate scrap is given relatively more attention. The recovery of tin-rich residues is discussed to the extent possible, given the complexity of such operations.

Recycling Technology

Collection of tin-containing secondary materials is often done industrially. Clean tinplate scrap generated by can manufacturers is the preferred input for a detinning operation because this feedstock is predictable and free of difficult contaminants. Recycled municipal waste is more heavily contaminated and may have been incinerated (which alloys the tin with the steel), making it more suitable for adding directly into the steelmaking process without detinning. Research is ongoing into scavenging additions that could remove tin from the basic structure of the steel. Such additions might greatly encourage the recycling of the ferrous fraction of municipal scrap.

Bronze and brass turnings, drosses, and so on are often collected by metal fabricators for return to the metal supplier. The supplier simply returns the scrap, after some cleaning, to the melting facility for input into similar alloys. Tinned copper wire scrap is also an obvious candidate for direct melting in copper alloys. In general, because tin is used in small proportions with other metals, successful recycling of the tin values depends on collection of the scrap metal at the earliest possible stage of fabrication, before additional dilution can take place.

The high-tin forms (block tin and high-tin babbitts) are collected after used during the dismantling of stills or bearings. The dismantlers will know the value of such parts (typically $2 to 3 per pound, much higher than most scrap) and will remove them as completely and efficiently as possible to maintain the high value. Also, it is important to keep block tin separate from high-tin babbitt or pewter to maintain the scrap value. Block tin is made from Grade A tin; if it is collected without contamination, it can simply be substituted for primary Grade A tin, which is the normal commercial quality tin metal.

Used electronic equipment is sometimes dismantled to allow recovery of the solder (see the section "Recycling of Electronic Scrap" in this article). Miniaturization of electronic components is making this recovery more difficult. Stott (Ref 19) has estimated the tin content of electronic scrap to be about 1% by weight.

Processing. The high-tin scrap (metallic type) is most often recycled by pyrometallurgical techniques, usually by realloying. Block tin will probably need no processing, except to convert it in the same manner as purchased tin ingot. High-tin babbitt or pewter will ordinarily be recycled by remelting, then adding the recycled material, all or part, to new metal during the melting and casting process. Attempts to refine the metal by removing either the antimony or copper from the alloy would prove very difficult. It is the affinity of tin for wetting and alloying with other metals that makes recycling, in the sense of recovering the tin values as tin, difficult to the point of extreme inefficiency.

Tin removal from a copper surface, especially by sweating, might be contaminated with copper. This copper can be removed by treatment with sulfur, which then itself must be removed by oxidizing. When iron is the contaminant of concern, it is removed by boiling. This procedure is akin to poling as practiced in the copper industry, even to the point of using green wood poles to accomplish it. Antimony is removed by an aluminizing treatment. Finally, for removing zinc, careful additions of ammonium chloride or sulfate can be used. Nearly all of these procedures can generate noxious fumes or by-products, and they should be practiced only by those with some experience (see Ref 20, 21).

Tinning or solder drosses (oxide type) from hot tinning or soldering pots are usually recycled by smelting. These drosses will normally contain substantial proportions of metal entrained in the oxides, which again is due to the wetting ability of tin. First, a liquidation process is used: The material is heated to above the metal (solder or tin) melting temperature and held at the temperature while the metal melts and is collected. Roasting or leaching may also be necessary as pretreatment steps. The resulting and remaining oxides can then be smelted by heating to a very high temperature with carbonaceous reducing material in a blast furnace or a reverberatory furnace (see Ref 19, 20, 21).

Detinning of tinplate scrap is usually accomplished by either an alkaline leaching method or chlorine detinning. The alkaline process has been the more popular in recent years. It involves dissolving the tin off the tinplate scrap by immersion into a caustic solution. This solution is then passed through electrolytic cells, where the tin is plated out of the solution. The tin thus recovered is easily refined to high purity, and the caustic solution is recycled. The steel that emerges from processing is a clean product that can be used directly by a steel mill or foundry.

Chlorine detinning uses dry chlorine gas at elevated temperature and pressure to react with the tin coating to produce stannic chloride in gaseous form. This reaction is exothermic; cooling is required to remove the heat and to condense the product. These complications, along with the relative difficulty of handling chlorine gas, have led to a decline in the use of this recovery method.

Tinplate is a significant portion of the ferrous fraction of municipal refuse. Therefore, the increasing interest in recycling municipal scrap is having a complex effect on the detinning industry (see the section "Current Trends and Future Expectations" in this article).

Recycled Metal Behavior

Recycled tin from a detinning operation, when it is electrolytically removed from the solution in a tankhouse, is comparable to or better than the fire-refined primary tin metal. In fact, some of the highest-purity tin has been produced

by such a recovery process. Provided both the primary tin metal and the secondary tin metal meet Grade A requirements, there should be no noticeable performance differences. Composition requirements of Grade A tin are:

Element	Content, %
Tin, min	99.85
Antimony, max	0.04
Arsenic, max	0.05
Bismuth, max	0.030
Cadmium, max	0.001
Copper, max	0.04
Iron, max	0.010
Lead, max	0.05
Nickel plus cobalt, max	0.01
Sulfur, max	0.01
Zinc, max	0.005

There has emerged some concern in certain solder-using industries, notably electronics assembly, that the use of secondary solder may produce more soldering defects, although concrete data seem to be lacking. Nevertheless, to help reassure solver users, some recent specifications (especially U.S. Naval Weapons Specification WS 6536) now call for regulating the sulfur and phosphorus contents of the incoming solder alloy. Typical recovery of secondary solder might begin with a sulfur treatment to remove excess copper. An oxidation step comes next, followed by a phosphorus treatment to reduce the oxides; the presence of oxides could lead to higher sulfur and phosphorus contents than in virgin solder. No other specifications seem to try to distinguish secondary product in this way.

Current Trends and Future Expectations

The recycling of tin is well established. Processes developed over the years have gained a degree of stability and acceptance, and developments are more a matter of refinement than of truly new processing. The current interest in recycling of materials may make more tin available for processing, but because tin is so valuable, most of the easily recoverable tin is already being processed.

Tinplate can be easily separated magnetically with the ferrous fraction of municipal scrap, and the recently established Steel Can Recycling Institute is encouraging municipalities to do so. Much of this tinplate scrap will be fed into the

steelmaking process without detinning because of its low tin content. Therefore, the tin will be recycled but not recovered as tin metal, unless it is separated from steelmaking residues.

Several recent developments in processing tinplate scrap are allowing increased rates of recycling for steel cans. Better pretreatment techniques allow detinners and recyclers to accept some food residues, paper labels, and aerosol and paint cans, all of which were previously unacceptable in the feed material (Ref 22). Some municipalities are beginning consumer curbside sorting. All these factors can lead to a cleaner, more dense steel input material for the steel mills. As scrap yards gain experience in the handling of steel can scrap, the recycling rate will no doubt continue to rise dramatically.

Research has shown other potential uses for tinplate scrap. Tin is well known as a useful addition to cast irons, functioning as a pearlite stabilizer at a level of about 0.1%. Adding tin can scrap to the melt can achieve this effect as efficiently as using tin metal additions. Thin is also added with copper to ferrous powder metallurgy parts in which it functions as a sintering aid. Research at the International Tin Research Institute has shown that tinplate scrap can be used for this purpose in place of tin metal with no detrimental effect on the product (Ref 23, 24).

It is much less clear how the recycling of solder can be increased. The recent trend in electronics assembly has been to use techniques, such as surface mounting, that use smaller and smaller joints of solder. Solder use has held steady due to the production of more joints, but these smaller joints make any attempts at recycling the metal very difficult.

Recycling of Lead

R. David Prengaman, RSR Corporation

LEAD HAS THE HIGHEST RATE of recycling of all metals. Because of its corrosion resistance, lead scrap is available for recycling decades or even centuries after it is produced. Environmental regulation in the United States has greatly reduced the dissipative uses for lead such as paint, leaded gasoline, pigments, stabilizers, solder, and ammunition. The remaining lead products are recyclable (Ref 25).

Production of Recycled Lead

Table 4 gives data for the world production of lead from recycled and mined (primary) sources for 1980 to 1988. At present, just under half of the total world lead production of 4.3 million metric tons (4.7 million tons) comes from recycling of scrap materials. As indicated in Table 4, there has been very little change in recent years in the total amount of lead production or in the percentage of recycled lead. Only in the past few years has the amount of recycled lead increased. This may be due to the increasing availability of batteries throughout the world.

Table 4 World lead production from 1980 to 1988

Type of lead	Production, metric tons × 10^3 (tons × 10^3)

Table 5 gives data for U.S. production of lead from recycled and mined sources for 1980 to 1988. Beginning in 1984, there was a dramatic increase in the percentage of lead produced from scrap in the U.S. despite a decrease in overall lead production. By 1984 the major dissipative use for lead, leaded gasoline, had decreased to a small percentage of the overall lead market. The percentage of recycled lead production has increased dramatically in recent years, from 50% of production in the late 1970s and early 1980s to about 65% in 1988. The rate of lead production from scrap materials is expected to increase dramatically in the future. The major market for lead in the United States is now lead acid batteries: Batteries constitute almost 80% of U.S. lead consumption.

Table 5 U.S. lead production from 1980 to 1988

Type of lead	**Production, metric tons × 10^3 (tons × 10^3)**

Sources of Lead Scrap

The major source of scrap lead for recycling in the United States and throughout the world is lead acid batteries. In the United States, scrapped lead acid batteries and the associated manufacturing plant scrap represent over 90% of the contained lead available for recycling. Used automobile batteries represent about 85% of the lead acid battery scrap materials. Other lead recycled scrap materials are sheaths from telephone and power cable, lead pipe and sheet, weights (particularly automobile and truck wheel weights), anodes, printing metals, drosses, residues, sludges, and dusts.

In Europe and throughout most of the rest of the world, scrapped lead acid batteries represent only about half of the lead scrap input to recycling plants. Scrap cable covering, lead sheet and pipe, and miscellaneous metal scrap items represent a much higher percentage of input scrap to recyclers in these countries than those in the United States. As the number of vehicles increases, the percentage of scrap represented by lead acid batteries will increase.

Battery-Recycling Chain

The battery-recycling chain has changed dramatically over the past ten years. The changes have resulted from environmental regulation, changes in battery-processing technology, changes in battery distribution and sales techniques, changes in lead-smelting technology, and changes in the lead alloys used in the batteries.

Battery Scrap Collection and Processing. In the 1970s, batteries were distributed primarily through full-service gasoline stations. Smaller amounts were distributed through hardware stores, automobile supply stores, and mass merchandise outlets. The scrap batteries were recovered by the service stations and sold to scrap dealers, who also recovered batteries from wrecked or worn-out automobiles. The scrap dealers then sold the batteries to battery breakers and smelters. The battery breakers (numbering about 300 in 1975) decased the batteries, drained the acid, and recovered the plates for sale to the lead smelters. The higher lead content of the battery plates made it cost-effective to ship plates longer distances than whole batteries.

Environmental Regulations. In the 1980s, environmental legislation was passed regulating lead acid battery recycling. Rules were promulgated regarding the storage, processing, and transportation of batteries and battery scrap. Batteries and battery components are considered hazardous waste after arrival at a battery breaker or smelter if they are cracked or leaking acid, or if they are disposed of in landfills. Scrap batteries can be stored for only 90 days, after which they must be sent to a recycler or disposed of in a hazardous-waste landfill. Because only permitted processors can break batteries, the number of battery breakers has declined markedly. Only a few breakers still remain. Battery breaking is now performed mainly by lead smelters.

Battery-Breaking Processes. In the 1970s, most battery breakers used saws for decasing. In this process, the top is severed, the acid is drained, and the plates are dumped from the case. The lead posts are recovered from the tops by crushing and separation. This process is still utilized by many lead smelters in the United States and throughout the world.

In the late 1970s and early 1980s, several mechanical processes were developed to break the batteries. Technologies were developed to crush the whole batteries, separate the case from the lead-bearing materials, separate the hard rubber (ebonite) and separators from the plastic cases, and, in some cases, separate the paste portion of the battery from the metallics (Ref 26, 27, 28). The acid is neutralized in a separate procedure. A recent innovation desulfurizes the paste, produces lead carbonate, recovers sodium sulfate crystals, and recycles the H_2O (Ref 29). Virtually all battery-wrecking processes now recycle the polypropylene battery cases. Battery breakers process from 5000 to more than 50,000 spent automobile batteries per day.

Lead-Smelting Processes

The major smelting processes to recycle lead scrap involve the use of blast furnaces, short rotary furnaces, long rotary kilns, reverberatory furnaces, electric furnaces, and top-blown rotary furnaces.

Blast Furnaces. For many years blast furnaces were the primary furnace for recycling lead. Today, about one-half of the U.S. recycling plants utilize blast furnaces as the primary smelting furnace (Ref 30). In other plants, blast furnaces are used to recycle slags, drosses, and residues from other processes. Blast furnaces require metallurgical coke, produce large volumes of gas that must be filtered, require a special charge, require afterburners to burn carbon monoxide contained in off-gases, and produce slag and matte that, in some cases, may be considered hazardous materials. Blast furnaces produce a bullion that is high in antimony; this bullion can be readily refined into lead-antimony alloys.

Rotary Furnaces. In most of the world other than the U.S., rotary furnaces (long, short, and top blown) have replaced blast furnaces as the major smelting vessel for lead recycling (Ref 31, 32, 33). Rotary furnaces are very versatile. They can accept virtually any type of lead-bearing feed material, including battery scrap, dust, drosses, scrap lead, and sludges. Rotary furnaces can use any carbon source such as coal, coke, or ebonite as reducing agent, and they can use a variety of fuels, such as oil, coal, or gas. Because they are batch furnaces, rotary furnaces can be operated in stages to produce low-impurity bullion for refining to pure lead, or they can completely reduce the charge to recover all metal values for production of lead-antimony alloys. Rotary furnaces generally use Na_2CO_3 and iron as fluxes, which produce a fluid, low-melting slag. Rotary furnace slags are generally considered hazardous wastes in the United States. Because of the hazardous nature of rotary furnace slag, these furnaces are not currently used by major lead-recycling companies in the United States. Most of the rest of the world does not classify rotary furnace slags as hazardous.

The reverberatory furnace is one of the major smelting furnaces used to recycle battery scrap in the Unites States. In the reverberatory furnace, battery scrap is melted and the alloying elements in the battery grids and scrap are oxidized to the slag. With the use of controlled reducing conditions, the reverberatory furnace can produce virtually all low-impurity bullion suitable for refining to pure lead. Slag from reverberatory furnaces is smelted in the second furnace, usually a blast furnace (Ref 34) or an electric furnace (Ref 35), to produce a high-antimony bullion for production of lead-antimony alloys. The electric furnace is capable of producing a nonhazardous slag.

Scrap as Charge for Primary-Lead Furnaces. Recycled battery scrap, particularly the paste portion, is often added in small amounts to the charge of sinter machines in primary-lead smelters. New lead-smelting processes can utilize lead battery paste as a substantial portion of the charge (Ref 36). Very little scrap is currently smelted by primary-lead companies in the United States.

Lead Sweat Furnaces. Small amounts of lead are recycled via lead sweat furnaces. The primary materials recycled in sweat furnaces are lead-coated power and communications cable, lead sheet and pipe, and other products that contain lead as a coating or as part of a complex part. The process is performed at relatively low temperatures and produces both metal for refining and dross; the dross is recycled to smelters. The total amount of lead recycled in sweat furnaces is estimated to be less than 18,000 metric tons (20,000 tons) per year.

Refining of Recycled Lead

In most of the world, lead recyclers produce lead-antimony alloys for use as battery grids and straps. The recycled pure lead generally goes into nonbattery sources such as sheet, pipe, cable, and gasoline additives. The pure lead for battery oxide is generally supplied by primary-lead smelters. In the United States, maintenance-free batteries with lead-calcium alloy grids make up about 30% of the market, and hybrid batteries with lead-antimony positive grids and lead-calcium negative grids represent 60%; lead-antimony grid batteries constitute only 10% of the battery market. Lead-calcium alloys account for 60% of automotive battery grid production in the United States. Virtually all standby batteries use lead-calcium alloys.

Initially, the lead-calcium was supplied by the primary-lead companies. Lead recyclers, however, changed their smelting and refining techniques to produce pure lead and lead-calcium alloys. Currently, virtually all lead recyclers in the United States produce pure lead and/or lead-calcium alloys for batteries; however, very few recyclers throughout the rest of the world produce substantial amounts of refined pure lead for batteries.

Specifications for Recycled Lead

Throughout much of the world, two lead specifications prevail: one with a minimum of 99.99% Pb and the other with a minimum of 99.97% Pb. The major impurities in lead are antimony, arsenic, bismuth, copper, nickel, silver, tin, and zinc. Recently, selenium and tellurium have been added as important impurities in the United States. Primary-lead companies generally produce the 99.99% Pb grade, whereas recyclers produce the 99.97% Pb grade. The major difference in the lead grades in that recyclers generally do not remove the bismuth and silver in their refining process. Recycled lead generally contains sufficient bismuth to preclude reaching 99.99% purity.

U.S. Lead Specifications. The ASTM B 29 composition specification for refined pure lead is shown in Table 6. This specification permits a content of up to 0.05% Bi. Because of this bismuth content, the purity of the lead can be as low as 99.94%. In virtually every U.S. application, bismuth contents of 200 to 500 ppm are permitted. Thus, recycled refined pure lead can be utilized in almost every application if the other impurity limits are also met.

Table 6 Composition specifications for pure lead in the United States

Element	Specified composition, max wt%			
	ASTM B 29	Common grade	Typical battery oxide grade	Typical highly refined recycled grade
Antimony	NS	NS	0.0010	0.0001
Arsenic	NS	NS	0.0010	0.0001
Tin	NS	NS	0.0010	0.0001
Antimony, arsenic, tin (combined)	0.002	0.002	NS	NS
Silver	0.0015	0.005	0.005	0.0017
Copper	0.0015	0.0015	0.0010	0.0005

Lead, min	99.94	99.94	99.97	99.85

(a) (a) NS, not specified

Gas-Producing Impurities. More important than restrictions of bismuth and silver in U.S. lead specifications has been the restriction of elements that increase gas generation in lead acid batteries. Many batteries in the United States are sealed or restrict access to the cells for water additions. Elements that promote decomposition of the electrolyte and production of gas upon charging are specified at very low levels regardless of the overall purity of the lead. The specification for pure lead for battery oxide given in Table 6 restricts antimony, arsenic, nickel, and tellurium to low levels, whereas nongassing impurities such as bismuth, silver, and copper are permitted at higher levels. In the most restrictive specifications, all the gas-producing impurities are restricted to a content of 1 ppm or less.

Recycled Pure Lead. Because the major concern of U.S. battery manufacturers is the gas-producing impurity elements in pure lead, lead-recycling companies have developed pyrometallurgical refining techniques to remove these elements to low levels (Ref 37). A typical analysis of highly refined recycled pure lead is given in Table 6. When refined pure lead is produced by recyclers, it is readily accepted by battery manufacturers. Only an occasional specification can be found that restricts bismuth or silver to levels not readily attained in recycled pure lead.

Government Regulations Regarding Recycling

The lead industry, and particularly the lead recycling industry, must conform to increasingly stringent environmental regulations. Lead acid batteries, the major raw material of recyclers, has been declared a hazardous waste. Because batteries are the largest source of lead, they constitute the major source of lead contamination in land-fills and incinerators.

Proposed legislation would require recycling of all lead acid batteries, require manufacturers or distributors to accept spent lead acid batteries, and require return of the batteries to recyclers to prevent improper disposal. If such legislation is passed, even higher rates of lead recycling will result.

New Lead Recycling Processes

Several new processes have been developed to recycle lead acid battery scrap that use hydrometallurgical processes (Ref 38, 39), rather than conventional pyrometallurgical processes, to treat the paste portion. In these processes, $PbSO_4$is

converted to $PbCO_3$, PbO_2 is converted to soluble form, and the lead is leached into solution and electrowon to produce high-purity cathodes. These processes have not been developed beyond the pilot state; however, several recyclers have announced plans to construct large-scale plants for recovery of lead from battery paste by electrowinning.

Recycling of Zinc

Michael Bess, Certified Alloys, Inc.

ZINC, in its various forms, can be recycled like most other nonferrous metals. Recycling can take the form of recovery of the metallic content from scrap zinc and by-products or by the conversion of various zinc-base residues into chemicals.

This article will deal with recovery of the metal content from zinc sources such as scrap and residues (such as galvanizing and die casting drosses).

The zinc recycling industry, worldwide, produces approximately 20% of total zinc production. Of this quantity, about 300,000 tons/year are in the form of secondary zinc metal. The scrap that feeds this industry is in the form of either process scrap (such as zinc sheet clips) or old scrap (discarded, used castings, and so forth), which becomes available after the products containing zinc are removed from service. Typical sources of scrap include: reject castings, flash, trim scrap, and dross from the die casting industry: clips, edge trim, and skeletons from zinc sheet processors; old zinc roofing; reject battery cans; and top and bottom dross from the galvanizing industry. Table 7 illustrates U.S. production of zinc from scrap for the years 1987 and 1988.

Table 7 Zinc recovered from scrap in the United States in 1987 and 1988

Scrap	**Amount recovered**			
	1987		**1988**	
	Metric tons	**Tons**	**Metric tons**	**Tons**
New scrap

Sources of Zinc Scrap

The majority of zinc used is consumed by the galvanizing industry. Zinc, which is metallurgically combined with steel during galvanizing, cannot be readily separated from galvanized steel scrap. This scrap is often reprocessed in steel mills, leading to the generation of flue dust. This dust contains a relatively high quantity of zinc (typically 20%), which is generally recovered as crude zinc oxide for metal production (see the section "Recycling of Zinc From EAF Dust" in this article).

Die casting consumes approximately 25% of the zinc in North America. The die casting alloys typically contain about 4% Al and up to 1% Cu. Zinc die castings are generally small, from less than one ounce up to several pounds in weight. They are frequently found as components in complex assemblies such as in automobiles, appliances, and electronics. Separation of castings from these larger assemblies is difficult, as is the identification of zinc in the presence of other nonferrous metals.

All operations involving the melting of zinc or zinc-rich alloys will generate oxides. These oxides usually entrap additional metal and create products commonly referred to as dross, ash, or skim. These products are collected and are treated to release the metallic content. Often they also become the starting raw material for the production of zinc oxide and other chemicals.

During various manufacturing processes, internally generated metallic scrap can usually be recycled in-plant. Zinc enters the recycling stream as a function of product life cycle. Building products such as roofing and flashing are readily recoverable and are an excellent source of zinc (typically greater than 80% is recovered), but the product life is long, greater than 25 years. Old die cast components also provide high metal recovery (80%), but recovery of the products they are contained in is typically low, averaging from 10% in appliances and hardware to 50% in automotive and large machinery applications. Product life cycles are somewhat shorter than for rolled zinc, in the range of five to twenty years.

On a worldwide basis, zinc consumed for galvanizing is the highest end use for the metal. Therefore, residues from galvanizing are the most important source of secondary zinc. Collection of drosses by steel mills is a good source, and the cycle time from initial zinc use to re-use is typically less than one year. Depending upon the steel and galvanizing process, drosses, ash, and skimmings range from 10 to 40% of the total zinc consumed in the galvanizing process.

Recycling Technology

As previously stated, the identification and separation of die castings from assemblies is difficult. Auto shredders and gravity separation are two of the most effective measures for recovering this type of recyclable zinc. For example, in the United States, die casting consumes about 25% of all zinc, but because of these difficulties, only 15% of recoverable zinc comes from this use sector. Where zinc scrap may be present with other, higher-melting metallics, the best processing equipment is a sweat furnace, which melts the zinc but not other materials such as copper, aluminum, and steel. Lower-

melting nonmetallics (plastics and rubber) are simply burned off in this process. Before treatment in a sweat furnace, removal of free ferrous materials by magnetic separation is preferred, to minimize iron pickup and reduce energy consumption.

Steel mill flue dust is reduced in rotary kilns, with zinc-lead vapor being produced along with chromium and iron in a slag. The vapor is reoxidized to produce feedstock for subsequent furnace recovery to metal.

Galvanizer's dross is high in zinc (90 to 95%) but also contains lead, tin, iron, and aluminum. Being heavier than the molten galvanizing alloy, these elements sink to the bottom of the galvanizing vessel for subsequent removal. Recovery of zinc is usually accomplished by distillation from a retort. Either metallic zinc dust or zinc oxide can be produced by this method. The light, galvanizer's top dross contains primarily zinc with smaller quantities of aluminum, lead, and tin. Iron is usually present in much lower levels than in bottom dross. This dross can be reacted with various chemical fluxes to release the entrapped metallic zinc, which can be cast into blocks for subsequent use as secondary zinc or as starting material for products like galvanizing brightener (a zinc-aluminum alloy added to galvanizing baths).

Die casting drosses usually are of high purity, their composition being similar to the high-purity die casting alloys from which they are formed, except for generally higher aluminum and iron levels. Again, simple melting and treatment with chemical fluxes is practiced to release the metallic content. Recovery is normally in the range of 50 to 75%. Metal recovered in this process generally is used to produce galvanizing brightener or other zinc-aluminum master alloys.

Recycling of Zinc From EAF Dust

Charles O. Bounds, Rhône-Poulenc, Inc.

ELECTRIC ARC FURNACE (EAF) dust, a baghouse product from environmental control activities, is generated by vaporization of metals such as zinc, lead, and cadmium during electric arc furnace steelmaking. Historically, the zinc content of the dust has been too low to permit economic recovery. As late as 1985, more than 70% of the dust was being discarded in landfills (Ref 41). However, the 1984 reauthorization of the U.S. Resource Conservation and Recovery Act (RCRA) recommended a moratorium on the landfilling of EAF dust after August 1988 (since delayed until August 1990). This legislation has substantially increased the cost of disposal, resulting in the emergence of a dust processing industry. Currently, more than 60% of the dust is being recycled in the United States (Ref 42); a similar pattern has emerged throughout the developed countries of the free world.

EAF Dust Characteristics

In the United States, carbon steel EAF dust, predominantly composed of submicron particles of magnetite, hematite, zinc oxide, and zinc ferrite (Ref 43), contains from about 5 to nearly 40% zinc (average ~20%) as well as the hazardous constituents lead, cadmium, and chromium (see Table 8). The lead, cadmium, and chromium contained in the dust are leachable in the Environmental Protection Agency (EPA) toxicity test, and thus, the dust is a listed hazardous waste.

Table 8 Typical chemical composition of EAF dust

Constituent	Amount, %
Valuable metals	

Zinc	5.0-37.8
Iron	13.0-44.0
Problem impurities	
Lead	0.7-7.0
Cadmium	0.01-0.16
Nickel	0.002-0.07
Chlorine	0.1-3.9
Fluorine	0.05-1.6
Sulfur	0.05-1.0
Sodium	0.2-2.0

Manganese	1.5-7.0
Silica	0.15-2.8
Calcium	1.7-3.0
Aluminum	0.05-1.2
Chromium	0.04-3.1

Source: Ref 43

Current estimates (see Table 9) of EAF dust generation and handling worldwide indicate that approximately 800,000 metric tons (880,000 tons) of dust are being processed annually in the free world, with more than 150,000 metric tons (165,000 tons) of zinc being recycled each year. The EAF dust generation rate is expected to grow substantially during the next decade. For example, in the United States the EAF market share is expected to grow from 30 to 50% by the year 2000, with an equivalent increase in EAF dust production (Ref 45). The quantity of zinc available for reclaiming could more than double if the percentage of galvanized steel production increases as expected by industry analysts.

Table 9 EAF dust processing statistics

Country	Amount processed annually	
	Metric tons	**Tons**
West Germany	55,000	60,500
Italy	65,000	71,500
Spain	70,000	77,000
Japan	295,000	325,000
United States	350,000	385,000
Total	**835,000**	**920,000**

Recycling Technology

The predominant technology used for the recovery of zinc from EAF dust is the Waelz kiln process, a technology employed since the early 1900s for the beneficiation of oxidic zinc ores. Currently 12 kilns arereported to be operating in the free world (Ref 46). The kilns are operated similarly worldwide (Ref 47, 48, 49, 50, 51), with the EAF dust being mixed with coal and a flux and fed to the kiln as shown in Fig. 16. The materials in the kiln roll along the inside slope of the kiln; hence, the name Waelz from the German word *waelzen,* which means "to roll."

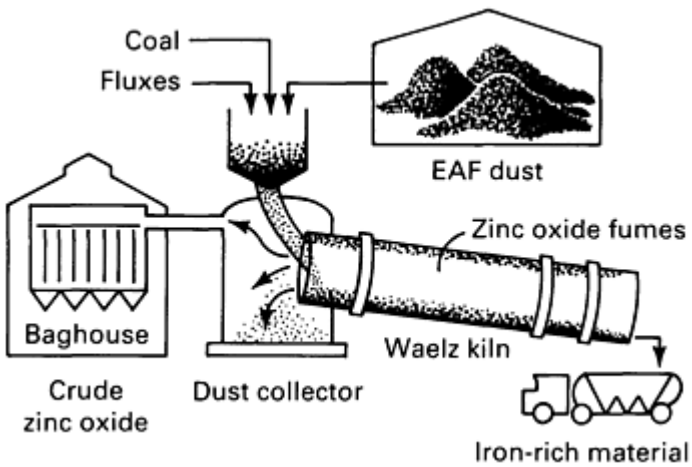

Fig. 16 Operation of a Waelz kiln for recycling zinc from EAF dust

Several different reactions occur as the material flows through the kiln:

- Feeds are dried and preheated
- Halide and alkali compounds are volatilized
- Iron oxides are partially reduced
- Zinc, lead, and cadmium are reduced and fumed
- Metals are reoxidized above the bed and collected

Thus, both reduction and oxidation are simultaneously occurring in the kiln. Occasionally, the energy provided by coal combustion is supplemented by natural gas or oil combustion via a burner at the discharge end of the kiln.

Dust processing in a kiln generates two marketable products: a mixed zinc/lead oxide and an inert iron-rich slag. Typical analyses of Waelz kiln feed and products are presented in Table 10. The leachate from the EPA toxicity test on kiln slag is consistently below the toxicity limit; the material has been sold as a road base, antiskid agent, Portland cement additive, and an aggregate in highway blacktop.

Table 10 Compositions of typical Waelz kiln feed and products

Element	**Composition, wt%**		
	EAF dust	**Oxide**	**Kiln slag**
Zinc	17.5	52.4	1.9
Iron	23.1	4.2	33.8
Calcium	9.1	1.4	11.4
Silicon	1.7	. . .	6.6
Sodium	0.64	1.2	0.51

Manganese	2.9	0.56	3.7
Magnesium	1.9	0.39	2.4
Aluminum	0.46	0.12	1.1
Lead	2.6	7.2	0.41

Cadmium	0.66	0.76	<0.001
Copper	0.23	0.087	0.47
Chromium	0.12	0.026	0.18
Nickel	0.03	0.01	0.07
Tin	0.04	0.09	0.02
Chlorine	1.03	3.58	<0.01

Source: Ref 42

The concentration of the alkali metals and halides, as well as other nonferrous metals, in the crude zinc oxide, limit its marketability as a zinc raw material. Generally, at least the alkalis and halides are removed by leaching, calcining, and/or hot briquetting. Even after preprocessing, the only significant outlet for the oxide is as a raw material for pyrometallurgical zinc plants, such as the Imperial Smelting Furnace or the Electrothermic Process. In fact, most Waelz kiln operations are integrated or closely aligned with a zinc smelter.

New Dust Processing Technologies

Alternative dust processing technologies have been under development throughout the 1980s. Hydrometallurgical techniques, both alkaline- and acid-base leaching processes, have been investigated but in general have rarely appeared economical (Ref 52). The new pyrometallurgical approaches have generally been targeted to directly produce metallic zinc and/or to be more economically scaled to small plants than the Waelz kiln. The most significant of these new developments are:

- *Tetronics Plasma Process:* This process (Fig. 17) unites a transferred arc plasma furnace to fume nonferrous metals with an Imperial Smelting Process (ISP) zinc condenser that recovers the metals in the molten state (Ref 53)
- *SKF Plasmadust Process:* Similarly, Plasmadust uses a coke bed to fume the nonferrous metals with the heat provided by the gas from a nontransferred arc plasma gun and the metal vapors being condensed in an ISP unit (Ref 54). One commercial plant was erected in Sweden for EAF carbon-steel dust processing, which has since been converted to process stainless dust because of repeated condenser failures.

- *Elkem Electric Furnace Process:* In the Elkem Multi-Purpose Electric Furnace (Ref 55), agglomerated EAF dust is charged into the furnace slag from which the nonferrous metals are selected, reduced, fumed, and then condensed in an ISP condenser. To date, one steelmaker has committed to install the Elkem Process
- *HRD Flame Reactor Process:* HRD has developed a natural gas-fired version of its Flame Reactor technology (normally fired with coal or coke breeze) to provide a lower capital cost, on-site processing unit (Ref 56). Reactor temperatures in excess of 1450 °C (2640 °F) selectively reduce the nonferrous metals and produce a vitrified, nonfluxed slag and a marketable mixed metal oxide similar to that produced in a Waelz kiln. The process is shown in Fig. 18
- *ZIA IRRS Process:* The ZIA approach is to fully reduce and volatilize the ferrous and nonferrous metals from pelletized EAF dust, collecting the fumed fraction as an oxide and returning the iron (85% metallized) to the electric arc furnace. The mixed oxide is to be reduced to metal in a vertical retort (Ref 57)
- *BUS Circulating Fluid-Bed Process:* The CFB reactor is being developed for steel dusts with low zinc and lead contents (Ref 58). In the fluid bed, lead and zinc are volatilized, leaving behind a highly metallized iron product

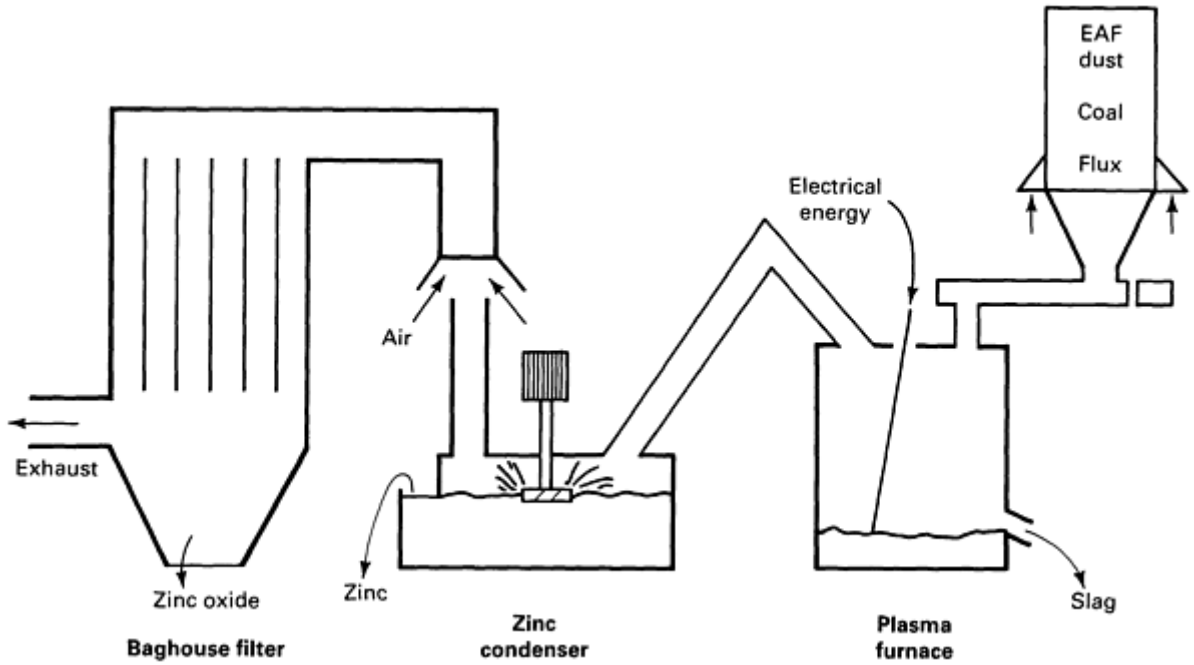

Fig. 17 Tetronics plasma treatment plant for recycling of zinc from EAF dust

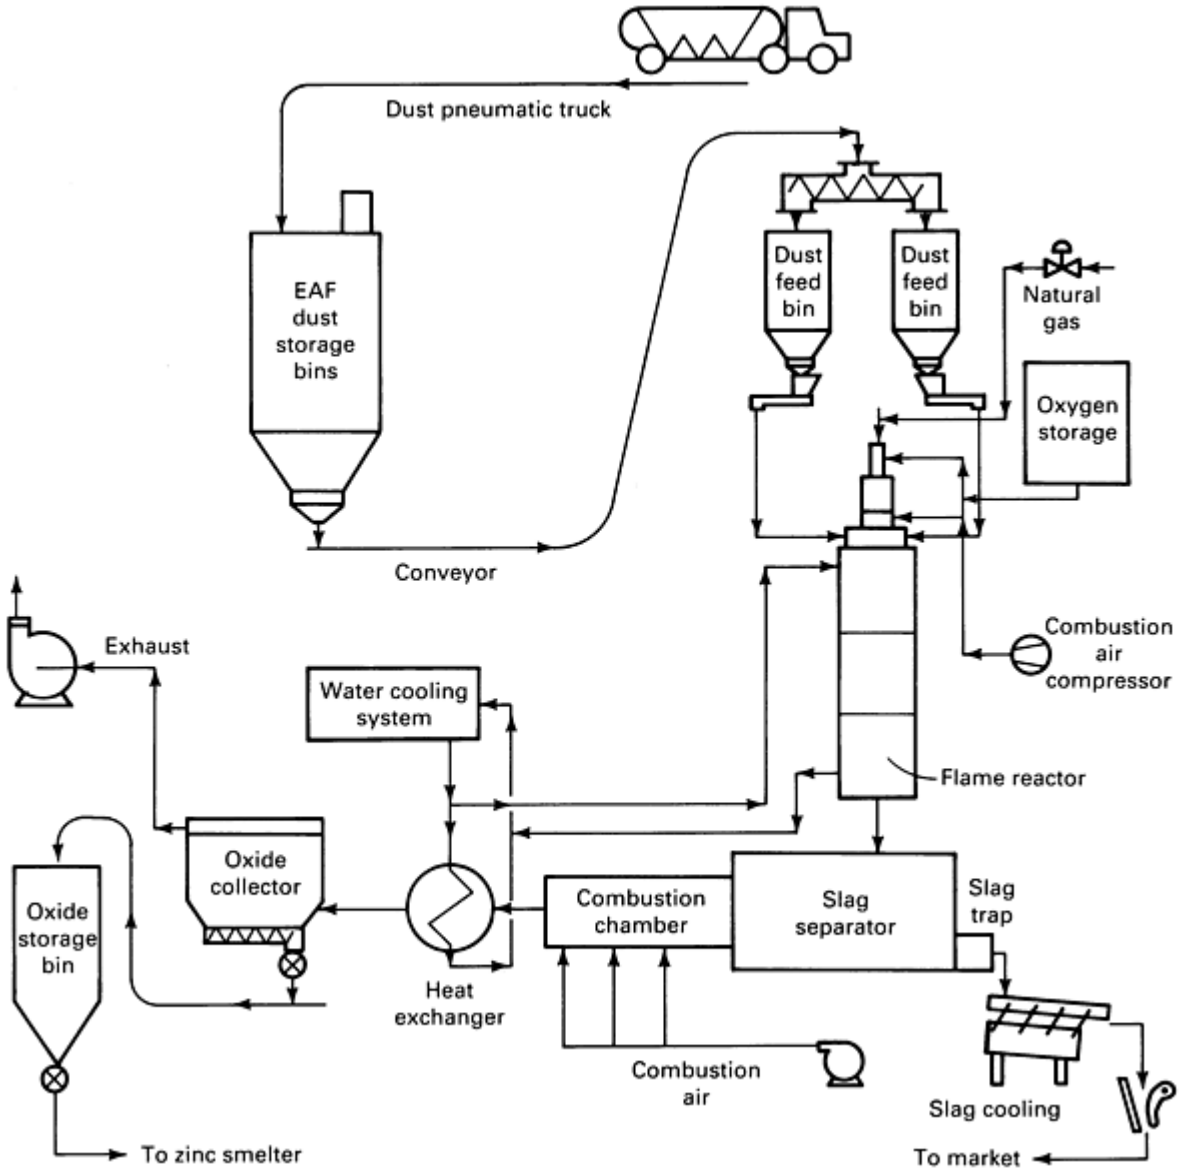

Fig. 18 The HRD flame reactor gas-fired process for zinc recycling from EAF dust. Source: Ref 56

Metallic zinc, condensed directly from reduced and volatilized EAF dust, will typically contain more lead and cadmium than even Prime Western grade zinc (GOB), for which markets are limited. Zinc purification via fractional distillation will likely be required for any direct condensation process to become widely adopted.

Summary

EAF dust, because of environmental legislation that has substantially raised the cost of its disposal, has become a significant source of reclaimed zinc in Europe, Japan, and the United States. To date, the dust generator has subsidized the reclamation activity by paying a processing fee that has varied from about $50 to more than $100 per metric ton, depending on the zinc content of the dust and the local conditions.

The Waelz kiln process will most likely continue to dominate the dust processing industry until at least the mid-1990s. However, as EAF dust generation continues to grow, the high cost to expand kiln capacity and to ship dust to large central plants should permit the introduction of new technology. Successful processes most likely will be based on the production of only nonhazardous, beneficially used materials by recycling the lead and cadmium as well as the zinc contained in EAF dust.

Recycling of Titanium

Michael Suisman and Leonard Wasserman, Suisman Titanium Corporation

---

TITANIUM begins with its two most common ores, rutile and ilmenite. Leucoxene and anatase are minor titanium ores. All of these are utilized either to produce pigments or to produce metal. For pigments, the titanium dioxide (TiO_2) content of the ore is employed. In the case of metals, the ores are converted by complex chemical processes into purified titanium tetrachloride ($TiCl_4$), commonly referred to as "tickle," and then further reduced either by magnesium or sodium into sponge.

Titanium ores are predominantly used for pigments, with about 90% being used as basic raw materials for pigments, paints, paper, and plastic. The titanium ores are the materials of choice to produce white pigmentation in those materials. At this time only 10% of the ores result in metal. Recycling takes place in metal only.

The Kroll Process, the conversion of tickle by a magnesium reduction process, was the breakthrough that permitted the commercial and economic introduction of titanium metal in the late 1940s. Sodium reduction (the Hunter Process) is also a traditional method of reduction. Electrolytic processes have been pursued for over 30 years, and attempts to commercialize such processes continue to be investigated.

About 80% of titanium usage is destined for aerospace applications including civilian and military airframes, engines, helicopters, rockets, and missiles. Much of the balance is devoted to the fabrication of equipment for industrial and commercial applications such as chemical processing, pulp and paper, and marine and power generation. Recently titanium has found favor in competitive sports equipment such as racing cars, boats, sleds, golf clubs, tennis rackets, and bicycles. In the medical sector, due to biochemical compatibility, titanium has proven to be a valuable asset in prosthetic devices, pacemakers, artificial heart components, and implanted drug administration devices. Consumer products such as wristwatches, writing instruments, cameras, pocket knives, jewelry, and eyeglass frames have also found titanium applications. Significant quantities of titanium have been utilized in Japan for architectural purposes. More information on titanium applications is availablein the article "Introduction to Titanium and Titanium Alloys" in this Volume.

Early Development of Titanium Recycling Technology

The first titanium scrap was generated in 1951. From the earliest years, recycling of titanium to the parent metal was hindered by a number of factors. Firstly, the chief end use of the metal was for aircraft, and consequently rigid controls or outright prohibitions were placed on scrap remelting. Then, as today, the ductility of titanium was critical, so that scrap that might contain high oxygen or other gases was suspect. The physical forms of titanium scrap, moreover, were often difficult to weld into the consumable electrodes of vacuum arc remelting (VAR) furnaces. Because titanium was melted under vacuum, there was little or no opportunity to adjust chemistry once the metal was molten.

Nonetheless, titanium recycling was begun in the 1950s. Timet attempted titanium turning recycling in 1952 but failed due to high-density inclusions (HDIs). Oremet began recycling bulk weldables in the late 1950s and in 1962 received approval to recycle rotor-turnings, chiefly for internal use. Timet also developed a system of scrap recycling known as hydrogenation. In the late 1960s, Viking Metallurgical-Quanex Corporation installed an electron beam furnace and became the first melter to recycle turnings for nonrotor purposes in a nonVAR furnace. In 1974, the U.S. Air Force sponsored a program to recycle aerospace metals, both titanium and superalloys, publishing an extensive report that urged melters, generators, and recyclers to develop systems to recycle titanium back into jet engines. Suisman Titanium Corporation received a patent in 1980 for the removal of HDIs from turnings, which allowed the first nonmelter processing of turnings for production of rotor-quality ingot.

Titanium Recycling

Sources. Titanium scrap is generated either during the melting process by ingot makers or companies producing castings, or during the fabrication process while converting mill products into semifinished or finished products. A small percentage, less than 2%, consists of obsolete ("old") scrap and is of little commercial significance; obsolete scrap results from aircraft overhaul, replacement of heat exchangers, and plating scrap.

U.S. melters have increased their use of scrap substantially over the last 25 years. In the 1960s, only 15 to 20% of U.S. ingot production was recycled metal; most of it was in-house scrap. Today 40 to 50% of ingot production is recycled metal (Fig. 19).

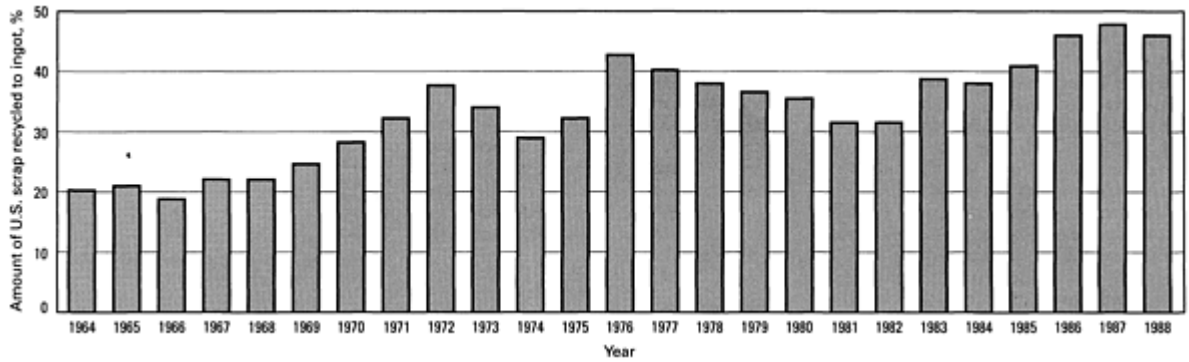

Fig. 19 Percentage of U.S. titanium scrap that was recycled to ingot from 1964 to 1988. Source: U.S. Bureau of Mines

Scrap generated at the melter's plant consists of billet cutoffs, crops, bar ends, plate trimmings, skulls, and so forth, and is called in-house or turnaround scrap; melters attempt to recycle their own scrap to the greatest degree possible, but some forms have physical and chemical characteristics (high oxygen, enfoliation, chemistry inter-mixture, and so on) that make them impractical to remelt as titanium.

When mill products are shipped as billet, bar, sheet, and plate, they are processed by turning, shearing, welding, forming, and so on, to semifinished or finished parts. During this fabrication, continuous fractions of metal are generated as scrap and are known as new production or open market scrap. All of this scrap must in turn be processed before it is recycled. A large portion of scrap generated by fabrication is purchased by scrap dealers or scrap processors. Most of this metal must be classified, processed, and analyzed by a processor approved by aerospace end users and melters. Some titanium scrap is returned directly to melters, who process the scrap themselves. Table 11 illustrates the usage of scrap in titanium ingot production.

Table 11 Use of scrap in production of titanium ingot from 1977 to 1988

Year	Consumption	
	Ingot	Scrap

	kg × 10^6	lb × 10^6	kg × 10^6	lb × 10^6
1977	24,040	53,000	9,798	21,600
1978	29,030	64,000	11,068	24,400
1979	33,942	74,828	12,610	27,800
1980	38,682	85,278	13,938	30,728
1981	41,920	92,417	13,422	25,590

Forms of Scrap. Titanium scrap is generated in the form of solids (bars, sheets, forge flashings, weldments, and so forth) and turnings or chips. The turnings usually contain cutting lubricants; solids may also be contaminated with oil or grease. These lubricants must be completely removed prior to melting.

Recycling to Titanium Melters. Ingot melters and casting companies require a very tightly controlled recycled metal. They purchase recycled metal segregated by physical form and chemical purity. Physical forms of solid scrap are designated bulk weldables, feedstock, and cobbles, depending on density and size. Turnings have even more stringent specifications, requiring not only spectral and gaseous chemistry, cleanliness, and size control, but also freedom from HDIs, mostly tungsten carbide tool bits that become intermixed with the turnings during the machining process.

Newly developed cold hearth furnaces, whose power sources are electron beam or plasma, have been approved by major end users for their abilities to remove HDIs as well as low-density inclusions (oxides, and so on) pyrometallurgically.

Complexity of Titanium Scrap Recycling. Because titanium metal is heavily oriented toward aerospace, and for technical and metallurgical reasons, the quality requirements for recycled titanium are much stricter than for most other recycled metals. Processors must utilize high-technology sorting devices, sophisticated processing equipment, and full-scale laboratories with highly trained staffs. High motivation for quality must be imbued in employees. Titanium processors also must be approved (qualified) by titanium melters and often the end users.

Fire Hazard of Titanium Turnings. Titanium turnings and chips can ignite, and fires have taken place over the years. The finely divided form, fines, is the most hazardous. The reader is advised to use the utmost caution, and refer to Ref 59.

Differences Between Recycled Metal and Sponge. Sponge comes from a limited number of sources, with only seven producers in the Western world. It is seldom compromised by HDIs, although LDIs are a constant concern.

Recycled metal emanates from a wide variety of sources, rendering it more heterogeneous upon generation. After recycling, however, titanium solids can once again attain physical uniformity and in-spec chemistry. Turnings can also achieve physical and chemical homogeneity, and if processed for HDI removal can be melted for rotor-quality applications; they tend to run slightly high in oxygen, however, due to oxygen pickup during the earlier machining. Recycled metal has the advantage of providing the alloy components, such as aluminum and vanadium within the scrap itself, whereas sponge-produced titanium alloy must always be produced with master alloy additions to the heat.

59. "Production, Processing, Handling and Storage of Titanium," Document NFPA481, National Fire Protection Association

Recycling for Sacrificial Uses

Ferrous Alloy Metallurgy. Titanium scrap is used in the steel and stainless steel industries either as a direct addition or after conversion into ferrotitanium. Titanium additions, either through alloying or as a gas scavenger, greatly improve the properties of ferrous products.

Aluminum Alloy Metallurgy. Titanium scrap additions to aluminum in the form of crushed, chemically cleaned turnings are used to make aluminum-titanium master alloys. Grain refinement of aluminum to which the master alloy has been introduced results in improvement in casting speed, eliminates cracking, and generally gives a more sound and uniform product.

Export of Titanium Scrap. Much of the titanium scrap utilized for sacrificial purposes is exported from the United States to the producers of ferrotitanium and master alloys. The volume of titanium scrap exports has risen by more than one-third in the last ten years.

New Trends in Titanium Recycling

Since the titanium industry is in its relative infancy, much can be expected technologically that will impact recycling. The aerospace industry's efforts to produce near net-shape components have fostered growth of titanium castings and to some degree have lessened scrap generation.

Cold hearth melting will also affect scrap recycling. The cold hearth furnaces are designed to melt high percentages of scrap. They also have the potential to cut recycling to traditional VAR furnaces.

The introduction of new titanium alloys, titanium aluminides, and metal matrix composites all carry with them new complexities to titanium recycling.

Recycling of Electronic Scrap

William D. Riley, Charles B. Daellenbach, and Robert C. Gabler, Jr., U.S. Bureau of Mines, Albany Research Center

PRECIOUS METALS (PM)--gold, silver, and the platinum-group metals (PGM) (platinum, palladium, rhodium, iridium, osmium, and ruthenium)--play a key role in the electronic and electrical industries. The recycling of these materials has a significant impact on the amounts that must be imported each year. For example, approximately 25% of the total demand for PM by all industrial uses is met by recycled material. The PM are essential in electrical and electronic applications because of their low contact resistance and resistance to corrosion and oxidation. A large amount of U.S. demand for PM is met by the recovery of metal values from electronic scrap. Typical processing steps for the recovery of PM from electronic scrap include hand disassembly or mechanical preparation followed by incineration, separation, and

classification. Final recovery is usually performed by leaching and precipitation followed by flux melting, refining, and casting. The final purity and uses of the recycled materials are comparable to those produced from virgin ore.

Nature and Quantity of Scrap Material

Precious metals are contained in platings of various thicknesses, relay contact points, switch contacts, wires, solders, transistors, printed circuit boards, electron tubes, batteries, and thermocouples. Typically, this scrap is classified as precious metals-containing electronic scrap, telephone relays, coated plugs, computers, and so forth. The precious metals may be in an alloy form, or a near-pure form; however, they may only comprise a small percentage of the total amount of electronic scrap produced. The PM content of individual pieces of electronic scrap is thought to have dropped from the 1960s (Ref 60) to the present (Ref 61); however, the total number of parts has increased as has the total demand for precious metals in the electronics industry. Estimates place the current content of PM contained in electronic scrap in the range of 2 to 10 troy ounces/ton of gold, 40 to 100 troy ounces/ton of silver, and >1 troy ounce/ton PGM (Ref 62). The general composition for electronic scrap processed in the mid-1960s is as follows: plastics (30 wt%); refractory oxides (30 wt%); nonprecious metals including copper, iron, nickel, tin, lead, aluminum, and zinc (40 wt%); precious metals (0.305 wt%). Approximately 27.3 million troy ounces of PM (0.4 million oz PGM, 1.1 million oz Au, 25.8 million oz Ag) was consumed by the electronic manufacturing industry in 1987 (Ref 63). As shown in Table 12, this is expected to increase to at least 34.6 million troy ounces (1.1 million oz PGM, 2.5 million oz Au, 31 million oz Ag) by the year 2000. The palladium demand is expected to double as it gradually replaces gold in many electronics uses. The secondary refining industry supplies a significant portion of the total demand for PM each year. In 1987, 26 million troy ounces Ag, 1.5 million troy ounces PGM, and 2 million troy ounces Au were recovered from all sources of old scrap. The recovery of these materials from scrap resources is not expected to change much by the year 2000 (Ref 65). The amount of materials generated by secondary recovery efforts is expected to remain relatively flat between now and the turn of the century, with most PMs experiencing only 2 to 4% increases in amount recovered (Ref 66).

Table 12 Consumption of precious metals in electronic components

Metal	**Consumption, troy ounce × 10^3**	
	1986	**2000 (estimated)**
Gold	1,070	2,500
Silver	25,857	31,000
Platinum	75	150
Palladium	250	450
Rhodium	8	12
Iridium	1	3
Ruthenium	71	100
Osmium	1[(a)]	1

(a) All osmium is included in this number.

Scrap Electronics: A Complex Ore

Currently, other than the U.S. Department of Defense (DoD) Precious Metals Recovery Program, there is no well-organized and coordinated program for the collection of PM-containing electronic scrap, although a few commercial firms have established limited programs. The DoD is thought to be the major source of PM-containing scrap. The defense industry electronic scrap usually contains the highest amount of PM because of the need for maximum reliability. Prompt scrap, generated during the production of electronic components, is recycled in a reasonably effective manner, but obsolete scrap presents problems because of the expense associated with collecting, identifying, and separating the material. In fact, it has been estimated that less than 10% of the PM was reclaimed from obsolete electrical contacts and electronic materials discarded in 1983 (Ref 67).

Precious-metals-containing scrap can be thought of as a low-grade complex ore. Both the complexity of the material and the low concentration of precious metals make getting a representative sample for analysis difficult. For example. Table 13 lists the results of an analysis for hand-dismantled avionic scrap. The scrap was thought to be pre-1957 because it included no printed circuit boards, but it is easy to see the wide variance in contained precious metals. The same sort of wide distribution of precious metals can be expected from consumer electronic scrap.

Preliminary Processing Options

Typically, various techniques are used to liberate the precious metals, or to concentrate them by removing as much of the base materials as possible. The general rule is the higher the precious metal concentration of the scrap, the greater the economic return. Technologies used to recover precious metals from electronic scrap include hand dismantling and segregation, mechanical processing to beneficiate the scrap, and various hydrometallurgical, pyrometallurgical, or electrometallurgical treatments to concentrate or recover the precious metals (Table 14). As a result of the complexity of recovery operations, there are numerous steps to the refining process, often carried out by different companies, with each step adding to the cost of the refined metal (Ref 68).

Table 14 Electronic scrap processing options

Process	Comments

Chemical stripping	Only of use on exposed gold surfaces. Recovery ~90%
Chemical treatment (acid dissolution)	Requires aggressive acids. Material encapsulated in ceramic not recovered. Produces large volumes of base metal effluent
Granulation and physical separation	PM from mixed scrap is dispersed in all the fractions, although most of it is concentrated in two fractions. Recoveries ~80%
Burn and smelt[(a)]	Suitable for all scrap. Recoveries approach 85%.

Source: Ref 61

(a) Hand dismantling is always the first stage in the operation.

Possible recovery options for electronic scrap are shown in Fig. 20. Not all options are used for each type of scrap, and in some cases additional steps may be required. For example, precipitated PM is normally so finely divided that flux melting is required before refining and casting. In addition, the material may be sent to a copper refiner after assay and the sludge processed for PM recovery. In most cases the initial disassembly is done by either the manufacturer or a specialized company. Typically, this involves cutting of connectors, removing printed circuit boards, buses, and so forth. The other nonprecious metal-containing parts separated during the hand dismantling operation can often generate enough proceeds to pay for this step; this additional value is approximately $200 per gross ton ofavionics material (Ref 69). Avionics contains a high percentage of aluminum in the cases; ground-based and Naval electronics would have the aluminum replaced by steel, a scrap value difference of $0.02/lb (steel) versus approximately $0.30/lb (aluminum). The fractions typically separated by disassembly are: iron, aluminum, and copper wire and solids, mixed breakage, precious metal-bearing material, and reusable parts. The removal of memory chips, tantalum capacitors, and so forth for sale as reusable merchandise can substantially improve the economics of this operation. It has been reported that a printed circuit board that contains several dollars worth of precious metals can have hundreds of dollars worth of memory chips on it (Ref 62). If no other processing is done, then the hand segregation is the most important step as far as the refiner is concerned (Ref 62).

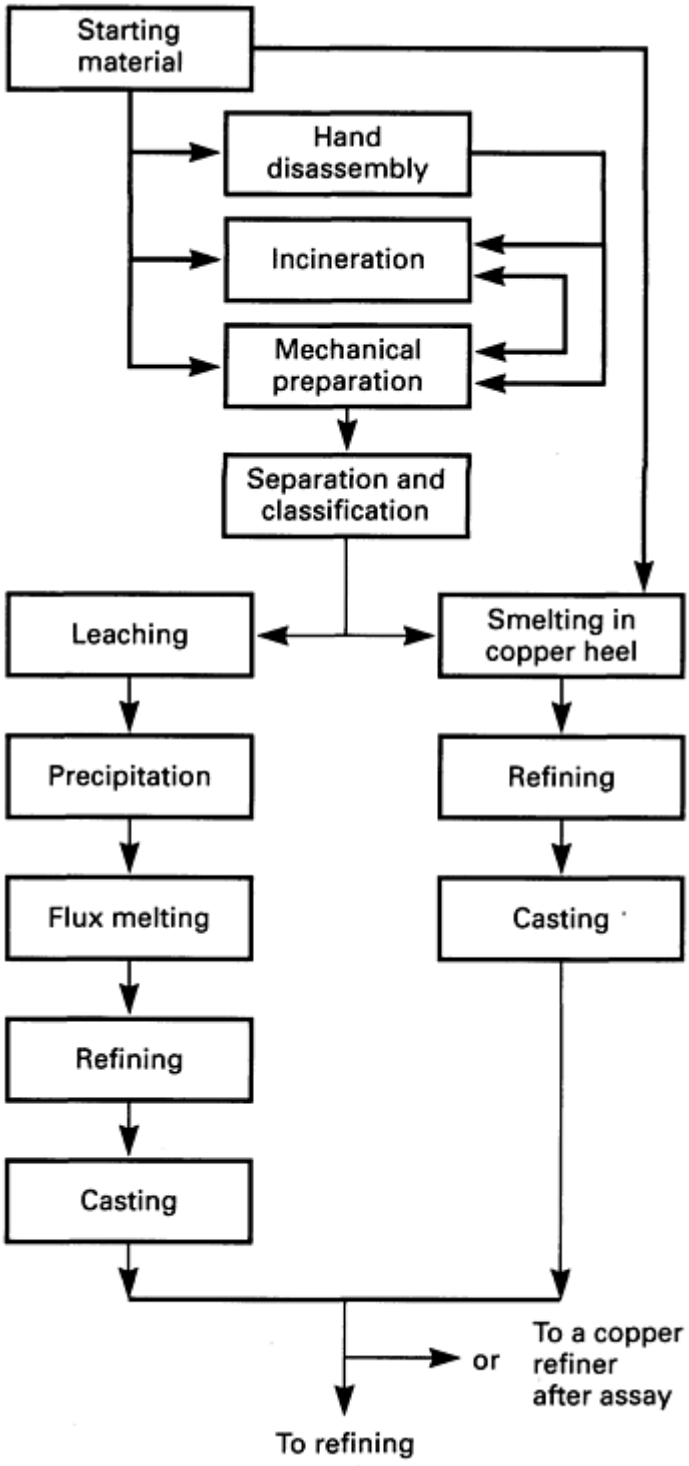

Fig. 20 Possible recovery options for the treatment of electronic scrap containing precious metals

Research has shown that electronic scrap can be mechanically upgraded (Ref 70, 71, 72). In this work, a series of unit operations was used to produce an iron-base fraction, an aluminum-base fraction, a wire fraction, and two precious metal fractions, one high-value and the other low. Table 15 lists the results from the application of a series of operations performed on printed circuit boards. The operations include hammer milling, air classification, magnetic separation, vibratory screen, wire separation screen, eddy current separation, and high-tension separation. The largest amounts of gold and silver and the PGM are always concentrated in the high-tension metal product. Most of the remaining precious metals can be found in the baghouse lights and wire bundles. This mechanical processing procedure or hand dismantling and segregation can greatly reduce shipping and toll refining costs by removing most of the extraneous materials.

Table 15 Material distribution and precious metal concentration in fractions of mechanically beneficiated printed-circuit cards

Fraction	Distribution, %	Contained precious metals, oz/ton	
		Gold	Silver
Baghouse lights	23.5	21.9	178
Wire bundles	1.2	19.6	286
Magnetic	30.7	8.7	11.3
Eddy-current aluminum	1.8	ND[a]	2.4
High-tension metal	35.2	43.8	451.8
High-tension rejects	7.8	6.6	108.3

(a) ND, not detected

The concentrated PM-containing material can then be processed by semirefiners who collect the material after initial disassembly and process it further. These companies may strip plastics from printed circuit boards chemically, or incinerate them at 400 to 500 °C (750 to 930 °F), followed by chopping or shredding the components. An additional step may include pulverizing capacitors to leave a pulp containing precious metals and smelting the material into a crude bullion for shipment to refiners. Another approach consists of incinerating plastics and other organics, followed by caustic leaching of the residue with NaOH to remove the aluminum, and finishing with smelting to produce a homogeneous product (Ref 73). A typical ingot analysis showed 85% Cu, 4% Fe, 0.2% Al, 333 oz/ton of silver, and 26 oz/ton of gold. These ingots can be electrorefined for copper recovery, and the precious metals, which concentrate in the anode sludge, can be processed for recovery by a precious metals refiner.

Another novel but costly metals separation approach proposes to avoid either mechanical processing or hand dismantling/segregation while still concentrating the precious metals. This process involves sweating the aluminum from the scrap. Both copper and the precious metals are dissolved in the ingot because of their high insolubility in the molten aluminum. The aluminum ingot can be refined in a three-layer electrorefining cell (Ref 73), where the precious metals are concentrated in the anode metal.

Still another processing approach involves some hand separation to remove bulky aluminum case, shredding, and magnetic separation, followed by incineration and melting of the remaining material to form a brittle ingot. The procedure has been used on partial assemblies, and plugs and connectors. The ingot, consisting of aluminum, copper, iron, manganese, nickel, zinc, and precious metals, is crushed and the material is agitated with an acidified copper sulfate solution for copper cementation. The iron fraction of the shredded material is used as the cement agent in a tumble-type cementation system. The cement copper precipitate contains better than 90% of the precious metals (Ref 74). The analysis of a typical precipitate after cementation is 89% Cu, 1.1% Fe, 0.32% Pb, 0.36% Sn, 1.5% insolubles, 4.0 oz/ton of gold, and 11.5 oz/ton of silver. After melting and casting the cementation product into an anode, it can be electrorefined, and the anode sludge containing the precious metals sent to a toll refiner.

Research has also been conducted on recovering PGM from telephone relay scrap, reed switches (Ref 75), and gold from various contacts (Ref 76) by mechanical processing and hydrometallurgical treatments (Ref 77). Usually base metal substrates are first removed with a strong hydrochloric acid leach. Then the gold and silver are leached using either sulfuric/nitric or nitric acid solutions. The PGM require a pressure leach under air sparging in an autoclave. The leach solutions from each stage are concentrated by evaporation, and the concentrated residue from the hydro-metallurgical treatments can be sent to a toll refiner for recovery of contained PGM.

A large portion of PM-containing scrap at one time consisted of tin-lead solders that were used to join electronic components to printed circuit boards. Soldering is usually accomplished by either dipping the board into a bath of solder or impinging a stationary wave of solder onto the circuit board. Some copper and precious metals are dissolved into the solder; as the content of the impurities increases, the solder loses its wetting property and is discarded. These solders on the average can contain 60 troy ounces/ton of PM. The increased use of integrated circuits has led to a diminishing of this technique, and it is reported that refiners receive less than 45 metric tons (50 tons) of the solder per year. Some of the contaminated solder is sold to automakers, and the precious metals are lost. It is possible to commercially recover the precious metals from the solder by fused-salt electrolysis in a molten chloride electrolyte (Ref 77).

Final Processing Options

Final recovery of the precious metals depends on the physical form, composition, grade, and associated metals in the concentrate. In general, most refiners specialize in the recovery of PM from certain kinds of scrap and semiprocess other types of scrap for recovery at other refinery operations. All of the scrap winds up as some kind of a bullion or sweeps (including dry precipitates). These materials are amenable to final recovery by a combination of smelting, fire, chemical, and electrolytic refining (Ref 78). Of all the recovery options for electronic scrap, the burn and smelt recovery systems seem to be the most effective. Table 14 summarizes the results of the research reported in the preceding sections.

Unlike most scrap metals, which are usually identified, segregated, and then remelted (oftentimes carrying along trace elements), the recycling of PM is unusual because they are reprocessed into extremely pure materials. For example, typical analysis for chemically refined gold produced from scrap is 99.95% while electrolytic gold ranges from 99.97 to 99.99% pure. Silver is typically 99.99% pure, and the PGM are 99.5% pure.

After refining, it is impossible to tell whether PM were recovered directly from ore or from printed circuit boards. There do not seem to be any reported problems with residual impurities in either pure materials or realloyed materials produced from PM-containing scrap. For example, because the precious metals are highly purified before reuse, palladium-nickel alloy for relay contacts can be produced from either recycled or virgin materials without any physical or compositional differences.

Future Use Trends

The rapid evolution of the electronics industry has lead to a continued improvement in the efficiency of the use of precious metals. For example, palladium was used for many years in telephone switching gear. This use is declining with the rapid introduction of solid-state switches. In addition, less expensive palladium-silver alloys are replacing the pure palladium that was previously used. However, the replacement of mechanical switches with solid-state switches has, in general, increased the demand for PGM because they are used as the contacts between the circuit and the outer package. In fact, 50% of the PGM and gold used in electronics industries goes into some kind of a contact. The introduction of ceramic capacitors containing gold-platinum-palladium or gold-palladium alloys also increased the demand for these metals. Inlay-clad gold and gold alloys are being increasingly used in electrical and electronic connections because they are an economic and reliable alternative to the use of electrodeposited gold (Ref 79). Other changes in the industry are the replacement of gold in printed circuit boards and edge connectors with palladium. The actual amount of precious metals contained in an individual item will decrease, for example, as the thickness of gold coatings decreases to a lower limit defined by reliability, and the ability increases to deposit any precious metal in a smaller, well-defined area. This will present new challenges to the recycling industry by requiring that new techniques for collecting PM-containing scrap be developed and better means of recovering the metal values from scrap be developed.

Currently large amounts of PM are recovered from obsolete computers, telecommunications, and DoD scrap. Once the existing supply of obsolete computers is scrapped, it is expected that recovery efforts will decline both because the precious metals content of the units is lower than in earlier-generation electronic scrap and because the smaller size of the units will cause this source to become dispersed. The same trends will be true in the telecommunications industry as existing circuitry is replaced with solid-state devices (Ref 80).

Electronics scrap is a complex material containing various recyclable fractions. The complexity of the material and the decrease in the amount of precious metals used in individual parts will make processing more difficult. Unless research is conducted on a continuing basis to develop technology to recover or concentrate PM from the new families of electronics entering the recycling stream, the increasing total consumption of precious metals for electronic equipment will have to be supplied by larger proportions of imports.

Toxicity of Metals

Robert A. Goyer, Department of Pathology, The University of Western Ontario

Introduction

METALS DIFFER from other toxic substances in that they are neither created nor destroyed by humans. Nevertheless, utilization by humans influences the potential for health effects in at least two major ways: first, by environmental transport, that is, by human or anthropogenic contributions to air, water, soil, and food, and second, by altering the speciation or biochemical form of the element (Ref 1, 2).

Metals are redistributed naturally in the environment by both geologic and biologic cycles (Fig. 1). Rainwater dissolves rocks and ores and physically transports material to streams and rivers, adding and deleting from adjacent soil, and eventually to the ocean to be relocated elsewhere on earth. The biologic cycles include bioconcentration by plants and animals and incorporation into food cycles. Human industrial activity may greatly shorten the residence time of metals in ore, form new compounds, and greatly enhance worldwide distribution. These natural cycles may exceed the anthropogenic cycle, as is the case for mercury. However, the role of human activity in redistribution of metal is demonstrated by the 200-fold increase in lead content of Greenland ice, beginning with a "natural" low level (about 800 B.C.) and a gradual rise in lead content of ice through the evolution of the industrial age, followed by a nearly precipitous rise in lead corresponding to the period when lead was added to gasoline in the 1920s (Ref 3). Metal contamination of the environment, therefore, reflects both natural sources and contribution from industrial activity.

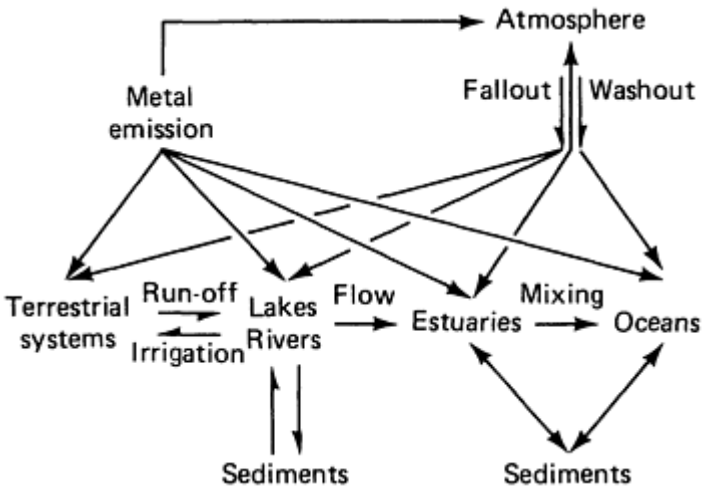

Fig. 1 Routes for transport of trace elements in the environment. Source: Ref 1

Metals emitted into the environment from combustion of fossil fuels in the United States are shown in Table 1. These include many of the metals most abundant in particulates in ambient air. The only metals or metal-like elements that may be emitted in gaseous discharges in measurable concentrations are mercury or selenium. Metals in raw surface water reflect erosion from natural sources, fallout from the atmosphere, and additions from industrial activities. Metals in soil and water may enter the food chain. For persons in the general population, food sources probably represent the largest source of exposure to metals, with an additional contribution from air. Further potential sources of human exposure include consumer products and industrial wastes as well as the working environment.

(e) Arsenic in water is extremely variable, 10 to 1100 μg/L 728 samples surface water 22% in 10 to 20 μg range.

Occupational exposure to metals is restricted to "safe" levels defined as the threshold limit value for an eight-hour day, five-day work week. These levels are intended to provide a margin of safety between maximum exposure and minimum levels that will produce illness. Permissible levels vary widely, and the differences reflect, in a sense, the toxicologic potency of the metal. As a general rule, the metals that are most abundant in the environment have lesser potential for toxicity as evidenced by the prevailing standard for permissible occupation exposure.

Metals are probably the oldest toxins known to humans. Lead usage may have begun prior to 2000 B.C. when abundant supplies were obtained from ores as a byproduct of smelting silver. Hippocrates is credited in 370 B.C. with the first description of abdominal colic in a man who extracted metals. Arsenic and mercury are cited by Theophrastus of Erebus (387-372 B.C.) and Pliny the Elder (A.D. 23-79). Arsenic was obtained during the melting of copper and tin, and an early use was for decoration in Egyptian tombs. On the other hand, many of the metals of toxicologic concern today are only recently known to humans. Cadmium was first recognized in ores containing zinc carbonate in 1817. About 80 of the 105 elements in the periodic table are regarded as metals, but fewer than 30 have compounds that have been reported to produce toxicity in humans. The importance of some of the rarer or lesser known metals such as indium or tantalum might increase with new applications in microelectronics or other new technologies.

The conceptual boundaries of what is regarded as toxicology of metals continues to broaden. Historically, metal toxicology has largely concerned acute or overt effects, such as abdominal colic from lead toxicity or the bloody diarrhea and suppression of urine formation from ingestion of corrosive (mercury) sublimate. There must still be knowledge and understanding of such effects, but with present-day occupational and environmental standards, such effects are uncommon. Beyond this, however, is growing inquiry regarding subtle, chronic, or long-term effects where cause-and-effect relationships are not obvious or may be subclinical. This might include a level of effect that causes a change that resides within the generally regarded norm of human performance, for example, lower I.Q. and childhood lead exposure. Assigning responsibility for such toxicologic effects is extremely difficult and not always possible, particularly when the end-point in question lacks specificity in that it may be caused by a number of agents or even combinations of substances.

The challenges, therefore, for the toxicologist are multiple. The major ones include the need for quantitative information regarding dose and tissue levels, greater understanding of the metabolism of metals particularly at the tissue and cellular level where effects that have specificity may occur, and finally, recognition of factors that influence toxicity of a particular level of exposure such as dietary factors or protein-complex formation that enhance or protect from toxicity. Treatment, particularly the administration of chelating agents, remains an important topic particularly for those metals that are cumulative and persistent, for example, Pb, Cd, Ni, and so forth. However, prevention of toxicity is the major objective of public health policies and occupational hygiene programs. There is increasing emphasis on the use of biologic indicators of toxicity such as heme enzymes in lead toxicity, renal tubular dysfunction in cadmium exposure, and neurologic effects in mercury toxicity, to serve as guidelines for preventive or therapeutic intervention.

Estimates of Dose-Effect Relationships

Estimates of the relationships of dose or level of exposure to a particular metal are, in many ways, a measure of dose-response relationships. Conceptual background for this topic is considered in Ref 8. Dose or estimate of exposure to a metal may be a multidimensional concept and is a function of time as well as concentration of metal. The most precise definition of dose is the amount of metal within cells of organs manifesting a toxicologic effect. Results from single measurements may reflect recent exposure or longer-term or past exposure, depending on retention time in the particular tissue. Blood, urine, and hair are the most accessible tissues in which to measure dose and are sometimes referred to as indicator tissues. *In vivo,* quantitation of metals within organs is not yet possible, although techniques such as neutron activation and fluorescence spectroscopy may hold promise for the future. Indirect estimates of quantities in specific organs may be calculated from metabolic models derived from autopsy data.

At the cellular level, toxicity is related to availability so that chemical form and ligand binding become critical factors. Alkyl compounds are lipid soluble and pass readily across biologic membranes unaltered by their surrounding medium. They are only slowly dealkylated or transformed to inorganic salts. Hence, their excretion tends to be slower than inorganic forms, and the pattern of organic toxicity differs. For example, alkyl mercury is primarily a neurotoxin versus the renal toxicity of mercuric chloride. Metals that have strong affinity for osseous tissue like lead and radium have a long retention time and tend to accumulate with age. Other metals are retained in soft tissues because of affinities for intracellular proteins, such as renal cadmium bound to metallothionein.

Blood and urine usually reflect recent exposure and correlate best with acute effects. An exception is urine cadmium where increased metal in urine reflects renal damage related to accumulation of cadmium in the kidney. Partitioning of metal between cells and plasma and between filterable and nonfilterable components of plasma should provide more precise information regarding the presence of biologically active forms of a particular metal. Such partitioning is now standard laboratory practice for blood calcium; ionic calcium is by far the most active form of the metal. Specification of toxic metals in urine may also provide diagnostic insights. For example, cadmium metallothionein in urine may be of greater toxicologic significance than total cadmium.

Hair can be useful in assessing variations in exposure to metals over the long term. Analysis may be performed on segments so that metal content of the newest growth can be compared to past exposures. Correlation between blood levels of metal and concentration in hair is not expected because blood levels reflect only current exposures. Caution must be taken in washing hair prior to analysis to assure removal of metal deposits from external contamination (Ref 9).

Factors Influencing Toxicity of Metals

There are only a few general principles available that contribute to understanding the patho-physiology of metal toxicity. Most metals affect multiple organ systems, and the targets for toxicity are specific biochemical processes (enzymes) and/or membranes of cells and organelles. The toxic effect of the metal usually involves an interaction between the free metal ion and the toxicologic target. There may be multiple reasons for a particular toxic effect. For instance, the metabolism of the toxic metal may be similar to a metabolically related essential element. Such is the case for some of the effects of lead, for example, lead and calcium in the central nervous system, and lead, iron, and zinc in heme metabolism. Cells that are involve in the transport of metals, such as gastrointestinal, liver, or renal tubular cells, are particularly susceptible to toxicity. However, for many metals, these cells have protective mechanisms involving protein complex formation that permits intracellular accumulation of potentially toxic metals without causing cell injury.

Metal-protein complexes involved in detoxication or protection from toxicity have now been described for a few metals (Ref 10). Morphologically discernible cellular inclusion bodies are present with exposures to lead, bismuth, and a mercury-selenate mixture. Metallothioneins form complexes with cadmium, zinc, copper, and other metals, and ferritin and homesiderin are intracellular iron-protein complexes. The protein complexes formed by lead, bismuth, mercury-

selenate, and iron, at least for homesiderin, have attracted interest because these complexes are insoluble in tissues and can be observed histologically. However, it is this lack of solubility that has made detailed biochemical study very difficult. On the other hand, for those metal-protein complexes that are stable and soluble in aqueous media, such as metallothionein and ferritin, there is considerable biochemical information. More is known about ferritin than perhaps any of these protein complexes because it is soluble and at the same time has a unique ultrastructural appearance so that it can be readily identified in cells and organelles. None of these proteins or metal-protein complexes have any known enzymatic activity. From these considerations it becomes clearer why speciation, that is, how much metal in a tissue that is in a particular biochemical form and what it is bound to, may be the ultimate determinant of toxicity.

Numerous exogenous factors influence the occurrence of toxicity in any particular subject (Ref 11). These include age, diet, and interactions and concurrent exposure with other toxic metals. Persons at either end of the life span, young children or elderly, are believed to be more susceptible to toxicity from exposure to a particular level of metal than adults. Rapid growth and cell division represent opportunities for genotoxic effects. Intrauterine toxicity to methyl mercury is well documented. Lead crosses the placenta, and it is recommended that maternal blood lead levels be lower than those of persons in the general population.

The major pathway of exposure to many toxic metals in children is with food, and children consume more calories per body weight than adults. Moreover, children have higher gastrointestinal absorption of metals, particularly lead. Experimental studies have extended these observations to other metals, and milk diet, probably because of lipid content, seems to increase metal absorption.

Effects of some dietary factors on metal toxicity are at the level of absorption from the gastrointestinal tract. There is an inverse relationship between protein content of diet and cadmium and lead toxicity. Vitamin C reduces lead and cadmium absorption, probably because of increased absorption of ferrous ion. On the other hand, metabolically related essentially metals may alter toxicity by interaction at the cellular level. Lead, calcium, and vitamin D have a complex relationship affecting mineralization of bone and more directly through impairment of 1-25-dihydroxy vitamin D synthesis in the kidney. Metal-metal interaction may have considerable influence on dose-effect relationships and are commented on in discussions of specific metals.

Lifestyle factors such as smoking or alcohol ingestion may have indirect influences on toxicity. Cigarette smoke itself contains some toxic metals such as cadmium, and cigarette smoking may influence pulmonary effects. Alcohol ingestion may influence toxicity indirectly by altering diet and reducing essential mineral intake. For instance, a decrease in dietary calcium will influence toxicity of major toxic metals, including lead and cadmium.

Chemical form of the metal may be an important factor, not only for pulmonary and gastrointestinal absorption but in terms of body distribution and toxic effects. Dietary phosphate generally forms less soluble salts of metals than other anions. Alkyl compounds, such as tetraethyl lead and methyl mercury, are lipid soluble and more soluble in myelin than inorganic salts of these metals.

For metals that produce hypersensitivity reactions, the immune status of an individual becomes an additional toxicologic variable (Ref 12). Metals that provoke immune reactions include mercury, gold, platinum, beryllium, chromium, and nickel. Clinical effects are varied but usually involve any of four types of immune responses. In anaphylactic or immediate hypersensitivity reactions the antibody, IgE, reacts with the antigen on the surface of mast cells releasing vasoreactive amines. Clinical reactions include conjunctivitis, asthma, urticaria, or even systemic anaphylaxis. Cutaneous, mucosal, and bronchial reactions to platinum have been attributed to this type of hypersensitivity reaction. Cytotoxic hypersensitivity is the result of a complement-fixing reaction of IgG immunoglobulin with antigen or hapten bound to the cell surface. The thrombocytopenia sometimes occurring with exposure to organic gold salts may be brought about in this manner. Immune complex hypersensitivity occurs when soluble immune complex deposits (antigen, antibody, and complement) within tissues producing an acute inflammatory reaction. Immune complexes are typically deposited on the epithelial surface of glomerular basement membrane, resulting in proteinuria, and occur following exposure to mercury vapor of gold therapy. Cell-mediated hypersensitivity, also known as the delayed hypersensitivity reaction, is mediated by thymus-dependent lymphocytes and usually occurs 24 to 48 hours after exposure. The histologic reaction consists of mononuclear cells and is the typical reaction seen in the contact dermatitis following exposure to chromium or nickel. The granuloma formation occurring with beryllium and zirconium exposure may be a form of cell-mediated immune response.

Carcinogenesis

Given the long history of human exposure to metals, knowledge of the potential carcinogenicity of metal compounds has evolved slowly, and most of this information has only been obtained in recent years (Ref 13, 14).

Furthermore, predictive *in vitro* methods using nonmammalian systems, such as the Ames test, do not seem as responsive as for organic compounds (Ref 15). Evidence of carcinogenicity for metals relates more precisely with specific compounds of metals than with the metal itself. That is, some forms of the metal seem to be carcinogenic; for example, nickel subsulfide (Ni_3S_2) is more carcinogenic than amorphorus nickel monosulfide (NiS); but such differences may be explained on the basis of cell uptake rates or solubility. Similar debates concern various compounds of chromium. Nevertheless, if any form of a metal is carcinogenic, the metal itself must be regarded as a carcinogen.

Although only a few metals show any evidence of carcinogenicity, this is an exceedingly important topic because of the ubiquity of most metals, their wide industrial use, and their persistence in the environment. Identification of metal carcinogens in industry is made even more perplexing because seldom is exposure to a single metal, but it is usually to mixtures. Also, there is the added question of the role of metals as promoters or cocarcinogens with organic carcinogens because of their persistance in tissues, as may be the case for lead.

The chronology of observations on the carcinogenicity of metals is shown in Fig. 2. Specific details pertaining to the carcinogenicity of each metal are discussed later in the chapter along with other toxicologic effects. However, the figure does provide an overview. Human case reports of skin cancer due to arsenic exposure were recognized in the nineteenth century, but epidemiologic support from case study observations did not occur until over 50 years later, and there has not yet been confirmation in experimental animals. On the other hand, lead is the only metal shown to be carcinogenic in animal models by oral administration. Yet, evidence in humans is limited to a couple of recent case reports. How much of what kind of evidence, animal and/or human, is required to label a metal as a carcinogenic must be decided for each metal. Animal studies that use routes of administration different from those by which humans may be exposed, such as by injection, have limitations for extrapolation to humans.

Chelation

Chelation is the formation of a metal ion complex in which the metal ion is associated with a charged or uncharged electron donor referred to as a ligand. The ligand may be monodentate, bidentate, or multidentate; that is, it may attach or coordinate using one or two or more donor atoms. Bidentate ligands form ring structures that include the metal ion and the two ligand atoms attached to the metal (Ref 16).

Chelating agents are generally nonspecific in regard to their affinity for metals. To varying degrees, they will mobilize and enhance the excretion of a rather wide range of metals, including essential metals such as calcium and zinc (Table 2). Their efficacy depends not solely on their affinity for the metal of interest, but also on their affinity for endogenous metals, mainly calcium, which compete in accordance with their own affinities for the chelator. Properties of a few of the commonly used chelators will be described.

Table 2 Ligands (chelating agents) preferred for removal of toxic metals)

Ligand	Metal
BAL[(a)]	Arsenic, lead (with Ca-EDTA), mercury, inorganic

DMPS[(b)]	Methyl mercury, inorganic mercury, cadmium, copper, and nickel
Calcium EDTA[(c)]	Lead
Penicillamine	Copper, lead
Calcium DTPA[(d)]	Cadmium (with BAL)
Desferrioxamine	Iron
Dithiocarb	Nickel carbonyl

(a) BAL, British Anti Lewisite.

(b) DMPS, 2,3-dimercapto-1-propanesulfonic acid.

(c) EDTA, ethylene diamine tetraacetic acid.

(d) DTPA, diethylenetriamine-pentaacetic acid

BAL (British Anti Lewisite) or 2,3-dimercaptopropanol was the first clinically useful chelating agent. It was developed during World War II as a specific antagonist to vesicant arsenical war gases based on the observation that arsenic has an affinity for sulfhydryl-containing substances (Ref 17). BAL, a dithiol compound with two sulfur atoms on adjacent carbon atoms, competes with the critical binding sites responsible for the toxic effects. These observations led to the prediction that the "biochemical lesion" of arsenic poisoning would prove to be a thiol with sulfhydryl groups separated by one or more intervening carbon atoms. This prediction was borne out a few years later with the discovery that arsenic interferes with the function of 6.8-dithiooctanoic acid in biologic oxidation (Ref 18).

BAL has been found to form stable chelates *in vivo* with many toxic metals including inorganic mercury, antimony, bismuth, cadmium, chromium, cobalt, gold, and nickel. However, it is not necessarily the treatment of choice for toxicity to these metals. BAL has been used as an adjunct in the treatment of the acute encephalopathy of lead toxicity. It is a potentially toxic drug, and its use may be accompanied by multiple side effects. Although BAl will increase the excretion of cadmium, there is a concomitant increase in renal cadmium concentration so that its use in cadmium toxicity is to be avoided. It does, however, remove inorganic mercury from kidneys but is not useful in treatment of alkyl or phenylmercury toxicity. BAL also enhances the toxicity of selenium and tellurium so it is not be used to remove these metals.

DMPS (2,3-dimercapto-1-propanesulfonic acid) is a water-soluble derivative of BAL developed to reduce the toxicity and unpleasant side effects of BAL. A recent study has found that DMPS reduces blood lead levels in children (Ref 19). It has the advantage over EDTA in that it is administered orally and does not appear to have toxic side effects. It has been widely used in Russia to treat many different metal intoxications and even atherosclerosis by the adherents of the notion that this degenerative disorder of blood vessels is due to metal-ion accumulations in the blood vessel wall leading to inhibition of enzyme metabolism.

DMPS is effective in removal of both inorganic and methyl mercury, probably because it is not lipophilic like BAL and does not penetrate tissues but removes extracellular metal (Ref 20). The important point is that it does not increase the concentration of metal in the brain and reduces organ concentration of metal including the kidney. It may also be effective in removal of copper, nickel, and cadmium immediately after exposure but not from tissue stores.

Calcium EDTA is the calcium disodium salt of ethylene diamine tetraacetic acid. The calcium salt must be used clinically because the sodium salt has greater affinity for calcium and will produce hypocalcemic tetany. However, the calcium salt will bind lead with displacement of calcium from the chelate. It is poorly absorbed from the gastrointestinal tract so it must be given parenterally, and it becomes rapidly distributed in the body. It is the current method of choice for treatment of lead toxicity (Ref 21). The peak excretion is within the first 24 hours and represents excretion of lead from of tissues. Removal from the skeletal system occurs more slowly with restoration of equilibrium with soft tissue compartments. Calcium EDTA does have the potential for nephrotoxicity, so it should be administered only when indicated clinically.

Penicillamine (B,B^1-dimethylcystein), a hydrolytic product of penicillin, is the choice for therapy of Wilson's disease (copper toxicity) and is effective in removal of lead, mercury, and iron (Ref 22). It is also important to note that penicillamine removes other physiologically essential metals including zinc, cobalt, and manganese. It also has the risk of inducing a hypersensitivity reaction with a wide spectrum of undesired immunologic effects including skin rash, blood dyscrasias, and possibly proteinuria and the nephrotic syndrome. It has cross-sensitivity to penicillin so it should be avoided by persons with penicillin hypersensitivity. Recent studies have shown the effectiveness of a new orally active chelating agent, triethylene tetramine 2HCl (Trien) in Wilson's disease, particularly in those persons who have developed sensitivity to penicillamine (Ref 23).

DTPA or diethylenetriamine-pentaacetic acid has chelating properties similar to those of EDTA. The calcium sale ($CaNa_2$ DTPA) must be used clinically because of its high affinity for calcium. It has been used for chelation of plutonium and other radioactive metals but with mixed success. More recently there has been considerable experimental study of BAL for removal of cadmium alone, or DTPA in combination with BAL, but with limited success (Ref 24).

Desferrioxamine is a hydroxylamine isolated as the iron chelate of *Streptomyces pilosus* and is used clinically in the metal-free from (Ref 25). It has a remarkable affinity for ferric iron and a low affinity for calcium and competes effectively for iron in ferritin and hemosiderin but not transferrin, or the iron in hemoglobin or heme-containing enzymes. It is poorly absorbed from the gastrointestinal tract so it must be given parenterally. Clinically usefulness is limited by a variety of toxic effects including hypotension, skin rashes, and possible cataract formation. It seems to be more effective in hemosiderosis due to blood transfusion but is less effective in treatment of hemochromatosis.

Dithiocarb (diethyldithiocarbamate) or DDC has been recommended as the drug of choice in the treatment of acute nickel carbonyl poisoning. The drug may be administered orally for mild toxicity but parenterally for acute or severe poisoning (Ref 26).

Major Toxic Metals With Multiple Effects

Overexposure to the metals described in this section can result in multiple toxicological effects. These metals include arsenic, beryllium, cadmium, chromium, lead, mercury, and nickel.

Arsenic

Arsenic is particularly difficult to characterize as a single element because its chemistry is so complex and there are many different compounds of arsenic. It may be trivalent or pentavalent and is widely distributed in nature. The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and arsenic trichloride. Pentavalent inorganic compounds are arsenic pentoxide, arsenic acid, and arsenates, such as lead arsenate and calcium arsenate. Organic compounds may also be trivalent or pentavalent such as arsanilic acid, or even methylated forms as a consequence of bimethylation by organisms in soil and fresh and seawaters. A summary of environmental sources of arsenic as well as potential health effects is contained in a World Health Organization (WHO) criteria document (Ref 27). Mechanical and physical properties of arsenic are summarized in the article "Properties of Pure Metals" in this Volume.

Arsenic is transported in the environment mainly by water, and airborne arsenic is generally due to contributions from industrial contamination and may range from a few nanograms to a few tenths of a microgram per cubic meter. The 133 stations of the National Air Sampling Network reported in 1964 that the average annual concentration of arsenic in air ranges from 0.01 $\mu g/m^3$ to 0.75 $\mu g/m^3$ in smelters. Near point emissions, concentrations may exceed 1 $\mu g/m^3$. Drinking water usually contains a few micrograms per liter or less. More than 18,000 community water supplies in the United States have concentrations less than 0.01 mg/L, but levels exceeding 0.05 mg/L have been found in Nova Scotia where arsenic content of bed rock is high. Even higher concentrations have been reported from various mineral springs, for example, Japan--1.7 mg As/L; Cordoba, Argentina--3.4 mg/L; Taiwan (artesian well water)--1.8 mg/L. Most foods (meat and vegetables) contain some level of arsenic, but the daily diet in the United States contains below 0.04 mg, but may contain 0.2 mg per day if the diet contains seafood. The total daily intake of arsenic by humans without industrial exposure, however, is usually less than 0.3 mg/day.

The major source of occupational exposure to arsenic in the United States is in the manufacture of pesticides, herbicides and other agricultural products (Ref 28). High exposure to arsenic fumes and dust may occur in the smelting industries; the highest concentrations most likely occur among roaster workers.

Disposition. Airborne arsenic is largely trivalent arsenic oxide, but deposition in airways and absorption from lungs is dependent on particle size and chemical form.

Studies show that 6 to 9% of orally administered ^{74}As-labeled trivalent or pentavalent arsenic is eliminated in feces in mice (Ref 29), indicating almost complete absorption from the gastrointestinal tract. Limited data also suggest nearly complete absorption of soluble forms of trivalent and pentavalent arsenic (Ref 30). Excretion of absorbed arsenic is mainly via urine. The biologic half-life of ingested inorganic arsenic is about 10 hours and 50 to 80% is excreted in about 3 days. The biologic half-life of methylated arsenic was found to be 30 hours in one study (Ref 31).

Arsenic has a predilection for skin and is excreted by desquamation of skin and in sweat, particularly during periods of profuse sweating. It also concentrates in nails and hair. Arsenic in nails produces Mee's lines (transverse white bands across finger-nails) appearing about six weeks after onset of symptoms of toxicity. Time of exposure may be estimated from measuring the distance of the line from the base of the nail and the rate of nail growth, which is about 0.3 cm/month or 0.1 mm/day. Arsenic in hair may also reflect past exposure, but intrinsic or systematically absorbed arsenic in hair must be distinguished from arsenic that is deposited from external sources. Human milk contains about 3 $\mu g/L$ of arsenic.

Placental transfer of arsenic has been shown in hamsters injected intravenously with high doses (20 mg/kg body weight) of sodium arsenate (Ref 32) and studies of tissue levels of arsenic in fetuses and newborn babies in Japan show that the total amount of arsenic in the fetus tends to increase during gestation indicating placental transfer. A more recent study of women in the United States found cord blood levels of arsenic to be similar to maternal blood levels (Ref 33).

Biotransformation of arsenic has been difficult to study because of analytical problems. Pentavalent arsenic compounds are reduced *in vivo* to more toxic trivalent compounds (Ref 34). However, ingestion of trivalent arsenic by experimental animals and humans is followed by excretion of some percentage of administered dose as pentavalent arsenic (Ref 35). The major form of arsenic in urine is dimethylarsinic acid, indicating *in vivo* methylation in humans.

Ingestion of arsenic-containing seafood does not result in increased excretion of inorganic arsenic and methyl- and dimethylarsinic acid, suggesting that the unknown organic compounds of arsenic are not converted to methylarsinic acid *in vivo* (Ref 31).

Cellular Effects. It has been known for some years that trivalent compounds of arsenic are the principal toxic forms, and pentavalent arsenic compounds have little effect on enzyme activity (Ref 17). A number of sulfhydryl-containing proteins and enzyme systems have been found to be altered by exposure to arsenic. Some of these can be reversed by addition of an excess of a monothiol such as glutathione; those enzymes containing two thiol groups can be reversed by dithiols such as 2,3-dimercaptopropanol (BAL) but not by monothiols.

Arsenic affects mitochondrial enzymes and impairs tissue respiration (Ref 36), which seems to be related to the cellular toxicity of arsenic. Mitochondria accumulate arsenic, and respiration mediated by nicotinamide adenine dinucleotide (NAD)-linked substrates is particularly sensitive to arsenic and is thought to result from reaction between arsenite ion and dihydrolipoic acid cofactor, necessary for oxidation of the substrate (Ref 37). Arsenite also inhibits succinic dehydrogenase activity and uncouples oxidative phosphorylation, which results in stimulation of mitochondrial adenosinetriphosphatase (ATPase) activity. Mitchell *et al.* (Ref 38) proposed that arsenic inhibits energy-linked functions of mitochondria in two ways: competition with phosphate during oxidative phosphorylation and inhibition of energy-linked reduction of NAD.

Toxicology. Ingestion of large doses (70 to 180 mg) may be acutely fatal (Ref 39). Symptoms consist of fever, anorexia, hepatomegaly, melanosis, and cardiac arrhythmia with electrocardiograph changes that may be the prodroma of eventual cardiovascular failure. Other features include upper-respiratory-tract symptoms, peripheral neuropathy, and gastrointestinal, cardiovascular, and hematopoietic effects. Acute ingestion may be suspected from damage to mucous membranes such as irritation , vesicle formation, and even sloughing. Sensory loss in the peripheral nervous system is the most common neurologic effect, appearing one or two weeks after large exposures and consisting of Wallerian degeneration of axons, but is reversible if exposure is stopped. Anemia and leukopenia, particularly granulocytopenia, occur in a few days and are reversible.

Liver injury is characteristics of longer-term or chronic exposure, is initially reflected by jaundice, and may progress to cirrhosis and ascites. Toxicity to hepatic parenchymal cells results in elevations of liver enzymes in blood, and studies in experimental animals show granules and alterations in the ultrastructure of mitochondria, nonspecific manifestations of cell injury including loss of glycogen.

Peripheral vascular disease has been observed in persons with chronic exposure to arsenic in drinking water in Taiwan and Chile, is manifested by acrocyanosis and Raynaud's phenomenon, and may progress to endarteritis obliterans and gangrene of the lower extremities (blackfoot disease). This specific effect seems to be related to the cumulative dose of arsenic, but prevalence is uncertain because of difficulties in separating arsenic-induced peripheral vascular disease from other causes of gangrene (Ref 40).

Carcinogenicity. Arsenic has specific effects on the endothelial cells of the blood vessels in the liver, and hemangioendothelial tumors or angiosarcoma of the liver has been reported in vineyard workers following many years of exposure to arsenic-containing drinking water, Fowler's solution, wine, and arsenic-containing pesticides (Ref 41).

The skin is the critical organ of arsenic toxicity, and a variety of skin lesions have been associated with arsenic intoxication, particularly from chronic exposure in drinking water and from certain occupational exposures. A characteristic finding is symmetric verrucous hyperkeratosis of the palms and soles. Hyperpigmentation or melanosis is also common. Cancer of the skin related to arsenic exposure was first reported by an English physician, Sir Jonathan Hutchinson, in persons with long-continued ingestion of Fowler's solution. Skin cancers from occupational exposures have since been well documented, particularly in the last 20 years. Available data suggest a dose-response relationship (Ref 40).

Workers engaged in the production of arsenic-containing pesticides showed increased lung cancer mortality (Ref 42), and workers involved in copper smelting, where arsenic exposure may be very high, are also reported to have an increased

risk or dying from lung cancer (Ref 43, 44). Nonworker populations living near point emission sources of arsenic to air may have increases in lung cancer as well, but the studies to date are not definitive (Ref 45). Nevertheless, the relationship of ingestion of arsenic with skin cancer and angiosarcoma and inhalation of arsenic containing particulates and lung cancer establishes arsenic as a human carcinogen. However, in contrast to most other human carcinogens, it has been difficult to confirm in experimental animals. In one study, rats given a mixture of calcium arsenate, copper sulfate, and calcium oxide by intratracheal instillation developed lung tumors (Ref 46), but other studies testing trivalent and pentavalent arsenic compounds by oral administration or skin application have not shown potential for either promotion or initiation of carcinogenicity. Similarly, experimental studies for carcinogenicity of organic arsenic compounds have been negative.

Studies on mutagenic effects of arsenic have been generally negative. Inorganic arsenic compounds do interfere with deoxyribonucleic acid (DNA) repair mechanisms in bacteria and dermal cell cultures. An increased frequency of chromosomal aberrations has been found among workers exposed to inorganic arsenic compounds and patients taking drugs containing arsenic (Ref 47).

Reproductive Effects and Teratogenicity. High doses of inorganic arsenic compounds given to pregnant experimental animals produce various malformations somewhat dependent on time and route of administration. However, no such effects have been noted in people with excessive occupational exposures to arsenic compounds.

Arsine. Arsine gas is formed by the reaction of hydrogen with arsenic and is generated as a by-product in the refining of nonferrous metals. Arsine is a potent hemolytic agent, producing acute symptoms of nausea, vomiting, shortness of breath, and headache accompanying the hemolytic reaction. Exposure may be fatal and may be accompanied by hemoglobinuria and renal failure, and even jaundice and anemia in nonfatal cases where exposure persists (Ref 48).

Biologic indicators or arsenic exposure are blood, urine, and hair (Table 3). Because of the short half-life of arsenic, blood levels are only useful within a few days of acute exposure but are not useful to assess chronic exposure. Urine arsenic is the best indicator of current or recent exposure and has been noted to be several hundred micrograms per liter with occupational exposure. Hair or even fingernail concentration or arsenic may be helpful to evaluate past exposures, but interpretation is made difficult because of the problem of differentiating external contamination.

Table 3 Biologic indicators of arsenic exposure

Indicator	Normal	Excessive exposure
Whole blood	<10 μg/L	Up to 50 μg/L
Urine[(a)]	<50 μg/L	>100 μg/L
Hair	<1 μg/kg	

(a) Best indicator of current or recent exposure

There are no specific biochemical parameters that reflect arsenic toxicity, but evaluation of clinical effects must be interpreted with knowledge of exposure history.

Treatment. BAL is used to treat acute dermatitis and pulmonary symptoms. BAL has also been used for the treatment of chronic arsenic poisoning, but there are no established biologic criteria or measures of effectiveness. BAL has been used most often in cases with dermatitis, but there is usually no change in the keratotic lesions or influence on progression to skin cancer.

Arsine toxicity is best treated symptomatically. BAL is not considered helpful (Ref 48).

Beryllium

The major toxicologic effects of beryllium are on the lung. It may produce an acute chemical pneumonitis, hypersensitivity, and chronic granulomatous pulmonary disease (berylliosis). A variety of beryllium compounds and some of its alloys have induced malignant tumors of the lung in rats and monkeys and osteogenic sarcoma in rabbits. Human epidemiologic studies are strongly suggestive of a carcinogenic effect in humans (Ref 49).

Beryllium in the environment largely results from coal combustion. Illinois and Appalachian coal contains an average of about 2.5 ppm; oil contains about 0.08 ppm. The combustion of coal and oil contributes about 1250 tons or more of beryllium to the environment each year (mostly from coal), which is about five times the annual production for industrial use. The major industrial processes that release beryllium into the environment are beryllium extraction plants, ceramic plants, and beryllium alloy manufacturers. These industries also provide the greatest potential for occupational exposure. A review published in 1959 states that inhalable beryllium in ore treatment rooms around baking furnaces or at the sites

of fluorescent phosphor blending, milling, and salvaging must have been around 1 mg/m^3. The major current use is as an alloy (see the article "Beryllium-Copper and Other Beryllium-Containing Alloys" in this Volume), but about 20% or world production is for applications utilizing the free metal in nuclear reactions, x-ray windows, and other special applications related to space optics, missile fuel, and space vehicles (see the article "Beryllium" in this Volume).

Knowledge of the disposition of beryllium has largely been obtained from experimental animals, particularly the rat. Clearance of inhaled beryllium is multiphasic; half is cleared in about two weeks; the remainder is removed slowly, and a residuum becomes fixed in the tissues probably within fibrotic granulomata.

Absorption of ingested beryllium probably only occurs in the acidic milieu of the stomach, where it is in the ionized form, but passes through the intestinal tract as precipitated phosphate (Ref 50). Transport in plasma is in the form of a colloidal phosphate probably bound to an α-globulin. Removal of radiolabeled beryllium chloride from rat blood is rapid, having a half-life of about three hours. It is distributed to all tissues, but most goes to the skeleton. High doses go predominantly to liver, but it is gradually transferred to bone. A variable fraction of the administered dose is excreted in urine, probably by way of transtubular secretion, rather than glomerular filtration.

Skin Effects. Contact dermatitis is the commonest beryllium-related toxic effect. Exposure to soluble beryllium compounds may result in papulovesicular lesions on the skin. It is a delayed-type allergic reaction. If contact is made with an insoluble beryllium compound, a chronic granulomatous lesion develops, which may be necrotizing or ulcerative. If insoluble beryllium-containing material becomes embedded under the skin, the lesion will not heal and may progress in severity. Use of a beryllium patch test to identify beryllium-sensitive individuals may in itself be sensitizing, and use of this procedure as a diagnostic test is discouraged.

Beryllium combines with proteins in the skin to act as the antigen in the hypersensitivity reaction. The hypersensitivity is cell mediated, and passive transfer with lymphoid cells has been accomplished in guinea pigs.

Pulmonary Effects. Two types of pulmonary disease will be described in this section. These include acute chemical pneumonitis and chronic granulomatous pulmonary disease.

Acute pulmonary disease (Chemical Pneumonitis) from inhalation of beryllium is a fulminating inflammatory reaction of the entire respiratory tract, involving the nasal passages, pharynx, tracheobroncheal airways, and the alveoli, and in the most severe cases produces an acute fulminating pneumonitis. It occurs almost immediately following inhalation of aerosols of soluble beryllium compounds, particularly fluoride--an intermediate in the ore extraction process. Severity is dose related. Fatalities have occurred, although recovery is generally complete after a period of several weeks or even months.

Chronic Granulomatous Pulmonary Disease (Berylliosis). This syndrome was first described in 1946 by Hardy and Tabershaw (Ref 51) among fluorescent lamp workers exposed to insoluble beryllium compounds, particularly beryllium oxide. The major symptom is shortness of breath, but in severe cases may be accompanied by cyanosis and clubbing of fingers (hypertrophic osteoarthropathy--a characteristic manifestation of chronic pulmonary disease). Chest x-rays show miliary mottling. Histologically, the alveoli contain small interstitial granulomata, which resemble those seen in sarcoidosis. In the early stages, the lesions are composed of fluid, lymphocytes, and plasma cells. Multinucleated giant cells are common. Later, the granulomas become organized with proliferation of fibrosis tissue, eventually forming small, fibrous nodules. As the lesions progress, interstitial fibrosis increases with loss of functioning alveoli and effective air/capillary gas exchange and increasing respiratory dysfunction.

Beryllium is one metal in which evidence for carcinogenicity was observed in experimental studies, beginning in 1946, before the establishment of carcinogenicity in humans (Ref 49). Epidemiologic confirmation in humans has been evolving, so that there is increasing acceptance that beryllium is, in fact, a human carcinogen. Studies of humans with occupational exposure to beryllium prior to 1970 were negative. However, three recent reports to worker populations studied earlier show a small excess of lung cancer, but the total number of cases is small. It was the conclusion of a work group report in 1981 that beryllium is indeed "the cause of the excess mortality" in persons with excess occupational/environmental exposure to beryllium (Ref 52).

In vitro studies of genotoxicity have shown that beryllium will induce morphologic transformation in mammalian cells (Ref 53). Beryllium will also decrease fidelity of DNA synthesis, but is negative when tested as a mutagen in bacterial systems (Ref 54).

Cadmium

Cadmium is a modern toxic metal. It was only discovered as an element in 1817, and industrial use was minor until about 50 years ago. But now it is a very important metal with many applications. The main use is electroplating or galvanizing because of its noncorrosive properties. It is also used as a color pigment for paints and plastics, and cathode material for nickel-cadmium batteries. Cadmium is a by-product of zinc and lead mining and smelting, which are important sources of environmental pollution. The toxicology of cadmium is reviewed in detail in Ref 55. Mechanical and physical properties of cadmium are reviewed in the article "Properties of Pure Metals" in this Volume.

Air concentrations as high as 4 to 5 mg/m^3 have been detected in certain workplace environments such as battery factories (Ref 56), but airborne cadmium in the present-day workplace environment is generally less than 0.02 $\mu g/m^3$. Typical concentrations in ambient air in rural areas are 0.001 to 0.005 $\mu g/m^3$ and up to 0.050 or 0.060 $\mu g/m^3$ in urban areas (Ref 57).

Meat, fish, and fruit contain 1 to 50 μg/kg, grains contain 10 to 150 μg/kg, and the greatest concentrations are in liver and kidney of animals. Shellfish, such as mussels, scallops, and oysters, may be a major source of dietary cadmium and contain 100 to 1000 μg/kg. Shellfish accumulate cadmium from the water and then bind to cadmium-binding peptides (Ref 58). Total daily intake from food in North America and Europe varies considerably but is generally less than 100 μg/day, whereas in heavily polluted areas as in parts of Japan, cadmium intake from food and water may be up to 150 μg/day (Ref 59).

Rice grown in soil contaminated with cadmium and other grains contributes to dietary content. Cadmium is more readily taken up by plants than other metals such as lead (Ref 60). Factors contributing to soil content of cadmium are fallout from air, cadmium content of water irrigating fields, and cadmium added with fertilizers. Commercial phosphate fertilizers usually contain less than 20 mg/kg, but Anderson and Hahlin (Ref 61) found an annual increase in soil and barley grain from continued use of phosphate fertilizer over a 15-year period. Another concern is use of commercial sludge to fertilize agricultural fields (Ref 62). Commercial sludge may contain up to 1500 mg of cadmium per kilogram of dry material.

Respiratory absorption of cadmium is about 15 to 30%. Workplace exposure to cadmium is particularly hazardous where there are cadmium fumes or airborne cadmium. Most airborne cadmium is respirable (Ref 63). A major nonoccupational source of respirable cadmium is cigarettes. One cigarette contains 1 to 2 μg cadmium, and 10% of the cadmium in a cigarette is inhaled (0.1 to 0.2 μg) (Ref 64). Smoking one pack or more cigarettes a day may double the body burden of cadmium.

Disposition. Gastrointestinal absorption is less than respiratory absorption and is about 5 to 8%. It is enhanced by dietary deficiencies of calcium and iron, and diets low in protein. Low dietary calcium stimulates synthesis of calcium-binding protein, which enhances cadmium absorption. Women with low serum ferritin levels have been shown to have twice the normal absorption of cadmium (Ref 65). Zinc decreases cadmium absorption probably by stimulating production of metallothionein.

Cadmium is transported in blood bound to red blood cells and large-molecular-weight proteins in plasma, particularly albumin. A small fraction of blood cadmium may be transported by metallothionein. Blood cadmium levels in adults without excessive exposure is usually less than 1 μg/dL. Newborns have low body content of cadmium usually less than 1 mg total body burden. The placenta synthesizes metallothionein and may serve as a barrier to maternal cadmium, but the fetus may be exposed with increased maternal exposure (Ref 66). Cow's milk and human milk are low in cadmium content, less than 1 μg/kg of milk (Ref 67). About 50 to 75% of the body burden of cadmium is in liver and kidneys; half-life in the body is not exactly known but is many years and may be as long as 30 years. With continued retention, there is progressive accumulation in soft tissues, particularly kidney, through ages 50 to 60 years when it begins to decline slowly. Because of the potential for accumulation in kidney, there is considerable concern for levels of dietary intake of cadmium by persons in the general population. Studies from Sweden have shown a slow but steady increase in cadmium content of vegetables over the years (Ref 68). Increase in body burden has been determined from an historic autopsy study (Ref 69).

Toxicity. Acute toxicity may result from ingestion of relatively high concentrations of cadmium, as may occur in contaminated beverages or food. Nordberg (Ref 70) relates an instance in which nausea, vomiting, and abdominal pain occurred from consumption of drinks containing approximately 16 mg/L of cadmium. Recovery was rapid without apparent long-term effects. Inhalation of cadmium fumes or other heated cadmium-containing materials may produce an acute chemical pneumonitis and pulmonary edema.

The principal long-term effects of low-level exposure to cadmium are chronic obstructive pulmonary disease and emphysema and chronic renal tubular disease. There may also be effects on the cardiovascular and skeletal systems (Ref 71, 72).

Chronic Pulmonary Disease. Toxicity to the respiratory system is proportional to the time and level of exposure. Obstructive lung disease results from chronic bronchitis, progressive fibrosis of the lower airways, and accompanying alveolar damage leading to emphysema. The lung disease is manifested by dyspnea, reduced vital capacity, and increased residual volume. The pathogenesis of the lung lesion is turnover and necrosis of alveolar macrophages. Released enzymes produce irreversible damage to alveolar basement membranes including rupture of septa and interstitial fibrosis. It has been found that cadmium reduces α-1-antitrypsin activity, perhaps enhancing pulmonary toxicity (Ref 73). However, no difference in plasma α-1-antitrypsin activity could be found between cadmium-exposed workers with and without emphysema (Ref 74).

Kidney. The effects of cadmium on proximal renal tubular function are manifested by increased cadmium in the urine, proteinuria, aminoaciduria, glucosuria, and decreased renal tubular reabsorption of phosphate. Morphologic changes are nonspecific and consist of tubular cell degeneration in the initial stages, progressing to an interstitial inflammatory reaction and fibrosis. The nephropathy occurs when cadmium concentration reaches a level in the kidney (200 μg/g) that has been widely referred to as the critical concentration of cadmium.

The proteinuria is principally tubular, consisting of low-molecular-weight proteins whose tubular reabsorption has been impaired by cadmium injury to proximal tubular lining cells. The predominant protein is a β_2 microglobulin, but a number of other low-molecular-weight proteins have been identified in the urine of workers with excessive cadmium exposure, such as retinol-binding protein, lysozyme, ribonuclease, and immunoglobulin light chains (Ref 74). High-molecular-weight proteins in the urine, such as albumin and transferin, indicate that some workers may actually have a mixed proteinuria and suggesting a glomerular effect as well. The nature of the glomerular lesion in cadmium nephropathy has not been studied extensively, but circulating antiglomerular basement membrane antibodies have been identified in humans and rats chronically exposed to cadmium, suggesting the presence of immunologically induced glomerular disease in addition to the tubulonephropathy (Ref 75).

Aminoaciduria in cadmium toxicity is generalized, reflecting increased excretion of amino acids normally reabsorbed by proximal tubular lining cells. The severity of the aminoaciduria is increased in cadmium workers with increasing levels of cadmium exposure. In addition, particularly large increases in proline and hydroxyproline excretion have been noted in patients with chronic cadmium toxicity with bone disease or Itai-Itai disease, but this probably reflects the changes in bone metabolism found in these people. Glucosuria and decreased tubular reabsorption of phosphate parallel the occurrence of low-molecular-weight proteinuria and aminoaciduria, reflecting the proximal tubular cell effect. Proximal tubular dysfunction may be symptom-free for a number of years, but tubular dysfunction may progress resulting in hypercalcuria, renal calculi, and rarely osteomalacia and evidence of distal tubular dysfunction (Ref 76).

Although most of the data available to date related to cadmium exposure and cadmium nephropathy have been obtained from workers with occupational exposure, there is some evidence now that persons in the general population with nonoccupational exposure to cadmium may also have cadmium-related renal tubular dysfunction. Among inhabitants of cadmium-polluted areas of Japan where dietary content of cadmium is increased, the prevalence of proteinuria and glucosuria is higher than in control areas, and there is some association between increased excretion of low-molecular-weight proteins in urine and level of cadmium pollution (Ref 77). Also, in 1980 Lauwerys *et al.* (Ref 78) studied a group of Belgian women and found that a group of women living near a nonferrous metal smelter had a higher body burden as reflected by an increased excretion of cadmium in urine and a higher prevalence of signs of renal dysfunction than women from a control area.

Critical Concentration of Cadmium. With this awareness that cadmium-induced nephropathy may occur in persons in the general population, it becomes of major public health importance to know what is the maximum level of cadmium that a person can be exposed to without risk of renal tubular dysfunction and cadmium nephropathy. Also, the concept of a critical concentration of cadmium has very important implications with regard to establishing maximum levels of cadmium that human populations may be exposed to with some margin of safety.

Kjellstrom *et al.* (Ref 79), in 1977 established a metabolic model relating daily intake of cadmium and concentration of cadmium in renal cortex. The geometric average intake of cadmium was 14 μg cadmium per day, corresponding to a concentration of cadmium in the renal cortex at about age 50 of around 10 μg/g. The WHO Task Force estimated that daily ingestion of 200 to 300 μg cadmium per day would be required to reach the critical kidney cortex concentration of

200 μg cadmium per gram at age 50 for a 70 kg (150 lb) man. Rats given daily injections of cadmium also develop a nephropathy when renal cadmium concentration reaches about 200 μg/g kidney weight (Ref 80).

Role of Metallothionein in Cadmium Toxicity. Accumulation of cadmium in the kidney without apparent toxic effect if possible because of formation of cadmium-thionein or metallothionein, a metal protein complex with a low molecular weight (about 6500 atomic mass units, or Daltons) (Ref 81).

The amino acid composition of metallothionein is characterized by approximately 30% cysteine and the absence of aromatic amino acids. Specific optical absorption is due to location of metal thiolate complexes in the protein. Metallothionein contains 61 amino acids and 20 are cysteine. Structural studies using nuclear magnetic resonance spectroscopy and electron spin resonance spectroscopy have identified two distinct metal clusters in mammalian metallothionein. The clusters seem to have significant differences in their affinity for different metal ions; one of the clusters has a high level of specificity for zinc. Metal binding is by trimercaptide bridges (Ref 82). Metallothionein is primarily a tissue protein and is ubiquitous in most organs but is in highest concentration in liver, particularly following recent exposure, and in kidney where it accumulates with age in proportion to cadmium concentration.

A number of studies from experimental animals, as well as tissue culture models, confirm the protective role of metallothionein. It has been found that synthesis of metallothionein in tissues is directly related to exposure to metal, and toxicity to kidney probably only occurs when exposure exceeds the ability of that organ to either synthesize metallothionein or store additional cadmium. Toxic cell injury is thought to be caused by unbound cadmium or free cadmium ion. Administration of metallothionein prepared with different ratios of cadmium and zinc to rats has demonstrated that renal tubular necrosis is related to the cadmium content, not the amount of metallothionein (Ref 81, 83).

Pretreatment of experimental animals with small doses of cadmium has been shown to prevent acute toxic effects of a large does of cadmium. This property is not restricted to protection from cadmium toxicity alone. Pretreatment of experimental animals with small doses of cadmium or mercury salts can prevent the nephrotoxic effects of high doses of mercury chloride. There is also some experimental evidence that suggests that the teratogenic effects of cadmium in Golden hamsters is prevented by pretreatment with zinc salts of small amounts of metallothionein. Other studies have shown that certain sulfhydryl-requiring enzymes are inhibited *in vitro* by small amounts of cadmium but not affected *in vivo* where intracellular cadmium is bound to metallothionein. Human cells in tissue culture, in which metallothionein has been induced by pretreatment with cadmium, become resistant to previously lethal exposure to cadmium (Ref 84).

Experimental studies have shown that cadmium administered parenterally as inorganic and cadmium bound to metallothionein has a different distribution in organs. Inorganic cadmium is largely recovered in liver whereas cadmium from cadmium metallothionein is preferentially taken up by kidney (Ref 85).

Skeletal System. Cadmium toxicity affects calcium metabolism, and individuals with severe cadmium nephropathy may have renal calculi and excess excretion of calcium, probably related to increased urinary loss, but with chronic exposure, urine calcium may be less than normal. Associated skeletal changes are probably related to calcium loss and include bone pain, osteomalacia, and/or osteoporosis. Bone changes are part of a syndrome recognized in postmenopausal multiparous women living in the Fuchu area of Japan prior to and during World War II. The syndrome consisted of severe bony deformities and chronic renal disease.

Excess cadmium exposure has been implicated in the pathogenesis of the syndrome, but vitamin D and perhaps other nutritional deficiencies are thought to be cofactors. "Itai-Itai" translates to "ouch-ouch," reflecting the accompanying bone pain (Ref 71).

Hypertension and Cardiovascular Disease. Schroeder and Balassa (Ref 67) first reported in 1961 that the chronic feeding of low levels (5 ppm) of cadmium in drinking water to rats could induce hypertension. These experimental results have been confirmed (Ref 86) and a number of mechanisms for the pathogenesis of the hypertension suggested, including increased sodium retention, direct vasoconstriction, hyperreninemia, and increased cardiac output. Recent studies from Japan found a twice-as-high cerebrovascular disease mortality rate among people who had cadmium-induced renal tubular proteinuria as among people in cadmium-polluted areas without proteinuria (Ref 87).

Carcinogenicity. An increase in carcinoma of the prostate was first noted in a mortality study of battery workers in England in 1965, but this was not found in a study of a large worker population (Ref 88). The problem of prostatic cancer is further complicated by the high incidence of latent (*in situ*) carcinoma of the prostate in elderly men in the general population

and the implication of numerous other factors, such as marital status (singles), race (nonwhites), and even religion. There have been numerous experimental studies supporting the potential carcinogenicity of cadmium. Metallic cadmium or cadmium sulfide or sulfate given subcutaneously or intramuscularly will induce sarcomata at the site of injection in experimental animals. The tumors are truly malignant and have been found to metastasize to lymph nodes and lungs. Also, it was found many years ago that injection of several milligrams of cadmium per kilogram body weight to mice causes acute testicular necrosis followed by Leydig cell tumors. The pathogenesis of the Leydig cell tumors appears to be hormone dependent and is preceded by decreases in serum testosterone levels and stimulation of Leydig cell hyperplasia and tumors. Testicular necrosis as well as Leydig cell tumor formation is prevented by supplemental zinc (Ref 89). Carcinoma of lungs has recently been produced by exposing rats to cadmium aerosols (Ref 90).

Biologic Indicators. The most important measure of excessive cadmium exposure is increased cadmium excretion in urine. In persons in the general population, without excessive cadmium exposure, urine cadmium excretion is both small and constant. That is, it is usually of the order of only 1 or 2 μg/day, or less than 1 μg/g creatinine. With excessive exposure to cadmium as might occur in workers, increase in urine cadmium may not occur until all of the available cadmium binding sites are saturated. However, when binding sites (metallothionein) are saturated, increased urine cadmium reflects recent exposure and body burden and renal cadmium concentration so that urine cadmium measurement does provide a good index of excessive cadmium exposure. Nogawa ***et al.*** (Ref 87), determined the urinary concentration of cadmium corresponding to 1% prevalence rate of a number of abnormal urinary findings (Table 4). Tubular proteinuria, as indicated by measurable excretion of β_2-microglobulin, occurred at the 1% prevalence rate with a urinary cadmium concentration of 3.2 μg/g of creatinine. This was at a slightly lower urine cadmium level than other signs of renal tubular dysfunction. Retinol binding protein may be a more practical and reliable test of proximal tubular function than β_2 microglobulin because sensitive immunologic analytic methods are now available, and it is more stable in urine (Ref 75). Changes in urinary excretion of low-molecular-weight proteins mainly observed in workers excreting more than 10 μg cadmium per gram creatinine (Ref 91).

Table 4 Urinary cadmium concentration corresponding to 1% prevalence rate for parameters of renal dysfunction

Urinary finding	**Urinary cadmium per μg/g creatinine**	
	Male	**Female**
Tubular proteinuria		
β_2-microglobulin	3.2	5.2
Retinal binding protein	4.4	7.4
Aminoaciduria (proline)	10.4	5.1
Proteinuria with glucosuria	7.4	7.4

Most of the cadmium in urine is bound to metallothionein, and there is good correlation between metallothionein and cadmium in urine in cadmium workers with normal or abnormal renal function (Ref 92). Therefore, measurement of metallothionein in urine provides the same toxicologic information as measurement of cadmium and, in addition, does not have the problem of external contamination. Radioimmunoassay techniques for measurement of metallothionein are evolving rapidly (Ref 93, 94).

Recently, *in vivo* neutron activation analysis has been used to measure cadmium in liver and kidney in exposed workers. The detection limits are at least 15 mg/kg in kidney cortex and 1.5 mg/kg in liver, so that the method is not sufficiently sensitive to measure *in vivo* tissue levels in persons in the general population (Ref 95). Applying this technique to

cadmium-exposed workers, Roels, Lauwerys, and co-workers found a wide range of variability and overlap in kidney cadmium concentration associated with and without renal disease. On the basis of their study of 309 workers, the critical concentration of cadmium in renal cortex may range from 215 to 390 ppm (Ref 96).

Treatment. Susceptibility of cadmium-induced toxicity is influenced by a number of factors, particularly ability of the body to provide binding sites on metallothionein. Protection is provided by dietary zinc, cobalt, or selenium. Treatment of the toxicity of cadmium on the kidney is to cease exposure to cadmium (Ref 11). What severity of cadmium-induced tubular dysfunction is reversible is still not certain.

Chelation therapy is not available for cadmium toxicity in humans. Experimental studies have shown that the action of chelating agents on the pharmacokinetics of cadmium depends on the time of administration of the chelators after cadmium exposure. When the chelators are given shortly after cadmium exposure, when no new metallothionein has been synthesized, the thiol-containing chelators such as BAL and penicillamine increase the biliary excretion of cadmium while EDTA, DTPA, and related chelators increase urinary excretion (Ref 97). For chronic cadmium exposure, when cadmium is bound to metallothionein, there is little effect from chelation therapy.

Chromium

Chromium is a generally abundant element in the earth's crust and occurs in oxidation states ranging from Cr^{2+} to Cr^{6+}, but only the trivalent and hexavalent forms are of biologic significance. The trivalent is the more common form. However, hexavalent forms of chromate compounds are of greater industrial importance. Sodium chromate and dichromate are the principal substances for the production of all chromium chemicals. Sodium dichromate is produced industrially by the reaction of sulfuric acid on sodium chromate. The major source of chromium is from chromite ore. Metallurgical-grade chromite is usually converted into one of several types of ferrochromium or processed for use in cobalt-base and nickel-base superalloys. Ferrochrome is used for the production of stainless steel (superalloys and stainless steels are described in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook*). Chromates are produced by a smelting, roasting, and extraction process. The major uses of sodium dichromate are for the production of chrome pigments, for the production of chrome salts used for tanning leather, mordant dying, wood preservatives, and as an anticorrosive in cooking systems, boilers, and oil drilling muds (Ref 98, 99).

Chromium in ambient air originates from industrial sources, particularly ferrochrome production, ore refining, chemical and refractory processing, and combustion of fossil fuels. In rural areas, chromium in air is usually less than 0.1 $\mu g/m^3$ and from 0.01 to 0.03 $\mu g/m^3$ in industrial cities. Particulates from coal-fired power plants may contain from 2.3 to 31 ppm, but this is reduced to 0.19 to 6.6 ppm by fly-ash collection. Cement-producing plants are another important potential source of atmospheric chromium. Chromium precipitates and fallout are deposited on land and water; land fallout is eventually carried to water by runoff, where it is deposited in sediments. A controllable source of chromium is waste water from chrome-plating and metal-finishing industries, textile plants, and tanneries. Chromium in food is low, and estimates of daily intake by humans is under 100 μg, mostly from food, with trivial quantities from most water supplies and ambient air.

Disposition. Trivalent chromium is the most common form found in nature, and chromium in biologic materials is probably always trivalent. There is no evidence that trivalent chromium is converted to hexavalent forms in biologic systems. However, hexavalent chromium readily crosses well membranes and is reduced intracellularly to trivalent chromium.

The known harmful effects of chromium in humans have been attributed to the hexavalent form, and it has been speculated that the biologic effects of hexavalent chromium may be related to the reduction to trivalent chromium and the formation of complexes with intracellular macromolecules. High concentrations of chromium are normally found in ribonucleic acid (RNA), but its role is unknown. Trace quantities of trivalent chromium are essential for carbohydrate metabolism in mammals. It is a cofactor for insulin action and has a role in the peripheral activities of this hormone by forming a ternary complex with insulin receptors, facilitating the attachment of insulin of these sites. The most biologically active form of insulin appears to be a naturally occurring complex containing niacin as well as glycine, glutamic acid, and cysteine (Ref 59).

Human chromium deficiency may be occurring in infants suffering from protein-caloric malnutrition and elderly people with impaired glucose tolerance, but this is not well documented. Prolonged use of a synthetic diet without chromium supplementation may lead to chromium deficiency, impaired glucose metabolism, and possibly effects on growth and on

lipid and protein metabolism. Half-time for elimination of chromium from rats is 0.5, 5.9, and 83.4 days, according to a three-compartment model (Ref 100).

Human kinetic studies have identified an erythrocyte chromium compartment that corresponds to the survival time of the red blood cell and is almost exclusively excreted in urine.

Toxicology. Systemic toxicity to chromium compounds occurs largely from accidental exposures, occasional attempts to use chromium as a suicidal agent, and previous therapeutic uses. The major acute effect from ingested chromium is acute renal tubular necrosis (Ref 101).

Exposure to chromium, particularly in the chrome production and chrome pigment industries, is associated with cancer of the respiratory tract (Ref 102). As early as 1936, German health authorities recognized cancer of the lung among workers exposed to chromium dust. In a review paper from 1950, Baetjer described 109 cases of cancer in the chromate-producing industry, 11 cases in the chrome pigment industry, and 2 cases in other industries. In a 1966 review of the histologic classification of 123 cases of lung cancer in chromate workers, Hueper (Ref 103) found 46 squamous cell carcinomas, 66 anaplastic tumors, and 11 adenocarcinomas. The greatest risk to cancer is attributed to exposure to acid-soluble, water-insoluble hexavalent chromium as occurs in the roasting or refining processes. Other studies have supported the greater risk to cancer form exposure to slightly soluble, hexavalent compounds rather than trivalent chromium compounds. Hexavalent chromium is corrosive and causes chronic ulceration and perforation of the nasal septum. It also causes chronic ulceration of other skin surfaces, which is independent of hypersensitivity reactions on skin. Allergic chromium skin reactions readily occur with exposure and are independent of dose. Trivalent chromium compounds are considerably less toxic than the hexavalent compounds and are neither irritating nor corrosive. Nevertheless, nearly all workers in industries are exposed to both forms of chromium compounds, and at present, there is no information as to whether there is a gradient of risk from predominant exposure to hexavalent or insoluble forms of chromium to exposure to soluble trivalent forms. In a 1981 review, Norseth (Ref 102) suggests that if there are similar increased risks in both groups, as estimated from the death rates, trivalent chromium should be considered as an equally potent carcinogen as are the hexavalent compounds.

Whether chromium compounds cause cancer at sites other than the respiratory tract is not clear. A slight increase in cancer of the gastrointestinal tract has been reported in other studies, but each involved only small groups of workers.

Animal studies support the notion that the most potent carcinogenic chromium compounds are the slightly soluble hexavalent compounds. Studies on *in vitro* bacterial systems, however, show no difference between soluble and slightly soluble compounds. Trivalent chromium salts have little or no mutagenic activity in bacterial systems. Since there is preferred uptake of the hexavalent form by cells and it is the trivalent form that is metabolically active and binds with nucleic acids within the cell, it has been suggested that the causative agent in chromium mutagenesis is trivalent chromium bound to genetic material after reduction of the hexavalent form (Ref 102).

Human Body Burden. Tissue concentrations of chromium in the general population have considerable geographic variation, as high as 7 μg/kg in lungs of persons in New York or Chicago with lower concentrations in liver and kidney (Ref 104). In persons without excess exposure, blood chromium concentration is between 20 and 30 μ/L and is evenly distributed between erythrocytes and plasma. With occupational exposure, increase in blood chromium is related to increase in chromium in red blood cells. Urinary excretion is generally less than 10 μg/day in the absence of excess exposure (Ref 59).

Lead

Lead, the most ubiquitous toxic metal, is detectable in practically all phases of the inert environment and in all biologic systems. Because it is toxic to most living things at high exposures and there is no demonstrated biologic need, the major issue regarding lead is at what dose does it become toxic. Specific concerns vary with the age and circumstances of the host, and the major risk is toxicity to the nervous system. Several reviews and multiauthored books on the toxicology of lead are available (Ref 105, 106, 107, 108, 109, 110, 111, 112). Applications and properties of lead are described in the articles "Lead and Lead Alloys" and "Properties of Pure Metals" in this Volume.

Sources. The principal route of exposure is food, but it is usually environmental and presumably controllable sources that produce excess exposure and toxic effects. These sources include lead-base indoor paint in old dwellings, lead in air from combustion of lead-containing auto exhausts or industrial emissions, lead-base paint, hand-to-mouth activities of young

children living in polluted environments, and, less commonly, lead dust brought home by industrial workers on their clothes and shoes, and lead-glaze earthenware.

The total daily intake of lead for an adult in the United States varies from less than 0.1 mg/day to more than 2 mg/day (Ref 105, 113). The major source of daily intake of lead in adults and children (without excess exposure) is food and beverages. Lead content of food is extremely variable, but there are practically no lead-free food items. The average adult diet contains from 150 μg/day, 0.75 to 120 μg/day for infants and small children. Most municipal water supplies measured at the tap contain less than the WHO-recommended limit of 0.05 μg/ml, so that daily intake from water is usually about 10 μg, and unlikely to be more than 20 μg.

Air is a third source of lead exposure for persons in the general population. Concentrations of lead in air vary widely and may be lower than 1.0 $\mu g/m^3$ in rural areas to 10 $\mu g/m^3$ in certain urban environments. For the contemporary urbanite, the magnitude of respired lead is about one-half the intake from the diet.

Disposition. The gastrointestinal absorption of lead is influenced by a large number of factors of which age and nutritional factors are of particular importance. Adults absorb 5 to 15% of ingested lead and usually retain less than 5% of what is absorbed. Children are known to have a greater absorption of lead than adults; one study found an average net absorption of 41.5% and 31.8% net retention in infants on regular diets.

Lead in the atmosphere exists either in solid forms, dust or particulates of lead dioxide, or in the form of vapors, particularly alkyl lead that has escaped by evaporation from automobile fuel systems.

Lead absorption by the lungs also depends on a number of factors in addition to concentration. These include volume of air respired per day, whether the lead is in particle or vapor form, and size distribution of lead-containing particles. Only a very minor fraction of particles over 0.5 μm in mean maximal external diameter are retained in the lung but are cleared from the respiratory tract and swallowed. However, the percentage of particles less than 0.5 μm retained in the lung increases with reduction in particle size. About 90% of lead particles in ambient air that are deposited in the lungs are small enough to be retained. Absorption of retained lead through alveoli is relatively efficient and complete.

More than 90% of lead in blood is in the red blood cells. There seem to be at least two major compartments for lead in the red blood cell, one associated with the membrane and the other with hemoglobin (Ref 114). Small fractions may be related to other red blood cell components. Plasma ligands are not well defined, but it has been suggested that plasma and serum may contain diffusible fractions of lead in equilibrium with soft tissue or end-organ binding sites for lead. This fraction is difficult to measure accurately, but there is an equilibrium between red cell and plasma lead.

Blood lead levels are a good indicator of recent exposure to lead and are influenced by inhalation and ingestion. A number of recent studies suggest that inhalation of air containing 1 $\mu g/m^3$ in respirable particles will increase blood lead concentrations by about 1 μg/dL when air lead concentrations are in the range of 1 to 5 $\mu g/m^3$ (Ref 107).

Lead in blood varies with age (Fig. 3) (Ref 115). Children under seven years of age have significantly higher blood lead levels than older children, and there is no difference between boys and girls under age 12. Blood lead levels decline during adolescence probably related to bone growth and deposition of lead in bones with calcium. Blood lead levels are lower in adult females than adult males.

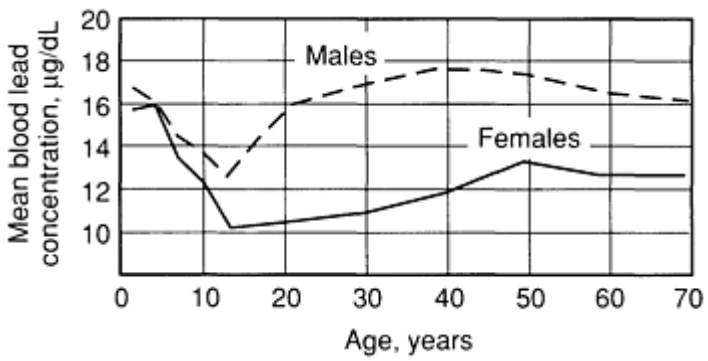

Fig. 3 National estimates of blood lead levels in the United States. Source: Ref 115

The total body burden of lead may be divided into at least two kinetic pools, which have different rates of turnover. The largest and kinetically slowest pool is the skeleton with a half-life of more than 20 years and a much more labile soft tissue pool. The total lifetime accumulation of lead may be about 200 mg and over 500 mg for an occupationally exposed worker. Kidney lead accumulates with age; lead in lung does not change. Lead in the central nervous system tends to concentrate in gray matter and certain nuclei. The highest concentrations are in the hippocampus, followed by cerebellum, cerebral cortex, and medulla. Cortical white matter seems to contain the least amount, but these comments are based on only a few reported human and animal studies.

Renal excretion of lead is usually with glomerular filtrate with some renal tubular resorption. With elevated blood lead levels, excretion may be augmented by transtubular transport.

Placental transfer of lead occurs. Cord blood generally correlates with maternal blood lead levels but is slightly lower. It is interesting that maternal blood lead decrease during pregnancy, suggesting that maternal lead is transferred to the fetus or excreted in some way.

Toxicity. The topic of greatest interest at the present time concerns the maximal level of lead exposure in the neonatal and young child that does not produce a cognitive or motor neurologic deficit. For the adult excess occupational exposure or even accidental exposure, the concerns are periphernal neuropathy and/or chronic nephropathy. Effects on the heme system provide biochemical indicators of lead exposure in the absence of chemically detectable effects, but anemia due to lead exposure is uncommon without other detectable effects or other synergistic factors. Other target organs are the gastrointestinal and reproductive systems.

Nearly all environmental exposure to lead is to inorganic compounds, even lead in food. Organolead exposures, including tetraethyl lead, have unique toxicologic patterns and will be discussed later.

Neurologic Effects. The central nervous system (CNS) effects of lead are the most significant in terms of human health and performance (Ref 110, 112). Manifestations of CNS effects are encephalopathy and/or peripheral neuropathy. Symptomatic encephalopathy is almost always a disease of childhood and varies from ataxia to stupor, coma, and convulsions. This form of lead intoxication has decreased appreciably in North America over the past 20 years with better understanding of factors that contribute to lead toxicity, particularly reduction of lead exposure in children. Morphologic effects of lead on the brain are nonspecific. Lead encephalopathy is accompanied by severe cerebral edema, increase in cerebral spinal fluid pressure, proliferation and swelling of endothelial cells in capillaries and arterioles, proliferation of glial cells, neuronal degeneration, and areas of focal cortical necrosis in fatal cases.

The pathogenesis of neuronal damage in lead encephalopathy is not well understood. In severe cases, there are obvious changes in hemodynamics (cerebral edema) and cellular hypoxia, but it is now apparent that there is a direct effect of lead on neuronal and possibly synaptic transmission at levels of lead exposure that do not produced apparent symptoms of intoxication. These effects are termed "low-level lead toxicity" because they are believed to be associated with blood lead levels of approximately 30 to 50 μg/dL or possibly even lower blood lead levels. These effects are also termed "subclinical lead toxicity" because they can only be detected by assessment of neuropsychologic behavior, such as hyperactivity, poor classroom behavior (decreased attention span), and even small decrements (point average in group studies) of four to five in I.Q. scores (Ref 116). Studies by others confirm the subclinical detrimental effects on I.Q., but possibly occurring at somewhat higher blood lead levels than found by Needleman (Ref 117). However, that low-level lead exposure (blood lead, 30 to 50 μg/dL) does, indeed, affect CNS function is further supported by the finding of changes in electroencephalogram (EEG) brain wave patters and CNS evoked potential responses in children displaying neuropsychologic deficits (Ref 118). Neuro-chemical studies in experimental models have shown that lead in the absence of morphologic changes does produce deficits in neurotransmission through inhibition of cholinergic function, possibly by reduction of extracellular calcium. Other noted changes in neurotransmitter function include impairment of dopamine uptake by synaptosomes and impairment of the function of the inhibitory neurotransmitter γ-aminobutyric acid.

Peripheral neuropathy is a classic manifestation of lead toxicity, particularly the footdrop and wristdrop that characterized the house painter and other workers with excessive occupational exposure to lead more than a half-century ago (Ref 119). Segmental demyelination and possibly axonal degeneration follow lead-induced Schwann cell degeneration (Ref 120). Wallerian degeneration of posterior roots of sciatic and tibial nerves is possible, but sensory nerves are less sensitive to

lead than motor nerve structure and function (Ref 121). Motor nerve dysfunction, assessed clinically by electrophysiologic measurement of nerve conduction velocities, has been shown to occur with blood lead levels in the 50 to 70 μg/dL range or lower (Ref 122).

Hematologic Effects. Lead has multiple hematologic effects. In lead-induced anemia, the red blood cells are microcytic and hypochromic, as in iron deficiency, and usually there are increased numbers of reticulocytes with basophilic stippling. This morphologic characteristic has long been recognized as a feature of lead-induced anemia and in the past (pre-World War II), it was employed as a method of monitoring workers in the lead industry (Ref 123).

The test is no longer useful because it is now known to be nonspecific and, most important, it is an uncommon occurrence with blood lead below 80 μg/dL, which is considerably above the present-day permissible industrial standard. Basophilic stippling results from inhibition of the enzyme pyrimidine-5-nucleotidase (Ref 124), which cleaves residual nucleotide chains remaining in erythrocytes after extrusion of the nucleus. The activity of this enzyme is decreased in persons with elevated blood lead levels even when stippling is not morphologically evident.

The anemia that occurs in lead poisoning results from two basic defects; shortened erythrocyte life span and impairment of heme synthesis. Shortened life span of the red blood cell is thought to be due to increased mechanical fragility of the cell membrane. The biochemical basis for this effect is not known but is accompanied by inhibition of sodium- and potassium-dependent ATPases (Ref 125).

A schematic presentation of effects of lead on heme synthesis is shown in Fig. 4. Probably the sensitive effect is inhibition of δ-aminolevulinic acid dehydratase (ALA-D), resulting in a negative exponential relationship between ALA-D and blood lead. There is also depression of coproporphyrinogen oxidase, resulting in increased coproporphyrin activity. Lead also decreases ferochelatase activity. This enzyme catalyzes the incorporation of the ferrous ion into the porphyrin ring structure. Bessis and Jensen (Ref 126) have shown that iron in the form of apoferritin and ferruginous micelles may accumulate in mitochondria of bone marrow reticulocytes from lead-poisoned rats. Failure to insert iron into protoporphyrin results in depressed heme formation. The excess protoporphyrin takes the place of heme in the hemoglobin molecule and, as the red blood cells containing protoporphyrin circulate, zinc is chelated at the center of the molecule at the site usually occupied by iron. Red blood cells containing zinc-protoporphyrin are intensely fluorescent and may be used to diagnose lead toxicity. Depressed heme synthesis is thought to be the stimulus for increasing the rate of activity of the first step in the heme synthetic pathway, δ-aminolevulinic acid synthetase, by virtue of negative feedback control as proposed by Granick and Levere (Ref 127). As a consequence, the increased production of *d*-aminolevulinic acid and decreased activity of ALA-D result in a marked increase in circulating blood levels and urinary excretion of *d*-ALA. Prefeeding of lead to experimental animals also raises heme oxygenase activity, resulting in some increase in bilirubin formation. The change in rates of activity of these enzymes by lead produces a dose-related alteration in activity of affected enzymes, but anemia only occurs in very marked lead toxicity. The changes in enzyme activities, particularly ALA-D in peripheral blood and excretion of ALA in urine, correlate very closely with actual blood lead levels and serve as early biochemical indices of lead effect.

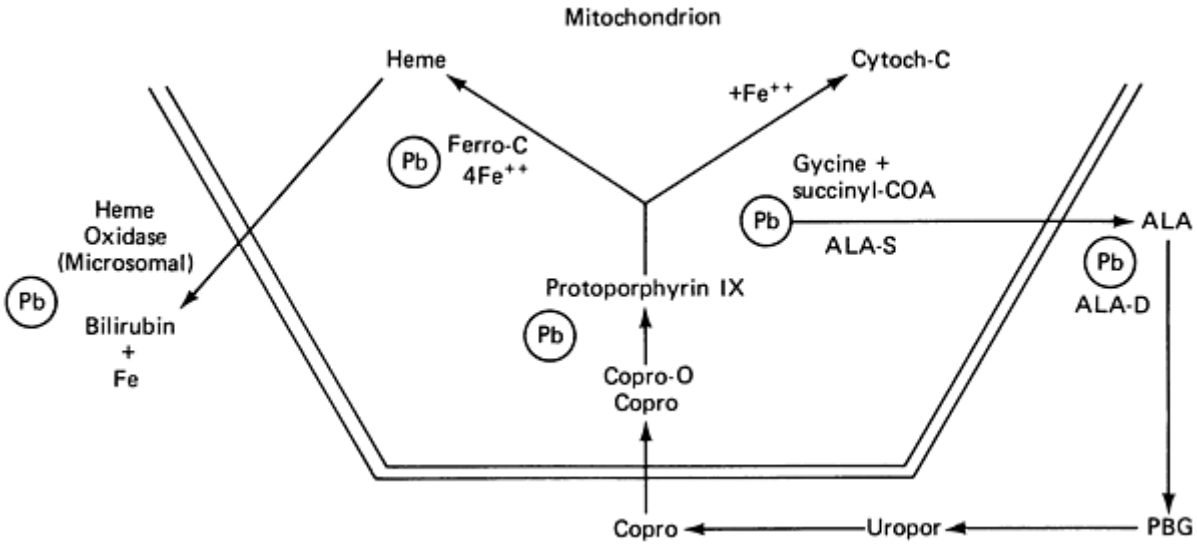

Fig. 4 Scheme of heme synthesis showing sites where lead has an effect. COA, coenzyme, A; ALA-S, aminolevulinic acid synthetase; ALA, *d*-aminolevulinic acid; ALA-D, aminolevulinic acid dehydratase; PBG, porphobilinogen; Uropor, uroporphyrinogen; Copro, coproporphyrinogen; Copro-O, coproporphyrinogen oxidase; Ferro-C, Ferrochelatase; Cytoch-C, cytochrome c; Pb, site for lead effect

Renal Effects. Toxicologic effects of lead on the kidney divide into two major concerns: reversible renal tubular dysfunction that occurs mostly in children with acute exposure to lead, usually associated with overt central nervous system effects, and irreversible chronic interstitial nephropathy characterized by vascular sclerosis, tubular cell atrophy, interstitial fibrosis, and glomerular sclerosis (Ref 128). It is most often seen in workmen with years of exposure to lead. In the early stages of excess lead exposure, morphologic and functional changes in the kidney are confined to the renal tubules and are most pronounced in proximal tubular cells.

A pathognomonic feature of lead poisoning is the presence of characteristic nuclear inclusion bodies (Ref 129). By light microscopy the inclusions are dense, homogeneous eosinophilic bodies. They are acid-fast when stained with carbolfuchsin. Ultrastructurally the bodies have a dense central core and outer fibrillary region, as shown in Fig. 5. The bodies are composed of a lead-protein complex (Ref 130). The protein is acidic and contains large amounts of aspartic and glutamic acids and little cystine. It is suggested that lead binds loosely to the carboxyl groups of the acidic amino acids. Most of the lead in the tubular cell is bound to the inclusion body. The sequestering of lead in these complexes may protect more susceptible organelles like mitochondria and endoplasmic reticulum (Ref 129).

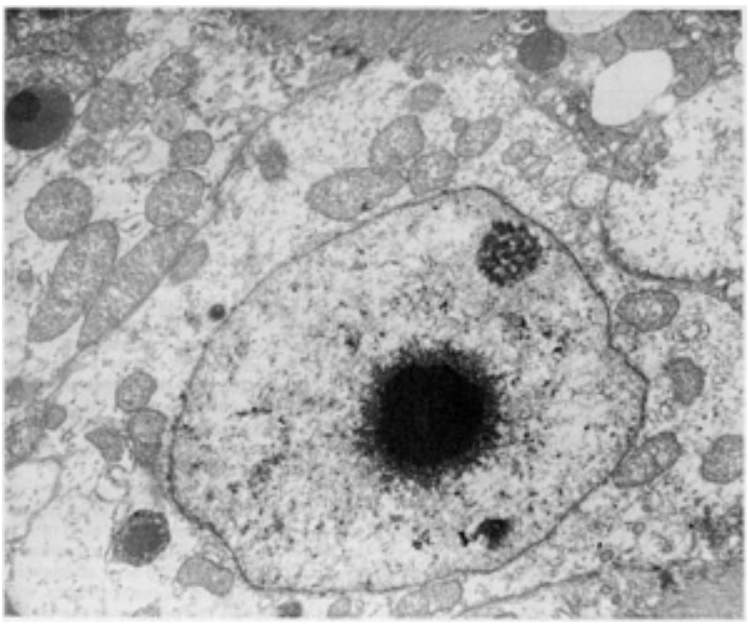

Fig. 5 Lead-induced inclusion bodies in nucleus of renal tubular lining cell

Experimental studies have shown that nuclear inclusion bodies are the earliest evidence of lead exposure and may be observed before any of the functional changes are detectable. Cells containing inclusion bodies are usually swollen and contain altered mitochondria. It has been shown that mitochondria isolated from kidneys of rats with lead toxicity have impaired oxidative and phosphorylative abilities. This may in part be responsible for the decrease in reabsorptive functions of proximal tubular cells. Experimental animals and people, that is, children and workmen with early exposure to lead, have a generalized amino aciduria, glycosuria, and hyperphosphaturia, and probably some impairment of sodium reabsorption. Some indirect evidence for an effect of lead on sodium transport is found in the clinical observation that the reninaldosterone response to sodium deprivation is altered in people with lead intoxication (Ref 131).

The pathogenesis of the inclusion bodies may be related to renal tubular cell transport and excretion of lead. Treatment of lead-exposed animals with chelating agents such as EDTA is accompanied by a sudden spike of urinary lead, which is maximum 12 to 24 hours after treatment (Ref 132). Also, no inclusion bodies can be found by morphologic study of renal tubular cells after EDTA therapy. The bodies may also be found intact in the urinary sediment of workmen with heavy exposure to lead (Ref 133). The bodies account for the major fraction of intracellular lead, and their loss in the urine may reflect a major pathways for lead excretion.

With continued exposure to lead there is a gradual change in morphology beginning with the appearance of peritubular and periglomerular fibrosis, particularly in the deep cortex of juxtamedullary zone (Ref 128). This is accompanied by atrophy of some tubules and hyperplasia of others. There are also fewer or no inclusion bodies present in the advanced stages of lead-induced nephrosclerosis. Recognition of interstitial fibrosis induced by lead, therefore, from any other forms of interstitial fibrosis is not possible morphologically, but must be made from history and knowledge of progression of the disease if this is available.

The most import feature of the changes associated with acute lead nephropathy is that they are reversible, either by reduction of lead exposure or by chelation therapy, but the progression into interstitial fibrosis is not reversible. It is very

important, therefore, to diagnose this disorder as early as possible so that exposure to lead can be discontinued and decrease in function halted. At the present time there is no single definitive diagnostic test that will recognize lead-induced interstitial nephropathy except possibly renal biopsy, but this is not a practical measure. There have been several clinical studies in recent years of renal function in workmen with long-term occupational exposure to lead (Ref 134, 135, 136). If looked at together, the conclusion is reached that an early functional accompaniment of interstitial fibrosis is a reduction in glomerular filtration rate.

The relationship between chronic lead exposure and gouty nephropathy, suggested more than a hundred years ago by the English physician Garrod, has received recent support from studies showing that gout patients with renal disease have a greater chelate-provoked lead excretion than do renal patients without gout (Ref 137). Lead reduces uric acid excretion (Ref 138). Elevated blood uric acid has been demonstrated in rats with chronic lead nephropathy (Ref 128).

The relationship between lead and hypertension is uncertain; it has been associated with lead poisoning in a number of studies but not in others. The second National Health and Nutrition Examination Survey (1976-1980) found a statistically significant relationship between blood pressure and blood lead levels in white males age 40 to 59 years (Ref 139). Hypertension may follow the vascular changes associated with lead-induced chronic renal disease, or changes in renin-angiotensinaldosterone metabolism (Ref 131, 140).

Carcinogenesis. The possible carcinogenic effects of lead have been receiving increasing attention (Ref 13). It is clear that lead can induce cancer in kidneys of rodents fed high doses of lead (Ref 141). On the other hand, the evidence that lead is carcinogenic to humans is very limited. A study of workmen in England many years ago with occupational exposure to lead did not show an increased incidence of cancer (Ref 142). A more recent study of causes of mortality in 7000 lead workers in the United States showed a slight excess of deaths from cancer (Ref 143), but the statistical significance of these findings has been debated (Ref 144, 145). The most common tumors found were of the respiratory and digestive systems, not the kidney. However, case reports of renal adenocarcinoma in workmen with prolonged occupational exposure to lead have appeared (Ref 146, 147).

Other Effects. Severe lead toxicity has long been known to cause sterility, abortion, and neonatal mortality and morbidity. Studies have demonstrated gametotoxic effects in both male and female animals. However, the impact of levels of lead exposure occurring in today's society on reproductive effects is uncertain. The greatest concern is for intrauterine effects on the unborn fetus. Umbilical cord blood levels are the same as those of mother's blood, and because of the greater sensitivity of the fetus, pregnancy must be regarded as a period of increased susceptibility to lead.

A few clinical studies have found increased chromosomal defects in workers with blood lead levels above 60 μg/dL (Ref 148). Experimental studies suggest that lead alters the humoral immune system and lead-induced immunosuppression occurs at low dosages in experimental animals in which there is no apparent evidence of toxicity (Ref 149). Also, children with asymptomatic increase in blood lead levels appear to have more frequent febrile illness (Ref 150).

Lead lines (Burton's lines) or purple-blue discoloration of gingiva is a classical feature of severe lead of toxicity in children with lead encephalopathy. However, this feature of lead toxicity as well as the presence of lead lines at the epiphyseal margins of long bones seen on x-rays of children with severe lead exposure are uncommon today.

Interaction With Other Minerals. Lead toxicity is enhanced by dietary deficiencies in calcium and iron and possibly zinc (Ref 151). The increased lead susceptibility found in animals on low calcium regimes is not a direct effect of calcium intake but of increased lead retention associated with decreased renal excretion of lead. In children, elevated blood lead is associated with decreased levels of 25-hydroxyvitamin D (synthesized in liver) and 1-to-25-dihydroxyvitamin D (synthesized in kidney). Iron deficiency is thought to increase gastrointestinal absorption of lead but does not otherwise affect lead metabolism. Relationships between lead and zinc have been studied in experimental animals and veterinary practice. Animals fed diets low in zinc accumulate greater amounts of lead in bones. Extra zinc in the diet has been found to protect horses brazing on lead-contaminated pastures from clinical manifestations of lead toxicity.

Organolead Compounds. Alkyl lead compounds used as gasoline additives, tetraethyl and tetramethyl lead, are rapidly absorbed into the nervous system and are much more severe neurotoxins on an equivalent dose basis than inorganic lead. Although these compounds may be emitted in small amounts from automobile exhaust, they degrade rapidly in the atmosphere. However, the practice of young people sniffing gasoline for psychodelic effects is particularly hazardous. Experimental studies have shown that tetraethyl lead is converted to triethyl lead and organic lead. Triethyl lead is relatively stable and becomes rapidly distributed between brain, liver, kidney, and blood (Ref 152).

Biological Indicators of Lead Toxicity. The most serious effects of lead are related to the central nervous system, although other effects such as chronic nephropathy may be important in some individuals with chronic exposure to high lead levels. Effects on heme synthesis are less evident from a clinical viewpoint, but these are the effects that in biochemical terms are best understood. With continual improvement in industrial hygiene and consciousness and control of potential environmental exposures to lead, concern for recognition of lead poisoning, in terms of traditional clinical signs and symptoms, is less relevant now than the matter of interpretation of more subtle neurologic and biochemical effects. Table 5 shows blood lead levels below which various parameters of lead toxicity are not detected. Blood lead level greater than 80 μg/dL is usually associated with clinical symptoms. Persons with blood lead levels above 60 μg/dL may also have clinical manifestations of lead poisoning, particularly in terms of minimal brain dysfunction. For these reasons children with blood levels in this range are sometimes treated with chelating agents. However, effects of lead on heme synthesis, along with increased urinary excretion of δ-ALA, are associated with blood lead levels of 40 μg/dL.

Table 5 Blood lead levels below which the listed effects have not been detected[(a)]

Blood levels, μg Pb/dL	Effect	Population
>10	Erythrocyte ALA-D inhibition	Adults, children
20-25	FEP[(b)]	Children
20-30	FEP	Adult, female
25-35	FEP	Adult, male
30-40	Erythrocyte ATPase inhibition	General
40	ALA excretion in urine	Adults, children
40	CP[(c)] excretion in urine	Adults
40	Anemia	Children
40-50	Peripheral neuropathy	Adults
50	Anemia	Adults
30-40	Minimal brain dysfunction	Children
60-70	Minimal brain dysfunction	Adults
60-70	Encephalopathy	Children
>80	Encephalopathy	Adults

(b) FEP, free erythrocyte protoporphyrin (see Fig. 4).

(c) CP, coproporphyrinogen (also Copro)

Heme Metabolism. The ALA-D activity of peripheral red blood cells may currently be the most sensitive biochemical parameter affected by lead. Samples collected from both children and adults have shown a negative correlation between the log of ALA-D activity and the blood lead concentration over a range to below 20 μg/dL. At present they are considered chemical effects of lead rather than adverse health effects. However, children with blood lead levels less than 40 μg/dL exhibit behavioral and fine-motor changes. Therefore, the maximum blood lead level that is not associated with harmful effects is not known. It may, indeed, differ for different segments of the population. Furthermore, blood lead levels and alterations in heme metabolism are indicative of recent exposure but do not reflect past exposure or body burden and may not correlate with the appearance and persistence of chronic effects of lead that are due to tissue level. This is particularly true of irreversible effects on the central nervous system and kidney.

Chelatable Lead. Urinary excretion of lead after chelation with EDTA or penicillamine reflects the mobilizable pool of lead located in soft tissue. Urinary excretion of lead in the 24-hour period after administration of the chelating agent correlates with blood lead levels for persons in the steady state, without unusual past or recent exposure to lead. However, for persons exposed to excess lead for one year or more, urinary excretion of lead is considerably greater. It has been estimated that nearly 20% of the body burden of lead is mobilized into the urine during the 24-hour period after an injection of 40 mg of $CaNa_2$ EDTA per kilogram body weight (Ref 153).

Lead in Teeth. Lead concentration in circumpulpal dentine of deciduous teeth has been proposed as a method for estimating exposure to lead during childhood. It has been shown that dentine lead content is dose dependent and not reduced by chelation. The distribution of lead in various components of the tooth including enamel, root dentine, and coronal dentine is similar. However, lead content in secondary or circumpulpal dentine, the area of dentine adjacent to pulp and in immediate contact with blood, is higher than in other areas of the tooth and seems to reflect actual exposure to lead throughout the life of the tooth. Several studies now have found substantially higher dentine levels in teeth from urban children living in deteriorated housing or attending school in proximity to a major manufacturer of paint and lead products than in teeth from children considered to be a low risk for lead exposure (Ref 154).

Treatment. Treatment of lead toxicity must go beyond medical care for specific tissue and organ effects and chelation of lead. For both asymptomatic excess exposure to lead as well as the symptomatic child or worker with occupational exposure, the sources of lead must be identified and controlled. For the child, this might involve a review of lifestyle including diet, particularly iron deficiency, type of dwelling, play habits, and pica. Treatment might involve social services, modification of dwelling, and parent education. For the workman, industrial hygiene practices must be reviewed including appropriate environmental and biologic monitoring and deficiencies corrected. One must always be aware of the relationship between occupation and the home. Practices of changing or washing contaminated workclothes must be reviewed, and potential sources of transfer of metal and contamination need to be corrected.

Chelation usually has a role in the treatment of the symptomatic worker or child. Institution of chelation therapy is probably warranted in workmen with blood lead levels over 60 μg/100 mL, but this determination must be made after assessment of exposure factors including biologic estimates of clinical and biochemical parameters of toxicity.

For children, criteria have been established that may serve as guidelines to assist in evaluating the individual case (Ref 111). These include blood lead levels from 30 μg/dl up to 60 μg/dL depending on FEP levels, and results of a lead mobilization test.

Also, cautionary measures for the safe use of chelating agents have been expressed particularly for Ca EDTA (Ref 155). Serum blood urea nitrogen and creatinine are followed as indicators of renal function, and serum calcium is measured to monitor untoward effects of EDTA. In children with severe lead poisoning including encephalopathy, the mortality rate may be 25 to 38% when EDTA or BAL is used singly; combination therapy of EDTA and BAL has been shown to be effective in reducing mortality.

Mercury

No other metal better illustrates the diversity of effects caused by different biochemical forms than does mercury, properties and applications of which are described in the article "Properties of Pure Metals" in this Volume. On the basis of toxicologic characteristics, there are three forms of mercury: elemental, inorganic, and organic compounds. The major source of mercury is the natural degassing of the crust of the earth, including land areas, rivers, and the ocean, and is estimated to be of the order of 25,000 to 150,000 tons per year (Ref 156, 157, 158). Metallic mercury in the atmosphere represents the major pathway of global transport of mercury. Although anthropogenic sources of mercury have reached about 8000 to 10,000 tons per year since 1973, nonanthropogenic sources are the predominating factors. Nevertheless, mining, smelting, and industrial discharge have been factors in environmental contamination in the past. For instance, it is estimated that loss in water effluent from chloralkali plants, one of the largest users of mercury, has been reduced by 99% in recent years. Also, the use of mercury in the paper pulp industries has been reduced dramatically and has been banned in Sweden since 1966. Industrial activities not directly employing mercury or mercury products give rise to substantial quantities of this metal. Fossil fuel may contain as much as 1 ppm of mercury, and it is estimated that about 5000 tons of mercury per year may be emitted from burning coal, natural gas, and the refining of petroleum products. Calculations based on mercury content of the Greenland icecap show an increase from the year 1900 to the present day and suggest that the increment is related to increase in background levels in rainwater and is related to man-made release. As much as one-third of atmospheric mercury may be due to industrial release of organic or inorganic forms. Regardless of source, both organic and inorganic forms of mercury may undergo environmental transformation. Metallic mercury may be oxidized to inorganic divalent mercury, particularly in the presence of organic material such as in the aquatic environment. Divalent inorganic mercury may, in turn, be reduced to metallic mercury when conditions are appropriate for reducing reactions to occur. This is an important conversion in terms of the global cycle of mercury and a potential source of mercury vapor that may be released to the earth's atmosphere. A second potential conversion of divalent mercury is methylation to dimethyl mercury by anaerobic bacteria. This may diffuse into the atmosphere and return to earth crust or bodies of water as methyl mercury in rainfall. If taken up by fish in the food chain, it may eventually cycle through humans.

Disposition. Toxicity of various forms or salts of mercury is related to cationic mercury *per se* whereas solubility, biotransformation, and tissue distribution are influenced by valence state and anionic component (Ref 159, 160, 161). Metallic or elemental mercury volatilizes to mercury vapor at ambient air temperatures, and most human exposure is by inhalation. Mercury vapor readily diffuses across the alveolar membrane and is lipid soluble so that it has an affinity for red blood cells and central nervous system. Metallic mercury, such as may be swallowed from a broken thermometer, is only slowly absorbed by the gastrointestinal tract (0.01%) at a rate related to the vaporization of the elemental mercury and is generally thought to be of no toxicologic consequence.

Inorganic mercury salts may be divalent (mercuric) or monovalent (mercurous). Gastrointestinal absorption of inorganic salts of mercury from food is less than 15% in mice and about 7% in a study of human volunteers, whereas absorption of methyl mercury is of the order of 90 to 95%. Distribution between red blood cells and plasma also differs. For inorganic mercury salts cell-plasma ratio ranges from a high of 2 with high exposure to less than 1, but for methyl mercury it is about 10. The distribution ratio of the two forms of mercury between hair and blood also differs; for organic mercury it is about 250.

Kidneys contain the greatest concentrations of mercury following exposure to inorganic salts of mercury and mercury vapor, whereas organic mercury has a greater affinity for the brain, particularly the posterior cortex. However, mercury vapor has a greater predilection for the central nervous system than does inorganic mercury salts, but less than organic forms of mercury.

Excretion of mercury from the body is by way of urine and feces, again differing with the form of mercury, size of dose, and time after exposure. Exposure to mercury vapor is followed by exhalation of a small fraction, but fecal excretion releases more toxin and is predominant initially after exposure to inorganic mercury. Renal excretion increases with time. About 90% of methyl mercury is excreted in feces after acute or chronic exposure and does not change with time (Ref 162).

All forms of mercury cross the placenta to the fetus, but most of what is known has been learned from experimental animals. Fetal uptake of elemental mercury in rats probably because of lipid solubility has been shown to be 10 to 40 times higher than uptake after exposure to inorganic salts. Concentrations of mercury in the fetus after exposure to alkylmercuric compounds are twice those found in maternal tissues, and methyl mercury levels in fetal red blood cells are 30% higher than in maternal red cells. The positive fetal-maternal gradient and increased concentration of mercury in fetal red blood cells enhance fetal toxicity to mercury particularly following exposure to alkylmercury. Although maternal

milk may contain only 5% of the mercury concentration of maternal blood, neonatal exposure to mercury may be greatly augmented by nursing.

Metabolic Transformation and Excretion. Elemental or metallic mercury is oxidized to divalent mercury after absorption to tissues in the body and is probably mediated by catalyses. Inhaled mercury vapor absorbed into red blood cells is transformed to divalent mercury, but a portion is also transported as metallic mercury to more distal tissues, particularly the brain where biotransformation may occur. Similarly, a fraction of absorbed metallic mercury may be carried across the placenta to the fetus. The oxidized divalent mercury is then accumulated by these tissues.

Alkylmercury also undergoes biotransformation to divalent mercuric compounds in tissues by cleavage of the carbon-mercury bond. There is no evidence of formation of any organic form of mercury by mammalian tissues. The aryl (phenyl) compounds are converted to inorganic mercury more rapidly than the shorter-chain alkyl (methyl) compounds. The relationship of these differences is rate of biotransformation versus rate of excretion and toxicity is not well understood. In those instances where the organomercurial is more rapidly excreted than inorganic mercury, increasing the rate of biotransformation will decrease the rate of excretion. Phenyl and methoxyethylmercury are excreted at about the same rate as inorganic mercury whereas methyl mercury excretion is slower.

Biologic half-times are available for a limited number of mercury compounds. Biologic half-time for methyl mercury is about 70 days and is virtually linear, whereas the half-time for retained salts of inorganic mercury is about 40 days. There are few studies on biologic half-times for elemental mercury or mercury vapor, but it also appears to be linear with a range of values from 35 to 90 days.

Cellular Metabolism. Within cells, mercury may bind to a variety of enzyme systems including those of microsomes and mitochondria, producing nonspecific cell injury or cell death. It has a particular affinity for ligands containing sulfhydryl groups. In liver cells, methyl mercury forms soluble complexes with cysteine and glutathione, which are secreted in bile and reabsorbed from the gastrointestinal tract. Organomercurial diuretics are thought to be absorbed in the proximal-tubule-binding specific receptor sites that inhibit sodium transport. In general, however, organomercury compounds undergo cleavage of the carbon-mercury bond, releasing ionic inorganic mercury.

Mercuric mercury, but not methyl mercury, induces synthesis of metallothionein probably only in kidney cells, but unlike cadmium-metallothionein it does not have a long biologic half-life. Mercury within renal cells becomes localized in lysosomes (Ref 163).

Toxicology. The toxic effects of mercury vapor, mercuric mercury, mercurous compounds, and organic mercury will be discussed in this section.

Mercury Vapor. Inhalation of mercury vapor may produce and acute, corrosive bronchitis and interstitial pneumonitis and, if not fatal, may be associated with symptoms of central nervous system effects such as tremor or increased excitability.

With chronic exposure to mercury vapor the major effects are on the central nervous system (Ref 164). Early signs are nonspecific and have been termed the "asthenicvegetative syndrome" or "micromercurialism." Identification of the syndrome requires neuroasthenic symptoms and three or more of the following clinical findings: tremor, enlargement of the thyroid, increased uptake of radioiodine in the thyroid, labile pulse, tachycardia, dermographism, gingivitis, hematologic changes, or increased excretion of mercury in urine. With increasing exposure the symptoms become more characteristics beginning with intentional tremors of muscles that perform fine-motor functions (highly innervated), such as fingers, eyelids, and lips, and may progress to generalized trembling of the entire body and violent chronic spasms of the extremities. This is accompanied by changes in personality and behavior, with loss of memory, increased excitability (erethism), severe depression, and even delirium and hallucination. Another characteristic feature of mercury toxicity is severe salivation and gingivitis.

The triad of increased excitability, tremors, and gingivitis has been recognized historically as the major manifestation of mercury poisoning from inhalation of mercury vapor and exposure in the fur, felt, and hat industry to mercury nitrate (Ref 165).

Sporadic instances of proteinuria and even nephrotic syndrome may occur in persons with exposure to mercury vapor, particularly with chronic occupational exposure. The pathogenesis is probably immunologic similar to that which may occur following exposure to inorganic mercury (see below).

Mercuric Mercury. Bichloride of mercury (corrosive sublimate) is the best-known inorganic salt of mercury, and the trivial name suggests its most apparent toxicologic effect when ingested in concentrations greater than 10%. A reference from the Middle Ages in Goldwater's book on mercury describes oral ingestion of mercury as causing several abdominal cramps, bloody diarrhea, and suppression of urine (Ref 165). This is an accurate report of effects following accidental or suicidal ingestion of mercuric chloride or other mercuric salts. Corrosive ulceration, bleeding, and necrosis of the gastrointestinal tract are usually accompanied by shock and circulatory collapse. If the patient survives the gastrointestinal damage, renal failure occurs within 24 hours owing to necrosis of the proximal tubular epithelium followed by oliguria, anuria, and uremia. If the patient can be maintained by dialysis, regeneration of tubular lining cells is possible. These may be followed by ultrastructural changes consistent with irreversible cell injury including actual disruption of mitochondria, release of lysosomal enzymes, and rupture of cell membranes.

Injection of mercuric chloride produces necrosis of the epithelium of the pars recta kidney (Ref 166). Cellular changes include fragmentation and disruption of the plasma membrane and its appendages, vesiculation and disruption of the endoplasmic reticulum and other cytoplasmic membranes, dissociation of polysomes and loss of ribosomes, mitochondrial swelling with appearance of amorphous intramatrical deposits, and condensation of nuclear chromatin. These changes are common to renal cell necrosis due to various causes.

Although exposure to a high dose of mercuric chloride is directly toxic to renal tubular lining cells, chronic low-dose exposure to mercuric salts or even elemental mercury vapor levels may induce an immunologic glomerular disease. This form of chronic mercury injury to the kidney is clinically the most common form of mercury-induced nephropathy. Exposed persons may develop a proteinuria that is reversible after workers are removed from exposure. It has been stated that chronic mercury-induced nephropathy seldom occurs without sufficient exposure to also produce detectable neuropathy.

Experimental studies have shown that the pathogenesis of chronic mercury nephropathy has two phases: an early phase characterized by an antibasement membrane glomerulonephritis followed by a superimposed immune-complex glomerulonephritis (Ref 167). The pathogenesis of the nephropathy in humans appears similar although antigens have not been characterized. Also, the early glomerular nephritis may progress in humans to an interstitial immune-complex nephritis (Ref 168).

Mercurous Compounds. Mercurous compounds of mercury are less corrosive and less toxic than mercuric salts, presumably because they are less soluble. Calomel, a powder containing mercurous chloride, has a long history of use in medicine. Perhaps the most notable modern usage has been as teething powder for children and is now known to be responsible for acrodynia or "pink disease." This is most likely a hypersensitivity response to the mercury salts in skin producing vasodilation, hyperkeratosis, and hypersecretion of sweat glands. Children develop fever, a pink-colored rash, swelling of the spleen and lymph nodes, and hyperkeratosis and swelling of fingers. The effects are independent of dose and are thought to be a hypersensitivity reaction (Ref 169).

Organic Mercury. Methyl mercury is the most important form of mercury in terms of toxicity, and health effects from environmental exposures and many of the effects produced by short-chain alkyls are unique in terms of mercury toxicity but are nonspecific in that they may be found in other disease states. Most of what is known about methyl mercury toxicity is from detailed epidemiologic studies of exposed populations (Ref 156).

Two major epidemics of methyl mercury poisoning have occurred in Japan in Minamata Bay and in Niigata. Both were caused by industrial release of methyl and other mercury compounds into Minamata Bay and into the Agano River, followed by accumulation of the mercury by edible fish. The median level of total mercury in fish caught in Minamata Bay during the epidemic was estimated to be about 11 mg/kg fresh weight and less than 10 mg/kg in fish from the Agano River. The largest recorded epidemic of methyl mercury poisoning took place in the winter of 1971-1972 in Iraq, resulting in admission of over 6000 patients to hospitals and over 500 deaths in hospitals (Ref 170). Methyl mercury exposure was from bread containing wheat imported as seed grain and dressed with methyl mercury fungicide. The mean methyl mercury content of wheat flour samples was 9.1 mg/kg (range 4.8 to 14.6 mg). In one village the average daily intake of contaminated loaves was 3.2 loaves per person, but it varied. On this basis, average daily intake of methyl mercury was calculated to be about 80 μg/kg ranging up to 250 μg/kg/day.

Several previous epidemics occurred in Iraq in 1961, in Pakistan in 1963, in Guatemala in 1966, and in other countries, but on a more limited scale. From studies of these episodes, data have been obtained to relate clinical manifestations, organ pathology, and level of exposure. The major clinical features are neurologic, consisting of paresthesia, ataxia, dysarthria, and deafness, appearing in that order. The main pathologic features of methyl mercury toxicity include degeneration and necrosis of neurons in focal areas of the cerebral cortex, particularly in the visual areas of the occipital

cortex and in the granular layer of the cerebellum. Experimental studies of both organic and inorganic mercury-related peripheral neuropathy show degeneration of primary sensory ganglion cells. The particular distribution of lesions in the central nervous system is thought to reflect a propensity of mercury to damage small nerve cells in cerebellum and visual cortex (Ref 171).

Biologic Indicators. Both metallic mercury and alkyl mercury are described below.

Metallic Mercury. For persons in the general population, it is estimated that daily mercury exposure is about 1 μg/day from air, less than 2 μg/day from food, but may be up to 75 μg/day depending on the amount of fish in the diet. The recommended standard (time-weighted average, TWA) for permissible exposure limits for inorganic mercury in air in the workplace is 0.05 mg Hg/m^3 (Ref 172) and is equivalent to an ambient air level of 0.015 mg/m^3 for the general population (24-hour exposure).

The central nervous system is the major site of toxicity from exposure to elemental mercury. It is believed that a worker exposed to a constant average concentration of mercury vapor achieves a state of balance (steady state) after one year of exposure, and it can be expected that there is a consistent relationship between air levels and mercury content of blood or urine. Mercury content in blood and urine only reflects recent exposure to metallic mercury. Table 6 is an estimate of mercury concentration in blood and urine related to air concentration of elemental mercury vapor and earliest clinical effects (Ref 156). Urine mercury should be less than 100 μg/L content.

Table 6 Time-weighted average air concentrations following long-term exposure to elemental mercury vapor[(a)]

Air, mg/m^3	Blood, μg/100 mL	Urine, μg/L	Earliest effects
0.05	3.5	150	Nonspecific symptoms
0.1-0.2	7-14	300-600	Tremor

Source: Ref 156

(a) Blood and urine values may be used only on a group basis owing to gross individual variations. Furthermore, these average values reflect exposure only after exposure for a year of more. After shorter periods of exposure, air concentrations would be associated with lower concentrations in blood and urine.

Alkyl Mercury. The federal standard for alkyl mercury exposure in the workplace is 0.01 mg/m^3 as an eight-hour TWA with an acceptable ceiling of 0.04 mg/m^3. Although a precise correlation has not been found between exposure levels and mercury content of blood and urine, study of the Iraq epidemic has provided estimates of the lowest mercury levels of mercury in blood due to alkyl mercury exposure associated with mild symptoms (Fig. 6). These studies do not indicate that percentage of people in the population who are sensitive at these levels, but other studies suggest that the frequency of parenthesia due to methyl mercury with these minimum mercury concentrations in blood and hair is 5% or less (Ref 156). However, studies reported from Minamata and elsewhere suggest that mothers with slight or no symptoms may have offspring who are retarded and have palsy. Mercury has been reported in breast milk of women exposed to methyl mercury from fish and from contaminated bread and averages about 5% of simultaneous concentrations in maternal blood. Figure 7 shows estimates of body burden of mercury onset and frequency of occurrence of these symptoms.

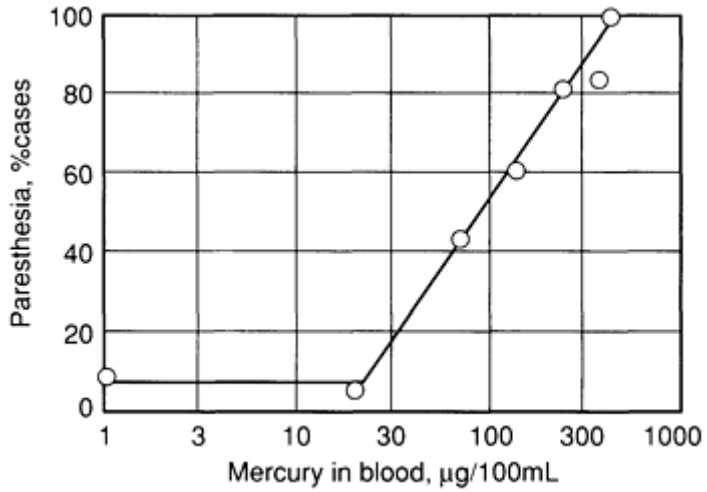

Fig. 6 Dose response relationship for methyl mercury using concentration of mercury in the blood as dose and paresthesia as response. Source: Ref 156, 170

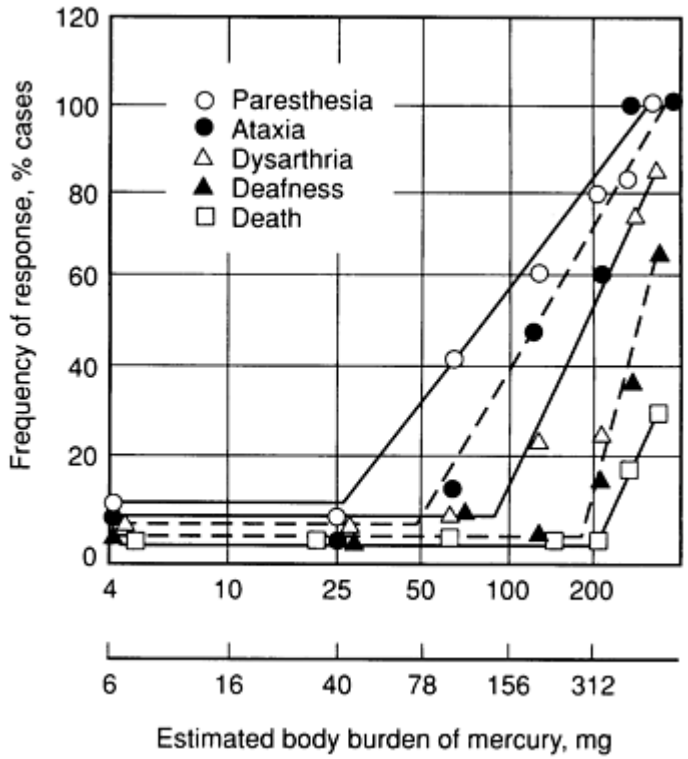

Fig. 7 Dose response relationships for methyl mercury. The upper scale of estimated body burden of mercury was based on the authors' actual estimate of intake. The lower scale, based on the body burden was calculated based on the concentration of mercury in the blood and its relationship to intake derived from radioisotopic studies of methyl mercury kinetics in human volunteers. Source: Ref 170

Mercury levels in hair may also be correlated with severity of clinical symptoms (Ref 170). Mild cases complained of numbness of extremities, slight tremors, and mild ataxia. Moderate cases had difficulty hearing, tunnel vision, and partial paralysis, and severe cases had some combination of complete paralysis, loss of vision, loss of hearing, loss of speech, and coma. Persons with no symptoms might have mercury hair levels up to 300 mg/kg, the mildly affected group in the range of 120 to 600 mg/kg, the moderate group in the range of 200 to 600 mg/kg, and the severely affected from 400 to 1600 mg/kg. Total dose of mercury for this group is not known.

It is not really understood why exposure to methyl mercury has such selective effect on cerebellum and visual cortex. Concentration of mercury in these areas of the brain is not very different from that in areas of the brain not affected by methyl mercury. Methyl mercury does inhibit protein synthesis in the brain before onset of signs of poisoning, and it has been found that recovery of protein synthesis does not occur in granular cells as it does in other types of neuronal cells (Ref 161).

Treatment. Therapy of mercury poisoning should be directed to lowering the concentration of mercury at the critical organ or site of injury. For the most severe cases, particularly with acute renal failure, hemodialysis may be the first measure along with infusion of chelating agents for mercury such as cysteine or penicillamine. For less severe cases of inorganic mercury poisoning, chelation with BAL may be effective. However, chelation therapy is not very helpful for alkyl mercury exposure. Biliary excretion and reabsorption by the intestine and the enterohepatic cycling of mercury may be interrupted by surgically establishing gallbladder drainage or by the oral administration of a nonabsorbable thiol resin that binds mercury and enhances intestinal excretion (Ref 173).

Nickel

Nickel is a respiratory tract carcinogen in workmen in the nickel-refining industry. Other serious consequences of long-term exposure to nickel are not apparent, but severe acute and sometimes fatal toxicity may follow nickel carbonyl exposure. Allergic contact dermatitis is common among persons in the general population. Deficiency of nickel alters glucose metabolism and decreases tolerance to glucose. From studies on rats, there is growing evidence that nickel may be an essential trace metal for mammals (Ref 174, 175). For information on the uses and properties of nickel, see the article "Nickel and Nickel Alloys" in this Volume.

Disposition. Nickel is only sparsely absorbed from the gastrointestinal tract. It is transported in the plasma bound to serum albumin and multiple small organic ligands, amino acids, or polypeptides. Excretion in the urine is nearly complete in four or five days. Kinetics have been described in rodents as a two-compartment model.

Dietary nickel intake by adults in the United States was estimated by Schroeder *et al.* (Ref 176), to be in the range of 300 to 600 μg/day. In a more recent study of nickel content of diets prepared in university or hospital kitchens in the United States, Myron *et al.* (Ref 177) found standard diet nickel intake to average 165 ± 11 μg/day or 75 ± 10 μg/1000 calories.

In one study, serum nickel was found to be 2.6 ± 0.9 μg/L (range: 0.8 to 5.2) and mean excretion of nickel in urine of 2.6 ± 1.4 μg/day (range: 0.5 to 6.4) (Ref 178). Serum nickel is influence by environmental nickel or nickel concentration in the ambient air. Serum nickel measured in persons living in Sudbury, Ontario, which is in the vicinity of a large nickel mine, showed concentrations of 4.6 ± 1.4 μg/liter (range: 2.0 to 7.3) and urinary concentrations were 7.9 ± 3.7 μg/day (range: 2.3 to 15.7). Generally, fecal nickel is about 100 times urine nickel concentration.

Nickel administered parenterally to animals is rapidly distributed to kidney, pituitary, lung, skin, adrenal, and ovary and testis (Ref 174).

The intracellular distribution and binding of nickel is not well understood. Ultrafiltrable ligands seem to be of major importance in transport in serum and bile and urinary excretion as well as intracellular binding. The ligands are not well characterized, but Sunderman (Ref 174) suggests that cysteine, histidine, and aspartic acid form nickel complexes either singly or as nickel-ligand species. *In vivo* binding with metallothionein has been demonstrated, but nickel at best induces metallothionein synthesis in liver or kidney only slightly.

A nickel-binding metalloprotein has also been identified in plasma with properties suggesting an α-2-glycoprotein with serum α-1-macroglobulin complex.

Evidence has accumulated over the past few years indicating that nickel is a nutritionally essential trace metal. Jackbean urease has been identified as a nickel metalloenzyme, and nickel is required for urea metabolism in cell cultures of soybean. However, a nickel-containing metalloenzyme has not yet been recovered from animal tissues. Nickel deficiency in rats is associated with retarded body growth and anemia, probably secondary to impaired absorption of iron from the gastrointestinal tract. In addition, there is significant reduction in serum glucose concentration. An interaction of nickel with copper and zinc is also suspected since anemia-induced nickel deficiency is only partially corrected with nickel supplementation in rats receiving low dietary copper and zinc (Ref 179).

Toxicology. This section will describe the carcinogenic effects of nickel, carbonyl poisoning, nickel dermatitis, and indicators of nickel toxicity.

Carcinogenesis. It has been known for 40 years that occupational exposure to nickel predisposes to lung and nasal cancer (Ref 180). Epidemiologic studies in 1958 showed that nickel refinery workers in Britain had a fivefold increase in risk to lung cancer and 150-times increase in risk to nasal cancers compared to people in the general population. More recently, increase in lung cancer among nickel workers has been reported from several different countries including suggestions of increased risks to laryngeal cancer in nickel refinery workers in Norway (Ref 181) and gastric carcinoma and soft tissue sarcomas from the Soviet Union. Six cases of renal cancer have been reported among Canadian and Norwegian workers employed in the electrolytic refining of nickel (Ref 182). McEwan (Ref 183) has been able to detect early cytologic changes in sputum of exposed workers prior to chest x-ray or clinical indicators of respiratory tract cancer.

Because the refining of nickel in the plants that were studied involved the Mond process with the formation of nickel carbonyl, it was believed for some time that nickel carbonyl was the principal carcinogen. However, additional epidemiologic studies of workers in refineries that do not use the Mond process also showed increased risk of respiratory cancer, suggesting that the source of the increased risk is the mixture of nickel sulfides present in molten ore. Indeed, studies with experimental animals have shown that the nickel subsulfide (Ni_3S_2) produces local tumors at injection sites and by inhalation in rats, and *in vitro* mammalian cell tests demonstrate that Ni_3S_2 and $NiSO_4$ compounds give rise to mammalian cell transformation (Ref 15).

Nickel Carbonyl Poisoning. Metallic nickel combines with carbon monoxide to form nickel carbonyl ($Ni[CO]_4$), which decomposes to pure nickel and carbon monoxide on heating to 200 °C (Mond process). This reaction provides a convenient and efficient method for the refinement of nickel. However, nickel carbonyl is extremely toxic, and many cases of acute toxicity have been reported. The illness begins with headache, nausea, vomiting, and epigastric or chest pain, followed by cough, hyperpnea, cyanosis, gastrointestinal symptoms, and weakness. The symptoms may be accompanied by fever and leukocytosis, and the more severe cases progress to pneumonia, respiratory failure, and eventually cerebral edema and death. Autopsy studies show the largest concentrations of nickel in lungs with lesser amounts in kidneys, liver, and brain (Ref 174).

Dermatitis. Nickel dermatitis is one of the most common forms of allergic contact dermatitis; 4 to 9% of persons with contact dermatitis react positively to nickel patch tests. Sensitization might occur from any of the numerous metal products in common use, such as coins and jewelry. The notion that increased ingestion of nickel-containing food increases the probability of external sensitization to nickel is supported by finding increased urinary nickel excretion in association with episodes of acute nickel dermatitis (Ref 184).

Indicators of Nickel Toxicity. Blood nickel levels immediately following exposure to nickel carbonyl provide a guideline as to severity of exposure and indication for chelation therapy (Ref 174). Sodium deithyldithiocarbamate is the preferred drug, but other chelating agents, such as *d*-penicillamine and triethylenetetraamine, provide some degree of protection from clinical effects.

Toxicity of Metals

Robert A. Goyer, Department of Pathology, The University of Western Ontario

Essential Metals With Potential For Toxicity

This group includes seven metals generally accepted as essential: cobalt, copper, iron, manganese, molybdenum, selenium, and zinc. Each of the seven essential metals has three levels of biologic activity, trace levels required for optimum growth and development, homeostatic levels (storage levels), and toxic levels. For those metals, environmental accumulations are generally less important routes of excess exposure than accidents or occupation.

Although chromium and arsenic are regarded as essential to humans and animals, respectively, the toxicologic significance of chromium and arsenic warrant their being discussed as major toxic metals in the context of this article. Tin and vanadium are also essential to animals but are of less importance toxicologically and are included in the group of minor toxic metals.

Cobalt

Cobalt is essential as a component of vitamin B_{12} required for the production of red blood cells and prevention of pernicious anemia. There is 0.434 μg of cobalt per microgram of vitamin B_{12}. If other requirements for cobalt exist, they are not well understood. Deficiency diseases of cattle and sheep, caused by insufficient natural levels of cobalt, are characterized by anemia and loss of weight or retarded growth.

Cobalt is a relatively rare metal produced primarily as a by-product of other metals, chiefly copper. It is used in high-temperature alloys, wear-resistant materials, and in permanent magnets (see the articles "Cobalt and Cobalt Alloys," "Permanent Magnet Materials" and "Cemented Carbides" in this Volume). Its salts are useful in paint driers, as catalysts, and in the production of numerous pigments.

Cobalt salts are generally well absorbed after oral ingestion, probably in the jejunum. Despite this fact, increased levels tend not to cause significant accumulation. About 80% of the ingested cobalt is excreted in the urine. Of the remaining, about 15% is excreted in the feces by an enterohepatic pathway, while the milk and sweat are other secondary routes of excretion. The total body burden has been estimated as 1.1 mg.

The muscle contains the largest total fraction, but the fat has the highest concentration. The liver, heart, and hair have significantly higher concentrations than other organs, but the concentration in these organs is relatively low. The normal levels in human urine and blood are about 98 and 0.18 μg/liter, respectively. The blood level is largely in association with the red cells.

Significant species differences have been observed in the excretion of radiocobalt. In rats and cattle, 80% is eliminated in the feces (Ref 185).

Polycythemia is the characteristic response of most mammals, including humans, to ingestion of excessive amounts of cobalt. Toxicity resulting from overzealous therapeutic administration has been reported to produce vomiting, diarrhea, and a sensation of warmth. Intravenous administration leads to flushing of the face, increased blood pressure, slowed respiration, giddiness, tinnitus, and deafness due to nerve damage (Ref 186).

High levels of chronic oral administration may result in the production of goiter. Epidemiologic studies suggest that the incidence of goiter is higher in regions containing increased levels of cobalt in the water and soil (Ref 187). The goitrogenic effect has been elicited by the oral administration of 3 to 4 mg/kg to children in the course of sickle cell anemia therapy (Ref 186).

Cardiomyopathy has been caused by excessive intake of cobalt, particularly from the drinking of beer to which 1 ppm cobalt was added to enhance its foaming qualities. Why such a low concentration should produce this effect in the absence of any similar change when cobalt is used therapeutically is unknown. The signs and symptoms were those of congestive heart failure. Autopsy findings revealed a tenfold increase in the cardiac levels of cobalt. Alcohol may have served to potentiate the effect of the cobalt (Ref 188).

Hyperglycemia due to β-cell pancreatic damage has been reported after injection into rats. Reduction of blood pressure has also been observed in rats after injection and has led to some experimental use in humans (Ref 185).

Occupational inhalation of cobalt salts in the cemented carbide industry may cause respiratory symptoms probably as a result of irritation of the pulmonary track. Allergic dermatitis of an erythematous papular type may also occur, and affected persons may have positive skin tests.

Single and repeated subcutaneous or intramuscular injection of cobalt powder and salts to rats may cause sarcomas at the site of injection, but there is no evidence of carcinogenicity from any other route of exposure (Ref 189).

Copper

Copper is widely distributed in nature and is an essential element. Copper deficiency is characterized by hypochromic, microcytic anemia resulting from defective hemoglobin synthesis. Oxidative enzymes, such as catalase, peroxidase, cytochrome oxidase, and others, also require copper. Medicinally, copper sulfate is used as an emetic. It has also been used for its astringent and caustic action and as an anthelmintic. Copper sulfate mixed with lime has been used as a fungicide. As a structural material, copper has a wide variety of applications. A number of articles describing the properties and applications of wrought, cast, and powder metallurgy copper and copper alloys are provided in this Volume.

Gastrointestinal absorption of copper is normally regulated by body stores (Ref 190, 191). It is transported in serum bound initially to albumin and later more firmly bound to α-ceruloplasmin where it is exchanged in the cupric form. The normal serum level of copper is 120 to 145 μg/L. The bile is the normal excretory pathway and plays a primary role in copper homeostasis. Most copper is stored in liver and bone marrow where it may be bound to metallothionein. The amount of copper in milk is not enough to maintain adequate copper levels in the liver, lung, and spleen of the newborn. Tissue levels gradually decline up to about 10 years of age, remaining relatively constant thereafter. Brain levels, on the other hand, tend to almost double from infancy to adulthood. The ratios of newborn to adult liver copper levels show considerable species difference: human, 15:4; rat, 6:4, and rabbit, 16:6. Since urinary copper levels may be increased by soft water, under these conditions concentrations of approximately 60 μg/L are not uncommon.

Copper is an essential part of a several enzymes, including tyrosinase, involved in the formation of melanin pigments, cytochrome oxidase, superoxide dismutase, amine oxidases, and uricase. It is essential for the utilization of iron. Iron deficiency anemia in infancy is sometimes accompanied by copper deficiency as well. Molybdenum also influences tissue levels of copper.

There are two genetically inherited in-born errors of copper metabolism that are in a sense a form of copper toxicity (Ref 191). Wilson's disease is characterized by excessive accumulation of copper in liver, brain, kidneys, and cornea. Serum ceruloplasmin is low, and serum copper, not bound to ceruloplasmin, is elevated. Urinary excretion of copper is high. The disorder is sometimes referred to as hepatolenticular degeneration in reference to the major symptoms. Clinical abnormalities of the nervous system, liver, kidneys, and cornea are related to copper accumulation. Although the etiology of this disorder is genetic, the basic defect at the biochemical level is not known. Increased binding of copper to an abnormal intracellular thionein or altered tissue excretion has been proposed. Cultured fibroblasts from persons with Wilson's disease have increased intracellular copper when cultured in Eagle's minimum essential medium with fetal bovine serum (Ref 192). Clinical improvements can be achieved by chelation of copper with penicillamine (Ref 22). Trien (triethylene tetramine, 2HCl) is also effective and has been used in patients with Wilson's disease who have toxic reactions to penicillamine (Ref 23).

Menkes' disease or Menkes' "kinky-hair syndrome" is a sex-linked trait characterized by peculiar hair, failure to thrive, severe mental retardation, neurologic impairment, and death before three years of age. There is extensive degeneration of the cerebral cortex and of white matter. Again, the basic defect is not known. There are low levels of copper in liver and brain but high concentrations in other tissues. Even in cells with increased copper concentration there is a relative deficiency in activities of some copper-dependent enzymes. Some laboratories have reported that larger-than-normal quantities of copper-thionein accumulated in fibroblasts so that the basic defect may be in regulation of metallothionein synthesis. The finding of increased amounts of other metallothionein binding metals (zinc, cadmium, mercury) in kidneys of patients with this disease supports this hypothesis (Ref 193).

Acute poisoning resulting from ingestion of excessive amounts of oral copper salts, most frequently copper sulfate, may produce death. The symptoms are vomiting, sometimes with a blue-green color observed in the vomitus, hematemesis, hypotension, melena, coma, and jaundice. Autopsy findings have revealed centrilobular hepatic necrosis (Ref 194). Few cases of copper intoxication as a result of burn treatment with copper compounds have resulted in hemolytic anemia. Copper poisoning producing hemolytic anemia has also been reported as the result of using copper-containing dialysis equipment (Ref 195).

Iron

The major interest in iron is as an essential metal, but toxicologic considerations are important in terms of accidental acute exposures and chronic iron overload due to idiopathic hemochromatosis or as a consequence of excess dietary iron or frequent blood transfusions. The complex metabolism of iron and mechanisms of toxicity are detailed by Jacobs and Worwood (Ref 196). Properties of pure iron are described in the article "Properties of Pure Metals" in this Volume. Its use in cast irons, steels, and superalloys is documented in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.*

Disposition. The disposition of iron is regulated by a complex mechanism to maintain homeostasis. Generally, about 2 to 15% is absorbed from the gastrointestinal tract, whereas elimination of absorbed iron is only about 0.01% per day (percent body burden or amount absorbed). During periods of increased iron need (childhood, pregnancy, blood loss) absorption of iron is greatly increased. Absorption occurs in two steps: absorption of ferrous ions from the intestinal lumen into the mucosal cells, and transfer from the mucosal cell to plasma where it is bound to transferrin for transfer to storage sites. Transferrin is a β_1-globulin with a molecular weight of 75,000 and is produced in the liver. As ferrous ion is released into plasma, it becomes oxidized by oxygen in the presence of ferroxidase I, which is identical to ceruloplasmin. There are 3 to 5 g of iron in the body. About two-thirds is bound to hemoglobin, 10% in myoglobin and iron-containing enzymes, and the remainder is bound to the iron storage proteins ferritin and hemosiderin. Exposure to iron induces synthesis of apoferritin, which then binds ferrous ions. The ferrous ion becomes oxidized, probably by histidine and cysteine residues and carbonyl groups. Iron may be released from ferritin by reducing agents; ascorbic acid, cysteine, and reduced glutathione release iron slowly. Normally, excess ingested iron is excreted, and some is contained within shed intestinal cells and in bile and urine and in even smaller amounts in sweat, nails, and hair. Total iron excretion is usually of the order of 0.5 mg/day.

With excess exposure to iron or iron overload, there may be a further increase in ferritin synthesis in hepatic parenchymal cells. In fact, the ability of the liver to synthesize ferritin exceeds the rate at which lysosomes can process iron for

excretion. Lysosomes convert the protein from ferritin to hemosiderin, which then remains *in situ* (Ref 197). The formation of hemosiderin from ferritin is not well understood, but seems to involve denaturation of the apo-ferritin molecule. With increasing iron loading, ferritin concentration appears to reach a maximum and a greater portion of iron is found in hemosiderin. Both ferritin and hemosiderin are, in fact, storage sites for intracellular metal and are protective in that they maintain intracellular iron in bound form.

A portion of the iron taken up by cells of the reticuloendothelial system enters a labile iron pool available for erythropoiesis and part becomes stored as ferritin.

Toxicity. Acute iron toxicity is nearly always due to accidental ingestion of iron-containing medicines and most often occurs in children. As of 1970, there were about 2000 cases in the United States each year, generally among children aged one to five years, who eat ferrous sulfate tablets with candylike coatings. Decrease of this occurrence should follow use of "childproof" lids on prescription medicines. Severe toxicity occurs after ingestion of more than 0.5 g of iron or 2.5 g of ferrous sulfate. Toxicity becomes manifest with vomiting, one to six hours after ingestion. The vomitus may be bloody owing to ulceration of the gastrointestinal tract; stools may be black. This is followed by signs of shock and metabolic acidosis, liver damage, and coagulation defects within the next couple of days. Late effects may include renal failure and hepatic cirrhosis. The mechanism of the toxicity is thought to begin with acute mucosal cell damage, absorption of ferrous ions directly into the circulation, which then cause capillary endothelial cell damage in liver.

Chronic iron toxicity or iron overload in adults is a more common problem. There are three basic ways in which excessive amounts of iron can accumulate in the body. The first circumstance is idiopathic hemochromotosis due to abnormal absorption of iron from the intestinal tract. The condition may be genetic. A second possible cause of iron overload is excess dietary iron. The African Bantu who prepares his daily food and brews fermented beverages in iron pots is the classic example of this form of iron overload. Sporadic other cases occur owing to excessive ingestion of iron-containing tonics or medicines. The third circumstance in which iron overload may occur is from the regular requirement for blood transfusion for some form of refractory anemias and is sometimes referred to as transfusional siderosis (Ref 198).

The pathologic consequences of iron overload are similar regardless of basic cause. The body iron content is increased to between 20 and 40 g. Most of the extra iron is hemosiderin. Greatest concentrations are in parenchymal cells of liver and pancreas, as well as endocrine organs and heart. Iron in reticuloendothelial cells (spleen) is greatest in transfusional siderosis and in the Bantu. Further clinical effects may include disturbances in liver function, diabetes mellitus, and even endocrine disturbances and cardiovascular effects. At the cell level, increased lipid peroxidation occurs with consequent membrane damage to mitochondria, microsomes, and other cellular organelles (Ref 199).

Treatment of acute iron poisoning is directed toward removal of the ingested iron from the gastrointestinal tract by inducing vomiting or gastric lavage and providing corrective therapy for systemic effects such as acidosis and shock. Desferrioxamine is the chelating agent of choice for treatment of iron absorbed from acute exposure as well as for removal of tissue iron in hemosiderosis. Ascorbic acid will also increase iron excretion as much as twofold normal (Ref 200).

Inhalation of iron oxide fumes or dust by workers in metal industries may result in deposition of iron particles in lungs producing an x-ray appearance resembling silicosis. These effects are seen in hematite miners, iron and steel workers, and arc welders. Hematite is the most important iron ore (mainly Fe_2O_3). A report of autopsies of hematite miners noted an increase in lung cancer, as well as tuberculosis and interstitial fibrosis (Ref 201). The etiology of the lung cancer may be related to concomitant factors such as cigarettes or other workplace carcinogens. Hematite miners are also exposed to silica and other minerals, as well as radioactive materials; other iron workers have exposures to polycyclic hydrocarbons (Ref 202). Dose levels of iron among iron workers developing pneumoconiosis have been reported to exceed 10 mg Fe/m^3.

Manganese

Manganese is an essential element and is a cofactor for a number of enzymatic reactions, particularly those involved in phosphorylation, cholesterol, and fatty acids synthesis. Manganese is present in all living organisms. While it is present in urban air and in most water supplies, the principal portion of the intake is derived from food. Vegetables, the germinal portions of grains, fruits, nuts, tea, and some spices are rich in manganese (Ref 59, 203). The industrial use of manganese is primarily that of an alloying element in steel (see *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook*, formerly 10th Edition *Metals Handbook*). Properties of manganese are described in the article "Properties of Pure Metals" in this Volume.

Daily manganese intake ranges from 2 to 9 mg. Gastrointestinal absorption is less than 5%. It is transported in plasma bound to a β_1-globulin, thought to be transferrin, and is widely distributed in the body. Manganese concentrates in mitochondria so that tissues rich in these organelles have the highest concentrations of manganese including pancreas, liver, kidney, and intestines. Biologic half-life in the body is 37 days. It readily crosses the blood-brain barrier and half-life in the brain is longer than in the whole body.

Manganese is eliminated in the bile and is reabsorbed in the intestine, but the principal route of excretion is with feces. This system apparently involves the liver, auxiliary gastrointestinal mechanisms for excreting excess manganese, and perhaps the adrenal cortex. This regulating mechanism, plus the tendency for extremely large doses of manganese salts to cause gastrointestinal irritation, accounts for the lack of systemic toxicity following oral administration or dermal application.

Manganese and its compounds are used in making steel alloys, dry-cell batteries, electrical coils, ceramics, matches, glass, dyes, in fertilizers, welding rods, as oxidizing agents, and as animal food additives.

Industrial toxicity from inhalation exposure, generally to manganese dioxide in mining or manufacturing, is of two types: The first, manganese pneumonitis, is the result of acute exposure. Men working in plants with high concentrations of manganese dust show an incidence of respiratory disease 30 times greater than normal. Pathologic changes include epithelial necrosis followed by mononuclear proliferation.

The second and more serious type of disease resulting from chronic inhalation exposure to manganese dioxide, generally over a period of more than two years, involves the central nervous system. In iron deficiency anemia, the oral absorption of manganese is increased, and it may be that variations in manganese transport related to iron deficiency account for individual susceptibility (Ref 204). Those who develop chronic manganese poisoning (manganism) exhibit a psychiatric disorder characterized by irritability, difficulty in walking, speech disturbances, and compulsive behavior that may include running, fighting, and singing. If the condition persists, a masklike face, retropulsion or propulsion, and a Parkinson-like syndrome develop (Ref 205). The outstanding feature of manganese encephalopathy has been classified as severe selective damage to the subthalamic nucleus and palladium (Ref 206). These symptoms and the pathologic lesions, degenerative changes in the basal ganglia, make the analogy to Parkinson's disease feasible. In addition to the central nervous system changes, liver cirrhosis is frequently observed.

Victims of chronic manganese poisoning tend to recover slowly, even when removed from the excessive exposure. Metal-sequestering agents have not produced remarkable recovery; L-dopa, which is used in the treatment of Parkinson's disease, has been more consistently effective in the treatment of chronic manganese poisoning than in Parkinson's disease (Ref 207).

The syndrome of chronic nervous system effects has not been successfully duplicated in any experimental animals except monkeys and then only by inhalation or intraperitoneal injection. After intraperitoneal administration of manganese to squirrel monkeys, dopamine and serotonin levels markedly decreased in the caudate nucleus regardless of whether or not behavioral effects were present. Manganese levels were increased in the basal ganglia and cerebellum. Histopathologic examination of animals did not reveal any morphologic changes (Ref 208). Exposure of rats to manganese dioxide for 100 days does increase the brain manganese concentration but does not produce any hematologic, behavioral, or histologic effects.

Molybdenum

Molybdenum is an essential metal as a cofactor for the enzymes xanthine oxidase and aldehyde oxidase. In plants it is necessary for fixing of atmospheric nitrogen by bacteria at the start of protein synthesis. Because of these functions it is ubiquitous in food. Because plankton tend to concentrate molybdenum 25 times that of seawater, shellfish tend to have high concentrations of molybdenum. Molybdenum is added in trace amounts to fertilizers to stimulate plant growth. The average daily human intake in food is approximately 350 μg. The concentration of molybdenum in urban air is minimal, but it is present in more than one-third of fresh-water supplies (Table 1) and in certain areas the concentration may be near 1 μg/L. Excess exposure can result in toxicity to animals and humans (Ref 59, 209).

The most important mineral source of molybdenum is molybdenite (MoS_2). The United States is the major world producer of molybdenum. The industrial uses of this metal include the manufacture of high-strength steels, heat-resistant steels, and superalloys (see *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook*) as well as the production of catalysts, lubricants, and dyes.

Disposition. While molybdenum exists in various valence forms, biologic differences with respect to valence are not clear. The soluble hexavalent compounds are well absorbed from the gastrointestinal tract into the liver. It is a component of xanthine oxidase, which has a role in purine metabolism and has been shown to be a component of aldehyde oxidase and sulfite oxidase. Increased molybdenum intake in experimental animals has been shown to increase tissue levels of xanthine oxidase. In humans, molybdenum is contained principally in the liver, kidney, fat, and blood. Of the approximate total of 9 mg in the body, most is concentrated in the liver, kidney, adrenal, and omentum. More than 50% of molybdenum in the liver is contained in a nonprotein cofactor bound to the mitochondrial outer membrane and can be transferred to an apoenzyme, transforming it into an active enzyme molecule (Ref 210). The molybdenum level is relatively low in the newborn and increases until age 20, declining in concentration thereafter. More than half of the molybdenum excreted is in the urine. The blood level, at least in sheep, is in association with the red blood cells. However, molybdenum has been detected in only about 25% of the blood samples of the human urban population. The excretion of molybdenum is rapid, mainly as molybdate. Excesses may be excreted also by the bile, particularly the hexavalent forms.

Inhalation of molybdenum by guinea pigs has resulted in increased bone levels. Injected radiomolybdenum increased liver and kidney levels, but the endocrine glands were also exceptionally high in content.

Toxicity. Pastures containing 20 to 100 ppm molybdenum may produce a disease referred to as "teart" in cattle and sheep. It is characterized by anemia, poor growth rate, and diarrhea. Copper or sulfate in the diet prevents the disease, and removal of the animals from pastures containing high levels of molybdenum facilitates their rapid recovery. Prolonged exposure has led to deformities of the joints. Experimental studies have revealed differences in toxicity of molybdenum salts. Molybdenum sulfide was well tolerated in rats at 500 mg/kg/day and was not injurious to guinea pigs at 28 mg/m^3. Hexavalent compounds were more toxic. In rats molybdenum trioxide at a dose of 100 mg/kg/day, by inhalation, was irritating to the eyes and mucous membranes and subsequently lethal. After repeated oral administration at sufficient levels, fatty degeneration of the liver and kidney was induced. In comparison with chromium and tungsten salts, sodium molybdate by intraperitoneal injection was less toxic in mice.

Interesting relationships of molybdenum with other metals with respect to toxicity in cattle and sheep have been documented. For example, copper prevents the accumulation of molybdenum in the liver and may antagonize the absorption of molybdenum from food. It is reported that by alternating the intake of copper and molybdenum at weekly intervals, black sheep can be made to grow striped wool. White wool in black sheep is a sign of copper deficiency. The antagonism of copper is dependent on sulfate in the diet. It has been suggested that sulfate may displace molybdate in the body. It may be that the anemia caused by molybdenum is due to the reduction of sulfide oxidase in the liver, resulting in the formation of copper sulfide, thereby inducing a functional copper deficiency. Feeding of tungstate has also been shown to displace molybdate. In addition, it has been reported that molybdenum may promote fluoride retention and thereby decrease dental caries (Ref 59), but the incidences of caries in children living in high molybdenum areas compared to children living in normal or low molybdenum areas do not differ (Ref 211).

Selenium

The availability as well as the toxic potential for selenium and selenium compounds is related to chemical form and, most important, to solubility. Selenium occurs in nature and biologic systems as selenate (Se^{6+}), selenite (Se^{4+}), elemental selenium (Se^{0}), and selenide (Se^{2-}), and deficiency leads to a cardiomyopathy in mammals including humans (Ref 59, 212).

Selenium in foodstuffs provides a daily source of selenium (Ref 213). Seafoods, especially shrimp, meat, milk products, and grains provide the largest amounts in the diet. River water levels of selenium vary depending on environmental and geologic factors; 0.02 ppm has been reported as a representative estimate. Selenium has also been detected in urban air, presumably from sulfur-containing materials. Additional information on selenium can be found in the article "Properties of Pure Metals" in this Volume.

Disposition. Selenates are relatively soluble compounds, similar to sulfates, and are readily taken up by biologic systems, whereas selenites and elemental selenium are virtually insoluble. Because of their insolubility, these forms may be regarded as a from of inert selenium sink. Selenides of heavy metals are also very insoluble compounds, in fact, so insoluble that the *in vivo* formation of mercury selenide by dietary administration of selenite has been proposed as a method for detoxication of methyl mercury. Other metallic selenides such as arsenic, cadmium, and copper also have low solubility affecting absorption, retention, and distribution within the body of selenium and heavy metal. Elemental selenium is probably not absorbed from the gastrointestinal tract. Absorption of selenite is from the duodenum. Monogastric animals have a higher intestinal absorption than ruminants, probably because selenite is reduced to an

insoluble form in rumen. Over 90% of milligram doses of sodium selenite may be absorbed by man and widely distributed in organs, with highest accumulation initially in liver and kidney, but appreciable levels remain in blood, brain, myocardium, and skeletal muscle and testis. Selenium is transferred through the placenta to the fetus, and it also appears in milk. Levels in milk are dependent on dietary intake. Selenium in red cells is associated with glutathione peroxidase and is about three times more concentrated than in plasma (Ref 214).

Selenium compounds may be biotransformed in the body by incorporation into amino acids or proteins or by methylation (Ref 215). Selenium amino acids, Se-cysteine, and Se-methionine are formed in plants and absorbed as free amino acid or from digested protein. Se-methionine can be directly incorporated into proteins in place of methionine (Ref 216). It is also suggested that selenite may be converted to Se-cysteine and incorporated into protein. Dimethyl selenium is an intermediate in the formation of a urinary metabolite, trimethyl selenium. It may be exhaled during acute selenium toxicity when its formation exceeds the rate of further methylation and urinary excretion (Ref 127).

The excretion pattern of a single exposure to selenite appears to have at least two phases; a rapid initial phase with as much as 15 to 40% of the absorbed dose excreted in the urine the first week. There is exponential excretion of the remainder of the dose with a half-life of 103 days. The half-life of Se-methionine is 234 days. In the steady state, urine contains about twice as much as feces and increased urinary levels provide a measure of exposure. Urinary selenium is usually less than 100 μg/liter.

Excretory products appear in sweat and expired air. The latter may have a garlicky odor due to dimethyl selenide. Within certain physiologic limits, the body appears to have a homeostatic mechanism for retaining trace amounts of selenium and excreting the excess material. Selenium toxicity occurs when the intake exceeds the excretory capacity (Ref 218, 219).

Essentiality. A biologic role for selenium is attributed to its incorporation in Se-cysteine at each of the four catalytic sites of the enzyme glutathione peroxidase. This enzyme uses glutathione to reduce organic hydroperoxides and protects membrane lipids and possibly proteins and nucleic acids against oxidant damage (Ref 220). Selenium is also a component of heme oxidase. The antioxidant activity of selenium-containing enzymes suggests a close relationship to vitamin E, but it may have a more subtle effect not yet defined in that selenium is beneficial to animals adequately supplied with vitamin E.

Selenium-deficient diets cause liver necrosis in rats and multiple organs (liver, heart, kidneys, skeletal muscle, and testes) in mice. In chicks, pancreatic fibrosis, exudative diathesis, and alopecia are responsive to selenium supplementation. Lambs and calves suffer from a muscle disease called stiff-lamb disease and white-muscle disease when raised in selenium ranges of selenium-deficient plants. Also, embryo mortality in ewes from selenium-deficient areas is reversed by supplementation. Liver necrosis and cardiac myopathy occur in young pigs on selenium-deficient diets and is prevented by the addition of selenium to the diet (Ref 59). While the role of selenium as an essential mineral seems certain in animals, the requirement for humans has been more difficult to establish. However, there are now reports of the efficacy of oral sodium selenite in the prophylaxis and treatment of an endemic cardiomyopathy in the People's Republic of China (Keshan disease) (Ref 221) and the alleviation by Se-methionine of muscle pain and tenderness in a New Zealand woman on intravenous feeding (Ref 222). Both reports are from regions where, for geochemical reasons, the indigenous population has a low intake of selenium. Selenium depletion has also been reported in association with cardiovascular disease and other cardiomyopathies. Although these case reports and the Chinese study are not the rigorous criteria required to establish the essentiality of a trace metal, for many it does seem that certain clinical situations may be improved with the administration of selenium (Ref 223).

Toxicity. Industrial exposure to hydrogen selenide, occurring as a result of a reaction to acid or water with metal selenides, produces "garlic" breath, nausea, dizziness, and lassitude. Eye and nasal irritation may occur. In experimental animals 10 ppm is fatal. Selenium oxychloride, a vesicant, presents an industrial hazard. In rabbits 0.01 ml applied dermally resulted in death. Percutaneous absorption increased blood and liver selenium concentrations.

Acute selenium poisoning produces central nervous system effects, which include nervousness, drowsiness, and sometimes convulsions. Symptoms of chronic inhalation exposure may include pallor, coated tongue, gastrointestinal disorders, nervousness, "garlic" breath, liver and spleen damage, anemia, mucosal irritation, and lumbar pain. It has been suggested that some of these symptoms are due to tellurium impurities (Ref 224).

"Blind stagger" caused by excess selenium in livestock consuming 100 to 1000 ppm is characterized by impairment of vision, weakness of limbs, and respiratory failure (Ref 225). Clear evidence of chronic selenium toxicity in humans occurs only in seleniferous areas when the local foods are processed. Signs of intoxication may include discolored or

decayed teeth, skin eruptions, gastrointestinal distress, lassitude, and partial loss of hair and nails. Livestock foraging on plants containing about 25 ppm suffer from "alkali" disease, which is characterized by lack of vitality, loss of hair, sterility, atrophy of hooves, lameness, and anemia. Fatty necrosis of the liver is frequent. In rats given 3 ppm of the material in drinking water, selenite has been reported to be more toxic than selenate. Selenite produced increased numbers of aortic plaques and was found to be more toxic in female than male mice. Selenium has produced loss of fertility and congenital defects and is considered embryotoxic and teratogenic on the basis of animal experiments (Ref 219, 225). Selenium sulfide produced an increase in hepatocellular carcinomas and adenomas, but selenium sulfide suspension and Selsun, an antidandruff shampoo containing 2.5% selenium sulfide, applied to the skin of Swiss mice did not produce dermal tumors (Ref 226, 227).

Epidemiologic investigations have indicated a decrease in human cancer death rates (age and sex adjusted) correlated with increasing selenium content of forage crops (Ref 228). In addition, experimental evidence supports the antineoplastic effect of selenium with regard to benzo[a]pyrene- and benzanthracene-induced skin tumors in mice, N-2-fluorenylacetamide- and diethylaminoazobenzene-induced hepatic tumors in rats, and spontaneous mammary tumors in mice. A possible mechanism of the protective effects of selenium has been postulated to involve inhibition of the formation of malonaldehyde, a product of peroxidative tissue damage, which is carcinogenic.

In addition to the apparent protective effect against some carcinogenic agents, selenium is an antidote to the toxic effects of other metals, particularly arsenic, cadmium, mercury, copper, and thallium. The mechanism underlying these interactions is unknown (Ref 229).

Zinc

Zinc is a nutritionally essential metal, and deficiency results in severe health consequences. On the other hand, excessive exposure to zinc is relatively uncommon and requires heavy exposure. Zinc does not accumulate with continued exposure, but body content is modulated by homeostatic mechanisms that act principally on absorption and liver levels (Ref 59, 230, 231, 232).

Zinc is ubiquitous in the environment so that it is present in most foodstuffs, water, and air. Content may be increased in contact with galvanized copper or plastic pipes. Seafoods, meats, whole grains, dairy products, nuts, and legumes are high in zinc content. Vegetables are lower. Zinc applied to soil is taken up by growing vegetables. Zinc atmospheric levels are increased over industrial areas. The average American daily intake is approximately 12 to 15 mg, mostly from food. The industrial uses and properties of zinc are described in the article "Zinc and Zinc Alloys" in this Volume.

Disposition. About 20 to 30% of ingested zinc is absorbed. The mechanism is thought to be homeostatically controlled and is probably a carrier-mediated process (Ref 233). It is influenced by prostaglandins E_2 and F_2 and is chelated by picolinic acid--a tryptophan derivative. Deficiency of pyridoxine or tryptophan depresses zinc absorption. Within the mucosal cell, zinc induces metallothionein synthesis and, when saturated, may depress zinc absorption. In the blood, about two-thirds of the zinc is bound to albumin and most of the remainder is complexed with λ_2-macroglobulin. Zinc enters the gastrointestinal tract as a component of metallothionein secreted by the salivary glands, intestinal mucosa, pancreas, and liver. About 2 mg of zinc is filtered by the kidneys each day, and about 300 to 600 μg/day is actually excreted by normal adults. Renal tubular reabsorption is impaired by commonly prescribed drugs, such as thiazide diuretics, and is further influenced by dietary protein. There is good correlation between dietary zinc and urinary zinc excretion.

Zinc concentration in tissues varies widely. Liver receives up to about 40% of a tracer dose, declining to about 25% within five days. Liver concentration is influenced by humoral factors including adrenocorticotropic hormone, parathyroid hormone, and endotoxin. In the liver, as well as other tissues, zinc is bound to metallothionein. The greatest concentration of zinc in the body is in the prostate, probably related to the rich content of zinc-containing enzyme acid phosphatase.

Deficiency. More than 70 metalloenzymes require zinc as a cofactor, and deficiency results in a wide spectrum of clinical effects depending on age, stage of development, and deficiencies of related metals.

Zinc deficiency in humans was first characterized in 1963 by Prasad and co-workers (Ref 234) in adolescent Egyptian boys with growth failure and delayed sexual maturation and is accompanied by protein-caloric malnutrition, pellagra, iron, and folate deficiency. Zinc deficiency in the newborn may be manifested by dermatitis, loss of hair, impaired healing, susceptibility to infections, and neuropsychologic abnormalities. Dietary inadequacies coupled with liver disease from chronic alcoholism may be associated with dermatitis, night blindness, testicular atrophy, impotence, and poor

wound healing. Other chronic clinical disorders, such as ulcerative colitis and the malabsorption syndromes, chronic renal disease, and the hemolytic anemias, are also prone to zinc deficiency. Many drugs affect zinc homeostasis particularly metal-chelating agents and some antibiotics, such as penicillin and isoniazid. Less common zinc deficiency may occur with myocardial infarction, arthritis, and even hypertension.

Biologic Indicators of Abnormal Zinc Homeostasis. The range of normal plasma zinc level is from 85 to 110 μg/dL. Severe deficiency may decrease plasma zinc to 40 to 60 μg/dl, accompanied by increased serum β_2-globulin and decreased α-globulin. Urine zinc excretion may decrease from over 300 μg/day to less than 100 μg/day. Zinc deficiency may exacerbate impaired copper nutrition and, of course, zinc interactions with cadmium and lead may modify the toxicity of these metals (Ref 231).

Toxicity. Zinc toxicity from excessive ingestion is uncommon, but gastrointestinal distress and diarrhea have been reported following ingestion of beverages standing in galvanized cans or from use of galvanized utensils. However, evidence of hematologic, hepatic, or renal toxicity has not been observed in individuals ingesting as much as 12 g of elemental zinc over a two-day period.

With regard to industrial exposure, metal fume fever resulting from inhalation of freshly formed fumes of zinc presents the most significant effect. The disorder has been most commonly associated with inhalation of zinc oxide fume, but it may be seen after inhalation of fumes of other metals, particularly magnesium, iron, and copper. Attacks usually begin after four to eight hours of exposure--chills and fever, profuse sweating, and weakness. Attacks usually last only 24 to 48 hours and are most common on Mondays or after holidays. The pathogenesis is not known, but is thought to be due to endogenous pyrogen released from cell lysis. Extracts prepared from tracheal mucosa and lungs of animals with experimentally induced metal fume fever produce similar symptoms when injected into other animals. Other aspects of zinc toxicity are not well established. Experimental animals have been given 100 times dietary requirements without discernible effects (Ref 235).

Exposure of guinea pigs three hours per day for six consecutive days to 5 mg/m^3 freshly formed ultrafine zinc oxide (the recommended threshold limit value, TLV) produced decrements in lung volumes and carbon monoxide diffusing capacity that persisted 72 hours after exposure. These functional changes were correlated with microscopic evidence of interstitial thickening and cellular infiltrate in alveolar ducts and alveoli (Ref 236).

Testicular tumors have been produced by direct intratesticular injection in rats and chickens. This effect is probably related to the concentration of zinc normally in the gonads and may be hormonally dependent. Zinc salts have not produced carcinogenic effects when administered to animals by other routes (Ref 237).

Metals With Toxicity Related To Medical Therapy

Metals considered in this group include aluminum, bismuth, gallium, gold, lithium, and platinum. Metals at one time were used to treat a number of human ills, particularly heavy metals like mercury and arsenic. Gold salts are still useful for the treatment of forms of rheumatism, and organic bismuth compounds are used to treat gastrointestinal disturbances. Lithium has become an important aid in the treatment of depression. The toxicologic hazards from aluminum are not from its use as an antacid but rather the accumulations that occur in bone and other tissues in patients with chronic renal failure receiving hemodialysis therapy. Platinum is receiving attention as an antitumor agent. Barium and gallium are used as a radiopaque and radiotracer material, respectively, so they do have importance in medical therapy. Toxicologic effects are unlikely and seldom occur.

Aluminum

Aluminum is one of the most abundant metals in the earth's crust, and it is ubiquitous in air and water, as well as in soil. The uses and properties associated with this metal are described extensively throughout this Volume (see in particular the Section "Specific Metals and Alloys" in this Volume).

The toxicity of aluminum may be divided into three major categories: first, the effect of aluminum compounds on the gastrointestinal tract; second, the effect of inhalation of aluminum compounds; and third, systemic toxicity of aluminum (Ref 238).

Aluminum compounds can affect absorption of other elements in the gastrointestinal tract and alter intestinal function. Aluminum inhibits fluoride absorption and may decrease the absorption of calcium and iron compounds (Ref 239) and possibly the absorption of cholesterol by forming an aluminum-pectin complex that binds fats to nondigestible vegetable fibers (Ref 240). The binding of phosphorus in the intestinal tract can lead to phosphate depletion and osteomalacia (Ref 241). Aluminum may alter gastrointestinal tract motility by inhibition of acetylcholine-induced contractions and may be the explanation of why aluminum-containing antacids often produce constipation.

Pulmonary effects of aluminum occur following inhalation of bauxite (Al_2O_3-$3H_2O$) fumes. The resultant pulmonary fibrosis produces both restrictive and obstructive pulmonary disease (Ref 242). Interestingly, inhalation of aluminum mists was used in the 1930s to serve as prophylaxis of pulmonary fibrosis due to inhalation of silica particles. It is suggested that aluminum and silicic acid compete for a common reactive site in the oxidative phosphorylation pathway (Ref 243).

There has been increasing interest in the possible relationship of aluminum to dementia in humans (Ref 244). Intracerebral injection of aluminum phosphate or injection of aluminum powder in cerebrospinal fluid of animals has been noted to induce a progressive encephalopathy and neurofibrillary degeneration histologically comparable to the changes found in persons with senile and presenile dementia of the Alzheimer type (Ref 245). However, some morphologic differences have been noted at the ultrastructural level, and why specific individuals are affected by such a ubiquitous metal is an unresolved question.

A progressive fatal neurologic syndrome has also been reported in patients on long-term intermittent hemodialysis treatment for chronic renal failure (Ref 246). The first symptom in these patients is a speech disorder followed by dementia, convulsions, and myoclonus. The disorder, which typically arises after three to seven years of dialysis treatment, may be due to aluminum intoxication. aluminum content of brain, muscle, and bone tissues is increased in these patients. Crapper (Ref 247) has shown that brain tissue of mammals normally contains 1 to 2 μg of aluminum per gram dry weight and that the toxic range is 4 to 8 μg/g dry weight of brain for the cat and rabbit.

Sources of the excess aluminum may be from oral aluminum hydroxide commonly given to these patients or from aluminum in dialysis fluid derived from tap water used to prepare the dialysate fluid. High serum and bone aluminum concentrations are generally present in these patients, and it is postulated that increased absorption may be related to increased parathyroid hormone due to low blood calcium and osteodystrophy common in patients with chronic renal disease. The syndrome may be prevented by avoidance of the use of aluminum-containing oral phosphate binders and monitoring of aluminum in the dialysate. Chelation of aluminum may be achieved with use of desferrioxamine, and progression of the dementia may be arrested or slowed (Ref 248).

Bismuth

Although bismuth is used for a variety of industrial uses (see the article "Indium and Bismuth" in this Volume), its primary use is in chemicals and pharmaceuticals. Both inorganic and organic salts have been used, depending on the specific application. There are three major categories of uses: antisyphylitic agents, topical creams, and antacids. Trivalent insoluble bismuth salts are used medicinally to control diarrhea and other types of gastrointestinal distress. Various bismuth salts have been used externally for their astringent and slight antiseptic property. Bismuth salts have also been used as radiocontrast agents. Further potential for exposure comes from the use of insoluble bismuth salts in cosmetics. Injections of soluble and insoluble salts, suspended in oil to maintain adequate blood levels, have been used to treat syphilis. Bismuth sodium thioglycollate, a water-soluble salt, was injected intramuscularly for malaria (*Plasmodium vivax*). Bismuth glycolyarsanilate is one of the few pentavalent salts that have been used medicinally. This material was formerly used for treatment of amebiasis (Ref 249). Exposure to various bismuth salts for medicinal use has decreased with the advent of newer therapeutic agents. However, in the 1970s reports appeared from France and Australia of unique encephalopathy occurring in colostomy and ileostomy patients using bismuth subgallate, bismuth subnitrate, and tripotassium-dicitrate-bismuthate for control of fecal odor and consistency. The symptoms included progressive mental confusion, irregular myoclonic jerks, a distinctive pattern of disordered gait, and a variable degree of dysarthria. The disorder was fatal to patients who continued use of the bismuth compounds, but full recovery was rapid in those in whom therapy was discontinued. The severity of the disorder seemed to be independent of dose and duration of therapy (Ref 250).

Most bismuth compounds are insoluble and poorly absorbed from the gastrointestinal tracts, or when applied to the skin, even if the skin is abraded or burned. Symptomatic patients taking bismuth subgallate had an elevated median blood bismuth level of 14.6 μg Bi/dL, patients without clinical symptoms had a median blood level of 3 μg/dL, and colostomy patients not on bismuth therapy had a median bismuth blood level of 0.8 μg/dL. Health laboratory workers had a median

bismuth blood level of 1.0 μg/dL. Binding in blood is thought to be largely due to a plasma protein with a molecular weight greater than 50,000 daltons.

A diffusible equilibrium between tissues, blood, and urine is established. Tissue distribution, omitting injection depots, reveals the kidney as the site of the highest concentration. The liver concentration is considerably lower at therapeutic levels, but with massive doses in experimental animals (dogs), the kidney/liver ratio is decreased. Passage of bismuth into the amniotic fluid and into the fetus has been demonstrated. The urine is the major route of excretion. Traces of bismuth can be found in milk and saliva. The total elimination of bismuth after injection is slow and dependent on mobilization from the injection site.

Acute renal failure can occur following oral administration of such compounds as bismuth sodium triglycollamate or thioglycollate particularly in children (Ref 251). The tubular epithelium is the primary site of toxicity producing degeneration of renal tubular cells and nuclear inclusion bodies composed of a bismuth-protein complex analogous to those found in lead toxicity (Ref 252, 253).

The symptoms of chronic toxicity in humans consist of decreased appetite, weakness, rheumatic pain, diarrhea, fever, metal line on the gums, foul breath, gingivitis, and dermatitis. Jaundice and conjunctival hemorrhage are rare, but have been reported. Bismuth nephropathy with proteinuria may occur.

Chelation therapy using dimercaprol (BAL) is said to be helpful in removal of bismuth from children with acute toxicity (Ref 254).

Gallium

Gallium is of interest because of the use of radiogallium as a diagnostic tool for localization of bone lesions. It is obtained as a by-product of copper, zinc, lead, and aluminum refining and is used in high-temperature thermometers, as a substitute for mercury in arc lamps, as a component of metal alloys, as a seal for vacuum equipment, and in semiconductor applications (gallium arsenide) (see the article "Gallium and Gallium Compounds" in this Volume). It is only sparsely absorbed from the gastrointestinal tract, but concentrations of less than 1 ppm can be localized radiographically in bone lesions. Higher doses will visualize liver, spleen, and kidney as well.

Gallium is not readily absorbed by the oral route, but occurs in bone at concentrations less than 1 ppm. Increasing intake produces slight increases in gallium levels in the liver, spleen, kidney, and bone. The urine is the major route of excretion.

There are no reported adverse effects of gallium following industrial exposure. Therapeutic use of radiogallium produced some adverse effects, mild dermatitis, and gastrointestinal disturbances. Bone marrow depression has been reported and may be due largely to the radioactivity. In animals gallium acts as a neuromuscular poison and causes renal damage. Photophobia, blindness, and paralysis have been reported in rats. Renal damage ranging from cloudy swelling to tubular cell necrosis has been reported. Aplastic changes in the bone marrow have been observed in dogs (Ref 186).

Gold

Gold is widely distributed in small quantities but economically usable deposits occur as the free metal in quartz veins or alluvial gravel. Seawater contains 3 or 4 mg/ton and small amounts, 0.03 to 1 mg%, have been reported in many foods. Gold has a number of industrial uses because of its electrical and thermal conductivity and is described in the article "Precious Metals" as well as numerous other articles in this Volume.

While gold and its salts have been used for a wide variety of medicinal purposes, their present uses are limited to the treatment of rheumatoid arthritis and rare skin diseases such as discoid lupus. Gold salts are poorly absorbed from the gastrointestinal tract. Normal urine and fecal excretions of about 0.1 and 1 mg/day, respectively, have been reported. After injection of most of the soluble salts, gold is excreted via the urine, while the feces account for the major portion of insoluble compounds. Gold seems to have a long biologic half-life, and detectable blood levels can be demonstrated for ten months after cessation of treatment.

Dermatitis is the most frequently reported toxic reaction to gold and is sometimes accompanied by stomatitis. Use of gold in the form of organic salts to treat rheumatoid arthritis may be complicated by development of proteinuria and the nephrotic syndrome, which morphologically consists of an immune-complex glomerulonephritis with granular deposits along the glomerular basement membrane and in the mesangium. The pathogenesis of the immune-complex disease is not

certain, but gold may behave as a hapten and generate the production of antibodies with subsequent disposition of gold protein-antibody complexes in the glomerular subepithelium. Another hypothesis is that antibodies are formed against damaged tubular structures, particularly mitochondria, providing immune complexes for the glomerular deposits (Ref 255).

The pathogenesis of the renal lesions induced by gold therapy is probably initiated by the direct toxicity of gold with tubular cell components. From experimental studies it appears that gold salts have an affinity for mitochondria of proximal tubular lining cells, which is followed by autophagocytosis and accumulation of gold in amorphous phagolysosomes (Ref 256), and gold particles can be identified in degenerating mitochondria in tubular lining cells and in glomerular epithelial cells by x-ray microanalysis (Ref 257).

Lithium

Lithium carbonate is an important aid in the treatment of depression. There must be careful monitoring of usage to provide optimal therapeutic value and not produce toxicity. Lithium is a common metal and present in many plant and animal tissues. Daily intake is about 2 mg. It is readily absorbed from the gastrointestinal tract. Distribution in the human organs is almost uniform. The normal plasma level is about 17 μg/L. The red cells contain less. Excretion is chiefly through the kidneys, but some is eliminated in the feces. The greater part of lithium is contained in the cells, perhaps at the expense of potassium. In general, the body distribution of lithium is quite similar to that of sodium, and it may be competing with sodium at certain sites, for example, in renal tubular reabsorption.

Lithium has some industrial uses, in alloys (see, for example, the article "Aluminum-Lithium Alloys" in this Volume), as a catalytic agent, and as a lubricant. Mechanical and physical characteristics of lithium are described in the article "Properties of Pure Metals" in this Volume. Lithium hydride produces hydrogen on contact with water and is used in manufacturing electronic tubes, in ceramics, and in chemical synthesis. From the industrial point of view, except for lithium hydride, none of the others salts or the metal itself is hazardous. Lithium hydride is intensely corrosive and may produce burns on the skin because of the formation of hydroxides (Ref 186, 258).

The therapeutic use of lithium carbonate may produce unusual toxic responses. These include neuromuscular changes (tremor, muscle hyperirritability, and ataxia), central nervous system changes (black-out spells, epileptic seizures, slurred speech, coma, psychosomatic retardation, and increased thirst), cardiovascular changes (cardiac arrhythmia, hypertension, and circulatory collapse), gastrointestinal changes (anorexia, nausea, and vomiting) and renal damage (albuminuria and glycosuria). The latter is believed to be due to temporary hypokalemic nephritis. These changes appear to be more frequent when the serum levels increase above 1.5 mEq/L, suggesting that careful monitoring of this parameter is needed rather than reliance on the amount given.

Chronic lithium nephrotoxicity can occur with long-term exposure even when lithium levels remain within the therapeutic range. Tubular defects, particularly nephrogenic diabetes insipidus, may occur. There is more recent awareness of the possible development of chronic interstitial nephritis (Ref 259).

The cardiovascular and nervous system changes may be due to the competitive relationship between lithium and potassium and may thus produce a disturbance in intracellular metabolism. Thyrotoxic reactions, including goiter formation, have also been suggested (Ref 260). While there has been some indication of adverse effects on fetuses following lithium treatment, none was observed in rats (4.05 mEq/kg), rabbits (1.08 mEq/kg), or primates (0.67 mEq/kg). This dose to rats was sufficient to produce maternal toxicity and effects on the pups of treated, lactating dams (Ref 261).

Lithium overdosage and toxicity may be treated by administration of diuretics and lowering of blood levels. Acetazolamide, a carbonic anhydrase inhibitor, has been used clinically. Animal studies have shown that urinary excretion of lithium can be further enhanced by the combined administration of acetazolamide and furosemide. Treatment with diuretics must be accompanied by replacement of water and electrolytes (Ref 262).

Platinum

Platinum-group metals include a relatively light triad of ruthenium, rhodium, and palladium, and the heavy metals osmium, iridium, and platinum (see the article "Precious Metals" in this Volume). They are found together in sparsely distributed mineral deposits or as a by-product of refining other metals, chiefly nickel and copper. Osmium and iridium are not important toxicologically. Osmium tetroxide, however, is a powerful eye irritant. The other metals are generally

nontoxic in their metallic states but have been noted to have toxic effects in particular circumstances. Platinum is interesting because of its extensive industrial application and use of certain complexes as antitumor agents.

Toxicological information for ruthenium is limited to references in the literature indicating that fumes may be injurious to eyes and lungs (Ref 186).

Rhodium trichloride produced death in rats and rabbits within 48 hours after intravenous administration at doses near the LD50 (approximately 200 mg/kg). It was suggested that death was attributable to central nervous system effects (Ref 263). In a single study, incorporation of rhodium (rhodium chloride) or palladium (palladous chloride) into the drinking water of mice at a concentration of 5 ppm over the lifetime of the animals produced a minimally significant increase in malignant tumors. Most of these tumors were classified as the lymphoma-leukemia type (Ref 264).

Palladium chloride is not readily absorbed from subcutaneous injection, and no adverse effects have been reported from industrial exposure. Colloid palladium ($Pd[OH]_2$) is reported to increase body temperature, produce discoloration and necrosis at the site of injection, decrease body weight, and cause slight hemolysis.

Platinum metal itself is generally harmless, but an allergic dermatitis can be produced in susceptible individuals. Skin changes are most common between the fingers and in the antecubital fossae. Symptoms of respiratory distress, ranging from irritation to an "asthmatic syndrome" with coughing, wheezing, and shortness of breath, have been reported following exposure to platinum dust. The skin and respiratory changes are termed platinosis. They are mainly confined to persons with a history of industrial exposure to soluble compounds such as sodium chloroplatinate, although cases resulting from wearing platinum jewelry have been reported.

The complex salts of platinum may act as powerful allergens, particularly ammonium hexachloroplatinate and hexachloroplatinic acid. The allergenicity appears to be related to the number of chlorine atoms present in the molecule, but other soluble nonchlorinated platinum compounds may also be allergenic. Biochemistry and antitumor activity of platinum complexes of major consideration for this group of metals are the potential antitumor and carcinogenic effects of certain neutral complexes of platinum such as *cis*-dichlorodiamine, platinum (II), and various analogs (Ref 265). They can inhibit cell division and have antibacterial properties as well. These compounds can react selectivity with specific chemical sites in proteins such as disulfide bonds and terminal-NH_2 groups, with functional groups in amino acids, and in particular with receptor sites in nucleic acids. These compounds also exhibit neuromuscular toxicity and nephrotoxicity.

For antitumor activity, the complexes should be neutral and should have a pair of *cis*-leaving groups. Other metals in the group give complexes that are inactive or less active than the platinum analog. At dosages that are therapeutically effective (antitumor), these complexes produce severe and persistent inhibition of DNA synthesis and little inhibition of RNA and protein synthesis. DNA polymerase activity and transport of DNA precursors through plasma membranes are not inhibited. The complexes are thought to react directly with DNA in regions that are rich in guanosine and cytosine.

Mutagenic and Carcinogenic Effects of Platinum Complexes. *Cis*-platin platinum has been used clinically to treat some cancers of the head and neck, certain lymphomas, and testicular and ovarian tumors. *Cis*-DDP is a strong mutagen in bacterial systems and has been shown to form both intra- and interstrand cross-links probably involving the whole molecule with human DNA in HeLa cell cultures. There is also a correlation between antitumor activity of *cis*-DDP and its ability to bind DNA and induce phage from bacterial cells. It also causes chromosome aberration in cultured hamster cells and a dose-dependent increase in sister chromatid exchanges.

Although *cis*-DDP has antitumorigenic activity in experimental animals, it also seems to increase the frequency of lung adenomas and give rise to skin papillomas and carcinomas in mice. These observations are consistent with the activity of other alkylating agents used in cancer chemotherapy. There are no reports of increased risk to cancer from occupational exposure to platinum compounds.

Nephrotoxicity. *Cis*-DDP is a nephrotoxin. It produces compounds with antitumor activity and produces proximal and distal tubular cell injury mainly in the corticomedullary region where the concentration of platinum is highest (Ref 266). Although 90% of administered *cis*-platinum becomes tightly bound to plasma proteins, only unbound platinum is rapidly filtered by the glomerulus and has a half-life of only 48 minutes. Within tissues, platinum is protein bound with largest concentrations in kidney, liver, and spleen, and has a half-life of two or three days. Tubular cell toxicity seems to be directly related to dose, and prolonged weekly injection in rats causes atrophy of cortical portions of nephrons and cystic dilatation of inner cortical or medullary tubules and chronic renal failure due to tubulointerstitial nephritis (Ref 267).

Minor Toxic Metals

There are a number of metals that pose a relatively minor toxic threat. Those covered in this section include antimony, barium, indium, magnesium, silver, tellurium, thallium, tin, titanium, uranium, and vanadium.

Antimony

Antimony may have a tri- or pentavalence and it belongs to the same periodic group as arsenic. Its disposition metabolism is thought to resemble that of arsenic. It is absorbed slowly from the gastrointestinal tract, and many antimony compounds are gastrointestinal irritants. Antimony tartar has been used as an emetic. The disposition of the tri and penta forms differ. Trivalent antimony is concentrated in red blood cells and liver whereas the penta form is mostly in plasma. Both forms are excreted in feces and urine, but more trivalent antimony is excreted in urine whereas there is greater gastrointestinal excretion of pentavalent antimony. Antimony is a common air pollutant from industrial emissions, but exposure for the general population is largely from food.

Antimony is included (both ferrous and nonferrous) in alloys in the metals industry and is used for producing fireproofing chemicals, ceramics, glassware, and pigments (properties are described in the article "Properties of Pure Metals"). It has been used medicinally as an antiparasitic agent. Accidental poisonings can result in acute toxicity, which produces severe gastrointestinal symptoms including vomiting and diarrhea.

Most information about antimony toxicity has been obtained from industrial experiences. Occupational exposures are usually by inhalation of dust containing antimony compounds, antimony penta and trichloride, trioxide and trisulfide. Effects may be acute, particularly from the penta and trichloride exposures, producing a rhinitis and even acute pulmonary edema, Chronic exposures by inhalation of other antimony compounds result in rhinitis, pharyngitis, tracheitis, and, over the longer term, bronchitis and eventually pneumoconiosis with obstructive lung disease and emphysema. Antimony does accumulate in lung tissue (Ref 268).

Oral feeding of antimony to rats has not produced an excess of tumors. However, increased chromosome defects occur when human lymphocytes are incubated with a soluble antimony salt (Ref 269), and Syrian hamster embryo cells undergo neoplastic transformation when treated with antimony acetate (Ref 270). Transient skin eruptions, "antimony spots," may occur in workers with chronic exposure.

Antimony may also form an odorless toxic gas, stibine (H_3Sb), which, like arsine, causes hemolysis.

Barium

Barium is used in various alloys, in paints, soap, paper, and rubber, and in the manufacture of ceramics and glass. (Its properties are described in the article "Properties of Pure Metals" in this Volume.) Barium fluorosilicate and carbonate have been used as insecticides. Barium sulfate, an insoluble compound, is used as a radiopaque aid to x-ray diagnosis. Barium is relatively abundant in nature and is found in plants and animal tissue. Plants accumulate barium from the soil. Brazil nuts have very high concentrations (3000 to 4000 ppm). Some water contains barium from natural deposits.

The toxicity of barium compounds depends on their solubility. The soluble compounds of barium are absorbed, and small amounts are accumulated in the skeleton. The lung has an average concentration of 1 ppm (dry weight). The kidney, spleen, muscle, heart, -brain, and liver concentrations are 0.10, 0.08, 0.08, 0.05, 0.05, and 0.03 ppm, respectively. Although some barium is excreted in urine, it is reabsorbed by the renal tubules. The major route of excretion is the feces. Occupational poisoning to barium is uncommon, but a benign pneumoconiosis (baritosis) may result from inhalation of barium sulfate (barite) dust and barium carbonate. It is not incapacitating and is usually reversible with cessation of exposure. Accidental poisoning from ingestion of soluble barium salts has resulted in gastroenteritis, muscular paralysis,

decreased pulse rate, and ventricular fibrillation and extrasystoles. Potassium deficiency occurs in acute poisoning, and treatment with intravenous potassium appears beneficial. The digitalislike toxicity, muscle stimulation, and central nervous system effects have been confirmed by experimental investigation (Ref 271).

Indium

Indium is a rare metal whose toxiocologic importance was related to its use in alloys, solders, and as a hardening agent for bearings (see the article "Indium and Bismuth" in this Volume). Use in the electronic industry for production of semiconductors and photovoltaic cells may greatly expand worker exposure. It is currently being used in medicine for scanning of organs and treatment of tumors. Indium is poorly absorbed from the gastrointestinal tract. It is excreted in the urine and feces. Its tissue distribution is relatively uniform. The kidney, liver, bone, and spleen have relatively high concentrations. Intratracheal injections produce similar concentrations, but the concentration in the tracheobronchial lymph nodes is increased.

There are no meaningful reports of human toxicity to indium. From animal experiments it is apparent that toxicity is related to the chemical form. Indium chloride given intravenously to mice produces renal toxicity and liver necrosis. These effects are accompanied by induction of P-450-dependent microsomal enzyme activity and decreased activity of heme-synthesizing enzymes (Ref 272). Hydrated indium oxide produces damage to phagocytic cells in liver and the reticuloendothelial system (Ref 273).

Magnesium

Magnesium is used in lightweight alloys, as an electrical conductive material, and for incendiary devices such as flares. The properties and applications are described in several articles in this Volume (see in particular, "Selection and Application of Magnesium"). It is also an essential nutrient whose deficiency causes neuromuscular irritability, calcification, and cardiac and renal damage, which can be prevented by supplementation. The deficiency is called "grass staggers" in cattle and "magnesium tetany" in calves. Magnesium is a cofactor of many enzymes; it is apparently associated with phosphate in these functions.

Magnesium citrate, oxide, sulfate, hydroxide, and carbonate are widely taken as antacids or one of the constituents of the universal antidote for poisoning. Topically, the sulfate is also used widely to relieve inflammation. Magnesium sulfate may be used as a parenterally administered central depressant. Its most frequent use for this purpose is in the treatment of seizures associated with eclampsia of pregnancy and acute nephritis.

Nuts, cereals, seafoods, and meats are high dietary sources of magnesium. The average city water contains about 6.5 ppm, but varies considerably, increasing with the hardness of the water (Ref 274).

Disposition. Magnesium salts are poorly absorbed from the intestine. In cases of overload this may be due in part to their dehydrating action. Magnesium is absorbed mainly in the small intestine. The colon also absorbs some. Calcium and magnesium are competitive with respect to their absorptive sites, and excess calcium may partially inhibit the absorption of magnesium.

Magnesium is excreted into the digestive tract by the bile and pancreatic and intestinal juices. A small amount of radiomagnesium given intravenously appears in the gastrointestinal tract. The serum levels are remarkable constant. There is an apparent obligatory urinary loss of magnesium, which amounts to about 12 mg/day, and the urine is the major route of excretion under normal conditions. Magnesium found in the stool is probably not absorbed. Magnesium is filtered by the glomeruli and reabsorbed by the renal tubules. In the blood plasma about 65% is in the ionic forms, while the remainder is bound to protein. The former is that which appears in the glomerular filtrate. Mercurial diuretics cause excretion of magnesium as well as potassium, sodium, and calcium. Excretion also occurs in the sweat and milk. Endocrine activity, particularly of the adrenocortical hormones, aldosterone, and parathyroid hormone, has an effect on magnesium levels, although these effects may be related to the interaction of calcium and magnesium.

Tissue distribution studies indicate that of the 20 g body burden, the majority is intracellular in the bone and muscle. Bone concentration of magnesium decreases as calcium increases. Most of the remaining tissues have higher concentrations than blood, except for fat and omentum. With age, the aorta tends to accumulate magnesium along with calcium, perhaps as a function of atherosclerotic disease.

Toxicity. Freshly generated magnesium oxide can cause metal fume fever if inhaled in sufficient amounts, analogous to the effect caused by zinc oxide. Both zinc and magnesium exposure of animals produced similar effects. It is reported that particles of magnesium in the subcutaneous tissue produce lesions that resist healing. In animals, magnesium subcutaneously or intramuscularly administered produces gas gangrene as a result of interaction with the body fluids and subsequent generation of hydrogen and magnesium hydroxide. The tissue lesion is reversible.

Conjunctivitis, nasal catarrh, and coughing up of discolored sputum results from industrial inhalation exposure. With industrial exposures, increases of serum magnesium up to twice the normal levels failed to produce ill effects but were accompanied by calcium increases. Intoxication occurring after oral administration of magnesium salts is rare, but may be present in the face of renal impairment. The symptoms include a sharp drop in blood pressure and respiratory paralysis due to central nervous system depression (Ref 186).

Silver

The principal industrial use of silver is as silver halide in the manufacture of photographic plates. Other uses are for jewelry, coins, electrical contact materials, and eating utensils (see the articles "Precious Metals" and "Electrical Contact Materials" in this Volume). Silver nitrate is used for making indelible inks and for medicinal purposes. The use of silver nitrate for prophylaxis of ophthalmia neonatorum is a legal requirement in some states. Other medicinal uses of silver salts are as a caustic, germicide, antiseptic, and astringent.

Silver does not occur regularly in animal or human tissue. The major effect of excessive absorption of silver is local or generalized impregnation of the tissues where it remains as silver sulfide, which forms an insoluble complex in elastic fibers resulting in argyria. Silver can be absorbed from the lungs and gastrointestinal tract. Complexes with serum albumin accumulate in the liver from which a fractional amount is excreted. Intravenous injection produces accumulation in the spleen, liver, bone, marrow, lungs, muscle, and skin. The major route of excretion is via the gastrointestinal tract. Urinary excretion has not been reported to occur even after intravenous injection.

Industrial argyria, a chronic occupational disease, has two forms, local and generalized. The local form involves the formation of gray-blue patches on the skin or may manifest itself in the conjunctiva of the eye. In generalized argyria, the skin shows widespread pigmentation, often spreading from the face to most uncovered parts of the body. In some cases the skin may become black with a metallic luster. The eyes may be affected to such a point that the lens and vision are disturbed. The respiratory tract may also be affected in severe cases.

Large oral doses of silver nitrate cause severe gastrointestinal irritation due to its caustic action. Lesions of the kidneys and lungs and the possibility of arteriosclerosis have been attributed to both industrial and medicinal exposures. Large doses of colloidal silver administered intravenously to experimental animals produced death due to pulmonary edema and congestion. Hemolysis and resulting bone marrow hyperplasia have been reported. Chronic bronchitis has also been reported to result from medicinal use of colloidal silver (Ref 186, 275).

Tellurium

Tellurium is found in various sulfide ores along with selenium and is produced as a by-product of metal refineries. Its industrial uses include an additive in steels to improve machinability, an additive in cast irons, applications in the refining of copper and in the manufacture of rubber (see the article "Properties of Pure Metals" in this Volume for additional information). Tellurium vapor is used in "daylight" lamps. It is used in various alloys as a catalyst and as a semiconductor.

Condiments, dairy products, nuts, and fish have high concentrations of tellurium. Food packaging contains some tellurium; higher concentrations are found in aluminum cans than tin cans. Some plants, such as garlic, accumulate tellurium from the soil. Potassium tellurate has been used to reduce sweating.

The average body burden in humans is about 600 mg; the majority is in bone. The kidney is the highest in content among the soft tissues. Some data suggest that tellurites also accumulate in liver (Ref 276). Soluble tetravalent tellurites, absorbed into the body after oral administration, are reduced to tellurides, partly methylated, and then exhaled as dimethyl telluride. The latter is responsible for the garlic odor in persons exposed to tellurium compounds. Tellurium in the food is probably in the form of tellurates. The urine and bile are the principal routes of excretion. Sweat and milk are secondary routes of excretion.

Tellurates and tellurium are of low toxicity, but tellurites are generally more toxic. Acute inhalation exposure results in decreased sweating, nausea, a metallic taste, and sleeplessness. The typical garlic breath is a reasonable indicator of exposure to tellurium by the dermal, inhalation, or oral routes. Serious cases of tellurium intoxication from industrial exposure have not been reported. In rats, chronic exposure to high doses of tellurium dioxide has produced decreased growth and necrosis of the liver and kidney (Ref 186, 277).

Sodium tellurite at 2 ppm in drinking water or potassium tellurate at 2 ppm of tellurium plus 0.16 μg/g in the diet of mice for their lifetime produced no effects in the tellurate group. The females of the tellurite (tetravalent) group did not live as long. In rats, 500 ppm in the diet or pregnant females induced hydrocephalus in the offspring. Abnormalities of and reduction in numbers of mitochondria were thought to be possible cellular causes of the transplacental effect.

One of the few serious recorded cases of tellurium toxicity resulted from accidental poisoning by injection of tellurium into the ureters during retrograde pyelography. Two of the three victims died. Stupor, cyanosis, vomiting, garlic breath, and loss of consciousness were observed in this unlikely incident.

Dimercaprol treatment for tellurium increases the renal damage. While ascorbic acid decreases the characteristic garlic odor, it may also adversely affect the kidneys in the presence of increased amounts of tellurium (Ref 278).

Thallium

Thallium is one of the more toxic metals and can cause neural, hepatic, and renal injury. It may also cause deafness and loss of vision. It is obtained as a by-product of the refining of iron, cadmium, and zinc. It is used as a catalyst, in certain alloys, optical lenses, jewelry, low-temperature thermometers, semiconductors, dyes and pigments, and scintillation counters (properties of thallium are summarized in the article "Properties of Pure Metals" in this Volume). It has been used medicinally as a depilatory. Thallium compounds, chiefly thallous sulfate, have been used as rat poison and insecticides. This is one of the commonest sources of thallium poisoning.

Disposition. Thallium is not a normal constituent of animal tissues. It is absorbed through the skin and gastrointestinal tract. After parenteral administration a small amount can be identified in the urine within a few hours. The highest concentrations after poisoning are in the kidney and urine. The intestines, thyroids, testes, pancreas, skin, bone, and spleen have lesser amounts. The brain and liver concentrations are still lower. Following the initial exposure, large amounts are excreted in urine during the first 24 hours, but after that period excretion is slow and the feces may be an important route of excretion.

Toxicology. There are numerous clinical reports of acute thallium poisoning in humans characterized by gastrointestinal irritation, acute ascending paralysis, and psychic disturbances. Acute toxicity studies in rats have indicated that thallium is quite toxic. It has an oral LD_{50} of approximately 30 mg/kg. The estimated lethal dose in humans, however, is 8 to 12 mg/kg. Rat studies also indicate that thallium oxide, while relatively insoluble, is more toxic orally than by the intravenous or intraperitoneal route (Ref 279). The acute cardiovascular effects of thallium ions probably result from completion with potassium for membrane transport systems, inhibition of mitochondrial oxidative phosphorylation, and disruption of protein synthesis. It also alters heme metabolism.

The signs of subacute or chronic thallium poisoning in rats were hair loss, cataracts, and hindleg paralysis occurring with some delay after the initiation of dosing. Renal lesions were observed at gross necropsy. Histologic changes revealed damage of the proximal and distal renal tubules. The central nervous system changes were most severe in the mesencephalon where necrosis was observed. Perivascular cuffing was also reported in several other brain areas. Electron microscope examination indicated that the mitochondria in the kidney may have been the first organelles affected. Liver mitochondria also revealed degenerative changes. The livers of newborn rats whose dams had been treated throughout pregnancy showed these changes. Similar mitochondrial changes were observed in the intestine, brain, seminal vesicle, and pancreas. It has been suggested that thallium may combine with the sulfhydryl groups in the mitochondrial and thereby interfere with oxidative phosphorylation (Ref 280). A teratogenic response to thallium salts characterized as achondroplasia (dwarfism) has been described in rats (Ref 281).

In humans, fatty infiltration and necrosis of the liver, nephritis, gastroenteritis, pulmonary edema, degenerative changes in the adrenals, degeneration of peripheral and central nervous system, alopecia, and in some cases death have been reported as a result of long-term systematic thallium intake. These cases usually are caused by the contamination of food or the use of thallium as a depilatory. Industrial poisoning is a special risk in the manufacturing of fused halides for the production

of lenses and windows. Loss of vision plus the other signs of thallium poisoning have been related to industrial exposures (Ref 180, 273).

Tin

Tin is used in the manufacture of tinplate, in food packaging, and in solder, bronze, and brass (see the article "Tin and Tin Alloys" in this Volume). Stannous and stannic chlorides are used in dyeing textiles. Organic tin compounds have been used in fungicides, bactericides, and slimicides, as well as in plastics as stabilizers. The disposition and possible health effects of inorganic and organic tin compounds have been summarized in a WHO report (Ref 282).

Disposition. There is only limited absorption of even soluble tin salts such as sodium stannous tartrate after oral administration. Ninety percent of the tin administered in this manner is recovered in feces. The small amounts absorbed are reflected by increases in the liver and kidneys. Injected tin is excreted by the kidneys, with smaller amounts in bile. A mean normal urine level of 16.6 μg/liter or 23,4 μg/day has been reported. The majority of inhaled tin or its salts remains in the lungs, most extracellularly, with some in the macrophages, in the form of SnO_2. The organic tins, particularly triethyltin, may be somewhat better absorbed. The tissue distribution of tin from this material shows highest concentrations in the blood and liver, with smaller amounts in the muscle, spleen, heart or brain. Tetraethyltin is converted to triethyltin *in vivo.*

Chronic inhalation of tin in the form of dust or fumes leads to benign pneumoconiosis. Tin hydride (SnH_4) is more toxic to mice and guinea pigs than is arsine; however, its effects appear mainly in the central nervous system and no hemolysis is produced. Orally, tin or its inorganic compounds require relatively large doses (500 mg/kg for 14 months) to produce toxicity. The use of tin in food processing seems to demonstrate little hazard. The average United States daily intake, mostly from foods as a result of processing, is estimated at 17 mg. Inorganic tin salts given by injection produce diarrhea, muscle paralysis, and twitching.

Toxicology. Some organic tin compounds are highly toxic, particularly triethyltin. Trialkyl compounds including triethyltin cause an encephalopathy and cerebral edema. Toxicity declines as the number of carbon atoms in the chain increases. An outbreak of almost epidemic nature took place in France due to the oral ingestion of a preparation (Stalinon) containing diethyltin diodide for treatment of skin disorders (Ref 283).

Excessive industrial exposure to triethyltin has been reported to produce headaches, visual defects, and EEG changes that were very slowly reversed (Ref 284). Experimentally, triethyltin produces depression and cerebral edema. The resulting hyperglycemia may be related to the centrally mediated depletion of catecholamines from the adrenals. Acute burns or subacute dermal irritation has been reported among workers as a result of tributyltin. Triphenyltin has been shown to be a potent immunosuppressant (Ref 285). Inhibition in the hydrolysis of adenosine triphosphate and uncoupling of oxidative phosphorylation taking place in the mitochondria have been suggested as the cellular mechanisms of tin toxicity (Ref 282).

Titanium

Most titanium compounds are in the oxidation state +4 (titanic), but oxidation state +3 (titanous) and oxidation state +2 compounds as well as several organometallic compounds do occur. Titanium dioxide, the most widely used compound, is a white pigment used in paints and plastics, as a food additive to whiten flour, dairy products, and confections, and a whitener in cosmetic products. Because of its high strength, low density, and resistance to corrosion, it has many metallurgical applications, including surgical implants and prostheses (see the articles on wrought, cast, and powder metallurgy titanium alloys in this Volume). It occurs widely in the environment; it is present in urban air, rivers, and drinking water and is detectable in many foods.

Disposition. Approximately 3% of an oral dose of titanium is absorbed. The majority of that absorbed is excreted in the urine. The normal urine concentration has been estimated at 10 μg/L (Ref 265/286).

The estimated body burden of titanium is about 15 mg. Most of it is in the lungs, probably as a result of inhalation exposure. Inhaled titanium tends to remain in the lungs for long periods. It has been estimated that about one-third of the inhaled titanium is retained in the lungs. The geographic variation in lung burden is to some extent dependent on air concentration. For example, concentrations of 430, 1300, and 91 ppm in ashed lung tissue have been reported for the United States. Delhi, and Hong Kong, respectively. Mean concentrations of 8 and 6 ppm for the liver and kidney, respectively, were reported in the United States. Newborns have little titanium. Lung burdens tend to increase with age.

Toxicology. Occupational exposure to titanium may be heavy, and concentrations in air up to 50 mg/m^3 have been recorded. Titanium dioxide has been classified as a nuisance particulate with a TLV of 10 mg/m^3. Nevertheless, slight fibrosis of lung tissue has been reported following inhalation exposure to titanium dioxide pigment, but the injury was not disabling. Otherwise, titanium dioxide has been considered physiologically inert by all routes (ingestion, inhalation, dermal, and subcutaneous). The metal and other salts are also relatively nontoxic except for titanic acid, which, as might be expected, will produce irritation (Ref 287).

A titanium coordination complex, titanocene, suspended in trioctanoin, administered by intramuscular injection to rats and mice, produced fibrosarcomas at the site of injection and hepatomas and malignant lymphomas (Ref 288). A titanocene is a sandwich arrangement of titanium between two cyclopentadiene molecules. Titanium dioxide was found not to be carcinogenic in a bioassay study in rats and mice (Ref 289).

Uranium

The chief raw material of uranium is pitchblende or carnotite ore. This element is largely limited to use as a nuclear fuel although, as described in the article "Uranium and Uranium Alloys" in this Volume, it is also used in applications where its high density can be taken advantage of (for example, kinetic energy penetrators).

The uranyl ion is rapidly absorbed form the gastrointestinal tract. About 60% is carried as a soluble bicarbonate complex, while the remainder is bound to plasma protein. Sixty percent is excreted in the urine within 24 hours. About 25% may be fixed in the bone (Ref 290). Following inhalation of the insoluble salts, retention by the lungs is prolonged. Uranium tetrafluoride and uranyl fluoride can produce a typical toxicity because of hydrolysis to hydrogen fluoride (HF). Skin contact (burned skin) with uranyl nitrate has resulted in nephritis.

The soluble uranium compound (uranyl ion) and those that solubilize in the body by the formation of bicarbonate complex produce systemic toxicity in the form of acute renal damage and renal failure, which may be fatal. However, if exposure is not severe enough, the renal tubular epithelium is regenerated and recovery occurs. Renal toxicity with the classic sign of impairment, including albuminuria, elevated blood urea nitrogen, and loss of weight, is brought about by filtration of the bicarbonate complex through the glomerulus, reabsorption by the proximal tubule, liberation of uranyl ion, and subsequent damage to the proximal tubular cells. Uranyl ion is most likely concentrated intracellularly in lysosomes (Ref 291, 292, 293).

Inhalation of uranium dioxide dust by rats, dogs, and monkeys at a concentration of 5 mg U/m^3 for up to 5 years produced accumulation in the lungs and tracheobronchial lymph nodes that accounted for 90% of the body burden. No evidence of toxicity was observed despite the long duration of observation (Ref 294).

Vanadium

Vanadium is a ubiquitous element. It is a by-product of petroleum refining, and vanadium pentoxide is used as a catalyst in the various chemicals including sulfuric acid. It is used in the hardening of steel (see *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook*), in the manufacture of pigments, in photography, and in insecticides (properties are summarized in the article "Properties of Pure Metals" in this Volume). It is common in many foods; significant amounts are found in milk, seafoods, cereals, and vegetables. Vanadium has a natural affinity for fats and oils; food oils have high concentrations. Municipal water supplies may contain on the average about 1 to 6 ppb. Urban air contains some vanadium, perhaps due to the use of petroleum products or from refineries (Table 1), about 30 mg. The largest single compartment is the fat. Bone and teeth stores contribute to the body burden. It has been postulated that some homeostatic mechanism maintains the normal levels of vanadium in the face of excessive intake, since the element, in most forms, is moderately absorbed. The principal route of excretion of vanadium is the urine. The normal serum level is 35 to 48 μg/100 ml. When excess amounts of vanadium are in the diet, the concentration in the red cells tends to increase. Parenteral administration increases levels in the liver and kidney, but these increased amounts may only be transient. The lung tissue may contain some vanadium, depending on the exposure by that route, but normally the other organs contain negligible amounts.

The toxic action of vanadium is largely confined to the respiratory tract. Bronchitis and bronchopneumonia are more frequent in workers exposed to vanadium compounds. In industrial exposures to vanadium pentoxide dust a greenish-black discoloration of the tongue is characteristic. Irritant activity with respect to skin and eyes has also been ascribed to industrial exposure. Gastrointestinal distress, nausea, vomiting, abdominal pain, cardiac palpitation, tremor, nervous depression, and kidney damage, too, have been linked with industrial vanadium exposure.

Ingestion of vanadium compounds (V_2O_5) for medicinal purposes produced gastrointestinal disturbances, slight abnormalities of clinical chemistry related to renal function, and nervous system effects. Acute vanadium poisoning in animals is characterized by marked effects on the nervous system, hemorrhage, paralysis, convulsions, and respiratory depression. Short-term inhalation exposure of experimental animals tends to confirm the effects on the lungs as well as the effect on the kidney. In addition, experimental investigations have suggested that the liver, adrenals, and bone marrow may be adversely affected by subacute exposure at high levels (Ref 295).

    - superconductor/insulating/superconductor
- **SMA**
    - shape memory alloy
- **SMAW**
    - shielded metal-arc welding
- **SME**
    - shape memory effect
- **SMES**
    - superconducting magnetic energy storage
- **SMS**
    - $SnMo_6S_8$
- **SPC**
    - statistical process control
- **SPF**
    - superplastic forming
- **SPS**
    - standard pipe size
- **SQUID**
    - superconducting quantum interference device
- **SSC**
    - superconducting supercollider
- **ST**
    - short transverse (direction)
- **std**
    - standard
- **STA**
    - solution-treated and aged
- **Sv**
    - sievert
- ***t***
    - thickness; time
- **T**
    - tesla
- ***T***
    - temperature
- T_A
    - annealing temperature

- T_b
  - boiling temperature
- T_c
  - critical ordering temperature; Curie temperature; critical transition temperature
- T_g
  - glass transition temperature
- T_m
  - melting temperature
- T_o
  - minimum ordering temperature
- T_s
  - minimum segregation temperature
- T_x
  - crystallization temperature
- **TBCCO**
  - Tl-Ba-Ca-Cu-O
- **TCP**
  - thermochemical processing
- **TCT**
  - thermochemical treatment
- **TD**
  - thoria dispersed
- **TEM**
  - transmission electron microscopy
- **TF**
  - toroidal field
- **TIG**
  - tungsten inert gas (welding)
- **TIR**
  - total indicator reading
- **TMP**
  - thermomechanical processing
- **tsi**
  - tons per square inch
- **TTT**
  - time-temperature transformation
- **UBC**
  - used beverage can
- **UNF**
  - Unified Numbering System
- **US-DPC**
  - United States-demonstration poloidal coil
- **UTS**
  - ultimate tensile strength
- ***v***
  - velocity
- **V**
  - volt
- ***V***
  - volume; velocity
- **VAR**
  - vacuum arc remelting
- **VAW**
  - Vereinigte Aluminum Werke AG
- **VD**
  - vapor deposited
- **V-D**

- vacuum degassing
- **VHP**
  - vacuum hot pressing
- **VIM**
  - vacuum induction melting
- **vol**
  - volume
- **vol%**
  - volume percent
- **VPE**
  - vapor-phase epitaxy
- **VPSD**
  - vacuum plasma structural deposition
- **W**
  - watt
- ***W***
  - width; weight
- W_h
  - hysteresis losses
- **wt%**
  - weight percent
- **XLPE**
  - cross linked polyethylene
- **YBCO**
  - Y-Ba-Cu-O
- ***Z***
  - impedance; atomic number
- **ZGS**
  - zirconia grain stabilized
- **ZTA**
  - zirconia-toughened alumina
- °
  - angular measure; degree
- **°C**
  - degree Celcius (centigrade)
- **°F**
  - degree Fahrenheit
- ***f***
  - direction of reaction
- **÷**
  - divided by
- **=**
  - equals
- ≅
  - approximately equals
- ≠
  - not equal to
- ≡
  - identical with
- **>**
  - greater than
- **?**
  - much greater than
- ≥
  - greater than or equal to
- ∞
  - infinity

- $\propto$
  - is proportional to; varies as
- $\int$
  - integral of
- $<$
  - less than
- $=$
  - much less than
- $\leq$
  - less than or equal to
- $\pm$
  - maximum deviation
- -
  - minus; negative ion charge
- $\times$
  - diameters (magnification); multiplied by
- $\cdot$
  - multiplied by
- /
  - per
- **%**
  - percent
- +
  - plus; positive ion charge
- $\sqrt{}$
  - square root of
- ~
  - approximately; similar to
- ∂
  - partial derivative
- Δ
  - change in quantity; an increment; a range
- **ε**
  - strain
- $\dot{e}$
  - strain rate
- **η**
  - viscosity
- Θ
  - Curie temperature
- **κ**
  - Ginzburg-Landau parameter; thermal diffusivity
- **λ(*T*)**
  - magnetic penetration depth as a function of temperature
- **μ**
  - friction coefficient; magnetic permeability
- **μF**
  - microfarads
- **μin.**
  - microinch
- **μm**
  - micrometer (micron)
- **μs**
  - microsecond
- **ν**
  - Poisson's ratio

- $x(T)$
  - temperature dependent coherence length
- π
  - pi (3.141592)
- ρ
  - electrical resistivity; density
- σ
  - liquid surface tension; stress
- σ_c
  - capture thermal neutron cross section
- σ_f
  - fission thermal neutron cross section
- Σ
  - summation of
- τ
  - time constant; applied stress
- $f(x,t)$
  - phase of the wave function, dependent on position and time
- Φ
  - magnetic flux contained in the loop
- Φ_0
  - magnetic flux quantum
- χ
  - magnetic susceptibility
- Ψ
  - macroscopic quantum mechanical wave function or order parameter
- ω
  - frequency of the ac magnetic field
- Ω
  - ohm

o **Greek Alphabet**

- **A, α**
  - alpha

- **Ψ, ψ**
  - psi
- **Ω, ω**
  - omega

o **Tradenames**

- **AF-56**
  - is a registered tradename of Allison Gas Turbine, Division of General Motors Corporation.
- **AL-6X, AL-6XN, AL 29-4C, AL29-4-2, AL 904L, AL-36, AL-42, AL-52, AL 2205, AL-4750, ALFA IV, E-Brite 26-1, Sealmet, and 203 EZ**
  - are registered tradenames of Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation.
- **AM1**
  - is a registered tradename of SNECMA/ONERA.
- **CM 247 LC and CMSX**
  - are registered tradenames of Cannon-Muskegon Corporation.
- **Cronifer**
  - is a registered tradename of Vereingte Deutsche Metallwerks.
- **Cryogenic Tenelon and Tenelon**
  - are registered tradenames of USS, Division of USX Corporation.
- **Custom 450, Custom 455, Gall-Tough, Glass Sealing, "49", Invar "36", Kovar, Low Expansion "42", Pyromet, TrimRite, 7-Mo PLUS, 18-18 PLUS, 20Cb-3, 20Mo-4, and 20Mo-6**
  - are registered tradenames of Carpenter Technology Corporation.
- **CU78, CW67 and CZ42**
  - are registered tradenames of Aluminum Company of America.
- **Discaloy**
  - is a registered tradename of Westinghouse Electric Corporation.
- **DISPAL**
  - is a registered tradename of Sintermetallwerk Krebsöge GmbH.
- **DP3**
  - is a registered tradename of Sumitomo Metal America, Inc.
- **Elinvar and Invar**
  - are registered tradenames of Imphy, S.A.
- **Esshete**
  - is a registered tradename of British Steel Corporation.

- **Ferralium**
  - is a registered tradename of Bonar Langley Alloy Ltd.
- **FVS-0611. FVS-0812, FVS-1212, and Metglas**
  - are registered tradenames of Allied-Signal Inc.
- **GlidCop**
  - is a registered tradename of SCM Metal Products, Inc.
- **Hastelloy and Haynes**
  - are registered tradenames of Haynes International, Inc.
- **Incoloy, Inconel, IncoMAP AL-905XL, Inco-MAP AL-9052, Monel, Nimocast, Nimonic, NI-Rodand NI-Span-Cl**
  - are registered tradenames of Inco Alloys International, Inc.
- **JS700**
  - is a registered tradename of Jessop Steel Company.
- **Kapton, Teflon and Tefzell**
  - are registered tradenames of E.I. Du Pont de Nemours & Company, Inc.
- **MAR-M**
  - is a registered tradename of Martin Marietta Corporation.
- **Monit**
  - is a registered tradename of Uddeholms Aktiebolag.
- **MP (Multiphase)**
  - is a registered tradename of Standard Pressed Steel Company.
- **Nextel**
  - is a registered tradename of 3M Company.
- **Nitronic and PH 13-8 Mo**
  - are registered tradenames of Baltimore Specialty Steels Corporation.
- **PH 15-7 MO, 12SR, 15-5 PH, 17-4 PH, 18 SRand 21-6-9**
  - are registered tradenames of Armco Advanced Materials Corporation.
- **PWA 1484**
  - is a registered tradename of Pratt & Whitney Aircraft.
- **RA85H**
  - is a registered tradename of Rolled Alloys, Inc.
- **Refrasil**
  - is a registered tradename of Thompson Company.
- **René**
  - is a registered tradename of General Electric Company.
- **René 41**
  - is a registered tradename of Allvac Metals Company, a Teledyne Company.
- **RR 2000 and SRR 99**
  - are registered tradenames of Rolls Royce, Inc.
- **Sanicro and 3RE60**
  - are registered tradenames of Sandvik, Inc.
- **Sea-Cure**
  - is a registered tradename of Crucible, Inc.
- **Stellite**
  - is a registered tradename of Deloro Stellite, Inc.
- **Tantology and Tribocor**
  - are registered tradenames of Fansteel Inc.
- **Transage 134 and Transage 175**
  - are registered tradenames of Lockheed Missile and Space Company.
- **Udimet**
  - is a registered tradename of Special Metals Corporation.
- **Unitemp**
  - is a registered tradename of Universal Cyclops Steel Corporation.
- **Uranus**
  - is a registered tradename of Compagnie des Ateliers et Forges de la Loire.
- **Vitallium**
  - is a registered tradename of Pfizer Hospital Products Group, Inc.

- **Waspaloy**
  - is a registered tradename of United Technologies, Inc.
- **Weldalite**
  - is a registered tradename of Martin Marietta Corporation.
- **253MA and 254SMO**
  - are registered tradenames of Avesta Stainless, Inc.
